Review Article

Radiopharmaceuticals

By WALTER WOLF and MANUEL TUBIS*

TWO MAJOR developments occurred in 1940–1946 that revolutionized the methodology of research involving biological systems, by lowering the amounts of materials detectable to the microgram and submicrogram level. They were the chromatographic methods of separation and the availability of radioactive nuclides for the labeling and tracing of molecules and submolecular fragments. These tools were rapidly applied in all areas of biological research, including the diagnosis of disease. The use of radionuclides in the diagnosis and therapy of disease created the new specialty of nuclear medicine, and the specific drugs used in this specialty are called radiopharmaceuticals. The birth of nuclear medicine, and the concomitant development of radiopharmaceuticals, predate the creation in 1946 of the United States Atomic Energy Commission.

The first use of radioactive nuclides in man is to be credited to Blumgart and Yens (1), who in 1927 measured circulation (in man), after injection of a saline solution that had been exposed to radon, using a cloud chamber as the radiation detection device. The isotopes available at the time were only those belonging to the natural uranium, thorium, and actinium series, which limited their use in clinical work. The discovery, by Joliot and Curie (2), that other nuclides could be produced artificially, and the subsequent syntheses, by nuclear transmutation, of hundreds of artificial radioactive nuclides (3, 4), provided the tools for their biological and clinical use.

The use of ^{128}I by Hertz, Roberts, and Evans (5) in 1938, for the study of thyroid function, marks the real beginning of the systematic clinical use of radionuclides. Developments since then have been astronomical, and they have been thoroughly reviewed by Christian in 1961 in *J. Pharm. Sci.* (6) and by many others elsewhere since (7–51). Of special interest are the proceedings, published in April 1966, of the November 1965 Oak Ridge Conference on radiopharmaceuticals (30).

The development of a new science can usually be divided into several phases. First, there is discovery, and there are hopes that the possibilities of the new tool will be nearly unlimited. In the second phase, problems begin to be better appreciated and the initial enthusiasm is somewhat abated. And in a third phase, the new field achieves maturity, becomes fully aware of its potential and limitations, and achieves considerable sophistication.

Radiopharmaceuticals have entered this third phase. Thus, while originally tests were devised to make use of available radionuclides, now new

Received from the Department of Pharmaceutical Chemistry, School of Pharmacy, University of Southern California, and the *Radioisotope Research Laboratory, Veterans Administration Center and Department of Radiology, School of Medicine, University of California at Los Angeles 90007.

This investigation was supported in part by grant GM-10721 from the National Institutes of Health, U. S. Public Health Service, Bethesda, Md., and grant GY-327 from the National Science Foundation, Washington, D. C.

The technical assistance of D. Fox, B. Goldstein, and C. Hays is gratefully acknowledged.

nuclides are being produced to meet the specific requirements of half-life, emission characteristics, and chemical properties tailored to a specific test. Pinajian has stated that most of the over 1000 nuclides known can now be prepared by reactor (52), cyclotron (53), or related processes (54). We will first discuss the radionuclides that have proven useful in nuclear medicine, and the radiopharmaceuticals that contain them.

Radioactive nuclides are measured by the radiation they emit, and considerable progress has been achieved in the instrumentation used in nuclear medicine. Solid-state circuitry has often decreased the size and weight of instruments to a fraction of the older tube models, and increased their accuracy and reliability. Special tools have been developed to measure specific radiopharmaceuticals in specific diagnostic tests. Thus, highlights of new instrumentation and their relevance to radiopharmaceuticals will be considered next. Following will be a discussion of the application of radiopharmaceuticals in clinical medicine, production, and use in ancillary areas.

If we define a pharmaceutical agent as a compound used in the diagnosis, mitigation, or therapy of a disease, then a number of chemical entities containing a radioactive nuclide meet these requirements. Such compounds are called "radiopharmaceuticals," and our present discussion is to be limited to recent advances in the nature, preparation, and detection of such labeled materials. We will thus not cover many other very closely related (and sometimes overlapping) areas, such as clinical use of radiation (55) (except when radiopharmaceuticals are used as therapeutic agents), activation analysis of biological materials (56–61), radiochemistry (62–65), radiobiology (66–69), Mossbauer effects (70–71), radiological health (72–75), and others (76–83).

While radiopharmaceuticals differ from other pharmaceuticals only in that they contain a radioactive nuclide, they have generally not been handled by pharmacists. This is due partly to historical reasons (radiopharmaceuticals are usually handled and dispensed by, or under the supervision of, the radiologist or the radioisotope department) and partly to lack of training. However, the number of schools of pharmacy that have radioisotope training in their curricula is increasing and it is hoped that a greater number of pharmacists will become more actively involved in dispensing radiopharmaceuticals (32) once they have adequate training.

Radiopharmaceuticals offer the pharmacist an unusual opportunity for returning to the type of work that was his own years ago, and for which he is still being trained—namely, that of preparing and compounding a pharmaceutical, not just repackaging a completely finished preparation. This is especially true if we consider that there are definite advantages in preparing radiopharmaceuticals at the place of use, particularly those containing many of the "short-lived" radionuclides (see below). The possibility that radiopharmaceuticals may be handled at the retail level (32) is remote, as labeled products cannot be properly transported, stored, and handled except in restricted areas.

DEFINITIONS, TERMS, AND NOTATIONS

While it is assumed that the reader has a working knowledge of radioactivity (62), certain terms and symbols pertinent to this field require some clarification. For more detailed glossaries and dictionaries, the reader is referred to *References 84–87.*

A *nuclide* is a unique atomic species, characterized by its atomic number Z, mass number A, and energy.

Nuclides can be stable or can suffer radioactive decay. Thus, hydrogen has a stable isotope, the nuclide ^{2}H (or D), deuterium, and a radioactive isotope, the nuclide tritium ^{3}H (T). As the term *isotope* has been used in a broad sense, and leads to some confusion when such terms as "isotopic purity," etc., are used, the more precise term nuclide is now being generally adopted.

Atomic species having the same atomic number but different mass numbers are *isotopes;* and atomic species having the same mass *and* atomic numbers, but differing in the energy content of the observable state, are called *isomers* (*e.g.*, ^{99m}Tc and ^{99}Tc, where m denotes metastable).

Radioactive decay is characterized by four parameters. (*a*) The half-life of the radioactive nuclide, *e.g.*, the time necessary for 50% of the material present to decay ($T_{1/2}$). (*b*) The nature of the radiation, *e.g.*, α, β^- (negatron), β^+ (positron), and γ radiation. Of interest also are such phenomena as EC (electron capture) and IT (isomeric transition). (*c*) The energy of the radiation emanating from the nuclide upon decay. (*d*) The nature of the nuclide remaining *after* the radioactive decay process (daughter element).

From a clinical point of view, it is desirable to use labeled molecules *in vivo* for only such time as is necessary and no longer, so as to minimize radiation exposure. For this reason, the terms "long-lived" and "short-lived" are very much used, but they have different meanings according to the interests of the user. Furthermore, in *in vivo* work, we do not have to consider only the physical half-life, T_p, but also the biological half-

life, T_b. This leads to the "effective" half-life T_e (19). We propose the following definitions of effective half-lives for radiopharmaceutical work.

"Very short-lived," T_e less than the duration of the clinical procedure.
"Short-lived," T_e equal to and up to 3 times the duration of the clinical procedure.
"Long-lived," T_e greater than 5 times the duration of the clinical procedure.

These definitions differ from those generally used chemically, where only the physical $T_{1/2}$ is relevant, and where nuclides of less than 2–3 months are considered "short-lived," and where "long-lived" applies to ^{14}C ($T_{1/2}$ = 5720 years) and similar nuclides (88).

Problems raised by the lack of precision in the terminology of radionuclides were carefully analyzed at the Oak Ridge Conference (30) especially by Cohen (89). Thus, while the International Union of Pure and Applied Chemistry adopted in 1952 and 1958 (90) the convention that the mass number is to be written as the *left superscript*, (*e.g.*, ^{14}C, *not* C^{14}), many authors still continue to use in 1967 the older (and incorrect) symbol. Much confusion also arises in the nomenclature of labeled molecules used as radiopharmaceuticals. Thus, U.L. stands for "uniformly labeled," meaning molecules usually obtained by a biological procedure where all the atoms of a given element are labeled with the same specific activity (88, 91). This is not to be confused with random labeling, *e.g.*, when a product is exposed to tritium by the Wilzbach technique (92–94), where large variations can occur in the specific activity of different chemical functions. Several lists of U. S. adopted names (USAN) have been published in the *Journal of the American Medical Association* (95).

Another source of confusion is the term "carrier free." A stable nuclide, *e.g.*, ^{127}I, is often added as a "carrier" to trace amounts of the radioactive nuclide ^{131}I. Sometimes this dilution is intentional, and sometimes it is inherent in the procedure of isolation and purification of the radionuclide (88, 96, 97). Thus, "carrier free" has been used alternatively to mean "no carrier added," and "no carrier present." To avoid confusion, when it is meant that no carrier has been added, it should be so stated (98). Furthermore, the nuclidic composition should be given. For a discussion of radiochemical, chemical, and radioisotopical purity, see under *Manufacture of Radiopharmaceuticals*. Another important designation is the *specific activity* of the radiopharmaceutical, defined as activity [in curies (c.) or fractions thereof] per unit weight or volume. Specific activities are often expressed as mc./m*M*, μc./mg., or μc./ml. A high turnover and a highly exchangeable biological pool of the material under study requires materials of high specific activity, especially in the newly developing field of radioimmunoassay (99, 100). The importance of a careful consideration of biochemical relationships, such as turnover, exchangeable pools, etc., has been carefully discussed by Bayly (101). The chemical stability or exchangeability of the radionuclide of the tagged radiopharmaceutical is also important to ensure the reliability of the chemical diagnosis (102, 103). Thus, many tagged products have a short shelf-life, and should be freshly analyzed before usage (104).

RECENTLY INTRODUCED RADIOISOTOPES AND THEIR COMPOUNDS FOR USE IN NUCLEAR MEDICINE AND PHARMACY

The use of radiopharmaceuticals in diagnostic nuclear medicine and therapy falls into several, not too rigidly defined, categories as shown in Table I. These illustrate the diversity of the uses and recent developments in radiopharmaceuticals.

Of the 102 elements and about 1,000 nuclides of these, only nine nuclides of six elements comprise 70% of the medical uses. These are ^{131}I, ^{51}Cr, ^{125}I, ^{99m}Tc, ^{132}I, ^{22}Na, ^{85}Kr, ^{197}Hg, and ^{203}Hg (31).

TABLE I.—SCOPE OF RADIOACTIVE TRACER METHODOLOGY IN BIOLOGY AND MEDICINE

Isotope Dilution	Diffusion and Flow	Metabolic Studies
Body compn., *e.g.*, total body K and H_2O.	Spatial distribution as in organ and whole body scanning.	Metabolism of amino acids *e.g.*, ^{75}Se-methionine.
Body spaces, *i.e.*, volumes of distribution, *e.g.*, chloride and hormone spaces.	Positive and negative concentration in organs and tissues by space-occupying structures.	Metabolism of carbohydrates, drugs, hormones, lipids, minerals, and proteins.
Body fluid volumes, *e.g.*, blood and plasma volumes.	Cardiac output.	
Exchangeable body elements, *e.g.*, Na and K.	Cell membrane absorption and permeability.	
	Regional circulation, *e.g.*, coronary, hepatic, and renal.	

A radiopharmaceutical or substance used in nuclear medicine is characterized by four major parameters: (*a*) its sojourn or time-course within the organ or lesion under study, relative to other structures as in tumor or organ scanning, (*b*) the type and rate of radioactive decay, (*c*) its detection characteristics, and (*d*) its production and preparation (31).

In view of the above parameters, it is readily understandable why the development of new radiopharmaceuticals has been in the direction of the use of compounds containing short-lived nuclides, preferentially those which produce only γ or positron radiation. These radionuclides provide radiation adequate for scanning with little or no useless and undesirable β radiation, and have only a short physical half-life, thereby yielding minimal total body or regional radiation.

Presently there are 32 γ or positron emitting radionuclides used in nuclear medicine, either as their inorganic salts, or as organic compounds. These nuclides vary in physical half-life from 1 hr. for ^{68}Ga to 10.3 years for ^{85}Kr (31). A major drawback in the development of nuclear medicine has been the limited ability to synthesize appropriate radiopharmaceuticals with definite biochemical behavior incorporating these short-lived radionuclides.

However, as an example of the successful preparation of such compounds, ^{99m}Tc with a physical half-life of 6 hr. and emitting only desirable γ rays for scanning, has been incorporated extemporaneously into several compounds with desirable biological behavior. These compounds are ^{99m}Tc-labeled human serum albumin as a sol (105) for placental scanning (106); as a macroaggregate of several particle sizes for distribution and scanning the liver and spleen and lung (107).

Several other ^{99m}Tc compounds have been prepared: colloidal ^{99m}Tc-sulfide has been used for liver scanning (108); ^{99m}Tc-thiocyanate dispersed in an injectable fat emulsion (109, 110) has also been used as a liver scanning agent. The pertechnetate, $^{99m}TcO_4^-$, has found wide acceptance as an agent for brain tumor scanning (110), for determining the trapping index of the thyroid (111), and for scanning the thyroid (112).

Technetium-99*m* is prepared as sodium pertechnetate by eluting or "milking" the generator or "cow" in which it is formed by the decay of ^{99}Mo which has a half-life of 2.8 days. Thus, the ^{99}Mo can be prepared at a reactor site or cyclotron, separated, and shipped as a "cow" and the ^{99m}Tc prepared extemporaneously.

Similarly, other generators are available for the production of other potentially desirable and useful short-lived radionuclides as radiopharmaceuticals. Six other generators are presently available—namely, ^{132}Te yielding ^{132}I (96); ^{87}Y yielding ^{87m}Sr (96); ^{137}Cs yielding ^{137}Ba (113); ^{68}Ge yielding ^{68}Ga (96); ^{113}Sn yielding ^{113m}In (54); and ^{103}Pd yielding ^{103m}Rh (54).

Iodine-132 is produced by decay of the parent ^{132}Te which has a $T_{1/2}$ of 3.2 days. Iodine-132, $T_{1/2}$ of 2.33 hr., has been used as the iodide for thyroid scanning and uptakes, especially in children and pregnant women in order to minimize the radiation dosage to the thyroid gland (114).

Other radioiodine isotopes have been proposed (115) for studies of thyroid physiology, measurement of uptake, and scanning based on short physical half-life and lack of undesirable radiation, but ^{131}I continues to be used most generally (114, 115).

In consideration of the parameters stated above for a radiopharmaceutical and the principle of minimum radiation dosage to the patient, the development of ^{57}Co-labeled cyanocobalamin (vitamin B_{12}) is exemplary.

Schilling (116) in 1953 devised a test for pernicious anemia using cyanocobalamin containing ^{60}Co. The liver is the repository of any unexcreted cyanocobalamin Co 60 and thus becomes the critical organ of exposure, especially since the biological half-life was shown to be from 315 to 450 days (117). In order to reduce the radiation received by the liver other radioisotopes of cobalt were sought which would reduce the radiation, and ^{57}Co appears best (118). By the substitution of ^{57}Co, the radiation dose to the liver is reduced to $^1/_{29}$th of that delivered by cyanocobalamin Co 60, a very desirable result.

In an attempt to reduce the radiation delivered to the kidneys during scanning of these organs (119) and also as a result of brain scanning using radioactive mercury-labeled chlormerodrin, ^{197}Hg has been substituted for ^{203}Hg in this compound (120). Since the $T_{1/2}$ of ^{197}Hg is 2.7 days *versus* a $T_{1/2}$ of 47 days for ^{203}Hg, the radiation dose is markedly reduced (28).

Recently, 1-mercuri-2-hyroxypropane labeled with ^{197}Hg has been proposed for scanning the spleen (121). This substance binds tightly to the red cells and damages them, so that now these damaged red cells are sequestered by the spleen, providing a tool for scanning that organ.

The spleen can also be scanned successfully by the use of red cells which were previously treated with sodium chromate Cr 51 and subsequently heat-damaged, resulting in their sequestration by that organ (122).

An example of the development of a new agent for scanning the pancreas for inflammation, car-

cinoma, and morphological abnormalities is that of ^{75}Se-L-methionine. This selenium analog of methionine is incorporated rapidly into pancreatic tissue with as much as 7% being incorporated in this organ and with a pancreas to liver ratio of concentration of 8:1 (123). Selenium-75 has a $T_{1/2}$ of 128 days and a principal γ ray energy of 0.27 Mev., quite suitable for scanning.

More recently ^{75}Se-L-methionine has been proposed as an agent for scanning the parathyroid gland (124). It was found that after injection, the activity in the parathyroids was 2 to 3 times higher than that found in thyroid, muscle, and blood. Adenomata were successfully located preoperatively, but this method awaits further clinical establishment.

In recent years attempts have been made to develop new radiopharmaceuticals for assessing the biochemical functions, or for delineating morphological structures, based on biochemical or physiological principles. The use of ^{131}I-labeled iodohippuric acid for kidney function testing and scanning was based on the well known conjugation and elimination of benzoic acid in the form of hippuric acid, and the established rapid renal tubular secretion of iodohippuric acid (125). Sodium Iodohippurate I 131[1] has become the agent of choice for renal function testing and has found wide use as an agent for measuring differential renal blood flow, coronary blood flow, and for many other dynamic fluid physiological studies. This compound is included in the U.S.P. XVII (126).

When no suitable radioisotope of an element is available, as is the case with chlorine, it has been possible to substitute one chemical element for an analog. This is exemplified by the use of ^{82}Br, as the bromide, instead of the chloride ion. Bromine-82 with a $T_{1/2}$ of 36 hr. has essentially the same body distribution as chloride and is used as an acceptable and reliable measure of the extracellular distribution of the latter (127).

Similarly, ^{86}Rb has been used to measure exchangeable potassium and suitable clinical methods have been developed (128).

In line with the thinking that minimal radiation to the patient is optimal, recent developments are the *in vitro* tests, as, for example, those used for thyroid function. In these tests, no radioiodine is administered to the patient; rather, the test is performed on the patient's serum, permitting even serial tests of children and pregnant females. These tests use L-iodothyronine I 131 and anion-exchange resins; more recently, the resin has been incorporated in a polyurethane sponge, thus simplifying the test and allowing greater reproducibility (129). Other techniques using anion-exchange resins to replace the red cells, as proposed by Hamolsky *et al.*, are also available (130).

A promising field of development likely to be expanded in the future is the preparation of chelates of many short-lived radionuclides. As an example, ^{197}Hg has been chelated with calcium and ethylenediaminetetraacetic acid for use in kidney scanning (131). It is selectively secreted by the renal cortex and the radiation dose to the patient is somewhat less than that from a much smaller dose of chlormerodrin Hg 203.

Heretofore, studies of magnesium, a biologically important element, have been hampered. Recently, however, ^{28}Mg with a half-life of 21.3 hr. became available with high specific activity. Extensive investigations of magnesium metabolism, such as exchangeable Mg in animals and in man, have been made possible (132, 133).

Recent advances in scanning techniques of great importance in nuclear medicine were coincident with the development of new radiopharmaceuticals and new forms of previously used radiopharmaceuticals. In "scanning," the delineation of the size, shape, location, or morphological characteristics of an organ or structure are indicated by a diagrammatic or photographic (light or dark) rendition of the localization of the radionuclide or its compound. It is obvious that radiopharmaceuticals, trophic to these structures by virtue of their biochemical or physiological characteristics, are desired.

Recent developments have occurred with the introduction of macroaggregates of human serum albumin containing radioiodine for scanning the liver, lung, and spleen (106, 107) and several compounds of ^{99m}Tc (108–111) for similar purposes; diuretics containing radioactive mercury for brain and kidney scanning; labeled amino acids for incorporation into organs rapidly synthesizing proteins, as for example, the use of ^{75}Se-L-methionine in pancreas scanning; and the labeling of erythrocytes with ^{51}Cr or 1-mercuri-2-hydroxypropane-^{203}Hg or MHP-^{197}Hg for spleen scanning (121).

The development of therapeutic radiopharmaceuticals is paralleling the development of diagnostic agents. As an example, ethiodized oil[2] I 131, which consists of the ethyl esters of the iodized fatty acids of poppy seed oil, has been prepared containing approximately 5 mc. ^{131}I

[1] Marketed as Hippuran I 131 by Volk Radiochemical Co.

[2] Marketed as Ethiodol by E. Fougera & Co., Inc., Hicksville, L. I., N. Y.

per ml. Following intralymphatic infiltration this material delivers therapeutic irradiation to pathological lymph nodes and can be used alone or in conjunction with irradiation for the destruction of malignant lymphatic tissue (134, 135).

Recent additions to the armamentarium of radioisotope therapy are the radioactive colloids. Yttrium-90, an almost pure β emitter with a half-life of 65 hr., is "milked" from a ^{90}Sr generator. The ^{90}Y is converted to the chloride which hydrolyzes at a pH of 7.0 to 7.8 and behaves like a colloid. It has been used to treat malignant serous effusions (136). Colloidal yttrium fluoride and hydroxide have been proposed also for use in yttrium therapy.

Recent investigations of the use of ^{131}I combined with colloidal size ion-exchange resins have been made for use in localized treatment of some types of cancer (136).

Radioisotopes for diagnostic and therapeutic uses have been prepared in a variety of dosage forms. (See Tables II and III.)

Capsules containing radioisotopes for diagnostic and therapeutic purposes were designed as a safe and effective method of administration (137) and are presently widely used for several labeled materials.

Radioiodinated human serum albumin is available in standardized doses in plastic disposable syringes from several suppliers. These can be used in conjunction with digital computing equipment for rapid blood volume determinations based on the principle of isotope dilution (138).

Most radioactive chemicals for use in nuclear medicine have been chosen on the basis of the characteristics of the radioisotope contained or its chemical or physical form, rather than its biological behavior or sojourn.

Only four commonly used radiopharmaceuticals can be classed as "biochemicals" and are used on the basis of their biochemical behavior (101). They are: labeled cyanocobalamin, thyroxine, triiodothyronine, and ^{75}Se-labeled selenomethionine.

According to the authors, a similar justifiable inclusion would be the labeled ions of iodide, phosphate, calcium, and those of some trace metals.

Obviously, there is need for the development of radiopharmaceuticals resembling natural biochemicals, which could be incorporated in tissues and biological structures. Such radiopharmaceuticals should have desirable characteristics for their detection in nuclear medical procedures. With the development of newer and simpler techniques for assaying ^{14}C and ^{3}H compounds, labeled analogs of natural biochemicals will find ever-increasing use in nuclear medicine.

METHODS OF DETECTION

When radionuclides decay they emit one or more types of radiation: α (helium nuclei), β^- (negatrons), β^+ (positrons), γ or X-rays. These radiations are able to ionize matter and produce ion-pairs. Thus, one method of detection of radioactive decay is based on the collection and measurement of the ions produced by the ionizing radiation. Such an instrument is the Geiger-Mueller (G.M.) tube. A second method of detection is based on the fact that certain molecules will absorb energy and not become ionized, but instead undergo a transition to an excited state. The decay of that excited molecule to the ground state is accompanied by the emission of electromagnetic energy, usually in the ultraviolet or visible range of the spectrum. This light pulse is converted by photomultipliers to an electrical pulse which is then measured. These techniques are called scintillation detection methods, and are the most widely used in the measurement of radionuclides of clinical interest. New methods of detection using semiconductor or solid-state detectors are being developed (139), but they are not yet used clinically to any great extent.

A fourth method of detection is based on chemical reactivity, with, for example, silver halides in photographic emulsion. Photographic methods of detection such as autoradiography are extensively used in pharmacology.

For a more detailed discussion of detectors, the reader is referred to Price (139). Recent progress in solid-state detection, which may become very useful for measurement of low energy γ emitters such as ^{125}I and ^{197}Hg, has recently been reviewed (140, 141).

Perhaps the most important development in the last 10 years has been the introduction of solid state electronics. Thus, large and bulky tube models have been replaced by more efficient, reliable, and compact solid-state electronic systems. For a full discussion of these topics, see Yanof (142) and Malmstadt (143).

Most radionuclides of biological interest are either β^-, γ, or β^+ emitters; practically no radionuclide of clinical interest is an α emitter. β^- Radiation is very easily absorbed by tissue, and does not lend itself easily to dynamic clinical studies of deep-seated organs. Best suited are radionuclides emitting γ radiation, either by direct decay, as a result of β^+ annihilation (the $T_{1/2}$ of the positron is 1.5×10^{-10} sec.) or X-rays emitted after electron capture. γ Radiation is

best detected by scintillation type detectors, and most instrumentation used in clinical work utilizes them.

The radiopharmaceuticals most widely used are discussed below. They are used in the visualization of organs for space-occupying defects, to assess their function, and to determine dynamic changes in body constituents.

Scanning was first utilized to visualize the thyroid gland (144) and has since developed into a most important procedure of nuclear medicine. Several comprehensive reviews cover the subject (145–147).

When a labeled compound localizes preferentially in an organ, *e.g.*, I^- in the thyroid gland, the intensity of the radiation emanating from each part of the organ under study will be proportional to its physiological state. Thus, a nonfunctional nodule will appear to concentrate less radioactivity, whereas a hyperfunctional area will concentrate a larger amount of the radiopharmaceutical.

A scanner is a scintillation detector, capable of moving mechanically over the area to be studied. A scanning system is composed of: (*a*) a detector, (*b*) a collimator and shield, (*c*) a mechanical movement device, (*d*) data presentation and display.

The original thyroid scanning detector used a $^1/_4$-in. crystal (144); the efficiency of such a system was low, and presently crystals of 2 × 2 in. and 3 × 2 in. are used routinely, with an increase in efficiency of over 100-fold. Larger detectors need larger shielding and efficient collimation, and much effort has been devoted to improving the quality of focusing collimators (148). Furthermore, the increase in shielding and in collimation increases the weight of the scanning device, creating severe mechanical problems. Further details on scanning devices can be obtained from several major manufacturers of such equipment.

A major effort has been devoted to improvement of data presentation. The original dot scan, giving series of black dots on white paper, has been considerably improved for greater ease of interpretation of the results obtained. Thus, Kakehi *et al.* (149) developed a device whereby the impulses from the spectrometer were fed into a strobo-tube, with different colors representing increasing intensities. A similar device is the photorecorder of Adams and Jaffe (150).

While scanning devices are still extremely important, they have several disadvantages, such as the long time needed to complete a scan and the high dose of radionuclide needed. A new approach is that of the scintillation cameras, first developed by Anger (151). The large crystal detector views the whole organ, and the scintillations are transmitted to a battery of small phototubes. The whole organ is thus seen in its entirety, reducing the time necessary for a single scan, allowing a dynamic observation of the organ, the use of nuclides of shorter half-life, etc. (152).

Several models of such cameras have been developed. The original Anger camera (151) consists of a single large crystal. A modification of the scintillation camera is the Autofluoroscope of Bender and Blau (153), consisting of a mosaic of several hundred scintillators. A third instrument has been described by Ter-Pogossian (154) which consists of a fluorescent screen and a specially designed image amplifier tube.

More recently, much interest has been raised by spark-chamber types of devices, such as the Spintharicon (155), the spark-chamber of Kellershohn (156) and the cross-wire spark-chamber (157), usable for both β and γ counting.

Decay by positron emission is followed in 1.5×10^{-10} sec. by positron annihilation, producing 2 photons of 0.51 Mev. each, that are emitted at an angle of 180°. The use of two scanners, 180° apart, or of two scintillation cameras, also 180° from each other, has been used for brain tumor localization (158), although conventional γ scanning appears to be equally effective.

Certain nuclides, such as ^{40}K, are distributed throughout the body. Their level can best be measured by whole body counters. These can be either of the NaI type, with one or more detectors (159–161), or of the liquid scintillation type first described by Anderson *et al.* (162). More recently, a system has been described with 18 organic plastic detectors employing 72 photomultiplier tubes, able to determine whole body counts as well as localization in organs (163).

Thus, a highly sophisticated array of instrumentation exists and is being developed for the measurement of radionuclides *in vivo*. As will be seen below, the next great advance in this field will come by the use of other radionuclides, which according to Stang can be "tailored to will" (164), and by a thorough understanding and application of biochemical and pharmacological principles applied to radiopharmaceutical drug design (31, 101).

Also, the development of clinical tests using ^{14}C and ^{3}H-labeled compounds has been made possible by improvements in counting techniques such as the liquid scintillation counters (139, 165, 166).

CLINICAL APPLICATIONS

The clinical applications of radiopharmaceuticals are divided into two main categories: (*a*) those used in diagnostic procedures and (*b*) those used for therapy. An extensive survey of these uses is beyond the scope of this review and the reader is therefore referred to some very excellent recent source material (14, 29, 31, 38, 167–169). However, the general lines of research and development will be presented here.

The improvement and simplification of counting techniques and equipment for weak β emitters has resulted in the use of ^{14}C and ^{3}H-labeled compounds in medical and biomedical techniques. Tritiated water is now widely used in the determination of total body water (170). Uniformly labeled ^{14}C-glucose has been used to study glucose kinetics in normal, diabetic, and acromegalic subjects (171). In this study the quantities of expired CO_2 and $^{14}CO_2$ in the mixture were monitored (172) and deviations from the normal range for the diabetic and the acromegalic subjects were observed.

Studies of fat absorption, using ^{131}I-labeled triolein, are open to serious question because the iodinated triolein is not a single compound, and frequently contains impurities. These have also been labeled, but they do not behave biologically like triolein (173). It is absolutely necessary to separate the labeled triglyceride from the other materials using techniques such as thin-layer chromatography and gas–liquid chromatography, both in their analytical and preparative aspects. It is incumbent upon the investigator to prove the purity of his materials so as to eliminate any uncertainty in the clinical test. Some investigators using the commercially available ^{131}I-labeled triolein in an empirical manner have obtained consistent results suitable for diagnostic purposes.

It has been argued that an iodinated, or an iodinated and chlorinated, fat or fatty acid no longer behaves biologically like the original fat or fatty acid, and only ^{14}C-labeled lipids prepared by biosynthetic methods truly resemble the unlabeled fat. This subject was recently reviewed (174).

Tables II and III illustrate the diversity of composition of some radiopharmaceuticals used in nuclear medicine. The doses given are variable, depend on the equipment and technique used, and are thus only approximate. The references

are representative and not exhaustive. Names follow the USAN nomenclature (95) where available; otherwise common names are used. They are arranged very generally in the order of frequency of use. The reader is also referred to a more extensive table compiled by Silver (169).

MANUFACTURE OF RADIOPHARMACEUTICALS

Radioisotopes used in the preparation of radiopharmaceuticals and labeled compounds are prepared by prime producers who use reactors or cyclotrons. The products are then processed, purified, prepared in pharmaceutically acceptable forms, and assayed. They may be purified to meet the official requirements of the U.S.P. XVII (126) if standards have been established for such materials. These standards are minimal and many manufacturers have set their own more rigid specifications for identity and purity.

The provisions of the Federal Food, Drug and Cosmetic Act of 1938, as amended, apply equally to radiopharmaceuticals as to all other kinds of drugs (208).

Standards of purity, for example, as applied to usual pharmaceuticals are wholly inadequate with reference to radiopharmaceuticals. Some consideration of the necessary criteria for radiopharmaceuticals and their significance will be discussed here. *Chemical purity* is used in the customary sense to denote the presence or absence of chemical substances other than the desired single or multiple species. *Radiochemical purity* might be defined as the fraction of the stated radionuclide in the stated chemical form, as for example, sodium *o*-radioiodohippurate I 131 should not contain I 131 in the form of radioiodide or *o*-radioiodobenzoate. *Radionuclidic purity* refers to the proportion of the total activity in terms of the designated radionuclide. For example, chlormerodrin Hg 197 ($T_{1/2}$ = 65 hr.) prepared from irradiated naturally occurring mercury might contain ^{203}Hg amounting to 4% at the time of receipt. This amount of long-lived ^{203}Hg ($T_{1/2}$ = 46.9 days) is acceptable for immediate use, though undesirable. However, this level will have risen to 21% of the total activity at the end of 1 week and this is not acceptable. The use of enriched ^{196}Hg for the preparation of the ^{197}Hg used in formulating radiomercury diagnostic agents is an important development (209). The use of ^{197}Hg with its $T_{1/2}$ of 65 hr. is desirable for reducing the radiation delivered to the kidneys.

In addition to the criteria of purity, injectable solutions must meet the requirements of sterility, nonpyrogenicity, and all the other standards for parenteral products. While these are the responsibility of the original manufacturer, they apply equally to extemporaneous dilutions and subdoses as prepared in the hospital or nuclear medical clinic. Terminal sterilization in the final container or sterilization by filtration are most acceptable for radiopharmaceutical preparations.

Radiopharmaceuticals suffer radiolytic disruption and change, especially during storage, due to the radiant energy contained. Therefore, the nature and content of the products must be known. Inasmuch as the biological behavior of the split products may be entirely different from that of the desired material, clinical or scientific deductions would be erroneous. Radiopharmaceutical manufacturers therefore subject their products to analysis at the time of preparation, and after appropriate storage, to determine

"shelf-life" (210). Methods employed are column and paper chromatography and autoradiography, electrophoresis, γ spectrometry for radionuclidic purity and contamination, spectrography, chemical separations by the use of carriers, and others (89). Instability associated with radiolytic breakdown is dependent upon the energy of decay of the radionuclide, the specific activity, and the usual physical factors of light, temperature, solvent, oxygen, etc.

The reader is referred to an excellent review of quality control concerning the preparation, formulation, sterility procedures, and all other operations involved in production of radiopharmaceuticals and extemporaneous dilutions for a moderately large installation (104). Many of the procedures are equally applicable to small hospital and nuclear medical clinics (211).

In the manufacture of radiopharmaceuticals, antioxidants, buffers, antibacterial preservatives, stabilizers, and solvents are all required. The composition and reactivity of these materials are of prime importance.

The maintenance of sterility in radiopharmaceutical solutions is achieved by the addition of antimicrobial agents such as phenol, the methyl and propyl esters of *p*-hydroxybenzoic acid, and, most frequently benzyl alcohol. The choice of the bacteriostat is of utmost importance. It has been reported that benzyl alcohol, used in high activity solutions of radioiodide, reacted with the products of the radiolysis of water to form iodinated products, which showed a lower thyroid uptake and urinary excretion in rats after 4 hr., compared to a solution not so preserved (212). However, similar studies in humans have not been reported.

β-Naphthol used as a bacteriostatic agent in gelatin capsules for ^{131}I led to an iodinated β-naphthol as a radiochemical impurity, which made this pharmaceutical unsuitable for determining the function of the thyroid gland (89).

Antioxidants such as ascorbic acid, sodium ascorbate, cysteine hydrochloride, sodium sulfite, and thiosulfate are used to maintain radionuclides in the reduced form and at the proper valence state. Examples are ferrous citrate Fe 59 and sodium iodide I 131. In the case of the latter, solutions not properly protected against oxidation led to erroneous thyroid uptakes (213).

Buffers and stabilizers are added to radiopharmaceuticals to prevent the precipitation and reactions of the pharmaceutical with contaminants in the solution and from the glass containers. Sodium citrate has been used by the manufacturers to prevent calcium precipitation in some solutions. Great care must be exercised in the choice of additives to radiopharmaceuticals, so as to prevent precipitation and loss or removal of the minute quantity of the radionuclide present, or of inducing chemical changes in the nature of the tagged material.

Sterility is of prime importance in injectable radiopharmaceuticals. The problem is compounded by the short half-life of the radionuclide and the time required for an adequate insurance of sterility and nonpyrogenicity. The U.S.P. XVII (126) prescribes the methods to be used. The manufacturers have been permitted to release parenteral radiopharmaceuticals before the completion of the usual sterility test. Extensive testing, as well as the use of additional techniques, and a backlog of experience in the preparation of injectables, have insured an excellent record for the manufacturers. Many lots of radiopharmaceuticals, where the half-life and other factors do not preclude the preparation in advance of the required demand, allow for adequate sterility and pyrogenicity testing. The experience of one manufacturer, which is typical, is of interest (214).

The large-scale producers and manufacturers have been quick to translate the research findings of the radiopharmaceutical chemists and clinicians into practical production. Although they have not themselves developed new radiopharmaceuticals, they have made an enormous contribution in furthering the development, assisting research, providing materials for clinical trials, and conducting research on product improvement, dosage forms, and availability. The radiopharmaceutical manufacturers have offered "custom" services in the preparation of new materials such as iodination and tritiation as well as the preparation of specifically labeled compounds and intermediates and providing commercially unavailable radionuclides. Product improvement has taken the form of providing radiopharmaceuticals which yield less radiation such as in the substitution of the radionuclides ^{57}Co or ^{58}Co in place of ^{60}Co in preparations of radiocyanocobalamin, and of ^{197}Hg in place of ^{203}Hg in chlormerodrin.

The record of the manufacturers in making ^{99m}Tc available as "cows" and as rapidly delivered sterile solutions is impressive. Much credit is to be given to Brookhaven National Laboratories for developing and making available "cows" or generators for short-lived radionuclides before they were available from other sources (96).

The presentation of dosage forms of radiopharmaceuticals by the manufacturers has facilitated their use. Capsules, predated to contain definite doses at some specified time, single

and multiple dose vials, and unitary packages of sterile precalibrated doses in disposable syringes, are some outstanding examples.

Research and development has resulted in safe and convenient containers designed to minimize the radiation hazard to those engaged in handling and dispensing them. One manufacturer ships the products in outer containers made of polyethylene and lead which prevents shattering if dropped and also provides for complete drainage while held in such a container. Another major manufacturer provides bottles coated with a thick plastic covering to prevent shattering if the bottle is dropped or subjected to stress. Ease of opening both inner and outer containers has been provided by the manufacturers. Containers are adequately shielded for shipment and storage (167).

In 1946, 38 licenses were issued by the U.S.A.E.C. to medical institutions and hospitals to use radioisotopes and in 1955 this grew to 1149, while in September 1965, the number issued to medical institutions and physicians increased to 3600, in addition to about 1900 government laboratories and 500 colleges and universities, many of which were using radiopharmaceuticals and labeled compounds (215). From these figures the growth of the radiopharmaceutical industry is readily understandable. One large company has recently opened a new plant reputed to double its output of radiopharmaceuticals. It has been reported that the radiopharmaceutical industry has grown about 20% per year (216) and current sales are about $8 million per year (217).

There are several large American pharmaceutical companies and a number of smaller ones providing a wide range of radiopharmaceuticals, radionuclides of varying quality, and labeled compounds as well as special services. Much desirable reference material is available without charge from these companies, and the reader is urged to consult these sources.

Attempts have been made to prepare labeled drugs by exposure to a neutron flux, so as to induce the formation of radionuclides from some element present. As an example, probenecid [*p*-(dipropylsulfamyl)benzoic acid] was irradiated with fast and slow neutrons giving rise to ^{35}S and ^{32}P, both β emitters (218). There was much decomposition but pure material was isolated with a specific activity of about 12 μc./m*M* as ^{35}S. A trace of ^{32}P was formed and not removable. The distribution was studied in rats and found to accumulate mostly in the kidney. 5-Acetamido-1,3,4-thiadiazole-2-sulfonamide[3] was also irradiated by these same workers and a very pure product was obtained in a lower yield containing ^{35}S.

In the U. S. another group has reported the results of preliminary investigations of neutron irradiation of many compounds such as ethanol, nicotinic, phenylacetic, and salicylic acids, glucose, reserpine, and tetracycline. The instrumentation and techniques as well as the advantages and disadvantages are described (219). In these techniques radioisotopic yields are small and extensive purification of the products is required.

However, while recoil labeling has considerable limitations, it may be a very useful tool for the tagging of radiopharmaceuticals with radionuclides of very short half-life, such as ^{11}C ($T_{1/2}$ = 20.3 min.), ^{18}F ($T_{1/2}$ = 1.7 hr.) and others (220). As an example of at the site production of radiopharmaceuticals we can cite the work of Matthews *et al.* (221) on radioactive gases, used for respiration and lung function. They used ^{15}O ($T_{1/2}$ = 2 min.), ^{13}N($T_{1/2}$ = 10 min.), and ^{11}C.

RADIOPHARMACEUTICALS AND PHARMACOLOGY

"The use of isotopes in experimental pharmacology has facilitated investigations that without their use would have been cumbersome or difficult, and in other cases impossible to solve," states Roth (222). The pharmacologist has thus been able to make good use of the extraordinary tool provided by labeled compounds (drugs). It might also be safe to say that practically all new pharmaceuticals that are being studied today are labeled at some stage of preclinical testing, to study their biotransformation and other parameters of biological significance. A recent symposium has been devoted to Isotopes in Experimental Pharmacology (223), and this specific topic was reviewed in *J. Pharm. Sci.* a few years ago (224) as well as elsewhere (225–228).

Perhaps the greatest use of labeled compounds is in the study of drug metabolism and biotransformation. The information that can thus be obtained is: (*a*) rate and route of elimination; (*b*) biotransformation: number, nature, and rate of elimination of metabolites; (*c*) localization and penetration of a drug and its metabolites in organs and on specific subcellular structures; (*d*) identification of any "active" metabolite, and evaluation of its pharmacological action.

It is impossible to list here all metabolic studies of drugs elucidated with the aid of radionuclides; the following examples will serve to illustrate the potentials of such techniques.

[3] Marketed as Diamox by Lederle Laboratories, Pearl River, N. Y.

Phenobarbital is excreted either unchanged or as conjugated derivatives, as established after a study of the fate of 2-^{14}C-phenobarbital. When, however, it was suggested that the opening of the pyrimidine ring also occurred, labeling in the 5 position (5-^{14}C-phenobarbital) gave products identical to those obtained from the 2-^{14}C radioisomer, precluding any significant contribution of other metabolic routes (229). Thus, not only should that position be labeled that is easiest from the synthetic point of view, but so should any others that will provide significant information.

An elegant technique has been developed by Lissitzky *et al.* (230) for the study of thyroid function and the action of several pharmacological agents on thyroid processes. Pregnant rats were fed on a ^{127}I free diet, (*e.g.*, Remington), and given ^{125}I as the single iodine source. After birth, the young rats were kept on this same diet, so that their thyroid had only ^{125}I. When dynamic studies were conducted, ^{131}I was used, allowing a clearer understanding of the pharmacological action of goitrogenic agents. Such studies illustrate the potential of the simultaneous use of several isotopes of the same element (115).

Another aspect is illustrated by the work of Buyske and co-workers (231) on the agents affecting the activity of tetracycline. Tritium-labeled tetracycline was used, by an isotope dilution technique, for the determination of tetracycline levels in blood. Other labeled materials could be rapidly screened as synergistic agents, and this led to an understanding of the interaction of calcium salts with tetracycline.

Body distribution of drugs is of the utmost importance. Several techniques have been developed recently, based on autoradiographic methods, for determining drug distribution and localization. They involved administration of the labeled drug to an animal, which is then sacrificed by freezing at $-80°$, and sections are prepared at $-10°$ (232) or at $-60°$ (233) followed by autoradiography of the dried sections. The results of such methods of cellular localization are only now beginning to emerge, and will certainly constitute an important tool in the determination of the mechanisms of drug action.

Roth *et al.* (234) have studied the entry of drugs into the brain in an attempt to understand the factors that influence and control the barrier function that restricts the entry of substances into the central nervous system. Among the drugs studied were acetazolamide, thiopental, diphenylhydantoin, and pyridine 2-aldoxime methiodide (2-PAM). These authors observed that the blood-brain barrier could be altered by the percentage of CO_2 in plasma, convulsions, and sensory stimulation, thus suggesting that proper manipulation of such factors may allow a directive effect in brain localization.

An intriguing tool is that of the deuterium isotope effect. Deuterium is an isotope of hydrogen with a mass of 2. Differences in reaction rates have been observed between H- and D-labeled compounds. When there is a transfer of the isotopic atom from the reactant to an acceptor, a primary isotope effect ($k_H/k_D = 1.5$ to 10.0) can be observed. A further isotope effect (secondary) is observed when no transfer occurs, but the isotope is strongly involved in the interaction with the active site of the enzyme ($k_H/k_D = 1.05$ to 1.30). The significance of such isotope effects has been studied by several authors. Thus, the flavoprotein nature of the monoamine oxidase system was demonstrated by Belleau (235), while the nature of the interaction between morphine and its receptor site was studied with the aid of *N*-deuteromethyl morphine by Elison *et al.* (236).

A variety of methods have been developed specifically for the synthesis of labeled radiopharmaceuticals. Stepka and Larson (237) isolated nicotine, digitoxin, and ephedrine, among others, from higher plants grown in an atmosphere enriched with $^{14}CO_2$. Chemical syntheses have been widely reviewed, and the reader is especially referred to excellent papers by Rothchild (238) and Bayly (101, 239) as well as to reviews previously mentioned (88, 91, 102, 103).

While both pharmacologists and biochemists have been making excellent use of radionuclides in the understanding of physiological, pharmacological, and pathological processes, the same cannot be said for those in nuclear medicine. As Bayly points out (101), only a few radiopharmaceuticals currently in use as diagnostic agents are true "biochemicals," while all others are either inorganic salts or tagged polymers. The need for designing new radiopharmaceuticals, based on the principles so successfully applied to experimental pharmacology and biochemistry, is great, and Wagner (240) has analyzed the characteristics of an ideal radiopharmaceutical, which should guide research in the development of new agents of this type.

USE OF RADIONUCLIDES AND RADIATION PROCEDURES IN THE PHARMACEUTICAL INDUSTRY

Since the last excellent review of the applications of radionuclides and radiation in the pharmaceutical industry (241) only a limited number

of reports have appeared concerning application of radioisotope techniques to the pharmaceutical industry.

This review will present and correlate these reports and will show some diversified applications. It is sincerely hoped that pharmaceutical scientists will acquire proficiency in the techniques of radioisotope methodology and adapt this unique tool to the pharmaceutical industry.

The system of quality control, pyrogen testing, and sterility control in operation in a large clinical center laboratory for the preparation of radiopharmaceuticals is well described by Briner (104, 211). The recommendations he makes are equally applicable to smaller nuclear-medical and radiopharmaceutical installations.

A patent was issued for a capsule for radioactive pharmaceuticals consisting of a nontoxic water-soluble material and containing a solid material that melts at body temperature. The material is compounded from a pharmaceutically acceptable oil and contains the radioactive product (242). The thickness of the wall of hard gelatin capsules is determined by measuring through the capsule wall the attenuation of the β radiation of a ^{36}Cl source on the tip of the steel dipping pin. A change of 0.0001 in. in thickness was detectable by a change in the counting rate (243).

The moisture content of rubber stoppers and aluminum ferrules used for packaging biological products was determined by measuring retained tritiated water (244).

The determination of moisture content of calcium carbonate, which should be equally applicable to other pharmaceutical materials, was determined by measuring the transmission of β particles from a ^{90}Sr source (245).

A radioisotopic method for evaluating dispersed systems such as liquid petrolatum emulsions for uniformity has been developed (246). The radioisotopic method was much faster for determining the phase uniformity of emulsions and for expressing ratios of creaming, than any other method used.

The determination of rates of settling of suspensions was determined by measuring the characteristic irradiation from a sealed β source. The source was immersed and the attentuation of the beam which passed through a vertical column of the suspension was measured. This method was suggested for determining the sedimentation rate of pharmaceutical suspensions containing elements of high atomic number (247).

Several contributions have referred to the use of activation analysis for the quantitation of trace quantities of metals and other materials used in pharmaceuticals (56–61).

The status of radiation sterilization of pharmaceuticals and medical supplies has not altered significantly since the last general reviews were presented in 1960 (7, 241).

These processes of sterilization are based on the lethal effects of high energy ionizing radiation on living organisms. The radiation may be very high energy electron beams produced in a linear accelerator, or γ radiation produced by a large ^{60}Co source.

The advantages of this type of sterilization are: (*a*) the product may be prepackaged in nonsterile materials in a nonsterile atmosphere and then the product and packaging sterilized; (*b*) it permits greater latitude in the choice of packaging materials; (*c*) bulk materials and products difficult to sterilize by either moist or dry heat can be sterilized; and (*d*) the processes can be made continuous, requiring only small numbers of personnel.

Certain disadvantages are: (*a*) the cost of sterilization is higher than that of heat sterilization and the initial cost of the installation is very high, although this might be offset somewhat by the savings of the cost of operation; (*b*) many materials are damaged by the radiation, suffering changes in color, decomposition, loss of potency, and in some cases, complete impairment of their therapeutic properties.

However, research in the methodology continues, and the following reports have appeared in the recent literature.

Antibiotics and hormones were irradiated in sealed containers by exposure to 10^6 reps without physical damage or loss of biological activity (248). Toxins and enzymes were sterilized with 5 million reps, based on a lethal dose for bacteria of 1 to 4 million reps (248). The rep, now an obsolete unit of absorbed ionizing radiation, was defined as an absorption of 93 ergs of radiation per gram of matter. It has been replaced by the rad, which is equivalent to the absorption of 100 ergs of radiation per gram of matter.

It is, however, generally believed that the lethal dose for bacteria varies from 0.1 to 2.5 megarads (1 megarad = 1 million rads) (249), and the latter figure is presently generally accepted as being safe. In Poland, drugs in ampuls were sterilized by exposure to rays from a ^{60}Co source. The enzyme cocarboxylase hydrochloride in dry form, contaminated with spores of *C. welchii*, *C. septicum*, and *E. coli* was sterilized with 4×10^5 reps from ^{60}Co. The material was sterile and showed no signs of decomposition. In aqueous solutions nonsporulating *E. coli* required 8×10^5

reps, while *C. welchii* and *C. septicum* required 1.6×10^6 reps (250).

Ophthalmic ointments containing oxytetracycline, chlortetracycline, tetracycline, and polymyxin in petrolatum and lanolin were sterilized and could be treated so in aluminum tubes and packaged. The dose was 2 million rads (2 Mrad) from a ^{60}Co source (251). The pH decreased slightly but the chemical composition and biological activity were unchanged, and the ointment was stable at room temperature for 14 months.

Ophthalmic ointments containing penicillin and fluorescein were sterilized by a dose of 2.5 Mrad from a γ ray source in their final containers and packages (252).

Antibiotics, anticoagulants, hormones, plasma, multivitamin preparations, and steroids were sterilized with 2 Mrads. The importance of preconditioning the containers was emphasized (253).

A report of 7 years' experience with radiation sterilization was presented (254). The types of products, the materials used, as well as certain aspects of processing and control and a comparison of irradiators, were given.

Recent developments in Sweden were reported (255). The following radiation sources have been used: β radiation, γ radiation from ^{60}Co and from spent fuel elements from reactors, megavoltage from Van De Graaff generators, and from linear accelators. The dose of 2.5 Mrad is equivalent to autoclaving at 120°/20 min. Unfortunately, many pharmaceuticals discolor and develop off-odors and decrease in potency. Glass is also discolored. γ Radiation does not seem too favorable. The area of greatest application is for disposable medical supplies such as adhesive, dressings, catheters, and especially plastic syringes and other items for single use. However, the cost is high. A novel suggestion is the addition of radionuclides of short half-life to injectables for self-sterilization, an idea fraught with legal complications.

A recent monograph reviews sterilization and disinfection as applied in medical, industrial, and laboratory practice, using ionizing and nonionizing radiation (256). A related application of γ radiation is its use in the preparation of noninfective antigens for the laboratory diagnosis of virus diseases such as influenza, mumps, herpes, and small pox (249). These antigens are commonly prepared in a stable, noninfective form using formaldehyde, but the infectivity of soluble antigens cannot be destroyed in this manner. γ Radiation offers an alternative way and appears to be superior for the preparation of the herpes simplex antigens.

The preparation of vaccines using γ radiation instead of formaldehyde is under investigation, and this technique shows promise (249).

Cold sterilization using linear accelerators has been used successfully for surgical sutures for many years.

Active research and development will undoubtedly show that many pharmaceuticals and medical supplies can be sterilized by radiation suitably and economically to compete with present day methods.

CONCLUSIONS

The authors have attempted to present here an overview of the present status of radiopharmaceuticals, the methods for detecting them, some of the advances in new short-lived radionuclides, and some directly related subjects.

If we would like to characterize developments in recent years, one single term would suffice to describe it: sophistication. Thus, newer, better, complex, and very reliable instrumentation has been developed for the detection both *in vitro* and *in vivo* of radionuclides, thanks in part to the notable developments in solid-state electronics. The ability of the A.E.C. sponsored national laboratories (Brookhaven, Argonne, Oak Ridge) to produce any desired radionuclide and of the nuclear industry to make these available at reasonable cost to investigators in the health sciences, has further widened the horizons of radiopharmaceuticals. The example of ^{99m}Te, a radionuclide with a half-life of 6 hr., is indicative of the present trend toward radionuclides with a shorter half-life involving much less exposure of the patient to radiation. *In vitro* testing of biological functions such as the various methods available for protein bound thyroid hormone based on the original work by Hamolsky in 1957 illustrates another trend: that of using radionuclides in the clinical lab without any exposure to the patient. A third development, only beginning, is that of the use of tritium and ^{14}C-labeled biochemicals for measurement of specific metabolic disorders.

The rationale for present and future developments is given by work in biochemistry and in experimental pharmacology where radionuclides constitute a self-evident and most significative tool.

The authors feel that radiopharmaceuticals are a rapidly growing field with a tremendous potential which has not been fully explored. Especially, new radiopharmaceuticals are required, more

directly based on metabolic functions and designed by applying biochemical and pharmacological principles. This challenge stands before the pharmaceutical sciences.

Aggregation of Certain Medicinal Amines in Aqueous Solutions of Their Salts

By BAHRAM FARHADIEH*, NATHAN A. HALL, and E. R. HAMMARLUND

The osmotic coefficient and the equivalent conductance of aqueous solutions of certain medicinal amine salts were determined in order to examine their aggregating properties. Procaine HCl and tripelennamine HCl formed small ionic micelles. Partially ionized micelles of approximately constant size were the main constituent of solutions of dibucaine HCl and bromodiphenhydramine HCl. Tetracaine HCl and diphenhydramine HCl formed aggregates of different sizes in their solutions. No definite conclusion could be drawn about the types of aggregates that were present in solutions of pyrilamine maleate. An apparent critical micelle concentration (CMC) was obtained only for dibucaine HCl and bromodiphenhydramine HCl. From the CMC values at 0° and 25° it was concluded that the standard enthalpy change associated with formation of micelles in solutions of these two salts was practically zero. This finding together with a negative change in the standard free energy of micellization indicated that the process of micelle formation was mainly an entropy effect.

AQUEOUS SOLUTIONS of many long chain amine salts, sulfonates, sulfates, etc., exhibit an abrupt change in physical properties over a relatively short concentration range (1). This phenomenon which is common to aqueous solutions of association colloids has been attributed to the formation of aggregates, and the concentration at which it occurs has been termed "the critical concentration for the formation of micelles" (CMC). The nature of the transition taking place at the critical concentration is as yet unknown and a controversy still exists concerning the possible existence of aggregates at lower concentrations (2).

The freezing point depression, ΔT_f, of aqueous solutions of many substituted amine salts of pharmaceutical interest has been measured by Hammarlund and co-workers (3). It was shown that in dilute solutions these amine salts behave as simple electrolytes. At higher concentrations, however, a number of them appear to form molecular aggregates as evidenced by a sharp change in slope when ΔT_f is plotted against the salt concentration. Recently Johnson *et al.* (4) measured the vapor pressure of aqueous solutions of several of these amine salts using a vapor pressure osmometer of their own design. They also concluded that these salts tend to form molecular aggregates above a certain concentration.

Generally, measurements of several physicochemical properties of a solution are needed in order to ascertain the formation of aggregates by a solute. The work presented here was designed to investigate the aggregating tendency of several amine salts by determining the molal osmotic coefficient as well as the equivalent conductance of their aqueous solutions.

EXPERIMENTAL

Materials.[1]—The amine salts used in this study were procaine HCl, tetracaine HCl, dibucaine HCl, tripelennamine HCl, pyrilamine maleate, diphenhydramine HCl, and bromodiphenhydramine HCl. Since they were of medicinal grade, no further purification was attempted. Only tetracaine HCl and dibucaine HCl lost weight upon drying in vacuum and in the presence of phosphorus pentoxide. These were dried to constant weight before use.

Preparation of Solutions.—Solutions employed for the determination of the osmotic coefficients were prepared on the molal basis in double distilled

water. For the study of electrical conductivity solutions were made on molar basis in conductivity water (specific conductance, 1–1.5 $\times$ 10^{-6} ohms^{-1} cm.$^{-1}$).

Apparatus and Measurement Procedures.—A Mechrolab[2] vapor pressure osmometer was used to determine the molal osmotic coefficients of the solutions. Since preliminary experiments with potassium chloride solutions showed stable readings within 6 min., all readings were taken 6 min. after the solution drop was placed on the sample thermistor bead. All measurements were made at 25.000 $\pm$ 0.001°.

A Dike-Jones conductivity bridge[3] was used to determine the electrical resistance of the solutions. The frequency of the bridge current was 1000 c.p.s. and the null point was detected by a cathode ray oscilloscope. Three different conductivity cells were employed. The cell constants were *A*, 1.0449; *B*, 1.0241; and *C*, 13.0078. Cell *A* had unplatinized electrodes and was used for the determination of resistance of the very dilute solutions. The polarization resistance introduced by the bright platinum electrodes of this cell amounted to less than 0.10% of the total resistance of the solutions at 1000 c.p.s. Therefore, the error due to polarization was considered to be negligible and no attempt was made to correct the electrical resistance of the very dilute solutions for this effect. The measurements were obtained at 25.00° in an oil bath which was maintained at 25.00° $\pm$ 0.02°. Usually readings were taken 45 min. after the cells containing the solutions were immersed in the oil bath.

The molal osmotic coefficients of the aqueous solutions of the samples were calculated from the following relationship (5):

$$\Delta R = \nu\alpha\phi m \qquad \text{(Eq. 1)}$$

where ΔR is the difference in the resistance of the sample and the solvent thermistor beads; ν is the theoretical number of ions per molecule of the solute; ϕ is the molal osmotic coefficient of the solvent; m is the molality of the solute; and α is the calibration constant of the thermoelectric vapor pressure osmometer.

Aqueous solutions of mannitol ranging in concentration from 0.04 to 0.250 molal were used for the calibration of the instrument. Mannitol was chosen because the molal osmotic coefficient of its aqueous solution is very nearly unity up to 1 molal (5). The calibration constant was obtained from the slope of a plot of the measured ΔR *versus* concentration. The plot gave a straight line, the slope of which, as calculated by the method of least squares, was 52.60 ohms/mole.

The accuracy of the method as well as the reliability of the vapor pressure osmometer were determined by calculating the molal osmotic coefficient of aqueous KCl solutions and comparing them with the corresponding reported values (6). The agreement between the two sets of data was excellent.

The amine salts used in this study have pKa's of about 8–9 and the pH's of their aqueous solutions is about 5–6. In this pH range the dissociation of the protonated amines to their corresponding free base is negligible. Thus, in calculation of the molal osmotic coefficients, the samples were treated as simple 1:1 electrolytes. Each ΔR used in either the determination of the calibration constant or the calculation of ϕ is a mean of four separate readings with a standard error of less than $\pm$0.04 ohms.

RESULTS

The osmotic coefficient of aqueous solutions of KCl and the amine salts are summarized in Table I and are plotted *versus* the square root of concentration in Figs. 1 and 2. In these figures are also included the lines representing the Debye-Huckel expression (6) which at 25° is:

$$\phi = 1.0 - 0.392\sqrt{m} \qquad \text{(Eq. 2)}$$

[3] Leeds and Northrup Co., Philadelphia, Pa.

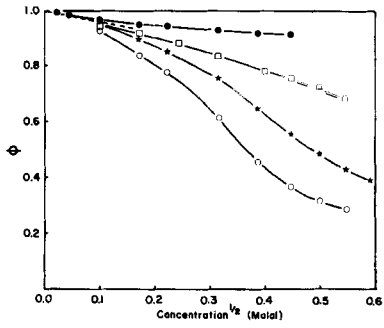

Fig. 1.—Molal osmotic coefficient of aqueous solutions. Key: ●, potassium chloride; □, procaine HCl; ★, tetracaine HCl; ○, dibucaine HCl; ----, Eq. 2.

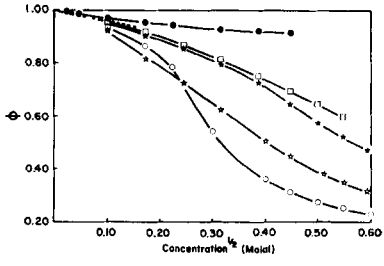

Fig. 2.—Molal osmotic coefficient of aqueous solutions. Key: ●, potassium chloride; □, tripelennamine HCl; ★, diphenhydramine HCl; ○, bromodiphenhydramine HCl; ☆, pyrilamine maleate; ----, Eq. 2.

Equation 2 holds true for extremely dilute aqueous solutions of a simple 1:1 electrolyte. Due to experimental limitations molal osmotic coefficients could not be measured for concentrations less than 0.01 molal. However, Figs. 1 and 2 indicate that at extremely dilute solutions the osmotic coefficient of the solutions should approach that given by the Debye-Huckel expression.

The equivalent conductance of solutions of NaCl and the amine salts used in this investigation are presented in Table II and are plotted *versus* the square root of concentration in Figs. 3 and 4. Each Λ is the average of two separate readings. According to Onsager (7), in extremely dilute solutions and at a temperature of 25° the equivalent conductance of any strong 1:1 salt is given by:

$$\Lambda = \Lambda_0 \left(1.0 - 0.22724 \sqrt{c}\right) - 59.730 \sqrt{c} \quad \text{(Eq. 3)}$$

[a] The numbers represent: *1*, NaCl; *2*, procaine HCl; *3*, tetracaine HCl; *4*, dibucaine HCl; *5*, tripelennamine HCl; *6*, diphenhydramine HCl; *7*, bromodiphenhydramine HCl; *8*, pyrilamine maleate. [b] Data obtained from literature.

where Λ_0 is the limiting equivalent conductance and c is the concentration of the solute expressed in gram-equivalents per liter of solution. Broken lines in Figs. 3 and 4 represent Eq. 3. The value of Λ_0 for each salt was obtained by extrapolating an expanded plot of Λ *versus* $c^{1/2}$ to zero concentration of the salt solution. In the calculation of the equivalent conductance the salts were treated as 1:1 electrolytes and the contribution by the free bases was neglected.

In Fig. 5 the quantity ϕm, the product of molal osmotic coefficient and the molality of bromodiphenhydramine HCl, is plotted *versus* molality. Figure 6 represents the plot of the specific conductance *versus* concentration for the same salt. Each plot consists of two straight lines with different slopes which intersect each other at the CMC of the salt (8, 9). In Fig. 5 the slope of the straight line segment below the CMC of bromodiphenhydramine HCl coincides with that of an ideal solution of a strong 1:1 electrolyte, *i.e.*, KCl. The CMC's of dibucaine HCl and bromodiphenhydramine HCl as obtained by these two methods were 0.061 and 0.052 M, respectively.

DISCUSSION

Examination of the plots of Λ *versus* $c^{1/2}$ for the amine salts (Figs. 3 and 4) show that in extremely dilute solutions, where the Onsager expression is accepted to be valid, the experimental points coincide with those obtained from the Onsager equation. This agreement of the experimental and the theoretical data indicates that in these dilute solutions, the salts are totally dissociated into their constituent ions and, therefore, can be considered to be strong electrolytes.

In the concentration range shown in Fig. 1 the values of the molal osmotic coefficients for aqueous solutions of procaine HCl are less than the values predicted by the Debye-Huckel theory. Although this theory does not apply at such high concentrations, all deviations expected and found for a strong 1:1 electrolyte, KCl, are in the opposite direction to that of procaine HCl. These deviations indicate the presence of aggregates in solutions of this amine salt. Since the behavior of the equivalent conductance of procaine HCl solutions (Fig. 3) is similar to that of a strong 1:1 electrolyte, NaCl, the aggregates formed may be of the small ionic type suggested by McBain (10) as an explanation of the similar behavior observed in dilute solutions of colloidal electrolytes. Due to their increased charge, when compared to simple ions, these small aggregates should enhance the electrical conductance of the solutions provided that the decreased mobility of the ions in aggregates is overcome by the increased number of charges carried by the aggregates. The similarity in the behavior of the molal osmotic coefficients and the equivalent conductances of tripelennamine HCl solutions (Figs. 2 and 4) to those of procaine HCl suggests the presence of small ionic aggregates in the moderately concentrated solutions of this salt also.

Assuming that normality approximates molality in the concentration range studied, Figs. 2 and 4 show that up to 0.04 molal the osmotic coefficient as well as the conductance of aqueous bromodiphenhydramine HCl solutions are similar to that of procaine HCl. At concentrations above 0.04

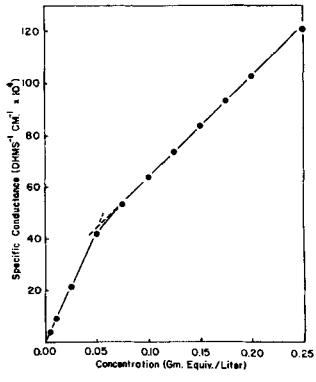

Fig. 6.—Specific conductance of aqueous bromodiphenhydramine HCl solutions.

molal the magnitude of the molal osmotic coefficient and the equivalent conductance decreases sharply over a narrow concentration region. At still higher concentrations the values of these two properties approach asymptotically a constant value. According to theories of micelle formation (2, 11, 12), the behavior of the physicochemical properties of bromodiphenhydramine HCl solutions are in accord with the formation of partially ionized aggregates of approximately constant size which are in equilibrium with the simple ions.

Figures 1 and 3 indicate that the behavior of dibucaine HCl solutions is similar to those of bromodiphenhydramine HCl. The abruptness of change in the physicochemical properties at the CMC is dependent on the micellar size and the ease with which the association equilibrium is established (2). The many polar groups that are present in dibucaine HCl molecules tend to reduce the ease of molecular association. Due to this fact the change in the physicochemical properties of dibucaine HCl, at the CMC, is not as abrupt as that of bromodiphenhydramine HCl.

The behavior of the osmotic coefficient and the equivalent conductance of dilute solutions of tetracaine HCl is similar to those of procaine HCl solutions. At higher concentrations these properties decrease slowly over an extended concentration region as seen in Figs. 1 and 3. These behaviors indicate the weak aggregating tendency of the tetracaine ions which should result in slow multiple equilibria between aggregates of different sizes. Due to the same reason no CMC value could be assigned to this salt. The slight drop in the molal osmotic coefficients together with a nearly linear decrease in the equivalent conductance of diphenhydramine HCl solutions with increasing concentrations also suggests the presence of aggregates of different sizes in moderately concentrated solutions of this salt.

The molal osmotic coefficient and the equivalent conductance of aqueous pyrilamine maleate solutions decreased without any noticeable change of slope at all concentrations studied (Figs. 2 and 4). It has been previously demonstrated by Stokes (13) that maleate ions tend to form ion pairs in aqueous solutions of the sodium salt. It is, therefore, possible that at the pH of the solution pyrilamine maleate ions form ion pairs.

According to Brady and co-workers (14) the amount of gegenions bound per mole of micellar ion is given by:

$$\frac{dm^B}{dm} = 1 - 2\,\frac{d\phi m}{dm} \qquad \text{(Eq. 4)}$$

where m^B is the concentration of the bound gegenions; m is the total concentration of the solute; ϕ is the molal osmotic coefficient of the solution; and $d\phi m/dm$ is the slope of ϕm *versus* m curve at concentrations above the CMC. For dibucaine HCl, this slope is 0.115 while for bromodiphenhydramine HCl (Fig. 5) it is 0.126. Consequently, dm^B/dm for the micelles of these two salts is 0.77 and 0.75, respectively. The excessive counter ion binding indicated by these data is in the expected range. The nonionic polar groups that are present in the molecules of dibucaine HCl and bromodiphenhydramine HCl tend to decrease the aggregation properties of these salts. Consequently, if aggregation is to occur, it is to be expected that the repulsive coulombic forces which come into play when the micelle-forming ions approach each other have to be practically neutralized by the gegenions.

Assuming that micelles are monodispersed and that their formation is governed by the law of mass action, Phillips (15) has shown that the standard free energy change, $\Delta F_m°$, and the standard enthalpy change, $\Delta H_m°$, of this process are given by the following equations:

$$\Delta F_m° = RT\left(\frac{\ln 3 + 2\ln N}{N} + \frac{2N - P - 1}{N}\ln \mathrm{CMC}\right) \qquad \text{(Eq. 5)}$$

and

$$-\frac{\Delta H_m°}{R}\left(\frac{1}{T_1} - \frac{1}{T_2}\right) = \left(2 - \frac{P}{N} - \frac{1}{N}\right)\ln\frac{\mathrm{CMC}_1}{\mathrm{CMC}_2} \qquad \text{(Eq. 6)}$$

where R is the gas constant, N is the aggregation number, P is the charge of the micelle, and CMC_1 and CMC_2 are the critical micelle concentrations at absolute temperature T_1 and T_2. The standard state chosen is mole fraction of unity, and, therefore, the CMC's should be expressed in mole fraction units. The freezing point depression of aqueous solutions of dibucaine HCl and aqueous bromodiphenhydramine HCl have been determined by Hammarlund and co-workers (3, 16). From their data the CMC of these two salts at the freezing points of their solutions were found to be 0.060 and 0.05 M, respectively. These CMC values, when compared with those obtained at 25° indicate that in the temperature range 0–25° the CMC of dibucaine HCl and bromodiphenhydramine HCl are not appreciably affected by the increase in temperature. According to Eq. 6, therefore, the $\Delta H_m°$ of micellization for both salts is practically zero. This finding would imply that $-\Delta F_m°/T = \Delta S_m°$. Since $N > 1$ and $P > 0$ for the micelles formed by dibucaine HCl and bromodiphenhydramine HCl, it follows that their $\Delta F_m° < 0$ and $\Delta S_m° > 0$. It can, therefore, be concluded that the formation of micelles in the solutions of these two salts is practically an entropy effect. A portion of the observed entropy increase should be due to the loss of ordered water that exists around the hydrocarbon moiety of both dibucaine HCl and bromodiphenhydramine HCl ions during micellization process (17, 18). Since the solvated polar groups present in the dissolved molecules of these two salts are practically desolvated during the course of aggregation, it should be expected that this desolvation will also contribute to the total entropy change (19).

Catharanthus Alkaloids XIII

Antineoplastic and Hypotensive Activity of Alkaloid Fractions and Certain Alkaloids from *Catharanthus lanceus*

By NORMAN R. FARNSWORTH, RALPH N. BLOMSTER, and J. P. BUCKLEY

Hypotensive evaluation of 14 alkaloid fractions derived from *C. lanceus* roots and leaves in anesthetized, normotensive rats and dogs revealed that eight of the fractions reduced blood pressure from 22–73 per cent for periods ranging from 38 to more than 378 min., at doses of 8–40 mg./Kg. Yohimbine, a potent α-adrenergic blocking agent, was isolated from three of the eight active fractions. However, removal of the yohimbine from one of these fractions did not result in a loss of hypotensive activity, thus indicating that other hypotensive agents may be present. Leurosine, perivine, and pericyclivine elicited only transient hypotensive activity, whereas vindoline, tetrahydroalstonine, ajmalicine, lochnerinine, and periformyline failed to induce a hypotensive response at several dose levels. The same crude alkaloid fractions were evaluated for antineoplastic activity against the P-1534 leukemia with only one of the 14 fractions being active against this neoplasm. Leurosine, isolated from the active fraction, was shown to be a potent antineoplastic alkaloid with a high degree of cytotoxicity. Lochnerinine, although devoid of activity against the P-1534 leukemia, exhibited reproducible cytotoxicity against the 9 KB cell culture. Vindoline, catharanthine, desacetylvindoline, perivine, perivinol, periformyline, pericyclivine, pericalline, catharine, ajmalicine, tetrahydroalstonine, and yohimbine were devoid of P-1534 leukemia activity, as well as cytotoxicity. Monitoring of column chromatographic cuts of the active fraction with the P-1534 leukemia has shown that at least one additional alkaloid, active against this neoplasm, is present.

THE MADAGASCAN periwinkle, *Catharanthus roseus* (*Vinca rosea*, *Lochnera rosea*), has yielded at least 66 alkaloids as a result of recent intensive phytochemical investigations. For the most part, these alkaloids have been discovered in the search for new antineoplastic agents, and many of them were obtained in only trace quantities. In certain instances, the small quantities available precluded any determination of their biological effects. However, the authors do know of the antineoplastic activity of vincaleukoblastine, leurocristine, leurosine, and leurosidine (1); of the pronounced oral hypoglycemic effects of vindolinine (hydrochloride), leurosine (sulfate), lochnerine, vindoline, desacetylvindoline, catharanthine (hydrochloride), and tetrahydroalstonine (2); and of the diuretic effect of catharanthine (hydrochloride) and vindolinine (hydrochloride) (3, 4); as well as the antidiuretic action of ajmalicine, lochnerine, and sitsirikine (sulfate) (3, 4). In addition, the antihypertensive and sedative properties of reserpine, also reported as present in *C. roseus*, are well known.

Because of interest in the isolation of biologically active compounds from plants, investigations were initiated on species of *Catharanthus* other than *C. roseus*. The antineoplastic activity of *C. lanceus* alkaloids (5, 6) and the isolation of leurosine, an alkaloid exhibiting a high order of activity against the P-1534 leukemia in DBA/2 mice (5, 6) were previously reported. Also, it has been reported that certain *C. pusillus* alkaloid fractions elicit marked hypotensive activity in anesthetized, normotensive rats (7).

Previous paper: Farnsworth, N. R., Fong, H. H. S., and Blomster, R. N., *Lloydia*, to be published.

No reports have appeared in the literature concerned with the biological activity of *C. trichophyllus*, *C. longifolius*, or *C. scitulus*, the remaining three species of the genus *Catharanthus*.

At this time the antineoplastic and hypotensive activity of alkaloid fractions derived from the roots and leaves of *C. lanceus* is reported, in addition to certain alkaloids isolated in our laboratories from this plant.

EXPERIMENTAL

Preparation of Fractions and Isolation of Alkaloids.—Seven alkaloid fractions were prepared according to the method of Svoboda (8) from *C. lanceus* root (9) and seven from leaf material (6) of Madagascan origin. Following column chromatography of certain of these fractions, a number of alkaloids were isolated by direct crystallization. The preparation of these alkaloids has previously been reported and include leurosine (6), perivine (6), yohimbine (6, 9), vindoline (6), pericyclivine (10), ajmalicine (9), perimivine (9), cathalanceine (9), catharanthine (11), pericalline (9), vincoline (11), vinosidine (12), lanceine (12), catharine (13), periformyline (14, 15), tetrahydroalstonine (14), and lochnerinine (14). Prior to these studies, Janot *et al.* had reported on the isolation of ajmalicine, tetrahydroalstonine, yohimbine, and lanceine from the roots of this plant (16–18).

Preparation of Alkaloid Fractions and Alkaloids for Biological Evaluation.—All alkaloid fractions were prepared for use in the hypotensive evaluations by first being dissolved in an appropriate organic solvent, followed by the addition of 0.1 *M* citric acid solution, and removal of the organic solvent by *in vacuo* steam distillation. After filtration, the acidic extract was adjusted to as near neutrality as possible with dilute ammonia solution without precipitation of free alkaloid bases, and then adjusted with distilled water to a known volume. Control solutions were prepared with 0.1 *M* citric acid, and ammonia solution added to a pH identical with the extract to be injected. The details for this phase of the study have been reported previously (7).

Alkaloids were administered either as their salts which were dissolved in distilled water, or as the free base treated in the manner described for the crude fractions, or as the free base dissolved in dimethylacetamide (DMAC) diluted with water.

For the antineoplastic and cytotoxicity evaluations, the extracts and alkaloids were suspended in normal saline solution for the P-1534 leukemia evaluations and either dissolved or suspended in propylene glycol for the 9 KB cell culture assays.

Hypotensive Evaluation of the Alkaloid Fractions and Alkaloids.—The prepared test solutions were administered to albino Wistar, normotensive, anesthetized rats (urethan, 1.25 Gm./Kg. i.p.), and evaluated for hypotensive activity as described by Bickerton *et al.* (19). Initially the dose was 1.0 mg./Kg. i.v., and subsequent doses adjusted accordingly in order to estimate that dose producing approximately a 50% decrease in mean arterial blood pressure. The approximate ED_{50} of each active fraction was administered to a minimum of four rats and the mean time for the blood pressure to return to the predrug levels determined. Each animal received only one dose of extract or alkaloid. Equivalent volumes of control solvent were administered i.v. to determine the effect of the pH and solvent on arterial blood pressure of anesthetized rats.

Certain of the fractions and alkaloids were further investigated for hypotensive activity in dogs anesthetized with sodium pentobarbital, 35 mg./Kg. i.v. Blood pressure was recorded from a femoral artery onto a slow moving kymograph. Pressor responses to a 10-sec. bilateral carotid occlusion (BCO), epinephrine, 1–2 mcg./Kg., and angiotensin II, 1 mcg./Kg., were obtained prior to and after administration of each fraction or alkaloid into an exposed femoral vein.

Antineoplastic Evaluation of Alkaloid Fractions and Alkaloids.—Alkaloid fractions from *C. lanceus* leaves and roots, as well as certain of the alkaloids isolated from this plant, were evaluated for activity against the P-1534 leukemia in DBA/2 mice and for

cytotoxicity against Eagle's human carcinoma of the nasopharynx (9KB) in cell culture (20). These tests were performed through the auspices of the Cancer Chemotherapy National Service Center, National Cancer Institute, Bethesda, Md.

RESULTS AND DISCUSSION

Hypotensive Activity.—Initial screening of the 14 *C. lanceus* alkaloid fractions in normotensive, anesthetized rats served to indicate that the root (A), (B), (B_1), and (C), as well as the leaf (A), (B), (B_1), and (D) fractions, elicited moderate to marked hypotensive effects (Table I). This activity was confirmed for the leaf (B) and (D) and the root (B) fractions in the anesthetized normotensive dog (Table II).

Of 10 alkaloids evaluated, only yohimbine was shown to elicit marked hypotensive activity of long duration. Leurosine, perivine, and pericyclivine induced only a transient hypotensive effect; whereas, vindoline, tetrahydroalstonine, lochnerinine, periformyline, ajmalicine, and pericalline were inactive as hypotensive agents. Pericalline also produced marked analeptic effects. (Table III.)

Since yohimbine was found to be present in the leaf (A) and (B) fractions, as well as the root (B) fraction, it most likely contributed to the hypotensive effect of these three fractions. The following experiment was conducted to determine the role of yohimbine in the over-all hypotensive activity of one of the four active crude alkaloid fractions.

The leaf (B) fraction, from which yohimbine was isolated (6) and which elicited marked hypotensive activity of long duration (Table I), was subjected to a column chromatographic separation (6). A total of 270 one-liter fractions were eluted from the column and yohimbine was isolated from cuts 115–164. Examination of the pre-115 and the post-164 cuts by thin-layer chromatography, and use of the ceric ammonium sulfate alkaloid detecting reagent (21), revealed that yohimbine was also present in

TABLE IV.—EFFECT OF YOHIMBINE-FREE *C. lanceus* LEAF ALKALOID (B) FRACTION ON THE BLOOD PRESSURE OF ANESTHETIZED NORMOTENSIVE RATS

Sex	Wt., Gm.	Dose, mg./Kg.	Normal Blood Pressure, mm. Hg	% Change	Time to Return to Normal, min.
M	294	10	80	62	180+[a]
M	265	10	82	58	179+[b]
M	410	10	92	47	166+[c]
F	199	20	84	57	203+[b]
F	165	20	112	33	209
F	153	20	106	39	192+[d]

[a] Blood pressure at termination of experiment was 60 mm. Hg. [b] Blood pressure at termination of experiment was 70 mm. Hg. [c] Blood pressure at termination of experiment was 78 mm. Hg. [d] Blood pressure at termination of experiment was 88 mm. Hg.

cuts 97–114 and 165–192. On the basis of this information, cuts 1–96 and 193–270 were combined and taken to dryness to yield a yohimbine-free alkaloid mixture. The mixture was then prepared for hypotensive evaluation as previously described.

In the normotensive, anesthetized rat, at doses of 10 and 20 mg./Kg., this yohimbine-free alkaloid (B) fraction retained its marked and prolonged hypotensive effects (Table IV). Equivalent activity of shorter duration was observed with the yohimbine-free fraction in the anesthetized dog at 8 mg./Kg. A 33% decrease in arterial blood pressure, which persisted for 32 min., decreasing the bilateral carotid occlusion response by 32%, reversing the epinephrine response (epinephrine produced a depressor effect after administration of the yohimbine-free fraction), was elicited by the fraction. The mechanism of action for the hypotensive alkaloid(s) in this fraction also appeared to be that of α-adrenergic blockade.

Although yohimbine was present in three of the active hypotensive fractions, and it must be considered to be one of the major alkaloids of *C. lanceus*, evidence has been presented suggesting that other hypotensive alkaloid(s) are present in this plant.

Antineoplastic Activity.—The data presented in Table V show that the total antineoplastic activity in *C. lanceus* resides in the leaf (A) alkaloid fraction. Leurosine, previously reported only from *C. roseus* by Svoboda (22, 23), was isolated in our studies

[a] One hundred grams of (A) fraction was chromatographed on 3 Kg. of partially deactivated Alcoa F-20 alumina as previously described (6). Eluate was collected in 1-L. fractions which were combined on the basis of thin-layer chromatographic patterns. [b] Evaluation of assay results by CCNSC is such that a material is considered active if it causes a prolongation of life in excess of 125%. [c] Not tested. Quantity insufficient for proper evaluation.

from this (A) fraction by means of column chromatography and has been shown to have a high order of activity against the P-1534 leukemia in mice (Table VI). In order to establish whether additional active alkaloids might be present in the leaf (A) fraction, selected grouped cuts from a chromatographic separation were monitored for activity against the P-1534 leukemia (Table VII). These results appear to support the conclusion that at least one additional alkaloid is present in cuts 741–824 from the column.

To date, 18 alkaloids have been isolated from *C. lanceus* in our laboratories. Twelve of these have been evaluated for antineoplastic activity against the P-1534 leukemia in mice and only leurosine is considered to be active (Table VI). These alkaloids have also been evaluated for cytotoxicity against Eagle's carcinoma of the nasopharynx (9KB cell culture), and lochnerinine, in addition to leurosine, is considered to be active, although the former alkaloid was found to be inactive against the P-1534 leukemia (Table VI).

SUMMARY

This investigation has been concerned with the evaluation of 14 crude alkaloid fractions derived from *C. lanceus* leaves and roots for hypotensive and antineoplastic activity. Several alkaloids isolated in our laboratories from this plant were similarly evaluated. From these studies, the following conclusions were made.

1. Eight of 14 crude alkaloid fractions elicited moderate to marked hypotensive activity in normotensive, anesthesized rats. Three of the fractions exhibited a similar activity in the anesthetized dog.

2. Of 10 alkaloids evaluated, yohimbine was found to be the most active as a hypotensive agent. Leurosine, perivine, and pericyclivine gave only a transient hypotensive effect, whereas vindoline, tetrahydroalstonine, ajmalicine, lochnerinine, and periformyline were inactive at the dose levels utilized.

3. Evidence has been presented that other highly active hypotensive alkaloids are present in crude alkaloid extracts from this plant. The identity of these alkaloids is presently unknown.

4. Only one of 14 alkaloid fractions from *C. lanceus* was active against the P-1534 leukemia in mice and leurosine was shown to be one of the alkaloids responsible for the activity of the fraction. Monitoring of chromatographic cuts of the active fraction against the P-1534 leukemia has shown that at least one additional active alkaloid remains in this plant.

5. Leurosine and lochnerinine were shown to have reproducible cytotoxic activity against Eagle's 9 KB carcinoma of the nasopharynx.

6. Perivine, periformyline, pericyclivine, vindoline, ajmalicine, tetrahydroalstonine, catharine, catharanthine, yohimbine, pericalline, desacetylvindoline, and perivinol were shown to be devoid of antineoplastic as well as cytotoxic activity.

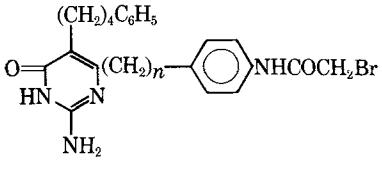
Irreversible Enzyme Inhibitors LXX

Candidate Active-Site-Directed Irreversible Inhibitors of Dihydrofolic Reductase IV. Substituted 1-Phenyl-1,2-dihydro-*s*-triazines

By B. R. BAKER and BENG-THONG HO

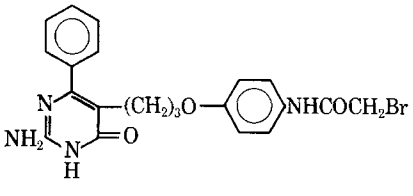
4,6-Diamino-1,2-dihydro-2,2-dimethyl-1-phenyl-*s*-triazines substituted on the phenyl ring by *p*-chloroacetyl (IV*a*), *m*-chloroacetyl (IV*c*), and 4-chloro-3-butanone-1-yl (IV*b*) groups were synthesized from the appropriate aromatic amine hydrochlorides, cyanoguanidine, and acetone. All three compounds were good reversible inhibitors of dihydrofolic reductase. However, none of the three compounds inactivated dihydrofolic reductase when incubated with the enzyme; this lack of active-site-directed irreversible inhibition by compounds of type IV has been attributed to the complexing of the phenyl group to the hydrophobic bonding region on dihydrofolic reductase—a region not apt to have attackable nucleophilic groups present.

SEVERAL active-site-directed irreversible inhibitors (1–3) of dihydrofolic reductase were successfully designed once the strong hydrophobic bonding area on the enzyme was discovered (4) and its effect on the mode of pyrimidine binding was explored (1, 5–10). When a hydrocarbon-type 5-side-chain was allowed to complex to the hydrophobic bonding region on the enzyme, the



I, $n = 2$

II, $n = 4$



III

6-side-chain of I and II could project to a hydrophilic area on the enzyme and form a covalent bond within the enzyme–inhibitor complex (11); similarly, the 6-phenyl group of III could complex to the hydrophobic region of dihydrofolic reductase with the result that the 5-side-chain projected into the hydrophilic area and formed a covalent bond with the enzyme (12).

Received August 5, 1966, from the Department of Chemistry, University of California, Santa Barbara, 93106, and the Department of Medicinal Chemistry, State University of New York at Buffalo 14214.

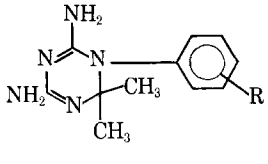
Accepted for publication September 27, 1966.

This investigation was supported by grants CA-05867, CA-06624, and CA-08695 from the National Cancer Institute, U. S. Public Health Service, Bethesda, Md.

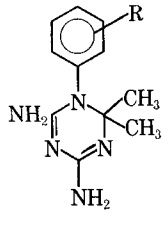
Previous paper: Baker, B. R., and Santi, D. V., *J. Pharm. Sci.*, unpublished data.

DISCUSSION

Prior to the synthesis and enzymic evaluation of I–III, over 30 candidate irreversible inhibitors for dihydrofolic reductase failed to inactivate the enzyme; most of these failures can now be rationalized on the basis that these heterocycles with a single large side chain bearing a covalent-forming group had their side chain complexed with the hydrophobic region of the enzyme where there was not apt to be a nucleophilic group on the enzyme that could be covalently linked with the inhibitor. One such unsuccessful class was derived from the 1-phenyl-1, 2-dihydro-*s*-triazine (IV) where the covalent forming group, R, was placed on the phenyl ring; these candidates failed since the dihydro-*s*-triazines presumably assumed a different conformation, IV*B*, rather than IV when complexed to the enzyme, due to the strong hydrophobic bonding of the phenyl group being determinate (10).



IV



IV*B*

a, R = *p*-$COCH_2Cl$

b, R = *p*-$(CH_2)_2COCH_2Cl$

c, R = *m*-$COCH_2Cl$

The enzymic evaluations of IV*a–c* are summarized in Table I; a successful active-site-directed irreversible inhibitor [II (11)] is included for comparison. Note that IV*a* and IV*c* are still excellent reversible inhibitors of dihydrofolic reductase even though they are $^1/_{12}$ and $^1/_{17}$ as effective as the unsubstituted 1-phenyl-*s*-triazine (V). This decrease in binding by IV*a* and IV*c* can now be rationalized from a study on the mode of phenyl binding (6) subsequent to the evaluation of IV*a* and *c*. The phenyl group is most probably complexed to a hydrophobic region on the enzyme; it was previously

[a] The dihydrofolic reductase was a 45–90% saturated ammonium sulfate fraction from pigeon liver that was prepared and assayed with 6 μM dihydrofolate and 12 μM TPNH in 0.05 M Tris buffer (pH 7.4) containing 10 mM mercaptoethanol, as previously described (13). [b] Dihydrofolic reductase was incubated in the absence of TPNH with the inhibitor at 37° in 0.05 M Tris buffer (pH 7.4) containing *no* mercaptoethanol as previously described (14); in each case an enzyme control was run that showed 0–4% thermal inactivation. Similar results with IV*a–c* were obtained in the presence of 12 μM TPNH. [c] Estimated from $K_i = I \times K_m/S$, where I = inhibitor concentration giving 50% inhibition (4, 15); this equation is valid since $S = 6\ K_m > 4\ K_m$. [d] Calculated from $[EI] = [E_t]/[1 + \frac{K_i}{I}]$, where $[E_t]$ = the concentration of total active enzyme, $[EI]$ = the fraction of E_t reversibly complexed by I (1, 16), and I = the inhibitor concentration. [e] Data from *Reference 17*. [f] Data from *Reference 6*. [g] Hydrobromide salt. [h] Data from *Reference 11*.

noted that polar groups on the *m*- or *p*-position of the phenyl (IV) such as *m*-hydroxymethyl (VII, Table I), cyano, carboxylate, carbethoxy, and aminomethyl cause a decrease in binding, presumably by repulsion of these polar groups on the inhibitor from the hydrophobic region of the enzyme (6). Since the carbonyl group of IV*a* and *c* is highly polar, it too could be repulsed; the relative polarity of the C=O group can be calculated to have a Hansch π-constant of −1.1 from the constants for $CH_3C{=}O$ ($\pi = -0.55$) and CH_3 ($\pi = +0.56$).[1] The 4-chloro-3-butanone-1-yl side chain of IV*b* was not repulsed and actually gave additional binding; note that IV*b* is about twice as good a reversible inhibitor than is the *p*-(*n*-butyl) phenyl-*s*-triazine (VI).

When IV*a–c* were incubated at 37° with dihydrofolic reductase at concentrations sufficient to reversibly complex 77–83% of the total enzyme, no inactivation occurred (Table I). In contrast, the irreversible inhibitor (II) gave 50% inactivation in about 18 min. when 50% of the enzyme was reversibly complexed (11). Furthermore, at a concentration of 10 μM, where II reversibly complexes 20% of the total enzyme, 43% inactivation in 25 min. was seen; the 10 μM concentration of II is only 10 times the incubation concentrations of IV*a* and *c*.

CHEMISTRY

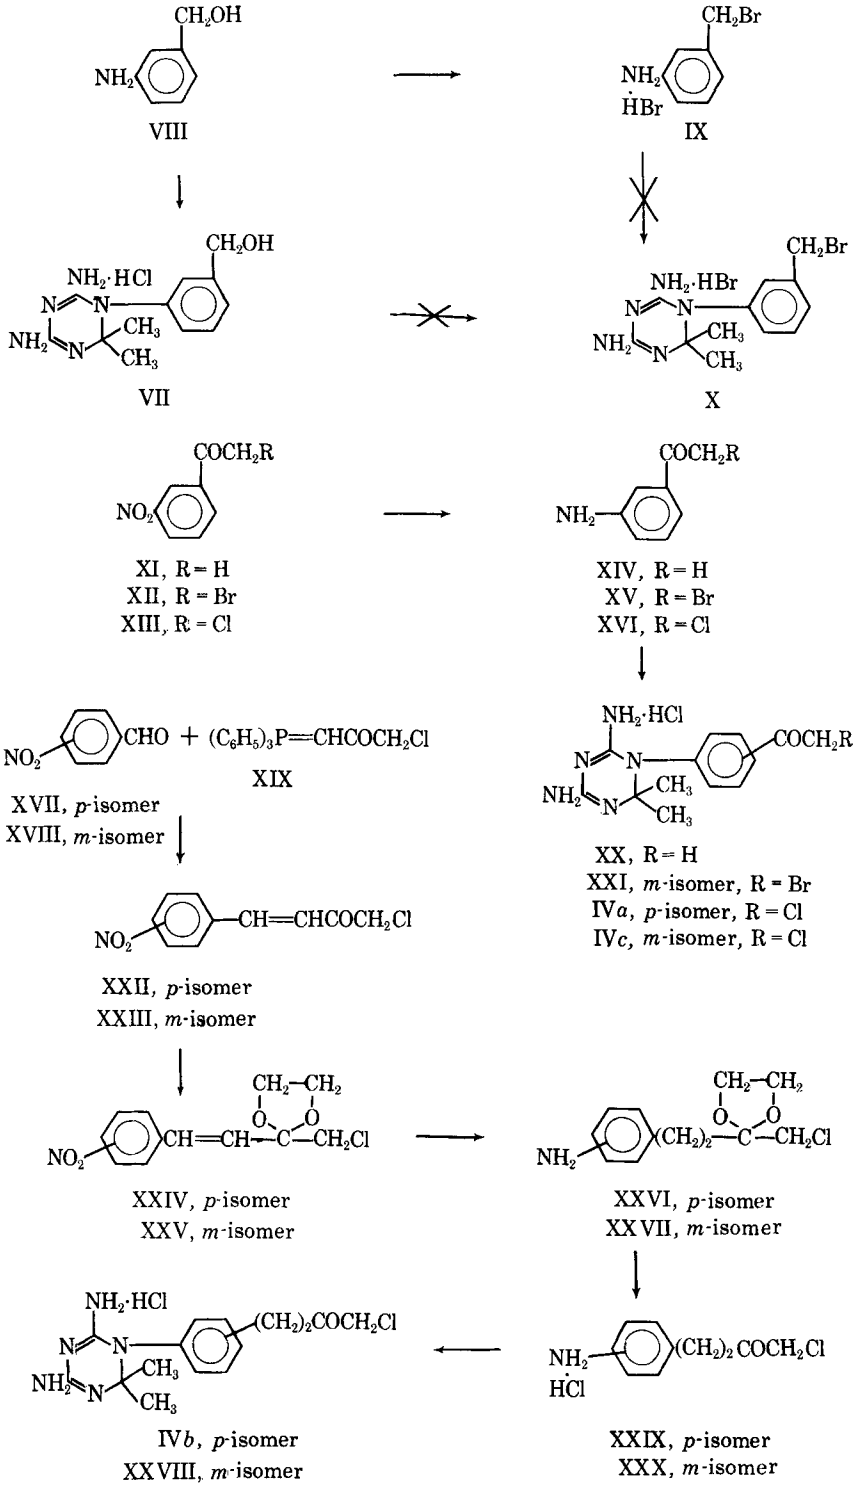
Methods

The first candidate active-site-directed irreversible inhibitor for dihydrofolic reductase chosen in this series was the *m*-bromomethylphenyl-*s*-triazine (X). *m*-Aminobenzyl alcohol (VIII) (19) was smoothly converted to the corresponding benzyl bromide, isolated as its hydrobromide salt (IX) in 76% yield, with hot 10% anhydrous hydrogen bromide in acetic acid. When attempts were made to convert IX to a dihydro-*s*-triazine (X) by the three component method of Modest using cyanoguanidine and acetone (20), a gummy, intractable (polymeric?) mass rapidly formed; apparently these conditions were not compatible with the high chemical reactivity of the benzylic bromide. The benzyl alcohol (VIII) was readily convertible to the *m*-hydroxymethylphenyl-*s*-triazine (VII) by the three component method (20) in 78% yield; unfortunately, treatment of VII with 10% anhydrous hydrogen bromide in acetic acid to give X—the type of conditions used for the conversion of VIII to IX—cleaved the triazine ring as shown by changes in the ultraviolet spectrum. Treatment of VII with anhydrous hydrogen bromide in acetic acid or 48% aqueous hydrobromic acid, both at 25°, gave oily mixtures.

Attention was therefore directed to the synthesis of the *m*-bromoacetylphenyl-*s*-triazine (XXI). Reduction of the nitro group of *m*-nitro-α-bromoacetophenone (XII) with copper powder in sulfuric acid also caused reduction of the halogen and led to *m*-aminoacetophenone (XIV) rather than the desired *m*-amino-α-bromoacetophenone (XV); these conditions had been used for the conversion of the corresponding α-chloro ketone (XIII) to *m*-amino-α-chloroacetophenone (21). The desired *m*-amino-α-bromoacetophenone (XV) was prepared by bromination of *m*-aminoacetophenone (XIV) in glacial acetic acid containing an excess of ethanesulfonic acid which protonated the amine and, in turn, stabilized the ring against halogenation; the product (XV) was isolated as the hydrobromide salt but

[1] The Hansch π-constant (18) is a measure of hydrophobic character on a log scale, where H is assigned $\pi = 0$.

direct bromination of XIV in acetic acid containing hydrogen bromide failed because of the insolubility of the hydrobromide salt of XIV. Attempts to convert XV to the dihydro-*s*-triazine, XXI, by the three component method (20) rapidly formed a brownish gummy (polymeric?) mass.



Scheme I

Since the attempts to prepare the dihydro-*s*-triazines (X and XXI) containing an active bromine appeared to fail because of the excessive chemical reactivity of this halogen, attention was directed toward the less reactive chloroacetyl-*s*-triazines (IV*a* and *c*). Commercially available *p*-amino-α-chloroacetophenone readily formed the requisite *p*-chloroacetylphenyldihydro-*s*-triazine (IV*a*) by the three component method (20) in 88% yield. Similarly, *m*-amino-α-chloroacetophenone (21) formed the *m*-chloroacetylphenyldihydro-*s*-triazine (IV*c*) in 42% yield. Although the *m*-acetylphenyldihydro-*s*-triazine (XX) was readily prepared from *m*-aminoacetophenone, bromination experiments to convert XX to XXI were discontinued when IV*a* and *c* were successfully synthesized.

4 - (*p* - Aminophenyl) - 1 - chloro - 2 - butanone hydrochloride (XXIX) was prepared in crystalline form by hydrolysis of the previously prepared dioxolane (XXVI) (22). Condensation of XIX with cyanoguanidine and acetone by the three component method (20) afforded the chlorobutanonyl-*s*-triazine (IV*b*) in 67% yield. The corresponding *m*-aminophenyl dioxolane (XXVII) was prepared *via* XXIII and XXV. The hydrochloride salt of XXX formed after acid hydrolysis of XXVII could not be purified; furthermore, the *s*-triazine (XXVIII) obtained from impure XXX by the three component method (20) also could not be purified. (Scheme I.)

Synthesis

Melting points were taken on a Fisher-Johns apparatus and those below 230° were corrected. Infrared spectra were determined in KBr pellet with a Perkin-Elmer 137B spectrophotometer. Ultraviolet spectra were determined with a Perkin-Elmer 202 recording spectrophotometer.

m-Aminobenzyl Bromide Hydrobromide (IX).—A solution of 0.550 Gm. (4.47 mmoles) of VIII (19) in 6 ml. of 10% anhydrous hydrogen bromide in glacial acetic acid was refluxed for 8 hr. The solution was cooled to about 20°; the product was collected on a filter and washed with a small amount of glacial acetic acid, then ether; yield, 0.91 Gm. (76%) of an off-white solid, m.p. 244° dec., with browning at 230°; $\nu_{max.}$ 2950, 2650 (NH, NH^+); 1600, 1575, 1550, 1525 (NH, NH^+, C=C); 885, 783 $cm.^{-1}$ (*m*-C_6H_4).

Anal.—Calcd. for $C_7H_8BrN \cdot HBr$: C, 31.5; H, 3.40; N, 5.25. Found: C, 31.6; H, 3.50; N, 5.40.

α-Chloro-m-nitroacetophenone (XIII).—To a solution of 1.65 Gm. (10 mmoles) of XI in 15 ml. of chloroform was added 2 ml. of sulfuryl chloride. After 24 hr. protected from moisture, the solution was spin-evaporated *in vacuo;* the crystalline residue was triturated with ether; yield, 1.34 Gm. (67%), m.p. 97–99°. Recrystallization from petroleum ether (b.p. 60–110°) with only slight loss gave light yellow crystals, m.p. 101–103°.

This procedure is considerably simpler than the direct treatment of molten XI with chlorine gas (23). [Lit. (23) m.p. 103°.]

m - Amino - α - bromoacetophenone (XV) Hydrobromide.—A mixture of 540 mg. (7 mmoles) of XIV, 5 ml. of glacial acetic acid, and 0.65 (8 mmoles) of ethanesulfonic acid was warmed to complete solution, then cooled to room temperature. After the addition of 0.21 ml. of bromine, the solution was magnetically stirred for 12 hr. with ultraviolet light irradiation. Some of the hydrobromide salt separated during this time. The mixture was treated with 3 ml. of 30% anhydrous hydrogen bromide in acetic acid, then diluted with about 5 vol.

Chloromethyl m-Nitrostyryl Ketone (XXIII).—A mixture of 0.705 Gm. (2 mmoles) of XIX (24) and 0.378 Gm. (2.5 mmoles) of *m*-nitrobenzaldehyde in 18 ml. of benzene was refluxed 18 hr., then spin evaporated *in vacuo*. The residue was triturated with petroleum ether, then recrystallized from absolute alcohol to give 0.333 Gm. (74%) of light yellow crystals, m.p. 120–121°; $\nu_{max.}$ 1700 (C=O); 1625, 1575 (C=C); 1525, 1340 $cm.^{-1}$ (NO_2).

Anal.—Calcd. for $C_{10}H_8ClNO_3$: C, 53.2; H, 3.57; N, 6.21. Found: C, 53.3; H, 3.70; N, 6.00.

2 - Chloromethyl - 2 - (m - nitrostyryl) - 1,3-dioxolane (XXV).—A mixture of 4.52 Gm. (20 mmoles) of XXIII, 35 ml. of benzene, 10 ml. of ethylene glycol, and 40 mg. of *p*-toluenesulfonic acid was refluxed under a Dean-Stark trap for 18 hr. The solution was washed with water, then spin evaporated *in vacuo*. Trituration of the residue with ether gave 5.2 Gm. (97%) of a pale yellow solid, m.p. 87–89°. Recrystallization from absolute ethanol gave 5.07 Gm. (94%) of pale yellow crystals, m.p. 90–91°; $\nu_{max.}$ 1530, 1350 (NO_2); 1040 (C—O—C); no C=O near 1700 $cm.^{-1}$.

Anal.—Calcd. for $C_{12}H_{12}ClNO_4$: C, 53.4; H, 4.49; N, 5.19. Found: C, 53.7; H, 4.81; N, 5.15.

Catalytic reduction of XXV as previously described for XXIV (22) proceeded smoothly to XXVII which was obtained as an oil that moved as a single spot on thin-layer chromatography (22); its ultraviolet spectrum showed that the double bond had been reduced.

4 - (p - Aminophenyl) - 1 - chloro - 2 - butanone Hydrochloride (XXIX).—A solution of 600 mg. (2.5 mmoles) of XXVI (22) in 6 ml. of ethanol and 6 ml. of 1 *N* aqueous hydrochloric acid was refluxed for 2 hr., then spin evaporated *in vacuo*. The solid residue was triturated with acetone, then collected on a filter and washed with ether; yield, 290 mg. (50%) of a beige-white solid, m.p. 160–162°; $\nu_{max.}$ 3450 (NH), 2850, 1950, 1570 (NH^+); 1730 (C=O); 1615, 1500 (C=C); 840, 810 $cm.^{-1}$ (*p*-C_6H_4). No suitable solvents for recrystallization could be found.

A similar hydrolysis of XXVII gave a gummy product that showed a C=O bond at 1730 $cm.^{-1}$, but could not be crystallized.

1 - (p - Chloroacetylphenyl) - 4,6 - diamino - 1,2-dihydro - 2,2 - dimethyl - s - triazine Hydrochloride (IVa).—A mixture of 848 mg. (5 mmoles) of *p*-amino-α-chloroacetophenone (Eastman), 450 mg. (5.35 mmoles) of cyanoguanidine, 3 ml. of acetone, and 0.42 ml. (5 mmoles) of 1 *N* aqueous hydrochloric acid was refluxed with magnetic stirring. Solution was complete when the b.p. was reached, then within 10 min. the product began to separate. An additional 5 ml. of acetone was added, then the mixture was refluxed for 17 hr. After 1 hr. at 0°, the mixture was filtered and the product was washed with acetone; yield, 1.46 Gm. (88%), m.p. 200–202°. Recrystallization from methanol–ether gave 587 mg. (36%) of white crystals, m.p. 198–199°; $\nu_{max.}$ 3450, 3350, 3200 (NH); 1700 (C=O); 1670, 1640, 1600, 1550, 1540, 1520, 1500 (NH, C=NH^+, C=N, C=C); 830 $cm.^{-1}$ (*p*-C_6H_4); $\lambda_{max.}$ (H_2O): 247 mμ (ϵ 17,200). See Table II for analytical data and additional compounds prepared by this method (20), except the second addition of acetone was omitted.

Irreversible Enzyme Inhibitors LXXI

Candidate Active-Site-Directed Irreversible Inhibitors of Dihydrofolic Reductase V. Derivatives of 6-Phenylpyrimidine

By B. R. BAKER and HOWARD S. SHAPIRO

A series of 2-amino-5-anilinopropyl-6-phenyl-4-pyrimidinols bearing *p*-chloroacetyl (V*a*), *p*-(4-chloro-3-butanon-1-yl) (V*b*), *p*-(4-chloro-1-buten-3-one-1-yl) (V*c*), and *p*-bromoacetamidoethyl (IV*d*) groups on the anilino moiety were synthesized as candidate active-site-directed irreversible inhibitors of dihydrofolic reductase. Only V*b* inactivated dihydrofolic reductase when they were incubated together at 37°; the half-life was about 60 min. when sufficient V*b* was utilized to convert 45 per cent of the enzyme to a reversible complex. That this inactivation by V*b* proceeded through a reversible enzyme–inhibitor complex and not by a random bimolecular mechanism was indicated by the lack of inactivation of dihydrofolic reductase by chloroacetone at 2.5 times the concentration of V*b*. The failure of IV*d* and V*e* to inactivate the enzyme at a concentration sufficient to convert 50–60 per cent of the enzyme to the respective reversible complexes indicated that the alkylating function of IV*d* and V*e* could not bridge to a nucleophilic site on the enzyme within the enzyme–inhibitor complex.

IN ORDER for a compound to be an active-site-directed irreversible enzyme inhibitor the following requirements must be met (1, 2): (*a*) a reversible complex between the compound and the enzyme must form; (*b*) the proper positioning of a leaving group on the inhibitor must be attained that does not interfere with reversible complex formation; (*c*) the leaving group on the inhibitor—when complexed to the enzyme—must be able to bridge to a nucleophilic group on the enzyme surface with resultant covalent bond formation *via* a neighboring group reaction.

An unusual amount of difficulty was encountered for the successful design of an active-site-directed irreversible inhibitor of dihydrofolic reductase; although studies on requirements (*a*) and (*b*) appeared to follow the normal course of the *modus operandi* for the design of these irreversible inhibitors (1, 2), factor (*c*) was particularly difficult until the strong hydrophobic bonding region of dihydrofolic reductase was discovered (3–8) and utilized properly (9, 10).

DISCUSSION

Successful candidates for active-site-directed irreversible inhibitors were achieved by complexing the hydrophobic region of the enzyme by the 5-phenylbutyl group of I and II (9) or the 6-phenyl group of III (10) which then positioned their bromoacetamido groups in a nucleophilic area of the enzyme. In order for I–III to irreversibly

Previous paper: Baker, B. R., and Ho B.-T., *J. Pharm. Sci.*, **56**, 28(1967).

inhibit dihydrofolic reductase, it was apparent that the leaving bromo group was properly juxtaposed to a nucleophilic site on the enzyme, thus forming a covalent bond within the enzyme–inhibitor complex. That this bridge distance (1, 2, 11, 12) between the binding locus for the 6-phenylpyrimidine and the leaving group on the inhibitor was an important factor in active-site-directed irreversible inhibition of dihydrofolic reductase was noted with compounds of types IV and V; three of the four compounds of type IV and V were at least as good reversible inhibitors as III, but only one inactivated the enzyme *via* a neighboring group reaction within the enzyme–inhibitor complex. Of the compounds in series IV, only the synthesis of $n = 2$ was completed—for reasons that will be discussed later. Three compounds of series V were synthesized.

The enzymic evaluation of these compounds are summarized in Table I. Compounds IV*d* and V*c*, at a concentration sufficient to convert 50–60% of the enzyme to a reversible complex, failed to show inactivation of dihydrofolic reductase in 60 min. at 37°; in contrast, III showed 50% inactivation in 45 min. at 37° with sufficient inhibitor to convert only 25% of the enzyme to the reversible complex (10). The chloromethyl ketones have about the same chemical reactivity toward thiosulfate as bromoacetamides and iodoacetamides (14); furthermore, the chloromethyl ketones can attack the same nucleophilic groups on a protein that are attacked by bromoacetamides. Therefore, the failure of IV*d* and V*c* to inactivate the enzyme is most probably due to the lack of juxtaposition of their respective leaving group with an enzymic nucleophilic group within the enzyme–inhibitor reversible complex. Stated another way, the respective leaving group of the inhibitors apparently cannot bridge to an enzymic nucleophilic group within the reversible complex (1, 2, 11, 12, 18).

Due to lack of solubility, the amount of reversible inhibition by the chloroketone (V*a*) could not be determined; nevertheless, V*a* was investigated at its limit of solubility (20 μM) as an irreversible inhibitor, but with negative results that could be due to either a lack of reversible complex formation or a lack of proper bridging.

Only one of the 6-phenyl-4-pyrimidinols in Table I showed inactivation of the enzyme in addition to the previously examined III (10); the chlorobutanone derivative (V*b*), when incubated at 37° with dihydrofolic reductase at a concentration to convert 45% of the enzyme to the reversible complex, showed inactivation of the enzyme with a half-life of about 60 min. This result was first attributed to a random bimolecular inactivation of the enzyme without complex formation (2, 16), since 1-chloro-4-phenyl-3-*p*-tolylsulfonamido-2-butanone (VII, Table I) (19, 20) showed no reversible inhibition of the enzyme, but could inactivate the enzyme even more rapidly than V*b*. The fallacy of this experiment became apparent when the lack of reversible inhibition by VII ($K_i > 13 \times 10^{-5} M$) was converted to the maximum amount of reversible complex that could be formed at a concentration of 40 μM; note that as much as 25% of the enzyme could have been reversibly complexed with VII.

In a later study on inhibitors that might complex only with the hydrophobic region of dihydrofolic reductase then bridge to and alkylate a nucleophilic group on the enzyme, the benzoic acid derivative

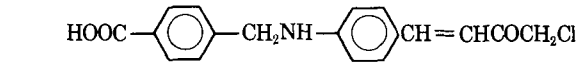
[a] Dihydrofolic reductase was a 45–90% ammonium sulfate fraction isolated from pigeon liver; the reversible inhibition studies were run with 6 μM dihydrofolate and 12 μM TPNH in 0.05 M Tris buffer (pH 7.4) containing 10 mM mercaptoethanol and 10% N,N-dimethylformamide as previously described (13). [b] The dihydrofolic reductase was incubated at 37° with the candidate irreversible inhibitor in 0.05 M Tris buffer (pH 7.4) containing *no* mercaptoethanol and *no* TPNH, but diluted with 10% N,N-dimethylformamide as previously described (14). [c] Ratio of concentration of inhibitor to 6 μM dihydrofolate giving 50% inhibition. [d] Calculated from $K_i = K_m \times [I/S]_{0.5}$ where $K_m = 1 \times 10^{-6} M$; this equation is valid if $S > 4\ K_m$ (3, 15). [e] Calculated from $[EI] = \frac{[E_t]}{1 + K_i + I}$, where $[EI]$ = the fraction of $[E_t]$ in a reversible enzyme–inhibitor complex and E_t = the total amount of active enzyme (2, 16); the rate of active-site-directed inactivation is dependent upon the fraction of $[E_t]$ in the complex, $[EI]$ (2, 16). [f] In all cases an enzyme control with no inhibitor was run as a control and either II or III was run as a standard simultaneously; 0–4% thermal inactivation of the enzyme control occurred and the per cent inactivation by the inhibitor was corrected for thermal inactivation. [g] Data from *Reference 10*. [h] Estimated from 27% inhibition at 0.4 mM, the maximum concentration allowing full light transmission. [i] Data from *Reference 17*. [j] No inhibition was observed at 0.2 mM, the maximum solubility; since 20% inhibition is readily detectable, the concentration for 50% inhibition is >0.8 mM (13).



IX

(IX) was investigated (21); at a concentration of IX sufficient to reversibly complex 50% of the dihydrofolic reductase, IX inactivated the enzyme, but some related compounds did not inactivate the enzyme. Therefore, chloroacetone was investigated for inactivation; at a concentration of 100 μM, chloroacetone showed no inactivation of dihydrofolic reductase in 120 min. at 37°, in contrast to V*b* and VII which showed 50% inactivation at 40 μM in 50 and 35 min., respectively. If either had inactivated the enzyme by the bimolecular mechanism, then chloroacetone should have also; *ergo*, neither V*b* nor VII inactivate by the bimolecular mechanism, but presumably inactivate through a complex. For example, if the K_i of the tosylamido ketone (VII) were 20×10^{-5} M—which is greater than 13×10^{-5} M [Table I (VII)]—the amount of reversible complex with 40 μM of VII would be 16% of the total enzyme; this could still give a reasonable rate of inactivation *via* the reversible complex.

Although the K_i of VII could not be determined due to its lack of solubility, it should be possible to determine K_i by observing the effect of concentration of inhibitor on the rate of inactivation (2, 22); as a first approximation, one should also see a "rate-saturation" effect (2, 16) if the inactivation proceeds through a complex. If the tosylamido ketone (VII) is weakly complexed to dihydrofolic reductase, it is most likely through hydrophobic bonding as seen with IX. Even though such studies with VII could be of scientific interest, they were off the main stream of the research goals of this laboratory (1, 2), and were, therefore, not pursued further. Thus, the main evidence that the chlorobutanone (V*b*) inactivates dihydrofolic reductase by the active-site-directed mechanism (1, 2) is the fact that chloroacetone at over twice the concentration of V*b* shows no inactivation. Furthermore, the corresponding chlorobutanone attached to a 6-methylpyrimidinol (VI) (17) shows barely detectable inactivation at a concentration sufficient to convert 71% of the enzyme to a reversible complex. This result further supports the concept (2, 8–10) that the 6-phenyl group of V*b* is complexed to the hydrophobic region of dihydrofolic reductase which then projects the 5-side-chain bearing the alkylating function into a polar nucleophilic region of the enzyme; in contrast, the 6-methylpyrimidine (VI) probably has its 5-side-chain bearing the alkylating function complexed to the hydrophobic region of the enzyme which is not apt to have polar nucleophilic groups present. The results clearly eliminate the possibility of a random bimolecular mechanism (1, 2) for inactivation and give strong support to the concept that 6-phenylpyrimidines and 6-methylpyrimidines complex to the enzyme in different rotomeric configurations (2, 8, 23)—else both V*b* and VI should have inactivated the enzyme at the same rate for the same percentage of reversible E···I complex.

Similar to the effect of the phenylbutyl pyrimidine (II) as an irreversible inhibitor (9), the rate of inactivation by the chlorobutanone (V*b*) and the tosylamidoketone (VII) was slowed by the presence of TPNH; whether or not I, II, III, V*b*, and VII all attack the same amino acid—presumably in the TPNH binding region of the enzyme—must await sequence experiments after inactivation of pure enzyme, a problem for specialists in protein sequence research.

CHEMISTRY

Methods.—Two general routes to 2-amino-6-R-4-pyrimidinols bearing a *p*-substituted anilinopropyl side chain at the 5-position such as IV and V have been developed (24–29). The first route involved reductive condensation of a substituted aniline with a pyrimidine-5-propionaldehyde such as X where the substituted anilino moiety is introduced last (24–26); the second route introduced the substituted anilinopropyl group at the first step (27–29). The first route was chosen for compounds such as IV and V since it is superior if a number of *p*-substituted anilino moieties are required.

Reductive condensation of X with *p*-aminoacetanilide with sodium borohydride in a mixture of *N,N*-dimethylformamide and methanol gave XIII*a* in 21% yield of what appeared to be pure material; although XIII*a* had the proper spectral characteristics and was uniform on thin-layer chromatography, it gave erratic results on combustion analyses. Furthermore, attempts to acid hydrolyze XIII*a* to XIV*a* gave intractable, unstable materials that could not be purified due in part to the air sensitivity of the *p*-phenylenediamine moiety. The alternate route (27–29) was not investigated since catalytic reduction of XII or its 6-methyl analog (27) could also lead to unstable, intractable materials. This problem was ultimately solved by using the more stable 5-(*p*-aminophenoxypropyl) side chain (30) which subsequently resulted in the synthesis and enzymic evaluation of the active-site-directed irreversible inhibitor (III) (10).

The higher homologs of XIII having more parafinic character proved to be easier to purify and gave satisfactory combustion results. Reductive condensation of X with *N*-(*p*-aminobenzyl) acetamide (XI*b*) (32) using the sodium borohydride procedure gave a 55% yield of XIII*b*. Unfortunately, attempts to remove the *N*-acetyl blocking group of XIII*b* with acid or base under a variety of conditions failed to give any isolatable *p*-aminomethylanilinopropyl pyrimidinol (XIV*b*); the *p*-aminomethylanilino system was unstable to such extended treatment and appeared to undergo a reverse Mannich reaction with formation of ammonia (or ammonium chloride) and formaldehyde which led to polymerization (Scheme I).

Reductive condensation of benzyl *N*-(*p*-aminobenzyl)urethan (XI*c*) with X using sodium borohydride in methanol did proceed, but the carbobenzoxy group of XIII*c* was transesterified to carbomethoxy; whether such a condensation could be performed in neutral or slightly acidic medium to avoid transesterification was not ascertained. An intermediate such as XIII*c* could well lead to the desired XIV*c* by cleavage of the carbobenzoxy group with hydrogen bromide in acetic acid.[1]

[1] By this time the synthesis and enzymic evaluation of III had led to an active-site-directed irreversible inhibitor (10); therefore, this sequence was not pursued further.

Scheme I

The reductive condensation of *N* - (*p* - aminophenethyl)acetamide (XI*d*) (32) with X using sodium borohydride proceeded smoothly to an 83% yield of XIII*d*. Hydrolysis of XIII*d* with hot 10% sodium hydroxide gave a 70% yield of the *p*-aminoethylanilinopropyl-4-pyrimidinol (XIV*d*), isolated as its monohydrochloride. The bromoacetylation of XIV*d* to the candidate irreversible inhibitor (IV*d*) with bromoacetic anhydride has been described previously in a paper on selective methods for bromoacylation of polyfunctional amides (31).

Reductive condensation of *N*-(*p*-aminophenylbutyl)benzamide (XI*e*) (33) with X also proceeded satisfactorily, an 85% yield of XIII*e* being obtained.[1]

Three 6-phenylpyrimidinols (V) bearing a chloromethyl ketone group in the *p*-position of 5-anilinopropyl moiety were synthesized by the route used for the corresponding 6-methyl pyrimidines (17). Condensation of the appropriate *p*-substituted aniline bearing a *p*-chloromethylketone function blocked as a dioxolane (XV) were used to reductively aminate the pyrimidine-5-propionaldehyde (X); the blocked derivatives (XVI) were obtained in 47–80% yields. Hydrolysis of the dioxolane with hot 0.25 *N* 25% aqueous alcoholic hydrochloric acid gave the candidate active-site-directed irreversible inhibitors V*a–c* in 49–76% yields of pure material (Scheme II).

EXPERIMENTAL

Melting points were taken in capillary tubes on a Mel-Temp block and those below 230° are corrected. Infrared spectra were determined in a KBr pellet with a Perkin-Elmer 137B recording spectrophotometer. Ultraviolet spectra were determined in 10% ethanol with a Perkin-Elmer 202 recording spectrophotometer. Thin - layer chromatograms (TLC) were run on Brinkmann Silica Gel GF and spots were detected by visual examination under ultraviolet light.

2 - Amino - 5 - (p - acetamidoethylanilinopropyl) - 6 - phenyl - 4 - pyrimidinol (XIIId).—*Method A*.—A solution of 100 mg. (0.351 mmole) of X (25) and 264 mg. (1.40 mmoles) of XI*d* (32) in 1 ml. of *N*,*N*-dimethylformamide was magnetically stirred for 20 min., then diluted with 10 ml. of methanol and treated portionwise with 150 mg. of sodium borohydride over a period of about 15 min. (24–26). After being stirred for about 18 hr., the mixture was spin evaporated *in vacuo* to near dryness. The residue was dissolved in 10 ml.

[a] In 10% ethanol. [b] Yield of analytically pure material; all compounds had infrared spectra compatible with their structures. [c] Ratio of XI:X = 5. [d] After recrystallization from aqueous 2-methoxyethanol. [e] Erratic CH values were obtained presumably due to difficulty in combustion. [f] The compound moved as a single spot on TLC in 3:1 benzene–methanol. [g] Ratio of XI:X = 1. [h] After recrystallization from aqueous ethanol. [i] Inflection. [j] Ratio of XI:X = 4. [k] Cl, Calcd.: 8.89. Found: 8.75. [l] For conversion to IV*d* see *Reference 31*. [m] See under *Experimental*. [n] Crystallized directly from reaction mixture; collected and washed with methanol. [o] Calcd. for monohydrate. [p] Calcd. for hemihydrate. [q] Oxygen, the nitrogen could not be completely combusted.

of water, then adjusted to about pH 8 with 3 *N* aqueous hydrochloric acid. After being cooled for several hours at 0°, the mixture was filtered and the white solid was washed with water. Recrystallization from aqueous ethanol gave 118 mg. (83%) of white crystals, m.p. 243–246°; $\lambda_{max.}$ 2.89, 3.00 (NH); 6.05, 6.29, 6.60 (NH, C=C, C=N, C=O); 12.25 (*p*-C_6H_4); 13.20, 14.3 μ (C_6H_5). For analytical data see Table II.

2 - Amino - 5 - (p - aminoethylanilinopropyl)-6 - phenyl - 4 - pyrimidinol Hydrochloride (XIVd).—*Method B.*—A solution of 1.00 Gm. (2.50 mmoles) of XIII*d* in 25 ml. of 10% aqueous sodium hydroxide was heated on a steam bath for 3 hr. The hot solution was clarified by filtration, then cooled in an ice-bath and adjusted to about pH 7 with 3 *N* hydrochloric acid. The white precipitate was collected on a filter, washed with water, then recrystallized from aqueous 2-methoxyethanol; yield, 0.636 Gm. (70%) of white crystals, m.p. 285–288° dec. $\lambda_{max.}$ 2.96 (NH); 6.01, 6.10, 6.30, 6.60 (NH, C=C, C=N, C=O); 12.24 (*p*-C_6H_4); 14.33 μ (C_6H_5). See Table II for analytical data.

2 - Amino - 5 - [p - (4 - chloro - 3 - oxo - 1 - buten-1 - yl)anilinopropyl] - 6 - phenyl - 4 - pyrimidinol (Vc).—*Method C.*—A solution of 200 mg. (0.428 mmole) of XVI*c* in 16 ml. of ethanol and 5.5 ml. of 1 *N* aqueous hydrochloric acid was refluxed for 1 hr., then diluted with 21 ml. of water. While being kept below 10° in an ice-bath, the stirred solution was made slightly alkaline by the dropwise addition of 10% aqueous sodium hydroxide. The product was collected on a filter and washed with water; yield, 162 mg. (90%) of orange solid, m.p. 220–225° dec. Recrystallization from warm ethanol by addition of water gave 108 mg. (62%) of orange crystals of unchanged m.p. $\lambda_{max.}$ 2.90 2.98 (NH); 6.05, 6.10, 6.30, 6.40, 6.59 (NH, C=O, C=C, C=N); 12.33 (*p*-C_6H_4); 14.3 μ (C_6H_5). See Table II for analytical data.

Irreversible Enzyme Inhibitors LXXII

Candidate Active-Site-Directed Irreversible Inhibitors of Dihydrofolic Reductase VI. Derivatives of Hydrophobically Bonded *p*-Alkyl and *p*-Aralkyl Benzoic Acids

By B. R. BAKER, THOMAS J. SCHWAN, and BENG-THONG HO

Since *p*-(bromobutyl)benzoic acid (IV), *N*-(*m*-aminobenzyl)-*p*-aminobenzoic acid (V), and *p*-benzylbenzoic acid (VI) showed good hydrophobic bonding to dihydrofolic reductase (6), four candidate active-site-directed irreversible inhibitors related to structures IV–VI were synthesized that contained a terminal alkylating function. Two of the candidates, *p*-(4-bromoacetamidobutyl)benzoic acid (IX) and *N*-(*m*-bromoacetamidobenzyl)-*p*-aminobenzoic acid (X), lost their ability to form a reversible complex with the enzyme. In contrast, α-(*p*-chloroacetylanilino)-*p*-toluic acid (XI) and α-[*p*-(4-chloro-1-buten-3-one-1-yl)anilino]-*p*-toluic acid (XII) formed reasonably good reversible complexes with dihydrofolic reductase and could inactivate the enzyme; chloroacetone under comparable conditions showed no inactivation, thus affording strong evidence that XI and XII inactivated the enzyme *via* a neighboring-group reaction within a reversible complex with the enzyme.

THE DISCOVERY of hydrophobic bonding to dihydrofolic reductase (1) with its conformational implications on the mode of binding of pyrimidines (2–8) soon led to the proper design of active-site-directed irreversible inhibitors of this enzyme (9–11). These successful candidates, such as I (9) and II*a* (10), were designed on the principle that the 5-phenylbutyl group of I could complex to the hydrophobic region on dihydrofolic reductase which then projected the 6-side-

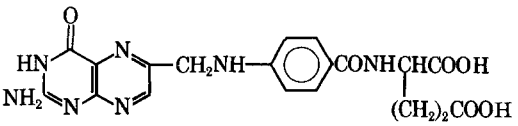
chain into a hydrophilic area on the enzyme, then formed a covalent bond (9); similarly, the 6-phenyl group of II*a* could complex with the hydrophobic region, thus projecting the 5-side-chain bearing an alkylating group into a nucleophilic region of the enzyme (10). In contrast, the candidate irreversible inhibitor (II*b*) with a 6-methyl group failed to inactivate the enzyme (12), since the 5-side-chain bearing the alkylating group was probably complexed to the hydrophobic region of the enzyme where nucleophilic groups are not apt to be present (2, 8, 11). Thus, over 30 candidate irreversible inhibitors failed to inactivate dihydrofolic reductase for the same reasons that III failed; some of these unsuccessful attempts—prior to knowledge of hydrophobic bonding to dihydrofolic reductase—have been described (11–15).

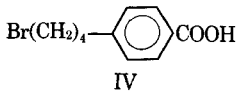
DISCUSSION

During the time that synthetic methods for structures such as I (16–19) and II*a* (10, 19) were being devised, a parallel investigation of candidate irreversible inhibitors of dihydrofolic reductase was embarked upon that utilized hydrophobic bonding in a different way. One of the studies on dihydrophobic bonding (6) sought to answer the question of where the hydrophobic bonding region on the enzyme was located with respect to the binding area for the substrate, dihydrofolic acid, or its inhibitor, folic acid (III). The results of this study suggested that the hydrophobic bonding region was near either the 4-position or 8-position of folic acid when it was complexed to the enzyme; furthermore, the hydrophobic region was not in between the pyrimidyl and *p*-aminobenzoyl-L-

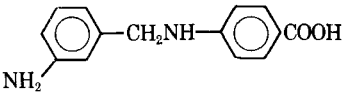


III

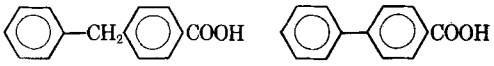
glutamate moieties when folic acid (III) was complexed to the enzyme. As part of the evidence for these deductions, it was observed that *p*-alkyl, *p*-aralkyl, or *p*-aryl groups on benzoic acid, such as IV–VII, could hydrophobically bind to dihydrofolic reductase. It was therefore reasoned that if a



IV



V



VI VII

terminal chloromethyl ketone or bromoacetamido group were attached to molecules such as IV–VII these alkylating functions might project into a hydrophilic area on the enzyme when the inhibitors were complexed to the hydrophobic region of the dihydrofolic reductase. In Table I are summarized the enzyme data on inhibitors of this type.

Since the *p*-bromobutyl group of IV showed hydrophobic bonding, the corresponding *p*-(4-bromoacetamidobutyl)benzoic acid (IX) was synthesized as a candidate irreversible inhibitor. Unfortunately, IX showed no reversible inhibition,

[a] The dihydrofolic reductase was a 45–90% ammonium sulfate fraction from pigeon liver that was prepared and assayed with 6 μM dihydrofolate and 12 μM TPNH as previously described (20). [b] Dihydrofolic reductase was incubated at 37° with the inhibitor in Tris buffer (pH 7.4) as previously described; in each case an enzyme control showed 0–4% inactivation. [c] I_{50} = millimolar concentration necessary for 50% inhibition. [d] Estimated from $K_i = K_m\,(I/S)$ where $K_m = 1 \times 10^{-6}$ *M*, *I* = inhibitor concentration, and *S* = dihydrofolate concentration; this equation is usually valid when $S > 4\ K_m$, since $S = 6\ K_m$ (1, 21). [e] Calculated from $[EI] = [E_t]/(1 + K_i/[I])$ where E_t = total enzyme, $[EI]$ = fraction of enzyme reversibly complexed, and *I* = inhibitor concentration (2, 22). [f] Data from *Reference 6*. [g] Estimated from 17% inhibition observed at 0.1 m*M*, the highest concentration allowing full light transmission. [h] Estimated from 34% inhibition observed at 0.6 m*M*, the highest concentration allowing full light transmission. [i] Intermediate times were not run to determine if 95% inactivation was reached sooner.

greater than fourfold loss in reversible binding occurring compared to IV; therefore, IX was not further investigated. One of the best benzoic acid derivations showing hydrophobic bonding was the *m*-aminobenzylamino derivative, V (6); when V was converted to its bromoacetyl derivative (X), reversible binding was again lost. Apparently the planar amide group of IX and X are not tolerated within the enzyme–inhibitor complex; furthermore, the amide group is quite polar and may still be in the vicinity of the hydrophobic region of dihydrofolic reductase. Therefore, the chloromethyl ketones (XI and XII) were synthesized and evaluated.

The α-chloroacetophenone derivative (XI) was one of the best reversible inhibitors of the *p*-substituted benzoic acid type with $K_i = 8 \times 10^{-5}$ *M*. When 0.2 m*M* of XI was incubated with dihydrofolic reductase at 37°, 35% inactivation occurred in 2 hr.; this concentration of XI is sufficient to convert 70% of the dihydrofolic reductase to a reversible complex.

Although XII with its longer *p*-group was not so good a reversible inhibitor as XI, XII was a better irreversible inhibitor; at a concentration of 0.2 m*M*, XII converts 50% of the available enzyme to a reversible complex, and then showed 95% inactivation in 2 hr. at 37°. Note that chloroacetone at 0.1 m*M* failed to show any inactivation in 1 hr. at 37°; if XI and XII had inactivated dihydrofolic reductase by a random bimolecular mechanism (2, 22), then XI, XII, and chloroacetone should have inactivated the enzyme at near the same rate; these differences in rates are taken as strong evidence that the inactivation of XI and XII occurs through a complex by the active-site-directed mechanism (2, 22).

Whether XI and XII alkylate the same amino acid on dihydrofolic reductase that is attacked by the pyrimidines (I and II*a*) must await experiments on a purified enzyme—a problem for protein structure chemists.

CHEMISTRY

Methods

When *p*-bromopropylbenzoic acid (XIV) (6, 23) was treated with 2.5 mole ratio of sodium cyanide in *N*,*N*-dimethylformamide, considerable polymeric material was found; presumably, the carboxylate anion of XIV displaced the bromine atom by intermolecular attack. When the ratio of sodium cyanide was increased to 6:1, the reaction proceeded more smoothly to give *p*-cyanobutylbenzoic acid (XV) in 60% yield with considerably less formation of polymer. Hydrogenation of the cyano group in alcohol containing a 2:1 ratio of hydrochloric acid (24) in the presence of platinum oxide proceeded smoothly to the hydrochloride of XVI in quantitative yield which was suitable for further transformation, but was characterized as the free base. Reaction of XVI hydrochloride as its anion in aqueous acetone containing two equivalents of sodium hydroxide with *p*-nitrophenyl bromoacetate (19) gave the candidate irreversible inhibitor (IX) in 38% yield; the purified IX moved as a single spot on TLC and gave a positive 4-(*p*-nitrobenzyl)pyridine test for active halogen (19).

In order to synthesize X, a number of blocking groups for the secondary amine group of XVII—such as tosyl—were investigated. Since these blocked derivatives gave a number of unexpected problems, the selective bromoacylation of XVII was investigated; a primary amino group should be more reactive than a secondary amino group and in addition this secondary amino group of XVII should be further deactivated by the electron-withdrawing *p*-carboxyl group (19). Reaction of XVII (6) with one equivalent of bromoacetic anhydride in acetone at 0° (19) gave the desired candidate irreversible inhibitor, X, in 71% yield; further purification gave a compound that moved as a single spot on TLC and gave a negative Bratton-Marshall test for primary aromatic amines, but gave a positive 4-(*p*-nitrobenzyl)pyridine test for active halogen (19)—thus showing that the bromoacetyl group had reacted with the primary amino group of XVII to give X.

Since the aminophenyl dioxolanes (XVIII and XIX) were readily available from another study (12), their reductive condensation with *p*-formylbenzoic acid was investigated. Reductive condensation of XVIII in methanol with the aid of sodium borohydride afforded XX in 69% yield; similarly, the styryl dioxolane (XIX) afforded XXI in 48% yield. Hydrolysis of the dioxolane blocking group of XX with boiling 65% ethanol containing 0.05 *N* hydrochloric acid afforded the active-site-directed irreversible inhibitor (XI) in 67% yield; similarly, hydrolysis of XXI gave XII in 34% yield (Scheme I).

Synthesis

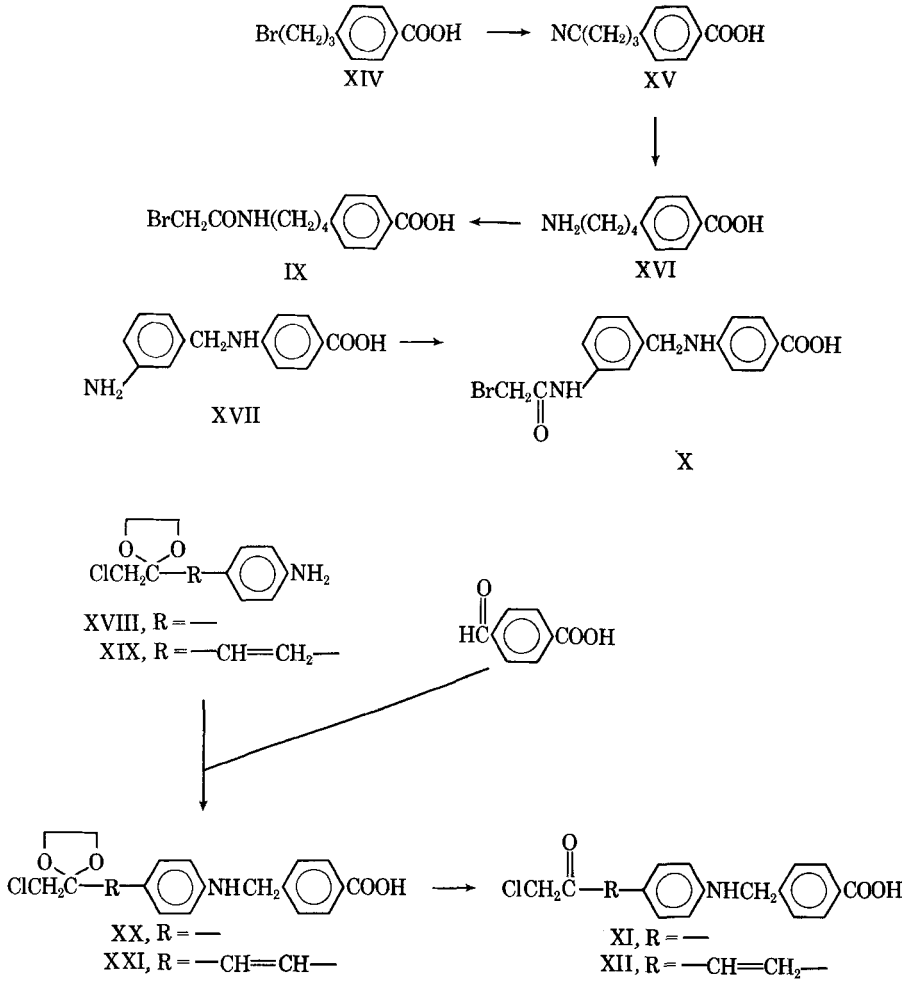
Melting points were determined in capillary tubes on a Mel-Temp block and those below 230° are corrected. Infrared spectra were determined in Nujol mull, unless otherwise indicated, with a Perkin-Elmer 137B spectrophotometer. Ultraviolet spectra were determined in 10% alcohol with a Perkin-Elmer 202 spectrophotometer. Thin-layer chromatograms (TLC) were run on Brinkmann Silica Gel GF and spots were detected by visual examination under ultraviolet light and by the 4-(*p*-nitrobenzyl)pyridine spray for active halogen (19).

p-Cyanopropylbenzoic Acid (XV).—A magnetically stirred mixture of 972 mg. (4 mmoles) of XIV (6, 23), 1.17 Gm. (23.9 mmoles) of sodium cyanide, and 40 ml. of *N*,*N*-dimethylformamide was heated in a bath at 100–110° for 18 hr. The cooled mixture was poured into 200 Gm. of ice water and the pH was adjusted to about 1 with dilute hydrochloric acid. The polymeric material was separated by filtration and had $\lambda_{max.}$ 5.88 (ester C=O); 5.95 (acid C=O); 9.08 μ (aromatic ester C—O—C).

The filtrate was extracted with chloroform (5 × 50 ml.). The combined, dried extracts were spin evaporated *in vacuo*. Recrystallization of the residue from benzene–petroleum ether (b.p. 60–110°) gave 451 mg. (60%) of product, m.p. 150–157°, suitable for further transformation. Recrystallization from the same solvent pair gave white crystals, m.p. 158–160°; $\lambda_{max.}$ (pH 1): 244; (pH 7): 235 mμ; $\lambda_{max.}$ 4.45 (C≡N); 5.94 (C=O); 6.24 μ (C=C).

Anal.—Calcd. for $C_{11}H_{11}NO_2$: C, 69.8; H, 5.86; N, 7.40. Found: C, 70.1; H, 5.83; N, 7.70.

p-(4-Aminobutyl)benzoic Acid (XVI).—A solution of 859 mg. (4.55 mmoles) of XV in 100 ml. of ethanol and 0.75 ml. of 12 *N* aqueous hydrochloric



Scheme I

acid was shaken with hydrogen at 2–3 Atm. in the presence of 100 mg. of platinum oxide until 3 mole equivalents of hydrogen were absorbed. The filtered solution was spin evaporated to dryness *in vacuo* to give 1086 mg. (>100%) of crude XVI hydrochloride, m.p. 230–240° dec., that was suitable for the next step; this material contained some ammonium chloride after recrystallization from methanol–ether, as shown by combustion analysis.

A portion of the hydrochloride was dissolved in 10 ml. of water, then the solution was clarified with decolorizing carbon. The solution was made basic with ammonia water, then spin evaporated *in vacuo*. Recrystallization from the minimum of hot water gave white crystals of XVI as a zwitterion, m.p. 259–262°; $\lambda_{max.}^{H_2O}$ (pH 1): 244; (pH 7): 234; (pH 13): 239 mμ; $\lambda_{max.}$ 2.90, 3.10 (NH); 4.74 (NH^+); 6.32 (C=C); 6.55–6.65 (COO^-); 11.80 μ (*p*-C_6H_4).

Anal.—Calcd. for $C_{11}H_{15}NO_2$: C, 68.4; H, 7.82; N, 7.25. Found: C, 68.1; H, 7.98; N, 7.36.

p - [4 - (Bromoacetamido)butyl]benzoic Acid (IX).—To a solution of 230 mg. (1 mmole) of XVI hydrochloride in 30 ml. of water was added 0.67 ml. (2 mmoles) of 3 *N* aqueous sodium hydroxide followed by 5 ml. of acetone. After addition of 291 mg. (1.1 mmoles) of *p*-nitrophenyl bromoacetate, the mixture was magnetically stirred at ambient temperature for about 1 hr. The solution was spin evaporated *in vacuo* to about 20 ml. when an oil separated. The supernatant liquid was decanted and the oil rinsed with two 10-ml. portions of water. The combined aqueous solutions were acidified to about pH 1 with dilute hydrochloric acid. The product was collected on a filter and washed with water; yield, 120 mg. (38%), m.p. 160–168°. Recrystallization from ethyl acetate–petroleum ether (b.p. 60–110°), then toluene gave white crystals, m.p. 175–176°; $\lambda_{max.}$ (pH 1): 247; (pH 7): 238 mμ; $\lambda_{max.}$ 3.04 (NH); 5.98 (carboxyl C=O); 6.09 (amide I); 6.24 (C=C); 6.50 μ (amide II). Thin-layer chromatography with benzene–methanol (3:1) showed a single spot under ultraviolet light; this spot gave a positive 4-(*p*-nitrobenzyl)pyridine test (19) for active halogen. Even though TLC indicated only one component, combustion analysis indicated the compound was only 90% pure.

Anal.—Calcd. for $C_{13}H_{16}BrNO_3$: C, 49.7; H,

5.12; N, 25.4. Found: C, 50.2; H, 5.10, Br, 23.1, 23.4.

N - (m - Bromoacetamidobenzyl) - p - aminobenzoic Acid (X).—To a solution of 484 mg. (2 mmoles) of XVII (6) in 4 ml. of acetone in an ice bath was added 520 mg. (2 mmoles) of bromoacetic anhydride (19). During 30 min. at 0°, the solution deposited tan crystals; 5 ml. of ether was added and the product was collected by centrifugation and washed with ether (5 × 8 ml.); yield, 518 mg. (71%), m.p. 192–195° dec. Recrystallization from aqueous ethanol with the aid of decolorizing carbon gave 355 mg. (49%) of nearly white crystals, m.p. 183–186°; $\lambda_{max.}^{KBr}$ 2.94, 3.03 (NH); 3.78–3.96 (broad, acidic OH); 6.05, 6.25, 6.43, 6.76 μ (C=O, NH, C=C). The compound gave a negative Bratton-Marshall test for primary aromatic amines (19) and a positive test for active halogen with 4-(*p*-nitrobenzyl)pyridine (19); it moved as a single spot on TLC in benzene–dioxane–glacial acetic acid (90/25/4).

Anal.—Calcd. for $C_{16}H_{15}BrN_2O_3$: C, 52.9; H, 4.16; Br, 22.0. Found: C, 53.1; H, 4.28; Br, 21.8.

2 - {p - [N - (p - Carboxybenzyl)amino]phenyl} - 2 - chloromethyl - 1,3 - dioxolane (XX).—To a magnetically stirred mixture of 1.285 Gm. (6 mmoles) of XVIII (12) and 0.903 Gm. (6 mmoles) of *p*-formylbenzoic acid in 150 ml. of methanol was added 3.0 Gm. of sodium borohydride in portions over about 30 min. with cooling in a water bath; at the end of the addition, the mixture was homogeneous. After being stirred for 18 hr. at ambient temperature, the solution was spin evaporated *in vacuo*. The residue was leached with 50 ml. of boiling benzene to remove any unreacted XVIII. The residue was dissolved in water, a little insoluble material was removed by filtration, then the filtrate was acidified to about pH 1 with dilute aqueous hydrochloric acid with cooling. After the addition of 2 Gm. of Celite, the mixture was filtered and the filter cake washed with water, then dried. The cake was extracted with boiling acetone (3 × 50 ml.). The combined, filtered extracts were spin evaporated *in vacuo*. The residue was triturated with petroleum ether; yield, 1.446 Gm. (69%), m.p. 206–208°. Recrystallization from ethyl acetate–petroleum ether (b.p. 60–110°) gave white crystals, m.p. 212–213°; $\lambda_{max.}$ (pH 1): 236; (pH 7): 259; (pH 13): 254 mμ; $\lambda_{max.}$ 2.95 (NH); 5.98 (carboxyl C=O); 6.21 (C=C); 9.65, 9.81 (ether C—O—C); 12.16 μ (*p*-C_6H_4).

Anal.—Calcd. for $C_{18}H_{18}ClNO_4$: C, 62.2; H, 5.22; N, 4.03. Found: C, 62.0; H, 5.26; N, 3.94.

2 - {p - [N - (p - Carboxybenzyl)amino]styryl} - 2 - chloromethyl - 1,3 - dioxolane (XXI).—This was prepared from 482 mg. (2 mmoles) of XIX as described for the preparation of XX. Recrystallization from ethyl acetate–petroleum ether (b.p. 60–110°) gave 358 mg. (48%) of product, m.p. 181–183°. Recrystallization from the same solvent pair gave nearly white crystals, m.p. 183–185°; $\lambda_{max.}$ (pH 1): 251; (pH 7): 232, 299; (pH 13): 291 mμ; $\lambda_{max.}$ 2.99 (NH); 6.00 (carboxyl C=O); 6.25 (C=C); 9.73, 9.85 (ether C—O—C); 12.25 μ (*p*-C_6H_4).

Anal.—Calcd. for $C_{20}H_{20}ClNO_4$: C, 64.3; H, 5.39; Cl, 9.48. Found: C, 64.0; H, 5.51; N, 9.62.

α - (p - Chloroacetylanilino) - p - toluic Acid (XI).—A solution of 363 mg. (1.04 mmoles) of XX in 54 ml. of absolute ethanol and 18 ml. of 0.2 *N* hydrochloric acid was refluxed for 30 min., then cooled overnight at 3°. The product (283 mg.) was collected on a filter and recrystallized from absolute ethanol to give 212 mg. (67%) of yellow crystals, m.p. 240° dec.; $\lambda_{max.}$ (pH 1): 242, 343; (pH 7): 238, 339; (pH 13): 235 (inflection), 343 mμ; $\lambda_{max.}$ 2.99 (NH); 5.82 (sh, ketone C=O); 6.03 (carboxyl C=O); 6.31 (C=C); 12.31 (*p*-C_6H_4); no C—O—C bands near 9–10 μ. The compound gave a positive 4-(*p*-nitrobenzyl)pyridine test (19) for active halogen and moved as a single spot on TLC in benzene–methanol (3:1).

Anal.—Calcd. for $C_{16}H_{14}ClNO_3$: C, 63.3; H, 4.65; Cl, 11.7. Found: C, 63.1; H, 4.79; Cl, 11.8.

α - [p - (4 - Chloro - 1 - butene - 3 - one - 1 - yl) anilino] - p - toluic Acid (XII).—This was prepared from XXI as described for XI. Recrystallization from absolute ethanol gave 88 mg. (34%) of yellow-orange crystals which blackened at 200° and did not melt to 250°; $\lambda_{max.}$ (pH 1): 292; (pH 7, 13): 240, 410 mμ; $\lambda_{max.}$ 3.00 (NH); 5.90 (sh, ketone C=O); 6.00 (carboxyl C=O); 6.38 (C=C); 12.45 (*p*-C_6H_4); no C—O—C bands near 9.5 μ. The product moved as a single spot on TLC in benzene–methanol (3:1) and gave a positive 4-(*p*-nitrobenzyl)pyridine test for active halogen (19).

Anal.—Calcd. for $C_{18}H_{16}ClNO_3$: C, 65.6; H, 4.89; Cl, 10.8. Found: C, 65.4; H, 4.82; Cl, 11.0.

Determination of Acetylsalicylic Acid and Barbiturate Combinations in Dosage Forms

By SONG-LING LIN* and MARTIN I. BLAKE

A nonaqueous differentiating titrimetric procedure is presented for determining dosage forms containing acetylsalicylic acid and barbiturate combinations. Preliminary extraction of the active components is avoided. The titrant is sodium methoxide in benzene–methanol and the titration solvent is methyl isobutyl ketone. Titrations are effected potentiometrically. An additive procedure is suggested when the ratio of acetylsalicylic acid to barbiturate is greater than 10 to 1. The effect of additives and other active constituents is considered.

THE A.O.A.C. method for the analysis of acetylsalicylic acid and phenobarbital tablets is a spectrophotometric procedure involving preliminary separation of the components on a column of diatomaceous earth[1] which has been treated with dipotassium phosphate. It is based on a procedure developed by Banes (1) for determining phenobarbital in the presence of salicylates, and modified by Byers (2). Although satisfactory results are obtainable by this procedure, it is tedious and time-consuming.

In a previous paper (3) synthetic mixtures of acetylsalicylic acid and a variety of barbiturates were analyzed by a differentiating nonaqueous titration procedure. Titration was effected with a Fisher titrimeter equipped with a glass-calomel or antimony-calomel electrode system. The titration solvent was methyl isobutyl ketone, and the titrant was sodium methoxide in benzene–methanol (10:1). In the present study the method is applied to numerous dosage forms which contain acetylsalicylic acid and barbiturates in addition to additives, excipients, and other active constituents. The dosage form is titrated differentially without preliminary extraction of the active constituents. The effect of interfering substances on the sensitivity of the procedure is considered.

EXPERIMENTAL

Apparatus.—All titrations were performed potentiometrically with a Fisher titrimeter, model 35, equipped with a sleeve-type calomel (Beckman No. 41240) and a glass (Beckman No. 40495) electrode system.

Reagents.—(*a*) Acetylsalicylic acid and all barbiturates were the best quality available from commercial sources and were purified as described in an earlier paper (3). (*b*) Tenth normal sodium methoxide in benzene–methanol (10:1) was prepared and standardized as described by Fritz and Lisicki (4). (*c*) Other chemicals and all solvents used in this study were reagent grade and were employed without further purification. (*d*) Dosage forms were obtained from commercial sources.

General Procedure.—Appropriate amounts of acetylsalicylic acid and phenobarbital, accurately weighed, were transferred to a 150-ml. beaker and dissolved in 70 ml. of methyl isobutyl ketone with the aid of magnetic stirring. The solution was titrated potentiometrically with 0.1 *N* sodium methoxide in benzene–methanol (10:1), using a glass-calomel electrode system. The end points were determined from the inflections of the titration curve obtained by plotting millivolts (mv.) *versus* volume (ml.) of titrant added. During the titration process, the titration beaker was covered with a rubber plate having holes for the passage of the electrodes and the buret tip.

Effect of Other Ingredients on Differentiating Titration.—Approximately 0.60 meq. of acetylsalicylic acid, 0.40 meq. of phenobarbital, and an amount of other active constituents as indicated in Table II, accurately weighed, were dissolved in 70 ml. of methyl isobutyl ketone. The titration and end point detection were carried out as previously described.

Application of Additive Method.—Twenty tablets were weighed and powdered. An aliquot of the powder mass equivalent to about 0.90 meq. of acetylsalicylic acid was accurately weighed and transferred to a 150-ml. beaker. Amounts of pure phenobarbital, accurately weighed, were added to aliquots of the powder mass to bring the phenobarbital content from 0.07 meq. to a maximum of 0.35 meq. The samples were then dissolved in 70 ml. of methyl isobutyl ketone, and the solutions were titrated as described previously.

Analysis of Dosage Forms.—Seven dosage forms containing acetylsalicylic acid, a barbiturate, and other active ingredients were analyzed for their content of both acetylsalicylic acid and barbiturate by differentiating nonaqueous titration. Twenty tablets were weighed and powdered, or 20 capsules were emptied as completely as possible and the

Received August 19, 1966, from the Department of Pharmacy, University of Illinois at the Medical Center, Chicago 60612.

Accepted for publication September 30, 1966.

The authors acknowledge the following companies for supplying samples of pure barbiturates and dosage forms used in this study: Burroughs Wellcome and Co., Eli Lilly and Co., A. H. Robins Co., Sandoz Pharmaceuticals, Smith Kline & French Laboratories, and the U. S. Vitamin and Pharmaceutical Co.

The authors express their appreciation to Mr. Jeffrey S. Rudolph for technical assistance in certain aspects of this study.

[1] Marketed as Celite 545 by the Johns-Manville Corp., New York, N. Y.

contents weighed. A sample of the powder mass equivalent to about 0.85 meq. of acetylsalicylic acid was accurately weighed and transferred to a 150-ml. beaker. The sample was dissolved in 70 ml. of methyl isobutyl ketone. When the additive method was employed, sufficient pure barbiturate powder was accurately weighed and added to the powder mass to make the ratio of acetylsalicylic acid-to-barbiturate more favorable for differentiating titration. The sample was then dissolved in 70 ml. of methyl isobutyl ketone. The direct titration procedure and the additive modification were applied to each dosage form. End points were determined as described previously.

RESULTS AND DISCUSSION

Differentiating nonaqueous titrimetry has provided a simple and useful technique for determining mixtures of acids (or bases) in dosage forms. The acids (or bases) in the mixture must differ significantly in their ionization constants, interfering substances must be absent, and the proper selection of titrant, titration solvent, and electrode system must be made. When these conditions have been met, complex dosage forms can be assayed by a single titration and preliminary treatment of the sample is unnecessary. Time-consuming and involved extraction procedures are avoided.

In an earlier paper (5) the differentiating titration of the weak bases acetophenetidin and caffeine in APC dosage forms was reported. The titrant was perchloric acid in acetic acid–acetic anhydride (1:1) and the titration solvent was acetic anhydride–chloroform–benzene (1:1:9). The differentiating

[a] Per unit dosage form. [b] Standard deviation is based on at least 4 determinations. [c] Corresponds to aspirin plus barbiturate involved.

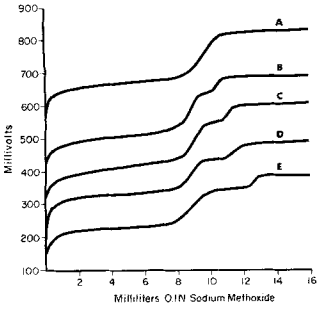

Fig. 1.—Titration curves for differentiating titration of acetylsalicylic acid and phenobarbital in dosage forms by additive method. Data are shown in Table III.

titration of synthetic mixtures of acetylsalicylic acid and barbiturates has been reported (3). The titration solvent was methyl isobutyl ketone and sodium methoxide in benzene–methanol was the titrant. In the present study this procedure has been applied to complex dosage forms containing acetylsalicylic acid and a variety of barbiturates in addition to certain additives, excipients, and other active constituents.

A series of 10 samples of a synthetic mixture of acetylsalicylic acid and phenobarbital was analyzed by the proposed method. The data in Table I indicate the accuracy and precision obtainable by the procedure.

Since acetylsalicylic acid and barbiturates are frequently combined with other therapeutic agents, the effect of these agents on the differentiating titration was studied. The constituents listed in Table II were added individually to a mixture of acetylsalicylic acid and phenobarbital and the combination was titrated by a differentiating titration. The content of the added active component was roughly that which is found in commercial dosage forms. It is apparent from the data in Table II that the added constituents do not interfere in the proposed assay pressured. In general, basic compounds and salts will not interfere. Acids comparable in strength to acetylsalicylic acid or phenobarbital will interfere with the titration. One of the commercial dosage forms procured for this study contained ascorbic acid in addition to acetylsalicylic acid and phenobarbital. A differentiating titration was not successful in this case.

The effect of disproportionate concentrations of acetylsalicylic acid to barbiturate on the differentiating titration was reported in an earlier paper (3). In synthetic mixtures when the acetylsalicylic acid-to-phenobarbital ratio was as high as 10:1, differentiation was not possible. Only one end point corresponding to the total acid present was obtained. An additive method is therefore proposed in which an amount of pure barbiturate is added to the powder mass to assure a ratio more favorable for differentiation. A similar technique (5) was shown to be useful in the differentiation of acetophenetidin and caffeine in APC combinations where dosage forms usually contain the components in the ratio of about 5:1. Dosage forms customarily (Table IV) contain a significantly greater proportion of acetylsalicylic acid than barbiturate. The applicability of the additive procedure was therefore tested on a typical dosage form. The data are reported in Table III. The ratio of the components in the dosage form was 13:1. By the direct titration method (no added phenobarbital) only one end point, corresponding to total acid present, was obtained. With the additive method the ratio of components was varied from 6.4:1 to 2.6:1. In each case differentiation was realized. Typical titration curves are shown in Fig. 1. Curves B through D show two distinct inflections, the first corresponding to the acetylsalicylic acid, and the second representing the barbiturate end point. Quantitative recoveries for both components are recorded in Table III.

Seven commercially available dosage forms were analyzed by the proposed assay using both the direct method and the additive modification. The results of the analyses are reported in Table IV. When the acetylsalicylic acid-to-barbiturate ratio is below 10:1, the direct method is suitable. For those dosage forms having a ratio of 10 or greater, the additive method must be applied.

The weak bases, caffeine and acetophenetidin, and the salt, amphetamine sulfate, did not interfere in the proposed assay. The excipients, coloring agents, diluents, and fillers employed in the formulation of the dosage forms apparently do not interfere. While these agents may suggest a possible source of difficulty in the titrimetric analysis of dosage forms, it has been shown by Chatten and Mainville (6) that in fact these agents do not represent an important source of interference even when the agents themselves are titratable.

Neutralization of Aluminum Hydroxide Dried Gel

Citrate and Tartrate Inhibition

By MILO GIBALDI and DANIEL MUFSON

Studies were conducted on the neutralization rate of aluminum hydroxide dried gel (AHDG) with HCl as a function of rate of agitation and amount of AHDG. On the basis of these studies it is suggested that the AHDG–HCl neutralization reaction is chemically controlled. Sodium citrate and tartrate were tested as inhibitors of AHDG. Their effect on the neutralization rate was investigated by neutralization, sedimentation, and complexation studies. It was concluded that a dual mechanism is operative to produce inhibition; the AHDG reacts with the salt to produce protons, and this effect, coupled with flocculation, causes a retardation in the rate of change of pH with time.

DESAI *et al.* (1), in 1963, employing the "buffering capacity" procedure, found extensive inhibition of the antacid activity of a large number of commercial antacid products when polypeptides were added to artificial gastric juice. The polypeptides had no effect on the time required to terminate the procedure, but greatly reduced the maximum pH attained. Products containing AHDG were most sensitive to this inhibitory effect.

Gibaldi and co-workers (2) found that the effect of polypeptides on "buffering capacity" could be ascribed to an inhibitory influence on the rate of neutralization. They, therefore, proposed that neutralization rate studies would be as indicative of the activity of a given antacid under different experimental conditions as the more elaborate "buffering capacity" experiments. These workers found that the neutralization rate is strongly dependent on the amount of aluminum hydroxide dried gel (AHDG) employed as well as the amount of inhibiting agent. Inhibition of activity was noted with various proteins, polypeptides, and amino acids. In addition, inhibition was found in the presence of acetate and citrate. Neither of these materials had a perceptible effect on the initial pH of the test solution or on the equilibrium pH. Two possible explanations for the observed inhibition effects, *viz.*, the formation of an *insoluble* AHDG–inhibitor complex and the adsorption of the inhibitor on the surface of the dispersed AHDG particles, were ruled out by the results of their investigations. The authors suggested the formation of a *soluble* complex between AHDG and the inhibitors tested.

In 1933, Tartar *et al.* (3) studied the influence of adsorbed ions on the dissolution of colloidal aluminum hydroxide in HCl. Aluminum hydroxide was allowed to dissolve in HCl in the presence of various salts. The solubility of aluminum hydroxide was determined at the end of 24 hr. at 25°. The data indicated that the greater the concentration of electrolyte, such as arsenate, phosphate, or sulfate, the greater the amount of aluminum hydroxide dissolved.

These authors noted that the "speed" (24-hr. solubility) of the reaction between colloidal aluminum hydoxide and 0.2 *N* hydrochloric acid is increased several-fold by the presence of electrolytes yielding anions of higher valence. It should be pointed out, however, that these workers did not clearly show that the test electrolytes increased the velocity of dissolution since only apparent equilibrium solubility was measured. They proposed that their findings were attributable to the ability of the anions of higher valence to modify the speed of the reaction by influencing the electrical potential at the solid-liquid interface. Tarter (3) also presented evidence which indicated that the change in the "speed" of the reaction was not due to an increase in the surface

Neutralization of Aluminum Hydroxide Dried Gel

Citrate and Tartrate Inhibition

By MILO GIBALDI and DANIEL MUFSON

Studies were conducted on the neutralization rate of aluminum hydroxide dried gel (AHDG) with HCl as a function of rate of agitation and amount of AHDG. On the basis of these studies it is suggested that the AHDG–HCl neutralization reaction is chemically controlled. Sodium citrate and tartrate were tested as inhibitors of AHDG. Their effect on the neutralization rate was investigated by neutralization, sedimentation, and complexation studies. It was concluded that a dual mechanism is operative to produce inhibition; the AHDG reacts with the salt to produce protons, and this effect, coupled with flocculation, causes a retardation in the rate of change of pH with time.

DESAI *et al.* (1), in 1963, employing the "buffering capacity" procedure, found extensive inhibition of the antacid activity of a large number of commercial antacid products when polypeptides were added to artificial gastric juice. The polypeptides had no effect on the time required to terminate the procedure, but greatly reduced the maximum pH attained. Products containing AHDG were most sensitive to this inhibitory effect.

Gibaldi and co-workers (2) found that the effect of polypeptides on "buffering capacity" could be ascribed to an inhibitory influence on the rate of neutralization. They, therefore, proposed that neutralization rate studies would be as indicative of the activity of a given antacid under different experimental conditions as the more elaborate "buffering capacity" experiments. These workers found that the neutralization rate is strongly dependent on the amount of aluminum hydroxide dried gel (AHDG) employed as well as the amount of inhibiting agent. Inhibition of activity was noted with various proteins, polypeptides, and amino acids. In addition, inhibition was found in the presence of acetate and citrate. Neither of these materials had a perceptible effect on the initial pH of the test solution or on the equilibrium pH. Two possible explanations for the observed inhibition effects, *viz.*, the formation of an *insoluble* AHDG–inhibitor complex and the adsorption of the inhibitor on the surface of the dispersed AHDG particles, were ruled out by the results of their investigations. The authors suggested the formation of a *soluble* complex between AHDG and the inhibitors tested.

In 1933, Tartar *et al.* (3) studied the influence of adsorbed ions on the dissolution of colloidal aluminum hydroxide in HCl. Aluminum hydroxide was allowed to dissolve in HCl in the presence of various salts. The solubility of aluminum hydroxide was determined at the end of 24 hr. at 25°. The data indicated that the greater the concentration of electrolyte, such as arsenate, phosphate, or sulfate, the greater the amount of aluminum hydroxide dissolved.

These authors noted that the "speed" (24-hr. solubility) of the reaction between colloidal aluminum hydoxide and 0.2 *N* hydrochloric acid is increased several-fold by the presence of electrolytes yielding anions of higher valence. It should be pointed out, however, that these workers did not clearly show that the test electrolytes increased the velocity of dissolution since only apparent equilibrium solubility was measured. They proposed that their findings were attributable to the ability of the anions of higher valence to modify the speed of the reaction by influencing the electrical potential at the solid-liquid interface. Tarter (3) also presented evidence which indicated that the change in the "speed" of the reaction was not due to an increase in the surface

area of the colloid. He notes, in fact, that the reverse is true; phosphate, arsenate, and sulfate ions exert a flocculating effect with an accompanying decrease in surface area.

Thus, a paradoxical situation appears to exist. On the one hand, the anions increase the solubility of the AHDG which should be attended by an increase in the reaction rate. On the other hand, these anions exert a flocculating effect and thereby decrease the effective surface area of the gel. The latter effect would tend to decrease the reaction rate and is in agreement with the recent findings of Desai (1) and Gibaldi (2).

It was the purpose of the present investigation to study the neutralization reaction of AHDG in HCl and to elucidate further the nature of the inhibition of AHDG by various anions. Of interest was the determination of whether the neutralization reaction is diffusion or chemically controlled, as well as the consideration of the role of flocculation and complex formation in the inhibition mechanism.

THEORETICAL CONSIDERATIONS

Neutralization.—Heterogeneous reactions are regulated by chemical effects and by physical phenomena occurring at the interface. When the chemical reaction rate is high, the physical effects become rate-limiting. Three separate steps are necessary for a heterogeneous reaction to proceed: (*a*) the reacting species must diffuse to the interface; (*b*) the chemical reaction occurs at the interface; and (*c*) the reaction products diffuse out into the bulk solution. The slowest of these three steps becomes the rate-limiting step.

Van Name and Hill (4) separated heterogeneous reactions into three classes: (*a*) the chemical reaction proceeds much faster than the diffusion, and the observed reaction rate will be determined by the rate of diffusion; (*b*) the chemical reaction is much slower than the diffusion and is, therefore, the controlling factor; and (*c*) chemical reaction rate and diffusion rate are both of the same order of magnitude, and the observed rate is a function of both.

Rate of agitation has a significant effect on the rate of a diffusion controlled reaction. Wurster and Taylor (5), in a recent review of dissolution rate theory presented the empirical equation,

$$DR = a(AR)^b \qquad \text{(Eq. 1)}$$

relating the agitation rate (AR) and the dissolution rate (DR), where a and b are constants. The value of b for a purely diffusion controlled reaction approximates unity. Its value for a chemically controlled reaction should approach zero.

Davion (6) presented an equation which describes the dissolution of a solid by a diffusion controlled process,

$$\frac{dW}{dt} = \frac{DA}{h}(C_s - C) \qquad \text{(Eq. 2)}$$

where dW/dt is the change in weight of the dissolving solid with time, D is the diffusion coefficient of the solute, h is the thickness of the diffusion layer, A is the area of the dissolving surface, C_s is the equilibrium solubility of the compound, and C is the concentration present in solution at time t. This equation permits one to visualize the effect of agitation on the rate of dissolution. As the stirring rate is increased, the diffusion layer becomes thinner and therefore, the value of h is lowered and the dissolution rate is increased. It may also be observed that for a diffusion controlled reaction the rate of dissolution is dependent on the magnitude of the diffusion coefficient. In addition, the rate of dissolution of a diffusion controlled reaction increases linearly with an increase in concentration of reagent (7). The reaction rate for chemically dependent reactions increases in a nonlinear fashion with increasing reagent concentration and reaches a maximum.

Inhibition.—The reported observations of the effect of anions on the neutralization of aluminum hydroxide are apparently contradictory. If a given salt forms a water-soluble complex with aluminum hydroxide, as has been shown by Zolotukhin (8) for tartrate and citrate, more aluminum hydroxide will be dissolved at equilibrium. This will tend to increase the C_s term in both Eq. 2 and in the equation presented by Zdanovskii (9) for the dissolution rate of a chemically controlled process. Zdanovskii's equation may be written as:

$$\frac{dW}{dt} = \alpha A(C_s - C_y) \qquad \text{(Eq. 3)}$$

where α is the rate constant for the chemical reaction occurring at the interface, C_s is the concentration at saturation, C_y is the concentration in the bulk solution, and the other terms have the same definitions as previously presented. Since the rate of dissolution is proportional to the equilibrium solubility, it would be expected that the formation of a water-soluble complex would increase the dissolution velocity. On the other hand, if aluminum hydroxide is also flocculated by these salts, one would expect a decrease in surface area resulting in a decrease in rate. It would appear that flocculation and complexation are exerting opposite effects on the dissolution velocity.

It has been established that anions decrease neutralization rate (2, 10). This indicates either that the flocculating effect of the anions overshadows its ability to complex aluminum hydroxide, or that dissolution rate cannot be equated with neutralization rate in this system. The latter situation would exist if the hydrated aluminum ion complexed the anion with the subsequent release of protons. This phenomenon would thereby produce a buffer effect. If this were the case, the neutralization rate would not be related to dissolution rate. This type of complexation has been shown by Das and co-workers (11) for the reaction of ferric ions with citric, tartaric, and malic acids.

EXPERIMENTAL

Materials

The various experiments were conducted with aluminum hydroxide dried gel U.S.P., F-1000, lot 194, supplied by Reheis Co., Inc., Berkeley Heights,

N. J. This sample was divided into several portions, and each portion was stored at room temperature in tightly sealed glass jars. All other chemicals were reagent grade and were obtained from Fisher Scientific Co., New York, N. Y.

Methods

Neutralization Studies.—A 1.0-Gm. sample of AHDG was added to a 250-ml. beaker containing 100 ml. of 0.1 *N* HCl well stirred. The test mixture was maintained at 37 ± 1° by immersing the beaker in a constant-temperature water bath. Stirring was effected by an overhead stirrer. Unless otherwise stated, the rate of agitation was 150 r.p.m. The pH changes were recorded with respect to time, utilizing a Beckman Zeromatic pH meter. When inhibitors were used, they were first dissolved in the 0.1 *N* HCl.

Mathematical Treatment of Neutralization Data.—The results obtained from the neutralization experiments were plotted as pH *versus* time. The curves were then evaluated to yield the time of maximum rate of reaction. The maximum reaction velocity occurs at the inflection point of the pH-time curve. The evaluation procedure to obtain the time at which the inflection point occurs consisted of obtaining the second derivative of the pH-time plot and plotting this derivative [Δ (Δ pH)] *versus* time. The time at which the curve crosses the *x*-axis is the inflection time.

Flocculation Studies.—Flocculation studies designed to evaluate the changes in sedimentation rate in the presence of inhibitors were conducted as follows: a 1.0-Gm. sample of AHDG was added to 300 ml. of 0.1 *N* HCl contained in an Andreasen pipet (12). With the breather hole closed, the pipet was shaken vigorously 10 times and placed securely in a constant-temperature water bath at 37 ± 1°. A 10-ml. sample was collected every 2 min. for 10 min. A steady suction was applied until the pipet was filled. The stopcock was then closed and the sample transferred to a previously tared 150-ml. beaker. Pressure was applied to blow out the sample at high velocity. The pressure was repeated several seconds later to insure full collection. The sampling procedure must proceed rapidly. If the stopcock is not closed immediately upon collection of the 10-ml. sample the heavier particles will begin to fall out of the chamber. After withdrawal of the sample the stopcock must be opened slowly so that the liquid remaining in the sample tube can flow into the settling chamber without stirring the suspension.

The suspension in the beakers was evaporated to dryness, allowed to cool, and weighed on a Mettler balance, model H 15. Particular care was taken to prevent overdrying and charring of the organic acid. In the flocculation studies involving the use of sodium citrate and sodium tartrate, 50 ml. of a 2 *N* solution of either salt was added to a sufficient quantity of HCl to yield 300 ml. A correction factor to account for the weight of the salt was applied in each case.

Potentiometric—Complexation Studies.—Solutions containing 0.2 *N* aluminum chloride, sodium citrate, or sodium tartrate, as well as combinations of aluminum chloride and sodium citrate, and aluminum chloride and sodium tartrate were prepared in deionized water by adding 10 ml. of a given 0.2 *N* salt solution to 20 ml. of 0.2 *N* HCl. The resulting solution was titrated with 0.2 *N* NaOH. The pH was monitored with a Beckman Zeromatic pH meter. The solution was stirred during the test by a Teflon-coated magnetic stirrer. Sufficient time was allotted between each addition of alkali to ensure that equilibrium was reached.

Table II.—The Effect of Various Anions on the Inflection Time (sec.) of the AHDG–HCl Neutralization[a]

Sodium Salt	Concn., eq./L. 10^{-3}	10^{-2}	10^{-1}
Citrate	630	1235	...
Tartrate	695	1020	>1860
Sulfate	...	460	270
Chloride	...	330	...
Acetate	...	320	...

[a] The inflection time for the control was 310 sec.

RESULTS AND DISCUSSION

Mechanism of Neutralization.—In an effort to establish whether the AHDG–HCl interaction was diffusion or chemically controlled, the effect of different agitation rates on the reaction velocity was studied. Experiments were conducted at stirring speeds ranging from 85 to 240 r.p.m. The results of this investigation are presented in Table I. Inspection of Table I indicates that the change in stirring rate had little effect on the neutralization

velocity. Therefore, it may be concluded that the value of the exponent *b* in Eq. 1 is approximately zero.

To further resolve the mechanism of the neutralization reaction, the reactant concentration was varied. AHDG was added to the reaction beaker in quantities ranging from 0.50–10.0 Gm. The results of these experiments are depicted in Fig. 1. It may be observed that neutralization rate is highly dependent upon the amount of antacid employed up to a maximum. Beyond this point (about 5 Gm.), it would appear that the neutralization rate is independent of the amount of AHDG present. It has been established (7) that in chemically controlled reactions, the reaction rate increases in a nonlinear fashion with increasing reagent concentration and reaches a maximum.

In view of the experimental results indicating that the value of exponent *b* in Eq. 1 approximates zero, and that the rate of reaction increases to a maximum with increasing AHDG concentration, it is reasonable to conclude that the reaction is predominantly chemically controlled.

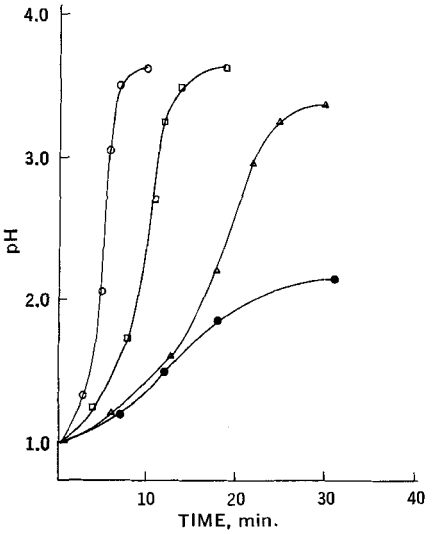

Fig. 2.—The effect of tartrate concentration on the AHDG–HCl neutralization. Key: O, 0.0001 *N*; □, 0.001 *N*; △, 0.01 *N*; ●, 0.1 *N*.

Mechanism of Inhibition.—Several salts were selected to be tested as inhibitors of AHDG, and were tested at several concentrations. The results of these investigations are listed in Table II.

Examination of the data contained in Table II reveals that the order of degree of inhibition exerted by the salts follows the Schulze-Hardy rule. Their descending order of effectiveness as coagulating agents follow their inhibitory activity, *viz.*, citrate = tartrate > sulfate > acetate = chloride. The fact that the experimental results follow this rule supports the mechanism of flocculation as a contributing factor in the inhibition process.

Figure 2 demonstrates the difference in neutralization velocities produced by different concentrations of sodium tartrate. It is typical of the effects observed with sodium citrate.

To confirm the flocculation mechanism for the inhibition of AHDG, sedimentation studies were conducted using the Andreasen pipet. Figure 3 shows that a significantly larger amount of AHDG was collected in the presence of citrate and tartrate as compared to the control. If flocculation did occur, one would expect the citrate- and tartrate-treated AHDG to settle faster due to a greater particle size. When a sample was withdrawn at a preset level there was more AHDG present at that level in the salt solutions. The results obtained from this study correlate to some degree with those obtained from the neutralization studies. It would appear that the salts act to reduce the surface area of the antacid, and thereby produce a concomitant reduction in neutralization velocity.

To investigate the possibility of anion–AHDG complexation with concurrent proton release, during the reaction of AHDG with sodium citrate and sodium tartrate, potentiometric titrations were performed. The results of these studies are shown in Figs. 4 and 5.

The inflection points of the sodium citrate and aluminum chloride curves in Fig. 4 are identical,

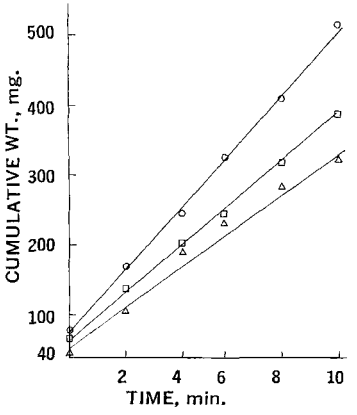

Fig. 3.—Cumulative weight of AHDG collected *versus* time. Key: △, AHDG; O, AHDG plus citrate; □, AHDG plus tartrate.

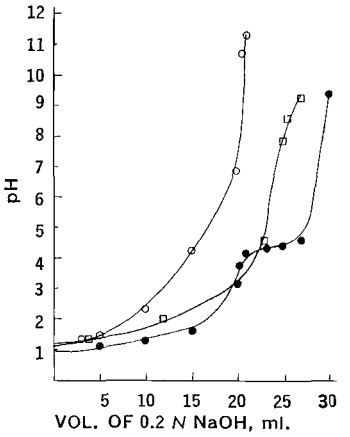

Fig. 4.—Potentiometric titrations of aluminum chloride (●), sodium citrate (O), and aluminum chloride plus sodium citrate (□).

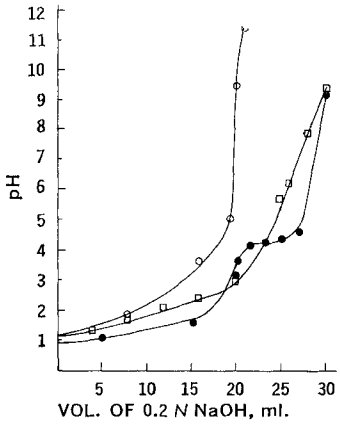

Fig. 5.—Potentiometric titrations of aluminum chloride (●), sodium tartrate (○), and aluminum chloride plus sodium tartrate (□).

both occurring at 20 ml. of alkali. However, the combination of these salts required more base for neutralization; the inflection point was displaced to the right, to about 24 ml. It is interesting to note that although the titration of aluminum chloride alone produced a precipitate of the hydroxide, no precipitate was observed in the presence of citrate or tartrate. This latter phenomenon suggests the presence of a water-soluble complex. In addition, since the system containing the aluminum complex required more alkali to produce neutralization than did either of the salts when tested separately, evidence is provided to indicate that the formation of this complex produces the release of excess protons and thereby decelerates the change of pH with respect to time. Similar results were found for the sodium tartrate–aluminum chloride potentiometric titration (Fig. 5).

In view of these findings we may conclude that a dual mechanism is operative to produce inhibition. AHDG reacts with sodium tartrate or citrate to produce a water-soluble complex with the concomitant liberation of protons. This effect coupled with flocculation causes a retardation in the rate of change of pH with time.

Cytotoxicity of North Dakota Plants I

In Vitro Studies

By I. A. MUNI, W. H. BHATTI, L. J. SCHERMEISTER, and M. C. VINCENT

In this study, a method is presented for the direct determination of cytotoxicity and antitumor activity of plant materials *in vitro* using HeLa cells. Fifty poisonous plants representing 96 plant parts were tested by this method, out of which 25 plants showed limited cytotoxicity and six plants were found to be highly cytotoxic. This procedure can be used on a large scale prior to *in vivo* evaluation.

THE IMPORTANCE of plant screening for various chemical constituents of medical importance is well established. Plants have provided innumerable drugs which are being used for the prevention or cure of various diseases. This work was directed to the search for new drugs which may find application in the prevention or cure of cancer.

In vitro screening for cytotoxicity based on morphological evaluation was first reported by Biesele and associates (1) in 1952 using nonsynthetic media. Fjelde *et al.* (2) introduced human tumor cell lines for cancer chemotherapy.

Cytotoxicity of North Dakota Plants I

In Vitro Studies

By I. A. MUNI, W. H. BHATTI, L. J. SCHERMEISTER, and M. C. VINCENT

In this study, a method is presented for the direct determination of cytotoxicity and antitumor activity of plant materials *in vitro* using HeLa cells. Fifty poisonous plants representing 96 plant parts were tested by this method, out of which 25 plants showed limited cytotoxicity and six plants were found to be highly cytotoxic. This procedure can be used on a large scale prior to *in vivo* evaluation.

THE IMPORTANCE of plant screening for various chemical constituents of medical importance is well established. Plants have provided innumerable drugs which are being used for the prevention or cure of various diseases. This work was directed to the search for new drugs which may find application in the prevention or cure of cancer.

In vitro screening for cytotoxicity based on morphological evaluation was first reported by Biesele and associates (1) in 1952 using nonsynthetic media. Fjelde *et al.* (2) introduced human tumor cell lines for cancer chemotherapy.

Received May 9, 1966, from the School of Pharmacy, North Dakota State University, Fargo 58103.
Accepted for publication August 22, 1966.
Presented to the Pharmacognosy and Natural Products Section, A.PH.A. Academy of Pharmaceutical Sciences, Dallas meeting, April 1966.
Abstracted in part from a thesis submitted by I. A. Muni to the North Dakota State University, Fargo, in partial fulfillment of Master of Science degree requirements.
The authors thank Dr. J. Dixon, Southern Research Institute, and Dr. K. Kajiwara, McArdle Laboratory, for the supply of HeLa cells.
This investigation was supported by institutional funds No. GU-NSF 922 from the National Science Foundation.

Eagle and Foley (3) described a technique for determination of cytotoxicity of chemical compounds for mammalian cells *in vitro* using semisynthetic media. Later they (4) reported cytotoxic activity of 180 compounds against the KB strain of human epidermoid carcinoma. Smith, Lummis, and Grady (5) determined the cytotoxic activity of various nucleic acids and vitamin antagonists, heavy metals, respiratory poisons, detergents, miscellaneous chemical solvents, and fermentation beers. Nitta (6,7) and other workers (8–11) have tested the different antibiotics for antitumor activity. A recent survey (12) indicates that about 400 plant species possess antitumor activity.

EXPERIMENTAL

Collection of Materials.—The investigational material was collected from wild growing plants throughout the State of North Dakota. Each plant under investigation was taxonomically classified and a sample of each specimen was retained in the herbarium for future reference.

The fresh plant material was air-dried at room temperature, separated into the respective plant parts, ground to a No. 40 powder, and stored in air-tight containers. When the presence of moisture interfered with grinding, the plant material was oven dried at 60°.

Preparation of Extracts.—Two extracts, aqueous and alcoholic, of all plant parts were prepared. The aqueous extract was prepared as follows. A 2-Gm. sample of dried material was macerated with 25 ml. of distilled water for 30 to 40 min. and filtered through Whatman No. 1 paper. The extracts were freeze dried and kept frozen until used. Prior to screening, each frozen extract, representing 2 Gm. of dried plant material, was dissolved in 2 ml. of isotonic saline. The pH of the solution was adjusted to 7.0 to 7.5 with 0.25 *N* HCl or 0.25 *N* NaOH. Then it was mixed with 0.5 ml. of 5X culture medium containing antibiotics and sterilized through UF-filtration. UF-filtration was accomplished by centrifuging in the closed system.

The same general procedure was used in preparing the alcoholic extracts, using 95% alcohol instead of water. However, to increase the solubility of the plant material, 2 drops of alcohol was added to the isotonic saline.

Preparation of Medium.—The culture medium recommended by Joseph (13) for the growth of HeLa cells was prepared as follows:

Medium 199 (10X)	8 ml.
Calf serum	20 ml.
Hank's BSS	72 ml.
Sodium bicarbonate solution, 7.5%	0.5 ml.
Potassium penicillin G	100 units/ml.
Streptomycin sulfate	100 mcg./ml.

The pH was found to be 7.0 to 7.5.

Fresh medium was prepared before running each set of samples and checked for sterility with alternative thioglycolate medium U.S.P. (14).

Cell Lines.—Stock cultures of HeLa cells were obtained from Southern Research Institute, Birmingham, Ala., and Microbiological Associates, Bethesda, Md. These cultures were maintained in Blake bottles containing culture medium 199 at 37°. Stock cultures were refed with fresh medium every 50 to 60 hr. A suspension of isolated cells was obtained by trypsinizing 75 to 80 hr. old cell cultures.

The number of cells present in the culture medium was determined in a hemocytometer. The required dilution was made with culture medium to obtain 40,000 to 50,000 cells/ml.

Screening Procedure.—Two-milliliter vinyl plastic cup trays were sterilized by immersing in 95% ethanol for 1 hr., and then dried for 4 to 6 hr. under ultraviolet light.

Cell suspensions were placed in a 125-ml. Pyrex flask, which was equipped with glass and rubber tubing connecting a 1-ml. Cornwall syringe. A three-way adapter was attached to the syringe to allow recirculation of medium that remained in the tubing between samples. The suspension was stirred either by circulation or by shaking the flask gently after every sample extraction.

Plant extracts were added to the cups in definite quantities, representing 4, 20, 40, 100, and 200 mg./ml. of dry plant material, using a syringe microburet. One-half milliliter of cell suspension was added to each cup and the volume was made up to 1 ml. with the addition of culture medium. A 30-gauge blunt-tip needle was used.

A series of controls were determined for each test series, such as sodium nitrofurantoin[1], methyl green, and Hank's basal salt solution for comparison. The plastic trays were covered with sterile plastic and sealed air-tight with strips of Scotch cellophane tape. All trays were incubated at 37°.

Evaluation of Data.—Toplin's evaluation method (15), accepted by CCNSC was used. The trays were examined after 75 to 80 hr. incubation for evidence of cytotoxicity. Cytotoxicity was evaluated by direct microscopic examination of cultures usually at 100 × magnification and, if necessary, at 430 × magnification. The cytotoxic end point (CE) and lethal end point (LE) were determined.

RESULTS AND DISCUSSION

Fifty poisonous plants, representing 96 plant parts, were tested for cytotoxicity using Gey's HeLa S-3 cells. The cytotoxic and lethal end point for all the plants tested is given for both alcoholic and aqueous extracts in Table I.

Toplin's direct microscopic method for cytotoxicity evaluation was used because it was simple, rapid, and reproducible.

The plant materials screened for cytotoxicity were used in concentrations representing 4 to 200 mg. of plant material per milliliter of culture medium. In Table II the comparison of *in vivo* results, as reported by Leiter *et al.* (16) and Hardinge *et al.* (17), with the *in vitro* cytotoxicity of the same plants at 200 mg. concentration indicated that the positive results were due to a general cellular, and not a specific, toxicity. For this reason, the highest concentration of plant material used was 200 mg./ml.

Both CE and LE values were necessary to determine the effectiveness of cytotoxic substances in the plant extracts. The effectiveness of these

[a] Reported in literature and in each case was tumor noninhibitory.

extracts in inhibiting HeLa cells was increased as the CE and LE values approached one another.

As shown in Table I, a CE value of 100 or lower was produced by 66 out of 192 extracts. Eight of these extracts had close CE and LE values and were considered highly inhibitory to HeLa cells. The most effective alcoholic extracts were obtained from the leaves of *Ascelpias ovalifolia*, *Astragalus caryocarpus*, *Penstemon grandiflorus*, *Penstemon nitidus*, and *Rumex venosus*, the stems of *Rumex venosus*, and the flowers and leaves of *Astragalus tenellus*. In the case of aqueous extracts, only the stem of *Rumex venosus* was included.

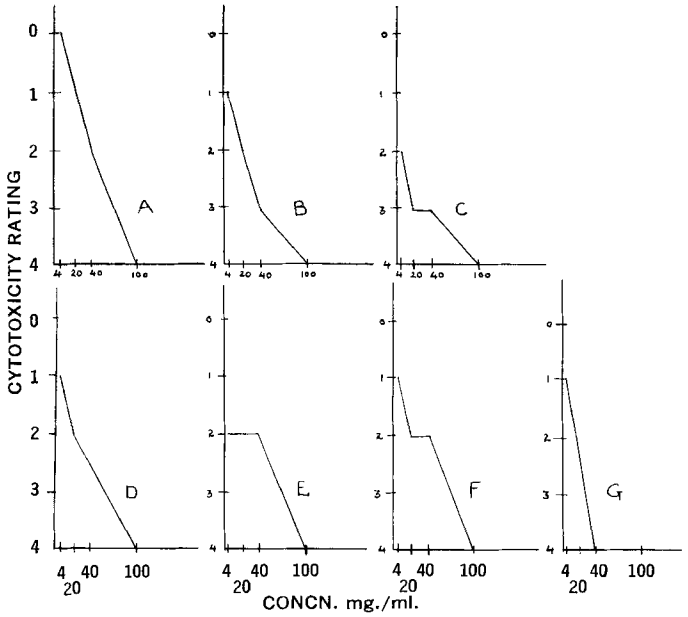

Fig. 1.—Graphical representation of cytotoxicity. Key: A, *Asclepias ovalifolia* leaves (alc.), B, *Astragalus tennellus* flowers and leaves (alc.) and *Astragalus caryocarpus* leaves (alc.); C, *Penstemon grandiflorus* leaves (alc.); D, *Penstemon nitidus* leaves (alc.); E, *R. venosus* leaves (alc.); F, *R. venosus* stem (alc.); G, *R. venosus* stem (aq.).

In order to determine which of the above plant extracts were more effective as cytotoxic agents, Toplin's plotting method was employed. These plots are presented in Fig. 1. From this figure it can be observed that plants which have greater cytotoxicity have a sharper slope. The sharpest slope was obtained with the aqueous extract of stems of *R. venosus*. All other effective extracts were alcoholic, and the decreasing order of cytotoxicity was as follows: leaves of *Ascelepias ovalifolia* and *Astragalus caryocarpus*, flowers and leaves of *Astragalus tenellus;* leaves of *Penstemon grandiflorus* and *Penstemon nitidus;* stems of *R. venosus* and the leaves of *R. venosus*.

The data in Table I indicate that the naturally occurring tumor inhibitory substances in these plants were more generally alcohol soluble. These alcohol soluble substances were more frequently found in leaves than in stems, while none were present in roots of those plants tested. Only the stems of *R. venosus* contained inhibitory substances which were soluble in both alcohol and water.

Of the 23 families of native plants tested, only four families contained species having cytotoxic constituents. They were *Polygonaceae, Asclepiadaceae, Fabaceae,* and *Scrophulariaceae.*

A slight inhibitory effect on HeLa cells was shown by 58 plant extracts. If the moderately cytotoxic plant extracts were further concentrated, other effective cytotoxic activities might be indicated.

The limitations of all *in vitro* studies are numerous and the correlation between antitumor activity in experimental animal tumors *in vivo* and cytotoxicity to mammalian cells *in vitro* can only be established by experiments.

SUMMARY

1. Gey's HeLa cells were used to determine *in vitro* cytotoxicity and antitumor activity of plant extracts.

2. Evaluation of cytotoxicity was based on microscopic observation of the cells after incubation with plant samples for 75 to 80 hr.

3. Fifty-eight out of 192 extracts tested were moderately cytotoxic in the range of 4 to 100 mg. of dry plant material per milliliter of culture media.

4. Eight plant extracts exhibited marked human cancer cell inhibitory activity.

5. More alcoholic extracts were found to be cytotoxic than the aqueous extracts for the plants tested.

Effect of Hypothermia on the Chlorpromazine-Induced Bradycardia and Hypotension in the Rat

By K. F. FINGER, R. L. CAVANAGH, and E. E. MOOG

The administration of chlorpromazine (0.5 mg./Kg.) caused a rapid fall in blood pressure and a decreased heart rate in rats. A significant potentiation in both the extent and the duration of the heart rate effects was observed in hypothermic animals as compared to normothermic animals. No significant differences were observed in the blood pressure effects during the period of observation. It was also established that fatty acid mobilization, reflexly induced by chlorpromazine's hypotensive action, was inhibited in hypothermic animals but not in normothermic animals. These data suggest that chlorpromazine more effectively inhibits adrenergic mechanisms in the hypothermic animal and this mechanism may explain the potentiation of heart rate effects observed in this study.

CHLORPROMAZINE exerts a variety of pharmacological actions in both man and laboratory animals. Included among these are antiadrenergic, antihistaminic, and anticholinergic effects and its characteristic central nervous system depression (1). These actions manifest themselves as a decrease in spontaneous motor activity, altered behavioral patterns (primarily in response to external environmental factors), hypothermia, hypotension, and alterations in heart rate (1–3). Interest centered around the effects of chlorpromazine on blood pressure and heart rate with particular reference to the quantitative aspects of its antiadrenergic actions. During the course of preliminary investigations, it was noted that in regard to its effects on heart rate, chlorpromazine appeared to exert a prolonged action in hypothermic animals as compared to those which were maintained normothermic. The investigations into the possible reasons for these differences is the subject of this report.

EXPERIMENTAL

Methods.—Male Sprague-Dawley rats, weighing between 350 and 400 Gm., were employed in this study. They were anesthetized with urethan (approximately 1.0 Gm./Kg. i.p.), their femoral and carotid vessels cannulated for purposes of drug administration and blood pressure and heart rate recording, respectively, and either maintained normothermic by the use of a warming element or allowed to become hypothermic by omitting the warming procedure. Rectal temperatures were monitored for all animals utilizing the Yellow Springs Instrument Co. Telethermometer. Blood pressures and heart rates were determined from tracings obtained with the E and M Physiograph equipped with a Statham P23 transducer.

Control periods of sufficient length to assure a stabilized blood pressure and heart rate were continuously recorded prior to drug administration. Chlorpromazine, 0.5 mg./Kg., was administered i.v. in a volume of 0.1 ml./Kg. and control animals received 0.1 ml./Kg. of saline. Blood pressures and heart rates were monitored continuously for 20 min. immediately following drug administration and thereafter for several minutes at 20-min. intervals for approximately 3 hr. At least six animals were employed in each group and the data to be presented here are expressed as the mean value obtained ± the standard error of the mean.

For the determination of nonesterified fatty acids in plasma, the animals were treated in the manner described above for the cardiovascular experiments except that blood samples were withdrawn *via* the carotid cannula and the plasma assayed for fatty acids by a modification of the method of Dole (4).

RESULTS AND DISCUSSION

Body Temperature Changes.—The changes in body temperature produced by drug treatment and the experimental procedures are shown in Fig. 1. These results show that the procedures employed produced a highly significant difference in rectal temperature between those animals maintained with a warming element and those which were not provided with an external heat source. It is apparent from this figure that the use of the warming element maintained body temperature at a reasonably constant value, while those animals which were not heated became hypothermic. Chlorpromazine, at the low dosage employed in this study, produced an observable but relatively small reduction in rectal temperature.

Effect of Chlorpromazine on Blood Pressure.—The intravenous administration of 0.5 mg./Kg. of chlorpromazine produced a rapid fall in both systolic and diastolic pressure. In Fig. 2, the per cent of initial mean blood pressure has been plotted and the rapid decrease in blood pressure is evident. This hypotensive phase of chlorpromazine's actions was

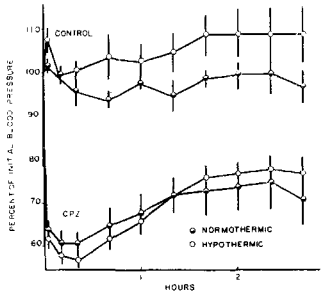

Fig. 2.—Effect of chlorpromazine on blood pressure of hypothermic and normothermic rats.

maintained throughout the period of experimental observation, although a moderate rise was observed to occur between 40 and 80 min. It is also apparent from Fig. 2 that the procedures themselves produced only minor alterations in blood pressure as can be seen in the control curves. It is interesting to note that the hypothermic control group showed slightly higher pressures than did the normothermic group, a result to be anticipated as a result of the induced hypothermia.

Effect of Chlorpromazine on Heart Rate.—Following the administration of chlorpromazine, a lag time occurred before the effects of chlorpromazine became evident on the heart rate. The lag time varied between 2 and 5 min. Following this brief lag period, the heart rate was slowed to an appreciable extent in both normothermic and hypothermic animals. These data are shown in Fig. 3. Twenty minutes after drug administration, the heart rates of the normothermic animals began to return toward normal values, while those of the hypothermic group decreased to even lower values. Indeed, the minimal value of heart rate in the hypothermic animals was still present 40 min. after drug administration, while the heart rate in the normothermic group had returned to approximately 85% of normal. The slope of the line describing the return toward normal values of the heart rate in the hypothermic group is also slightly less than that observed for the normothermic group. In addition, the mean heart rate of the hypothermic group did not return to control values during the period of observation but appeared to plateau out at approximately 85% of the initial value.

It is also interesting to note that there exists a difference in the time at which potentiation of chlorpromazine's heart rate effects are observed and the time of maximum decrease in body temperature. These data are interpreted to indicate that it is not the body temperature *per se* that is the important factor but rather the physiological events, yet unknown, which result in both a decrease in body temperature and the observed potentiation. It is not unusual for body temperature changes to lag behind other events inasmuch as the decrease in body temperature could be due to at least two factors: (*a*) decreased heat production and (*b*) increased heat loss, both of which would be relatively slow and continuous phenomena.

It is also apparent in Fig. 3 that the heart rate of the normothermic control (no drug) group remained quite stable, while a slight tachycardia was observed in the hypothermic control group.

Effect of Hypothermia and Chlorpromazine Treatment on Mobilization of Fatty Acids.—Two different experimental approaches were followed in an attempt to explain the effect of hypothermia on the chlorpromazine-induced changes in heart rate. They were (*a*) to attempt to explain the observed differences in terms of an altered rate of drug metabolism and (*b*) to attempt to obtain evidence indicating alterations in the ability of the chlorpromazine treated, hypothermic animals to respond to reflex homeostatic mechanisms.

The available analytical procedures were not sufficiently sensitive to quantitate the metabolic transformations of chlorpromazine at the dosage employed in this study (0.5 mg./Kg.). Utilizing higher doses, 10 and 30 mg./Kg., the authors were able to identify and quantitate parent drug, chlorpromazine sulfoxide, desmethyl-chlorpromazine, and its corresponding sulfoxide. Preliminary results indicated that while some differences were apparent in the concentrations of certain metabolites, a significant portion of the metabolized chlorpromazine was not accounted for by the moieties assayed. Furthermore, the rather high dosages employed in this phase of the study may have flooded enzymic systems, thus masking relatively small but significant alterations in metabolic rates. While this work is continuing, definitive statements on the rate of chlorpromazine metabolism in this system cannot be made.

The second experimental approach was based on the experimental finding reported by Costa *et al.* (5) and those of Pletscher *et al.* (6). These workers have shown that the release and/or uptake of biogenic amines is inhibited by chlorpromazine in hypothermic animals, but this effect is negated when the animals are maintained normothermic or heated. Costa and co-workers (5) were able to

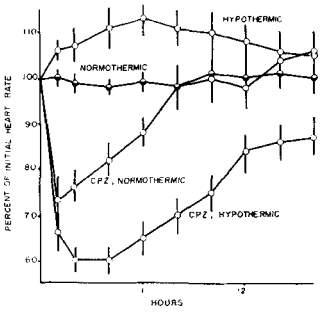

Fig. 3.—Effect of chlorpromazine on heart rate of hypothermic and normothermic rats.

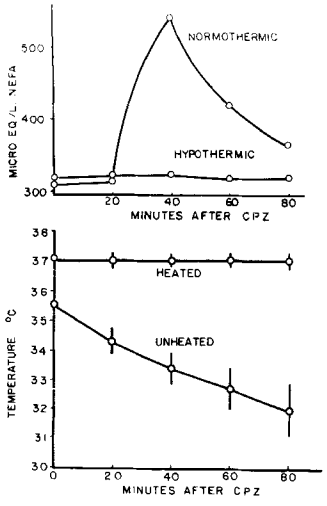

Fig. 4.—Top, effect of hypothermia on fatty acid mobilization in chlorpromazine treated rats. Chlorpromazine dose = 0.5 mg./Kg. i.v. Bottom, rectal temperatures obtained in both heated and unheated chlorpromazine treated rats.

show that chlorpromazine blocked the release of catecholamines by reserpine when the animals were hypothermic but that this action of reserpine was unaffected by chlorpromazine in normothermic animals. Similarly, Pletscher *et al.* (6), studying the uptake of tryptamine as influenced by drugs, found that body temperature had an influence on chlorpromazine's blockade of tryptamine uptake. To ascertain whether a similar effect was operative in this system, an experimental procedure was sought which was (*a*) under the primary control of the sympathetic nervous system and (*b*) sensitive enough to respond to homeostatic, sympathetic mechanisms in the anesthetized animals employed in the present study. Previous work (7–10) had shown that the mobilization of fatty acids from adipose tissue *in vivo* satisfied these criteria. Thus, it was decided to investigate the effect of hypothermia and chlorpromazine treatment on the mobilization of fatty acids *in vivo*.

The results of this phase of the study are shown in Fig. 4. The lower portion of the graph illustrates the changes in body temperature observed in the two groups of animals. Chlorpromazine was administered to both groups of animals at a dose of 0.5 mg./Kg. It is apparent in Fig. 4 that hypothermia effectively antagonized the elevation of plasma fatty acids. These results also show that the dose of chlorpromazine employed was not sufficient to block fatty acid mobilization *per se* inasmuch as significant elevations in plasma fatty acids were obtained in the chlorpromazine treated, normothermic animals. It would appear that an increased sympathetic outflow occurred as a result of the blood pressure lowering effects of the chlorpromazine treated group of animals, probably mediated by the release of catecholamines both locally in adipose tissue and systemically *via* adrenal medullary release. In the hypothermic, chlorpromazine treated animals, however, this manifestation of increased sympathetic tone was antagonized presumably by either inhibiting the release of catecholamines or by a more effective chlorpromazine antagonism of fatty acid mobilization.

It is well known that cold-stressed animals respond by mobilizing fatty acids (9, 10) and the hypothermia *per se* observed in these experiments therefore would have been expected to produce an elevation of nonesterified fatty acids. In contrast to the expected results with hypothermia, chlorpromazine, in sufficient dosage, would have been expected to antagonize fatty acid mobilization (11, 12), yet, in the dose employed, failed to do so in normothermic animals. The combination of chlorpromazine (at a low dose) and hypothermia, however, effectively antagonized fatty acid mobilization.

CONCLUSIONS

It is concluded that the chlorpromazine-induced bradycardia is potentiated by hypothermia with respect to both the extent and the duration of the response. The potentiation may be explained by a reduction in the ability of the hypothermic, chlorpromazine treated animal to respond to reflex homeostatic mechanisms. The antagonism of adrenergic mechanisms implicit in such an explanation may be due to either an effect on the release of adrenergic neurohumoral agents or by a more effective inhibition of adrenergic responses by chlorpromazine in the hypothermic animals.

Absorption, Metabolism, and Excretion of Riboflavin-5′-phosphate in Man

By WILLIAM J. JUSKO and GERHARD LEVY

Evidence is presented which indicates that riboflavin-5′-phosphate (FMN) is absorbed from the gastrointestinal tract of man by specialized transport rather than by passive diffusion. Oral administration of the vitamin after a meal results in more extensive absorption which appears to be primarily due to a decrease in intestinal transit rate resulting in longer retention of FMN at absorption sites in the small intestine. Both FMN and riboflavin are excreted in the urine primarily, if not solely, as free riboflavin. The urinary recovery of riboflavin is the same when equimolar amounts of either form of the vitamin are administered orally in solution. The time course of urinary excretion of riboflavin after administration of high doses of FMN, together with data available in the literature, suggest that the vitamin is subject to enterohepatic cycling.

THE AUTHORS have recently found that the urinary recovery of riboflavin after oral administration to fasted normal humans decreases with higher doses and that absorption is limited mainly to the upper region of the gastrointestinal tract (1). The saturability and site-specificity of riboflavin absorption, together with other evidence summarized previously (1), led to the conclusion that the vitamin is absorbed mainly or solely by specialized transport rather than by passive diffusion. Unlike the results obtained when riboflavin was administered on an empty stomach, administration of the vitamin immediately after breakfast resulted in a constant per cent urinary recovery independent of dose. These results, which were obtained in the dose range of 5 to 30 mg., were interpreted as being due to decreased intestinal transit rate in the presence of food, resulting in prolonged retention of the vitamin at specialized absorption sites in the small intestine. If this interpretation is correct, it should be possible to observe saturation effects in the absorption of riboflavin even when the vitamin is administered on a full stomach, provided that sufficiently large doses are administered. The limited solubility of riboflavin itself made such a study unfeasible, since administration of the vitamin in suspension, rather than in solution, could lead to misleading results (1). This solubility problem is not encountered with riboflavin-5′-phosphate (FMN) and, provided that this form of the vitamin is subject to the same transport mechanism as is riboflavin itself, it should be possible to observe saturation effects when FMN is administered in sufficiently high doses after a meal. The purpose of the study to be described here was, therefore, to determine the mechanism of gastrointestinal absorption of FMN, and, if saturation effects become evident after oral administration of FMN on an empty stomach, to determine if similar saturation effects occur with sufficiently high doses when the vitamin is administered on a full stomach. In the course of the study, information has been obtained also concerning the metabolic fate of FMN and evidence will be presented which is indicative of the enterohepatic cycling of riboflavin.

EXPERIMENTAL

Absorption Study.—Four healthy male volunteers, 22 to 37 years of age, served as test subjects. The same subjects participated in the previous study (1). Each subject received doses of sodium FMN[1] equivalent to 5, 10, and 30 mg. of riboflavin dissolved in 100 ml. of 0.02 *N* acetic acid. The container was rinsed with a small amount of water which was also ingested. The vitamin solution was administered either on an empty stomach (after an overnight fast) or immediately after a standard breakfast. Three of the subjects received sodium FMN also in doses equivalent to 150 and 300 mg. of riboflavin. The breakfast, urine collections, and other details of the protocol were essentially the same as in the study of riboflavin absorption (1). The subjects were permitted to eat their usual lunches at the normal time, except when it was desired to determine the effect of withholding lunch on the excretion of riboflavin.

In another phase of the study, the effect of volume of gastrointestinal contents on the absorption of riboflavin was determined. Three of the subjects ingested 600 ml. of water on an empty stomach, followed by 30 mg. of riboflavin in 100 ml. of 0.02 *N* acetic acid (plus about 40 ml. of water to rinse the container) to approximate the volume of food and drink ingested when the vitamin was administered after the standard breakfast (1).

At least two 24-hr. blank urine collections, with

[1] Sodium riboflavin-5′-phosphate, Hoffmann-LaRoche, Nutley, N. J.

and without breakfast, were carried out in each subject.

Analytical Methods.—Riboflavin and FMN in the urine were determined fluorimetrically by the method of Burch *et al.* (2) and by a modified U.S.P. XVI assay procedure (3) using the Turner Fluorometer, model 111, with primary filter 47-B and secondary filter 2A-12. The modifications of the two assays have been described in a previous publication (1).

All data were corrected for blank values which averaged 0.6 mg./24 hr. by the Burch procedure and 1.0 mg./24 hr. by the modified U.S.P. procedure.

RESULTS

The urinary recoveries of riboflavin as a function of the administered dose of FMN, given either on an empty stomach or after a standard breakfast, are shown in Fig. 1. The curves shown in the figure are those obtained with the same subjects after ingestion of equivalent doses of riboflavin, as described in a previous publication (1). It is evident that the relation between dose and urinary recovery is essentially the same for FMN and riboflavin. There is a linear relationship between the dose of FMN and the amount of riboflavin excreted when doses of FMN from 5 to 30 mg. were ingested after a standard breakfast. The average recovery of riboflavin after oral administration of FMN in doses ranging from 5 to 30 mg. was 63%. This is essentially identical to the 62% recovery found previously when riboflavin itself was ingested after breakfast. When FMN was administered on an empty stomach (after an overnight fast), the per cent recovery of riboflavin in the urine decreased with increasing dose. This apparent saturation effect is also very similar to that found previously with riboflavin itself.

Since the similarity in the gastrointestinal absorption characteristics indicates that both forms of the vitamin are absorbed by the same mechanism,

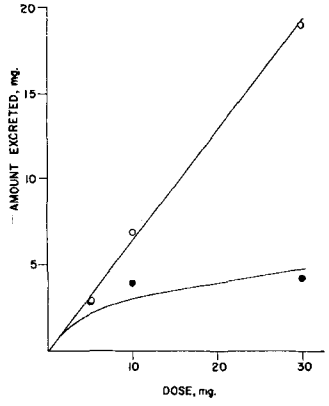

Fig. 1.—Urinary recovery of riboflavin after oral administration of FMN as a function of dose when given on an empty stomach (●) and after a standard breakfast (○). The curves are taken from Fig. 1 of *Reference 1* and represent data obtained after administration of riboflavin as such. Mean of four subjects. The two data points for the 5-mg. dose are superimposed.

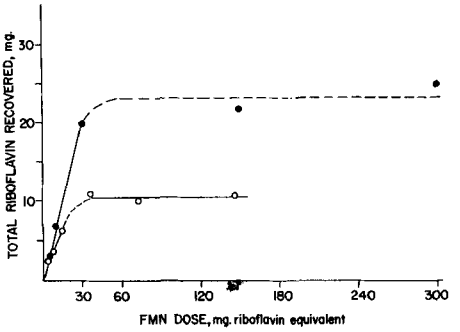

Fig. 2.—Urinary recovery of riboflavin after oral administration of FMN as a function of dose when given after a standard breakfast, showing the limited absorption capacity evident in the high dose range (●). Lower curve (○) taken from Fig. 2 of *Reference 4* (see text).

it was possible to take advantage of the greater solubility of FMN to determine if apparent saturation effects can be observed even if the vitamin is administered on a full stomach. Therefore, three subjects were given 150- and 300-mg. doses of riboflavin as sodium FMN after the standard breakfast. The relative urinary recovery decreased with increasing dose of FMN, demonstrating a definite upper limit in the gastrointestinal absorption of the vitamin (Table I, Fig. 2). This upper limit was somewhat above 30 mg. under the experimental conditions of the study. There was one unusually high recovery (48.0 mg. in subject *J* after a 300-mg. dose), but repetition of the experiment in the same subject resulted in a urinary recovery of 22.5 mg. The 48.0-mg. value was not included in the average data of Fig. 2 because of the large discrepancy relative to the remainder of the data. Figure 2 also includes data reported by Stripp (4) which appeared while the present study was in progress. Stripp's data also show a definite upper limit in the absorption of FMN. The absolute difference in the plateau values may be due to differences in the dietary regimen used in the respective studies.

The results of an experiment in which three subjects ingested 30 mg. of riboflavin (*a*) on an empty stomach, (*b*) after a standard meal, and (*c*) after

drinking a volume of water approximately equal to the volume of the standard breakfast are shown in Table II. The ingestion of 600 ml. of water before taking riboflavin increased the urinary riboflavin recovery from 15.0 to 21.6%, but the limited number of subjects does not permit determination of the significance of this difference. However, ingestion of riboflavin after breakfast resulted in an even greater recovery, namely 57.5%.

Analysis of the urines by both the Burch and modified U.S.P. methods permitted estimation of the respective amounts of riboflavin and FMN excreted after ingestion of either form of the vitamin. Riboflavin and FMN exhibit equal fluorescence intensities at equimolar concentrations in the modified U.S.P. assay, while the fluorescence intensity of riboflavin in the Burch assay is 3.4 times that of an equimolar concentration of FMN. The presence of significant amounts of riboflavin as FMN in the urine would result in appreciable differences between the results of the Burch and U.S.P. assays. There was no statistically significant difference in the urinary recovery of riboflavin as determined by the two assay methods. However, since the assay method is not sufficiently sensitive to permit determination of small amounts of FMN in the presence of considerably larger amounts of riboflavin, it can be concluded only that FMN is excreted largely, if not entirely, as free riboflavin.

All data presented in this report are based on the results obtained with the modified U.S.P. assay.

Figure 3 shows the time course of urinary excretion of riboflavin by subject *J* after oral administration of 30 and 300 mg. of riboflavin as FMN after breakfast. Maximum excretion of riboflavin after the 30-mg. dose occurred in the period 1 to 1.5 hr. after ingestion of the vitamin and was followed by an exponential decrease in the excretion rate with an apparent half-life of 1.1 hr. This was followed by a slower excretion phase after the 4th hr. The excretion curve obtained after ingestion of a 300-mg. dose of riboflavin as FMN after breakfast appeared to represent a plateau indicative of an upper limit in the absorption rate of FMN and the curve was drawn on the basis of that assumption. However, additional experiments in subject *J* and in other subjects have shown that the time course of urinary excretion rate after administration of large doses of FMN exhibits more than one maximum, and that the data for the upper curve in Fig. 3 represent two definite, although not very distinct, excretion rate maxima. More representative of the majority of results are the data shown in Fig. 4, where the excretion rate of riboflavin after administration of 150 and 300 mg. of FMN exhibited two distinct maxima.

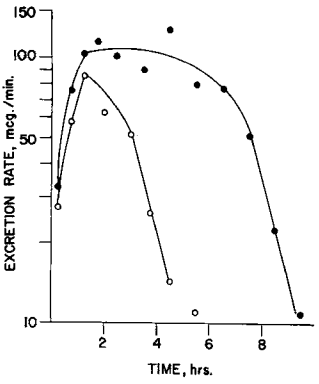

Fig. 3.—Urinary excretion rate of riboflavin as a function of time after oral administration of 30 mg. (○) and 300 mg. (●) of riboflavin as molar equivalents of FMN after a standard breakfast. Subject *J*.

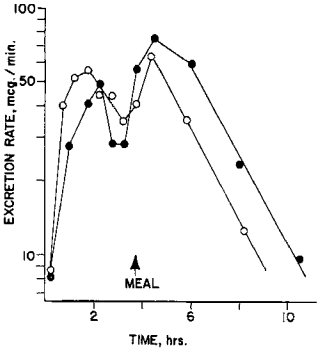

Fig. 4.—Urinary excretion rate of riboflavin as a function of time after oral administration of 150 mg. (○) and 300 mg. (●) riboflavin as molar equivalents of FMN after a standard breakfast. Subject *A*.

The second excretion maximum had a definite relation to lunch time in all of the experiments. When the experiments were repeated in two subjects with lunch being omitted, the second excretion rate maximum decreased appreciably in magnitude, but did not disappear entirely. This is shown in Fig. 5 for subject *A*. The amounts of riboflavin recovered in the urine after administration of large doses of FMN after breakfast were similar whether the subject ate lunch or omitted it (Table I).

DISCUSSION

The results of the present study show that FMN has the same absorption and excretion characteristics as does riboflavin. The data suggest strongly that riboflavin and FMN are absorbed by the same specialized transport process which is saturable and located mainly or solely in the proximal region of the gastrointestinal tract. Just as with riboflavin, administration of FMN after a meal resulted in enhanced absorption of the vitamin,[2] and the post-

[2] The reader is reminded that this is a relatively specific effect and that food decreases the absorption of certain other drugs.

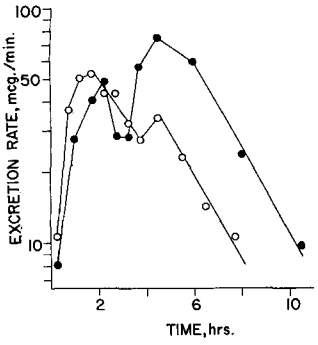

Fig. 5.—Urinary excretion rate of riboflavin as a function of time after oral administration of 300 mg. riboflavin as a molar equivalent of FMN after a standard breakfast with (●) and without (○) lunch. Subject *A*.

absorption excretion rate declined exponentially with a half-life of about 1.1 hr., followed by a slower component after about 4 hr. The latter may reflect the elimination of riboflavin from a "deep" compartment or it may be due to decreased renal clearance at low riboflavin concentrations, similar to the excretion characteristics of another B vitamin, pantothenic acid (5). It has now been possible to demonstrate by the use of large doses of FMN that saturation of the absorption process responsible for the gastrointestinal absorption of vitamin B_2 can be achieved even when the vitamin is administered after a meal. These results are consistent with the assumption that the more extensive absorption of riboflavin and FMN, when given on a full stomach, is due to prolonged retention of the vitamin at sites of absorption. The effect of food on the urinary recovery of riboflavin is not primarily a volume effect since the ingestion of an equivalent volume of water rather than food prior to riboflavin administration does not result in the marked increase in urinary recovery of riboflavin obtained when the vitamin is taken after a standard breakfast (Table II). However, the ingestion of a large volume of water may have a significant effect on riboflavin absorption, possibly by increasing the contact area of riboflavin with intestinal absorption sites.

The maximum amount that was recovered from the subjects under the experimental conditions was around 25 mg. as shown in Table I and Fig. 2, except for the one unusual value of 48.0 mg. The data reported recently by Stripp (4), which are also plotted in Fig. 2, show a lower maximum value. This difference in the maximum amount recovered is probably mainly due to the fact that a standard breakfast was ingested before administration of the vitamin in the present study, while the subjects in the Stripp study were "on an unrestricted diet."

The authors' previous data (1) and those of Stripp have shown that the upper limit in the urinary recovery of riboflavin is not due to a renal transport maximum, although there is evidence that riboflavin is excreted not only by glomerular filtration, but also by renal tubular secretion (6). Renal excretion rates over 450 mcg./min. (based on a 45-min. collection period) were observed by Stripp when 84 mg. of riboflavin was administered by intravenous infusion (4).

A review of the literature provides considerable information to explain the similarity in the absorption and excretion characteristics of FMN and riboflavin. There is extensive evidence showing that FMN is rapidly and almost completely dephosphorylated to free riboflavin in the small intestine. Okuda has found that FMN is rapidly decomposed enzymatically to free riboflavin in pancreatic juice, in homogenates of the small intestinal mucosa, and when injected into the lumen of the small intestine of rats (7, 8). Similar results were obtained by Turner and Hughes, who used isolated rat intestinal preparations (9). Okuda has found pronounced phosphomonoesterase activity in the jejunum and somewhat less in the duodenum and ileum of the rat (10). In this connection, it is of interest that betamethasone phosphate was found to undergo rapid dephosphorylation during gastrointestinal absorption and that only the free drug was found in the jugular blood of dogs after oral administration of this steroid ester (11).

Other studies reveal that riboflavin is eventually converted or reconverted to the phosphate ester (FMN) before it leaves the intestinal mucosa. Yagi and Okuda (12), Chen and Yamauchi (13), and Englard (14) have reported that riboflavin is phosphorylated enzymatically in the mucosa during absorption. Interestingly, Tedeschi and Canali (15, 16) find predominantly FMN in the *mesenteric* blood of rabbits after introduction of FMN or riboflavin into the intestine, while Stripp finds only the free vitamin in the *venous* blood of humans after oral administration of FMN (4). Thus, it appears that FMN is dephosphorylated in the intestinal lumen, rephosphorylated in the intestinal mucosa, transported in the blood to the liver as the phosphate ester, rapidly dephosphorylated in the liver, circulated as free riboflavin, and excreted mainly as such. This scheme represents the quantitatively important pathways in the metabolic disposition of large doses of the vitamin, and neglects the nutritionally more important but quantitatively minor biotransformation and retention of riboflavin in the form of FAD and various flavoproteins. The similarity in the absorption and excretion characteristics of riboflavin and FMN, respectively, can therefore be readily explained by the frequent and rapid interconversions of the two forms of the vitamin in the body. Such a pattern is by no means unique; Lawrence *et al.* have suggested that repeated hydrolysis and re-esterification in the intestinal mucosa occur during the absorption and storage of vitamin A (17).

Metabolism of Riboflavin and FMN.—Orally administered FMN was excreted in the urine mainly or solely as riboflavin. The same was true for riboflavin since no appreciable differences were found between the result of the Burch and modified U.S.P. assays of urines after oral administration of riboflavin (1). These findings are consistent with those of other investigators who could detect only riboflavin itself in the urine after oral or intravenous administration of riboflavin and FMN (4, 18, 19). However, Utsumi found that about 20% of an intravenous dose of FMN or riboflavin was excreted as FMN by ureter-cannulated patients with kidney disease (20). Since it is known that FMN is

hydrolyzed enzymatically in bladder urine (21), the results obtained by Utsumi may be due to by-passing of the bladder. It is of interest that Utsumi found FMN in the urine after intravenous administration of FMN as well as riboflavin (20). This may be due to some phosphorylation of riboflavin in the kidneys (22).

Apparent Enterohepatic Cycling of Riboflavin.—The second maximum in the excretion rate of riboflavin as a function of time (Figs. 3–5) appears to be due to the enterohepatic cycling of the vitamin. There is considerable evidence in the literature to support this hypothesis. In 1929, Makimura noted the presence of vitamins A, B, ascorbic acid, and vitamin D in the bile and proposed that enterohepatic cycling is responsible for the conservation of these vitamins (23). DePreux found riboflavin, mainly as FMN, in bile obtained by duodenal cannulation of healthy men (24). Tedeschi found mainly free riboflavin in the bile after introduction of FMN into the mesenteric circulation of rabbits (25). Yagi observed an accumulation of riboflavin in the small intestine of rats after subcutaneous injection of riboflavin and suggested that enterohepatic cycling was responsible (26). He provided additional data in support of this hypothesis in a recent study using ^{14}C-labeled riboflavin (27). Mizuhara (28) and Ono (29) perfused rabbit livers with blood containing riboflavin and dehydrocholic acid (the latter was used apparently to stimulate bile flow) and found that about 50% of the vitamin appeared in the bile.

Since Najjar *et al.* (30) found no increase in fecal riboflavin after intravenous injection of 5 to 30 mg. of riboflavin in man, and Stripp recovered 97% of an 84-mg. intravenous dose of riboflavin in the urine (4), it may be concluded that, in man at least, any riboflavin secreted into the bile is almost fully reabsorbed. It appears, therefore, that when large doses of riboflavin or FMN are administered, part of the absorbed vitamin is eliminated in the bile. When bile flow is stimulated by food, the vitamin enters the intestine and is reabsorbed, yielding the second peak in the excretion rate *versus* time plots obtained after riboflavin administration.

The possibility that the second peak in the excretion of riboflavin is due to delayed gastric emptying of a portion of the dose is ruled out by the similarity in the urinary recoveries of riboflavin in the experiments with and without lunch. Delayed gastric emptying of riboflavin would result in more extensive absorption of the vitamin in view of the saturability of its absorption mechanism.

In the two instances when the subjects repeated the experiments but did not eat lunch, the second excretion rate peak was considerably reduced in magnitude, but did not disappear entirely. Apparently, the thought of food at lunch time and the sight of others enjoying their lunch was sufficient to stimulate some flow of bile in the subjects. It is known that, while the emptying of the gallbladder normally follows the ingestion of certain foods, psychic influences will play a role. The sight and smell of food alone can produce a reflex stimulation of the gallbladder in both man and animals (31).

The second peak in the excretion rate of riboflavin was seldom seen with low doses (30 mg. or less) of riboflavin or FMN. While the reason for this is not readily apparent, it may be due to a concentration dependent relationship in the handling of riboflavin by the liver.

Stability of Certified Dyes in Tablets III

By FRANK W. GOODHART, HERBERT A. LIEBERMAN, DHIRAJ S. MODY*, and FRED C. NINGER

A colorimetric method is given for studying the stability of pharmaceutical tablet formulations. The data obtained were employed to calculate color difference units by using the Adams-Nickerson and the MacAdams equations. The fastness of the colorants in the particular formulation studied was rated relative to one another, and these ratings were compared to other pharmaceutical stability references. The methodology of studying color stability is applicable to many types of pharmaceutical preparations.

METHODS OF determining the stability of pharmaceutical colorants have appeared in several reports (1–5). Spectrophotometric measurements have provided a physical evaluation of color; but, in order to obtain a quantitative color measurement which relates to human color perception, colorimetry must be used. With the use of colorimetric instruments, the techniques of measurements and means of analyzing data have been continually expanding. The variation in physical form and composition of pharmaceutical dosage forms present additional problems in both instrumental methods and data analysis.

The pharmaceutical formulator has a need for predicting the fastness or stability of pharmaceutical colorants. Reference tabulations (6, 7) have served as his guide for color selection for many years. Modern instrumentation applied to simple, colored pharmaceuticals aged under standardized conditions provides useful data for the formulator. Similar studies have been carried out in the textile and paint industries (8–10) and furnish a guide for color stability testing of pharmaceuticals.

The purpose of this study is to describe a method of measuring color stability of pharmaceutical tablets. Color difference units are used to describe the chromaticity and lightness changes of the colors before and after aging. Particular colorants will be rated for color stability in the specific pharmaceutical composition studied. The fastness of the colorants will be rated relative to each other, and these ratings will be compared to those listed in other pharmaceutical color stability references (1, 6, 7). Differences in ratings of color stability in several references will be explained and reasons given why the color ranking proposed in this report is regarded as superior. The methodology involved is applicable to color stability testing of many pharmaceutical dosage forms.

EXPERIMENTAL

Colorants.—D&C and FD&C colorants were employed in several concentrations and are listed in Table I.

Formulations.—A basic formula was chosen and used throughout so that the relative inherent color stabilities could be determined. Mannitol was employed as the diluent because of its inertness and its ability to be uniformly colored. Magnesium stearate, 1%, was employed as the lubricant because of its wide usage. Since most formulations contained pigments, a dry blending and milling procedure was used for their preparation. In some instances, soluble colorants were used and these were dissolved in an appropriate solvent, and the resulting solutions were used to dye the mannitol. Tablets weighing 20 Gm. and measuring $2^1/_4$ in. in diameter were compressed on the Carver press at 20,000 lb./sq. in.

Exposure.—After initial measurement, tablets were exposed to cool, white fluorescent light measuring 1000 ft.-candles as determined by a model 614 Weston light meter. The fluorescent light was furnished by a metal cabinet which enclosed a bank of twelve 30-w. and four 20-w. General Electric bulbs (F30T12·CW·RS and F20T12·CW). Heat buildup was prevented by a constantly operating fan.

Measurement.—Colorimetric measurements were made at various time intervals that were appropriate depending on rapidity of color fading. The Color-Eye[1] model D-1 colorimeter was used with the nonspecular insert and white vitriolite standards. The following sets of equations were used to calculate the tristimulus values X_{CIE}, Y_{CIE}, and Z_{CIE}.

$$X_{CIE} = .69664\ X_{CE} + .17416\ Z_{CE} \quad \text{(Eq. 1)}$$

$$Y_{CIE} = .8937\ Y_{CE} \quad \text{(Eq. 2)}$$

$$Z_{CIE} = 1.0574\ Z_{CE} \quad \text{(Eq. 3)}$$

The subscript *CIE* denotes the true tristimulus

[a] Concentration of pure dye. [b] Based on 10 days exposure to cool white fluorescent light at 1000 ft.-candles. Less than 6 MacAdam units, good (*G*), less than 16 MacAdam units, moderate (*M*), and greater than 16 MacAdam units, poor (*P*). Tablet excipient, mannitol, lubricant magnesium stearate 1%. [c] Δe, MacAdam color difference at 240,000 ft.-candle hr. or 10 days at 1000 ft.-candle hr. exposure. Range of Δe's given when two colorants concentrations were used. [d] From *Reference 6*. [e] From high intensity fluorescent light (1). Best colorant given rating of 10 and next best successive whole number ratings less than 10. [f] From *Reference 7*.

values while the subscript CE denotes Color-Eye readings. The constants in the above equations are furnished for each piece of vitriolite standard.

Computation.—The Univac SS II computer was used for calculation of Adams-Nickerson color difference, ΔE. The Codic (11) was used to calculate MacAdam color differences ΔC and Δe.

DISCUSSION

Colorimetric Measurement.—Colorimetric measurement includes three factors: (*a*) objective measurement of the reflection or transmission characteristics of a material, (*b*) suitable weightings of the measurements dependent on the illuminant properties, and (*c*) inclusion of the sensitivity of the human eye to color. Since illuminant and the eye are included in determining the final data, colorimetry is *subjective*. This is not true of spectrophotometry which involves a purely physical measurement. The Color-Eye has been found to be a very satisfactory instrument for colorimetric measurements of pharmaceutical dosage forms.

Color Differences.—Past work on color stability in pharmaceutical systems has not come to grips with the concept of color difference. Fading has been described as a function of absorbance (1–3) and as a logarithmic function of the Kubelka-Munk equation (4, 5). Since these treatments have not been related to color in the subjective sense, it was suggested that basic colorimetry be applied to the determination of color fading (5). This technique is well developed and documented, and it is reasonable to study color in pharmaceuticals in this way. A number of color difference formulas have been developed (12), but at the present time only two are used extensively and will be described below.

Adams-Nickerson.—Several formulas for the degree of color difference were tested by Nickerson and Stultz (13). One of these was based on the combination of the Adams chromatic-value diagram combined with the Munsell value scale. Color difference, ΔE, is defined as:

$$\Delta E = 40\,\{(0.23\Delta V_y)^2 + [\Delta(V_x - V_y)]^2 + [0.4\,\Delta(V_z - V_y)]^2\}^{1/2} \quad \text{(Eq. 4)}$$

V_x, V_y, and V_z are Munsell value functions given in the following three equations:

$$\frac{X}{98.04} = 1.2219V_x - 0.23111V_x^2 + 0.23951V_x^3 - 0.021009V_x^4 + 0.0008404V_x^5 \quad \text{(Eq. 5)}$$

$$\frac{Y}{100} = 1.2219V_y - 0.23111V^2{}_y + 0.23951V_y^3 - 0.021009V_y^4 + 0.0008404V_y^5 \quad \text{(Eq. 6)}$$

$$\frac{Z}{118.10} = 1.2219V_z - 0.23111V_z^2 + 0.23951V_z^3 - 0.021009_z{}^4 + 0.0008404V_z^5 \quad \text{(Eq. 7)}$$

The terms X, Y, and Z are the tristimulus values obtained by colorimetric measurement. A tabulation of V_x, V_y, and V_z appears in Judd (12) as a function of the tristimulus values. However, the calculations are cumbersome and time consuming;

therefore, the use of a computer for solving the above equations is quite useful.

MacAdam.—The former color difference equations just described assume that color space may be satisfactorily transformed uniformly throughout the *CIE* diagram using one equation. The MacAdam formula (14, 15), however, establishes sets of transformation equations which define a uniform color space within a restricted portion of *CIE* space. The general formulas giving ΔC, the chromaticity difference, and Δe, the over-all color difference in MacAdam units are given below:

$$\Delta C = K(g_{11}\overline{\Delta x^2} + 2g_{12}\Delta x\Delta y + g_{22}\overline{\Delta y^2})^{1/2} \quad \text{(Eq. 8)}$$

$$\Delta e = (\Delta C^2 + g_{33}\Delta Y^2)^{1/2} \quad \text{(Eq. 9)}$$

Substituting Eq. 5 in Eq. 6 gives:

$$\Delta e = K^2(g_x\overline{\Delta x^2} + 2g_{12}\Delta x\Delta y + g_{22}\overline{\Delta y^2}) + g_{33}\overline{\Delta Y^2} \quad \text{(Eq. 10)}$$

In Eqs. 8–10, x and y are chromaticity coordinates, and Y is lightness. The Δ's refer to differences between sample and standard. The constants in the equations K, g_{11}, g_{22}, g_{33} have been determined experimentally and vary depending on the part of color space that includes the color under study.

Since Eq. 10 requires a great deal of time for calculation, simplified means have been devised for its solution. The use of charts for rapid calculation first was described by Davidson and Hanlon (15) and later was formalized by Simon and Goodwin (16). However, when many color differences are to be calculated, the use of a suitable computer is mandatory. A color difference computer, the Codic (11), is marketed by Davidson and Hemmendinger, Easton, Pa. This desk-top-size computer allows one to calculate ΔC (Eq. 5) and ΔE (Eq. 7) in several minutes. The tristimulus values of the sample and standard along with the constants are placed into the computer by means of potentiometer dials, and the chromaticities and color differences are calculated by nulling a meter. The Codic has precision surpassing visual sensitivity; therefore, it is an excellent tool for color matching work as well as fading studies.

Studies of the merits of various color difference formulas have been conducted. Ingle *et al.* (17) compared the loci of unit color differences for the MacAdam, Adams–Nickerson, and NBS color-difference equations. His comparison points out that the three formulas vary in their sensitivities and position throughout the chromaticity diagram. Berger and Brockes (18), in a study of eight color difference formulas, concluded that only the values obtained with the MacAdam equation agreed with the results of visual color comparison. The authors' data, therefore, are interpreted using the MacAdam color difference equation.

RESULTS

Since the Adams-Nickerson color difference also was calculated, a comparison of the numerical values of ΔE and Δe from the MacAdam equation was made. Often it was found that Δe was 2 or 3 times greater than ΔE, however, exceptions were frequent depending on the magnitude of the color differences. Figure 1 gives the various color differences for B6[2] at a concentration of 0.097%. The ratio of Δe to ΔE varies from about 2.28 at the lowest exposure time to about 2.65 at the highest exposure time. This variability illustrates the nonalignment of the two color difference formulas, and this illustration is typical of the results obtained from the other colorants studied. The chromaticity difference, ΔC, gives the color difference without regard to lightness change. It was found in this study that the largest part of the color change was that of chromaticity, and the magnitude of differences in Fig. 1 between ΔC and Δe were the exception rather than the rule. If the Adams-Nickerson equation had been used as a basis of comparison instead of the MacAdam, the over-all ranking of colorant stability that would have resulted would have been nearly the same since gross deviations were not obtained.

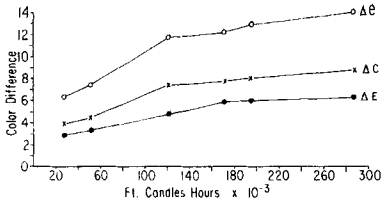

Fig. 1.—Plot of various color differences for D&C Blue No. 6, 0.097%, as a function of ft.-candle hr. exposure at 1000 ft.-candle .

In Fig. 2, MacAdam color differences are illustrated for the blue, green, and violet colorants. A wide range in stabilities can be seen for this group of colors varying from very small changes for B2 and G6 to very high and rapid color differences for B1 and V1.

A nearly consistent dependency of degree of fading on concentration can be seen in Fig. 2. Not all colorants were tested in two concentrations; but of those studied, it is seen that the color of the tablet containing the higher concentration fades to a greater extent over the same time period. The one exception is the colorant B2. This phenomenon readily is apparent visually by comparison of tablets of two colorant concentrations to their respective nonfaded standards. The lighter colored tablet after fading is closer to white, but the color difference is less than that found for the darker tablet. Godlove (19, 20) has written on the perceptibility and acceptability aspects of color acceptance with particular reference to "on tone" and "off tone" fading. He found, for instance, that the consumer is more disturbed by a change in hue than by equally perceptible changes in strength and brightness. Hue change is the exception rather than the rule in this work, but a similar question of acceptance is apparent when the same colorants in two concentrations are compared. While the tablet with the lighter color fades to a smaller degree, it may be less acceptable because of the tendency of its color to change toward white and hence diminution of color.

[2] Abbreviations for colorants will be used; the first letter of the colorant name is used for its designation and D&C and FD&C are omitted.

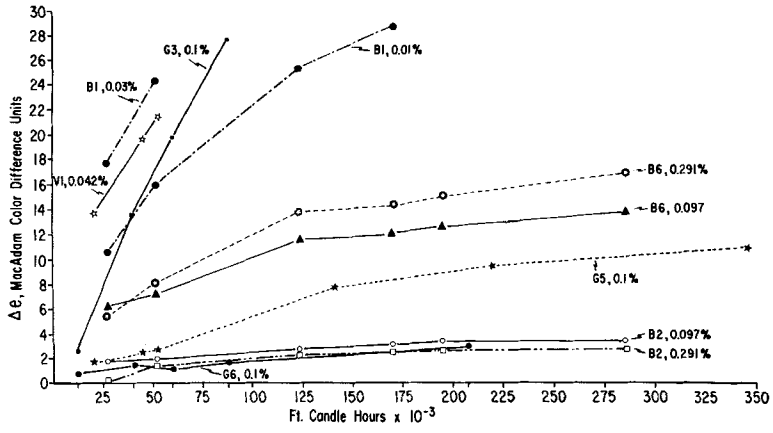

Fig. 2.—Plot of MacAdam color differences for blue, green, and violet colorants as function of ft.-candle hr. exposure at 1000 ft.-candles.

An arbitrary ranking of colorant stability in tablets is given in Table I. Also listed are the concentration ranges employed, the chemical type and CI number, along with stabilities listed by two other authors. The ranking is arbitrary and was deduced from the following considerations. A color showing fading of 6 MacAdam units after 240,000 ft.-candle hr. was given a good ranking (*G*), a color fading 16 MacAdam units after 240,000 ft.-candle hr. was given a moderate ranking (*M*), and color fading of more than 16 MacAdam units over the same period was listed as poor (*P*).

A maximum fading of 6 MacAdam units for a good rating is stringent since 2 to 3 MacAdam units are needed to give a visual color difference. Therefore those colorants in Table I having a good rating only show slightly perceptible color differences after 10 days (240,000 ft.-candle hr.). Testing for longer periods in many cases showed a leveling off of fading, and apparently the colors listed as good would not undergo further change under continued exposure. Some of the colorants given a moderate rating are satisfactory for product usage depending upon the use to which the colorant is put and its concentration. This would be especially true for R2 and R36. That group of colorants having poor stability are probably not satisfactory under any conditions of usage where the product is exposed to any light whatsoever. Among these that are highly unstable are R3, R19, R21, R28, B1, V1, and G3.

At the present time, guides to colorant stability have limited usefulness; and probably the best references are personal ones based on experience. Among the stability references are those found in Peacock's "The Application Properties of the Certified 'Coal Tar' Colorants" (6). The booklet lists the relative fastness of dyes to light as well as to oxidizing agents, reducing agents, and other chemicals. The substrate used in arriving at the rating is unknown but no doubt it had a definite effect, and this could explain the discrepancies. The same relative stabilities are listed in the *Encyclopedia of Chemical Technology* (7). Another listing of relative colorant stabilities has been given by Lachman *et al.* (1). This relative listing is based on reduction of absorbance and not on colorimetric data.

For comparison, Table I also lists colorant stabilities given by Peacock (6) and Lachman (1). It readily is seen that no correlation exists between the authors' ranking and those given by the above authors. The fact that this laboratory's data are based on colorimetry, not spectrophotometry, would explain the lack of correlation. The use of colorimetry affords a means of calculating subsequent color differences and relates directly to the actual psychophysical effect of color on the average human observer. Another point that must be kept in mind is that the substrate and additives may contribute a significant effect toward color stability. It is thought that the authors' colorimetric data should, however, be useful in predicting the stability of colorants in tablets.

48	17.8	18.1	30.0			

[a] Y = 73.2 for tablet *1* and 74.4 for tablet *2*. [b] Y = 61.7 for tablet *1* and 60.7 for tablet *2*.

No general relationship between the chemistry of colorants and stability has been found. However, the indigoid, pyrazolone, and quinoline types rank high in stability. Xanthene, fluoran, and triphenylmethane dyes rank low. Monoazo and anthraquinone colorants generally are intermediate. Functional groups and their positions no doubt are important factors in colorant stability.

Tablets of R3 were run in duplicate in order to obtain an estimate of reproduciblity. The data for the various color differences and two concentrations of the colorant are summarized in Table II. Color differences for each concentration are of different magnitudes as was noted previously. However, an inverse correlation between color difference and lightness, Y, is seen. For the lower concentration, tablet *1* has a lightness of 73.2 *versus* 74.4 for tablet *2*. Tablet *2* shows a smaller degree of fading in all instances, an effect related to the change in concentration. Even though the tablets contained the same amount of colorant, the compression of the powder gave tablets of variable lightness, a factor that alters stability to some extent. The same correlation can be seen for the higher concentration where tablet *1* is lighter than tablet *2*.

SUMMARY AND CONCLUSIONS

A method of testing color stability using a colorimetric procedure has been described. The same methodology is satisfactory for testing a variety of pharmaceutical products. A ranking of colorant stabilities in tablets is given which is intended to provide a guide for selecting a stable color for related formulations.

Tissue Culture of *Digitalis mertonensis* I

Effect of Certain Steroids on the Callus Growth and Formation of Baljet Positive Substances in *D. mertonensis*

By R. S. MEDORA*, D. P. N. TSAO, and L. S. ALBERT

Static culture conditions for the growth of *Digitalis mertonensis* callus tissue are described. Effects of different steroidal "precursors" on the growth of this callus tissue and the production of total constituents, positive to the Baljet reagent, in the callus and media are estimated.

THE FIRST work on tissue culture of the genus *Digitalis* was reported by Gautheret (1). Staba and co-workers (2–5) also described the growth and metabolism of static and suspension cultures of *Digitalis purpurea* L., *Digitalis lanata* Ehrh., and *D. purpurea* var. *gloxinaeflora* Hort., including a biotransformation study of digitoxigenin using cultures of *Digitalis mertonensis* Buxton and Darlington.

Steroids have been known to stimulate or inhibit growth in microorganisms and plant tissues (6). Tsao (7) found that 0.25% of sodium glycocholate stimulated and 5% concentrations inhibited glycoside production in *D. purpurea*. On the other hand, Chan and Tsao (8) found that sodium cholate inhibited glycoside

Tissue Culture of *Digitalis mertonensis* I

Effect of Certain Steroids on the Callus Growth and Formation of Baljet Positive Substances in *D. mertonensis*

By R. S. MEDORA*, D. P. N. TSAO, and L. S. ALBERT

Static culture conditions for the growth of *Digitalis mertonensis* callus tissue are described. Effects of different steroidal "precursors" on the growth of this callus tissue and the production of total constituents, positive to the Baljet reagent, in the callus and media are estimated.

THE FIRST work on tissue culture of the genus *Digitalis* was reported by Gautheret (1). Staba and co-workers (2–5) also described the growth and metabolism of static and suspension cultures of *Digitalis purpurea* L., *Digitalis lanata* Ehrh., and *D. purpurea* var. *gloxinaeflora* Hort., including a biotransformation study of digitoxigenin using cultures of *Digitalis mertonensis* Buxton and Darlington.

Steroids have been known to stimulate or inhibit growth in microorganisms and plant tissues (6). Tsao (7) found that 0.25% of sodium glycocholate stimulated and 5% concentrations inhibited glycoside production in *D. purpurea*. On the other hand, Chan and Tsao (8) found that sodium cholate inhibited glycoside

production in *D. purpurea* in concentrations of 0.5 and 2.5%. Much (9) has shown that 2% of cholesterol stimulated growth of digitalis while Tsao and Youngken (10) showed that 0.5 and 2% of cholesterol increased the glycosides in the leaves of *D. purpurea*. Buvat (11) and Levine (12) found that the degradation products of cholesterol produced more callus and organ growth in other species of plants.

These and other findings prompted the authors to investigate the effects of certain solubilized sterol mixtures and cholesterol on glycoside production when added to a medium for the callus growth of *D. mertonensis*.

EXPERIMENTAL

Sterol *A*,[1] sterol *B*,[2] and pure cholesterol[3] were selected as steroidal "precursors" to study their effects on the growth and glycoside production in the callus tissue of *D. mertonensis*. Sterol *A* (13,14) is an oil-soluble, hydrophilic, multisterol, nonionic surfactant, emolient, emulsifier, and comprises mainly the sterols from lanolin solubilized in a vehicle. Sterol *B* (13, 14) is a stable, active, water-soluble, ethoxylated derivative of cholesterol. The sterol *B* molecule is comprised of 25% pure cholesterol and 75% of the 24-molecule ethylene oxide side chain.

Preparation of the Media for Static Cultures.—Except where specified, all inorganic compounds used were of analytical reagent grade and the organic compounds[4] employed were of better available grades. A modification of White's (15) basic media was used for all experiments carried out with a semisolid media. In addition to vitamins of Eagle's solution (16), *myo*-inositol, biotin, and nicotinic acid in quantities of 200 mg., 1 mg., and 0.4 mg./L., respectively, were also included in the list of vitamins. Among others were sodium ferric ethylenediaminetetraacetate (NaFeEDTA), glycine, coconut water, sucrose, and the supplement suggested by Staba (2) for growth of digitalis callus tissue. Agar (0.7%) was added to give a semisolid consistency to the media, and 2,4-dichlorophenoxyacetic acid (2,4-D) and 2-benzothiazoleoxyacetic acid (BTOA) in quantities of 1 mg. and 2 mg./L., respectively, were used to induce callus formation. The ingredients in formula 1 (Table I) were dissolved in glass distilled water and if necessary adjusted between pH 5.4–5.7 with potassium hydroxide. The media was then distributed into 125-ml. wide mouth conical flasks plugged with nonabsorbent cotten, covered with paper cups, and autoclaved. The ingredients of the supplement [formula 2 (Table I)] also were dissolved in glass distilled water, adjusted to the same pH as above, passed through a Millipore[5] HA filter and aseptically added to the luke warm autoclaved flasks. Totally, 20 ml. of semisolid sterile media (formulas 1 and 2) was then used in each flask to grow callus tissue.

TABLE I.—MEDIA FOR STATIC CULTURE

	mg./L.
Formula 1	
White's Modified Basal Media	
$MgSO_4 \cdot 7H_2O$	625
$Ca(NO_3)_2 \cdot 4H_2O$	200
Na_2SO_4 (anhydrous)	200
KNO_3	80
KCl	65

Conditions of Growth and Incubation.—MacLachlan (17) has noted that soybean seedling produced more sterols in the dark than in the light. Blackley and Stewart (18) reported that suspension cultures of *Hoplopappus* grown in the dark are more friable. It was the experience of the authors that static cultures grown in the dark were lighter in color and more friable. Friable cultures have been considered better for initiating suspension cultures (19). As the authors were interested in cultures which produced steroidal glycosides, all experiments were carried out in complete darkness.

All plant tissues were incubated in a Hotpack constant temperature room[6] model 1288-14 (operating temperatures 0 to 40°) adjusted to 27 ± 1°. The humidity of the incubator was maintained 50 to 80% by a De Vilbiss vaporizer[7] model 144.

Aseptic manipulations were carried out between Bunsen burners or in a sterile transfer chamber[8] which maintained positive air pressure and which was equipped with an ultraviolet lamp. The seeds of *D. mertonensis* were obtained from the Drug Plant Gardens, University of Washington, Seattle. They were sterilized by the method described by Staba (2). The sterile seeds were then distributed in Petri dishes, 9 cm. in diameter, which contained disks of Whatman No. 1 filter paper soaked in 10

to 12 ml. of distilled water. The seeds were then incubated for 14 days. On the 14th day two germinated seedlings were aseptically transferred to each conical flask containing sterile media for static tissue culture. The seedlings were allowed to grow and develop into callus tissue. On the 37th day in all experiments the callus tissue from the first generation of growth was harvested, weighed (fresh weight), dried at 50° for 72 hr., and weighed again (dry weight).

Extraction of Callus from Static Culture.—The dried callus was weighed and coarsely ground. A tincture was prepared according to the U.S.P. method for digitalis tincture (20). The callus tincture was then stored in a refrigerator until used.

Extraction of the Culture Media.—On the basis of the moisture present in the media, enough alcohol was added to the media to give the same alcohol concentration as that of the menstruum used to extract the callus. Later, more menstruum was added, so that the total volume of menstruum corresponded to 2 ml. for each milliliter of the media at the start of incubation. The flasks with the media and menstruum were then shaken for 24 hr. The extractive from each lot was pooled separately, filtered through cheese cloth, and filtered twice through Whatman No. 1 filter paper. The clear extractive was evaporated to a syrupy consistency in a flash evaporator at temperatures below 50° and then lyophilized. The lyophilized extract was weighed and stored in a desiccator for future use. Two grams of the lyophilized extract was shaken for 8 hr. in 10 ml. of the menstruum. The solution was then filtered and the tincture stored for future use.

Colorimetric Assay of Baljet Positive Constituents[9] in the Callus and Media.—The assay method of the standard preparation of digitoxin in the U.S.P. XVII (21) was closely followed and a standard curve was plotted with micrograms of digitoxin *versus* absorbance. The total amounts of constituents in the callus and media tinctures were calculated as digitoxin and were determined by the modified method of Knudson and Dresbach (22) after preliminary decolorization of the tincture. To a suitable aliquot of decolorized tincture an equal volume of alkaline picrate was added. The absorbance of this solution was read on a Beckman DU spectrophotometer[10] at 495 mμ 16 min. after the addition of the alkaline picrate, against a blank using 0.5-cm. cells. The blank was prepared exactly the same way as the tincture, using aliquots of menstruum instead of the tincture.

Experiment A.—In the preliminary experiments, the concentration of 0.5% of sterol *A* was found to be optimum for the growth of the callus tissue on the basis of its dry weight. Therefore, 0.5% of sterol *A* was added to the media of some lots in this experiment. Equal quantities of the media for the growth of callus tissue were distributed in flasks with the Brewer automatic pipeting machine,[11] model 07-502, The flasks were divided into 6 lots. To the media of lots 1 and 4, 0.5% of sterol *A* was added while an equivalent amount of vehicle[12] was incorporated in lots 2 and 5. Lots 3 and 6 were used as controls. The media was prepared exactly as described earlier, except that sterol *A* was incorporated in formula 1 for lots 1 and 4 while the vehicle of sterol *A* was added to formula 1 for lots 2 and 5. Therefore, both sterol *A* and its vehicle were subjected to autoclaving with the rest of the media before ingredients of formula 2 were aseptically added. In all experiments, the callus tissue was grown in flasks of lots 1, 2, and 3, while lots 4, 5, and 6, respectively, were kept as controls for the above lots. For all experiments, the callus from each lot was harvested on the 37th day, dried, and the total constituents determined colorimetrically (Table II). The media tincture was also analyzed for the presence of total constituents (Table III).

Experiment B.—The lanolin fraction containing sterols in sterol *A* is about 1.2% (23). Sterol *B* is a molecule containing 25% by weight of pure cholesterol and 75% by weight of 24 moles of ethylene oxide side chain (14). On the basis of these data, enough sterol *B* was added to the nutrient media, such that the weight of cholesterol in it was approximately equivalent in weight to the total sterols present in sterol *A* previously added.

The side chain of sterol *B* is made up of 24 molecules of ethylene oxide and this is approximately equivalent to a molecule of polyethylene glycol 1000.[13] Therefore, polyethylene glycol 1000 was used in the media of one lot along with sterol *B* in another. Polyethylene glycol 1000 was added to the media of lots 2 and 5 in quantities equivalent to 75% of the sterol *B* added above. These lots were especially prepared to determine whether the 24 molecule ethylene oxide side chain of sterol *B* had an independent effect of its own on the callus tissue.

Totally, 6 lots were prepared for this experiment. Lots 1 and 4 contained 0.024% of sterol *B* in the media, lots 2 and 5 contained 0.018% polyethylene glycol 1000 and lots 3 and 6 were used as controls. The media was prepared the same way as described earlier. Sterol *B* and polyethylene glycol 1000 were added as extra ingredients to formula 1 of the media. The callus from each lot was harvested separately and the constituents were determined in the callus and media (Tables II and III).

Experiment C.—This experiment was carried out to determine whether pure cholesterol had any effect on the callus tissue. In the preliminary experiments, different methods were tried to incorporate cholesterol in the nutrient media in a fine suspension and the method which gave the finest suspension was employed. The ingredients of formula 1 were mixed together as described earlier and then cholesterol dissolved in chloroform was poured in the warm media agitating its container continuously. This gave the finest suspension of cholesterol. The flasks were then sterilized and the ingredients of formula 2 were added after filtration through a Millipore filter.

For this experiment 6 lots were prepared. To the flasks in lots 1 and 4 totally 0.1-ml. quantities

[9] Baljet positive constituents will be referred to as merely "constituents." Throughout the paper, constituents will be defined as total extractives of callus tissue and culture media which give a positive reaction to alkaline picric acid.

[a] Calculated as digitoxin on the basis of the digitoxin standard curve. [b] The capital alphabets A, B, and C signify the experiments. The arabic numbers indicate treatment of the media, and "m" stands for the media extracts. In lots No. 3 and 6 in each experiment the media was not treated. In all experiments, No. 1, 2, and 3 indicate callus grown lots and No. 4, 5, and 6, respectively, are controls of the above lots with no callus grown in them.

of 20% cholesterol solution in chloroform were added with a microburet. To flasks in lots 2 and 5, which were controls, 0.1 ml. of chloroform was added, and lots 3 and 6 served as controls without any adjuncts. The callus from each lot was harvested and dried. The tinctures of callus and media were assayed for their constituents (Tables II and III).

RESULTS AND DISCUSSION

Some of the seeds grown in distilled water sprouted on the 3rd day of incubation while more than 50% of the total viable seeds sprouted by the end of the first week. The seedlings were allowed to grow in the dark for 2 weeks; at the end of this period the radicle sizes varied from 1–2 in. The seedlings grown in the untreated media had the following pattern of growth. On the 6th day after the seedlings had been transferred to the nutrient media, a thickening was observed at the proximal end of the radicle, while the radicle tips of some seedlings showed slight browning. After the 10th day of in-

cubation, the thickening began to appear all over the radicles and they turned light brown. By the time the seedlings had been incubated for 12 days the thickening was very profuse and turned into a homogeneous mass of cells (callus). Some masses of callus also started to give off branches with fluffy protuberances. From this point on, the callus tissue grew larger in size, in the form of interrupted nodules, and started to turn darker in color. When this callus tissue from the first generation of growth was harvested on the 37th day and examined, it was found to be a friable, undifferentiated mass of homogeneous cells.

The callus grown in the media treated with sterol *A* grew in the form of clumps, was more friable, had more protuberances, and was lighter in color. Callus in the vehicle, cholesterol, chloroform, and polyethylene glycol 1000 treated lots had a more or less similar pattern of growth as the controls. In the case of sterol *B*-treated media, the seedlings turned yellow and then light brown even before callus growth was observed. Growth was poorer than the controls and callus tissue did not appear until the beginning of the 3rd week. The development of callus in the cholesterol-treated media was also delayed by about 2 days as compared with the controls.

In experiment *A*, sterol *A* used in 0.5% quantities in the media, showed an increase in the weights of fresh and dry callus as compared with its control (Table II). The callus from the lot treated with the vehicle showed an increase of 3.65% of the dry weight as compared with its control. However, the fact that the callus from the sterol *A*-treated media was 9.86% higher in weight than the one treated with the vehicle, showed that something else in sterol *A* besides the vehicle stimulated the growth of the callus.

In the colorimetric assay, the tincture prepared from the callus grown in the sterol *B*-treated media (Alc), showed an increase of 13.84% of the constituents per milligram dry weight of the callus compared to tincture of the callus grown in media treated with the vehicle (A2c). Compared to the tincture of the untreated callus (A3c), the increase in constituents in the tincture Alc is almost twice as much as that in A2c. Therefore, it could be surmised that, although the vehicle portion of sterol *A* has a stimulating effect on the production of constituents in the callus, the lanolin portion in sterol *A* also has a stimulating effect of its own.

The relatively high amounts of constituents in the media tinctures (Table III) are difficult to explain, particularly because the separated constituents of the media extract on a thin-layer plate are negative to Kedde's reagent. It seems, therefore, that while trying to extract the steroidal glycosides from the media, some portion of the media ingredients, along with other callus metabolites released in the media, were also extracted. Rowson (24) has pointed out that discrepancies do arise if impurities are present in the tinctures assayed for cardiac glycosides. The tincture of the untreated media (A3m), the tincture of the sterol *A*-treated media (Alm), and that of the vehicle-treated media (A2m) in which callus was grown gave a much higher reading for constituents than the tinctures of their respective controls. This indicates that during its growth the callus may have released certain constituents in the media. These constituents do not seem to resemble the digitalis glycosides as they were negative to Kedde's reagent.

From the evidence available, it is difficult to pinpoint which compounds in addition to digitalis glycosides produced a color with alkaline picrate. However, compounds such as glucose, ascorbic acid, creatinine, and lactams of α-guanidine acids, commonly found as plant and animal metabolites, are known to react with alkaline picrate (25, 26). Ascorbic acid has been known to occur in the genus digitalis (27) and Staba (3) has shown that *D. purpurea* suspension cultures hydrolyze sucrose to glucose and fructose. In spite of this, it is unlikely that the sugars are responsible for the color reaction if the absorbance is noted within 20 min. after the addition of the Baljet reagent (25).

The metabolites which react with alkaline picrate seem to be in higher quantities in tincture of untreated media than the sterol *A*-treated one. The reverse is true in the callus tincture, *i.e.*, there are greater amounts of the constituents in the callus from the treated media than from the untreated one. The A2m tincture seems to have smaller amounts of constituents compared with A3m. It seems possible, therefore, that in the absence of the vehicle or the vehicle with the lanolin fraction, more constituents are leached out of the callus cells into the media.

In experiment *B*, the presence of both sterol *B* and polyethylene glycol 1000 in the media seemed to inhibit growth of the callus tissue (Table II). However, the presence of polyethylene glycol 1000 in the media increased the constituents per milligram dry weight of the callus as compared to its control. On the other hand the presence of sterol *B* in the media did not seem to bring about a significant change in the constituents per miligram dry weight of the callus.

There was a significant increase in constituents in the media containing sterol *B*, although only a slight increase in constituents in the media containing polyethylene glycol 1000. The data obtained (Tables II and III) of the growth, constituents of callus, and release of constituents in the media for sterol *B* and polyethylene glycol 1000 treatment vary considerably. However, it is probable the 24-molecule ethylene oxide side chain on sterol *B* is not so inhibitory to growth of the callus as is the cholesterol moiety itself.

In experiment *C*, due to the breakdown in the refrigeration mechanism of the growth chamber, the temperatures in the chamber rose above 27° on various occasions. This retarded the growth of the tissue and the final yield of callus at harvest was less in weight compared to experiments *A* and *B*. Because of the fluctuation in temperature, the authors are skeptical about the results of experiment *C*.

The dry weight of the callus harvested from the cholesterol-treated media was 21.54% higher than the callus harvested from the untreated media; however, only 6.75% higher than the chloroform-treated media. The chloroform-treated lot showed an increase in 13.85% compared to its control. After autoclaving the media, it seems doubtful that enough chloroform stayed behind to produce an effect on the callus growth. However, if some did stay behind, the stimulating effect of less than

0.5% chloroform on the callus is not surprising in light of the findings that solvents such as alcohol in concentration of 0.2 to 0.3% enhanced Avena coleoptile elongation (28).

There is a decrease in the constituents in the callus harvested from the media treated with cholesterol as compared to the callus obtained from its chloroform control. However, in case of the media tincture, the condition is reversed. Because of fluctuation in temperature during experiment *C*, it is not possible to draw any definite conclusions.

From the over-all data of experiment *A*, it seems reasonable to recommend 0.5% sterol *A* as an extra adjunct to the media for the cultivation of static callus cultures of *D. mertonensis*.

SUMMARY

A method is described for the growth of callus tissue from the seedlings of *D. mertonensis* in tissue culture. Certain sterols were also studied for their effects on callus growth and digitalis-like glycoside production.

Increases in callus growth and constituents positive to the Baljet test were observed when a solubilized lanolin fraction sterol *A* was added to the nutrient media in amounts of 0.5%.

Cholesterol, as an adjunct to the culture media in quantities of 0.1%, stimulated callus growth. However, 0.024% of an ethoxylated derivative of cholesterol sterol *B* with a 24-molecule ethylene oxide side chain and a polymer of ethylene oxide (polyethylene glycol 1000) in quantities of 0.018% inhibited callus growth.

Constituents in the callus, positive to the Baljet test increased slightly in the presence of cholesterol and polyethylene glycol 1000. There was no significant change in the callus constituents when sterol *B* was added to the media.

Heats of Transition of Methylprednisolone and Sulfathiazole by a Differential Thermal Analysis Method

By J. KEITH GUILLORY

Heats of transition and fusion have been determined for methylprednisolone and sulfathiazole by differential thermal analysis calorimetry. Methylprednisolone undergoes an endothermic transition at 209°, with heat of transition, 1380 ± 50 cal. mole^{-1}. Fusion occurs at 240°, with heat of fusion, 5350 ± 200 cal. mole^{-1}. Sulfathiazole undergoes an endothermic transition at 161°, with heat of transition, 1420 ± 40 cal. mole^{-1}. Fusion occurs at 200°, with heat of fusion, 5960 ±210 cal. mole^{-1}.

As part of a program investigating the phenomenon of polymorphism in pharmaceuticals it was desirable to obtain reliable data on the heats of transition and fusion for a large number of compounds. Adiabatic calorimetry (1), solubility measurements (2–4), and differential thermal analysis were among the techniques considered for use in these determinations. Calorimetry was rejected as being too time consuming for routine analyses. There are a num-

Heats of Transition of Methylprednisolone and Sulfathiazole by a Differential Thermal Analysis Method

By J. KEITH GUILLORY

Heats of transition and fusion have been determined for methylprednisolone and sulfathiazole by differential thermal analysis calorimetry. Methylprednisolone undergoes an endothermic transition at 209°, with heat of transition, 1380 ± 50 cal. mole^{-1}. Fusion occurs at 240°, with heat of fusion, 5350 ± 200 cal. mole^{-1}. Sulfathiazole undergoes an endothermic transition at 161°, with heat of transition, 1420 ± 40 cal. mole^{-1}. Fusion occurs at 200°, with heat of fusion, 5960 ±210 cal. mole^{-1}.

As part of a program investigating the phenomenon of polymorphism in pharmaceuticals it was desirable to obtain reliable data on the heats of transition and fusion for a large number of compounds. Adiabatic calorimetry (1), solubility measurements (2–4), and differential thermal analysis were among the techniques considered for use in these determinations. Calorimetry was rejected as being too time consuming for routine analyses. There are a num-

ber of factors which tend to reduce the utility of the solubility method. Practically speaking, its use is restricted to systems exhibiting only two polymorphic forms. It is further limited to those systems in which transitions occur within a temperature range for which liquids having appropriate solvent properties are available if one is to obtain data that can be extrapolated with confidence.

Differential thermal analysis (DTA) is a technique in which the heat loss or gain resulting from physical or chemical changes occurring in a sample is recorded as a function of temperature or of time as the substance is heated at a uniform rate. Heat or enthalpic changes, either endothermic or exothermic, are caused by phase transitions—such as fusion, crystalline structure inversions, boiling, sublimation, and vaporization. Solid–solid transitions, fusion, and dehydration generally produce endothermic effects, whereas crystallization and oxidation produce exothermic effects (5).

In DTA a sample substance and a thermally inert reference substance are heated at a fixed rate by an external furnace. The junctions of a differential thermocouple are embedded in or near the sample and inert reference. As the temperature increases the electromotive forces developed by the junctions are amplified and compared by displaying on a recorder. Exothermic or endothermic changes are consequently recorded as deviations from a base line, and appear as peaks on one side of the base line or the other (6).

Although primarily a tool for qualitative analysis, DTA has been employed for estimating heats of reaction, fusion, and transition. These thermodynamic functions can be evaluated by integrating the endothermic or exothermic peak produced as the sample reacts, melts, or undergoes a solid-state transition. The area of the peak is proportional to the heat absorbed or evolved in the sample transformation. The heat involved in the process, ΔH, is given by

$$\Delta H = \psi \int_{t_1}^{t_2} \theta \, dt$$

where ψ is the proportionality constant, usually evaluated experimentally, or (rarely) calculated from instrument parameters; t_2 and t_1 are the times at the end and beginning of the peak; θ is the differential temperature; and t is the time.

Kung and Goddard (7) used this technique to obtain an estimate of the heat effects associated with the formation of a complex between sodium lauryl sulfate or myristyl sulfate and lauryl alcohol or myristyl alcohol. They pointed out that although the area of the DTA peak is primarily controlled by the enthalpy change involved, it is, at constant heating rate and sample size, also a function of the heat capacity and thermal conductivity of the sample. The latter property for solid substances is affected by the state of packing of the sample.

Varma (8) determined the heats of fusion for a group of organic compounds, including catechol and naphthalene. Care was taken to maintain the quantity of material employed in each determination exactly the same. Effects of thermal diffusivity of the different materials used in the analyses were ignored, however.

Sakurai and Yabe (9) have calculated the heat absorbed in the solid phase transition and fusion of *n*-hexadecanamide. Other quantitative applications of DTA have been reviewed periodically by Murphy (10).

There are a number of shortcomings associated with the use of conventional DTA equipment for the quantitative evaluation of thermodynamic functions, and several of these shortcomings have been pointed out by Speros and Woodhouse (6). In an attempt to overcome these objections, various design modifications have been proposed from time to time to improve the precision and accuracy of DTA instruments. The equipment used in this investigation incorporates modifications which were first proposed by Boersma (11). Holders for sample and reference are located in separate cavities in a nickel heating block. A resistance heating element is wound around this block, and chromel–alumel thermocouples contact the bottoms of the holders. This construction affords high resistance to heat transfer. When a sample undergoes transition or reaction, the heat developed is retained by the sample and its holder. As a result, the heat values obtained are independent of sample size, specific heat, and packing density.

The primary purpose of this investigation was to determine whether DTA calorimetry could be employed routinely, conveniently, and with confidence in the determination of thermodynamic parameters for organic crystalline materials undergoing polymorphic transformations. Two substances whose heats of transition had previously been determined by an independent method, methylprednisolone (3) and sulfathiazole (4), were selected for examination by DTA calorimetry.

EXPERIMENTAL

Materials.—Gallium, indium, tin, and zinc were

Fisher certified reagents. Ethanol U.S.P. was employed as recrystallization solvent for sulfathiazole, and Merck and Co. reagent grade acetone was employed as recrystallization solvent for methylprednisolone. Sulfathiazole N.F. XI was obtained from Merck and Co. Methylprednisolone[1] N.F. was supplied by Upjohn Laboratories.

Calibration of the Calorimeter Cell.—The instrument employed in these determinations was the Dupont 900 differential thermal analyzer equipped with a Dupont modular calorimeter cell. The cell was calibrated with gallium, indium, tin, and zinc. Six samples of each of these substances were weighed into aluminum sample liner holders fashioned with the aid of a dowel pin. The aluminum foil used for this purpose was 0.001 in. thick. No liner was employed in the reference holder.

The samples were weighed on a Cahn Electrobalance to ±0.002 mg. Sample sizes ranged from approximately 4 mg. for gallium to as much as 13 mg. for indium, the sample size being selected to produce a fusion peak whose area could be measured with an error of not more than 2%.

Samples of indium, tin, and zinc were each heated in the calorimeter cell from room temperature to 20–50° above the melting point. Samples of gallium were cooled to −40° with the aid of a dry ice–acetone mixture, then heated to 20° above the melting point. The heating rate used was 10° min.$^{-1}$.

In each case a graph of differential temperature as a function of reference temperature gave an essentially straight base line, with a single endothermic peak corresponding to fusion. The areas of these endothermic peaks were determined by use of a Keuffel and Esser Compensating Polar Planimeter. The area to be measured was found by drawing a line from the point where the thermogram first departed from the base line to the point where the base line was resumed following fusion.

The fusion temperature for each material was taken as the extrapolated onset temperature of the endothermic peak. The low temperature side of the fusion peak was extrapolated to the prefusion base line. Since the temperature response of the chromel-alumel thermocouples employed in the calorimeter cell is nonlinear, a small temperature correction (never more than 4°) had to be applied to obtain the corrected fusion temperature.

Calibration coefficients were calculated from the following equation:

$$E = \frac{\Delta H\ M\ a}{A\ T_s \Delta T_s}$$

where

E = calibration coefficient, mcal. °C.$^{-1}$ min.$^{-1}$,
ΔH = heat of fusion, mcal. mg.$^{-1}$,
M = sample mass, mg.,
a = heating rate, °C. min.$^{-1}$, 10° min.$^{-1}$,
A = peak area, in.^{2},
T_s = x-axis sensitivity, °C. in.$^{-1}$, 20° in.$^{-1}$, except for zinc, 50° in.$^{-1}$,
ΔT_s = y-axis sensitivity, °C. in.$^{-1}$, 0.5° in.$^{-1}$.

Heats of fusion employed in the above equation were as follows: gallium, 19.9 cal. Gm.$^{-1}$; indium, 6.79 cal. Gm.$^{-1}$; tin, 14.2 cal. Gm.$^{-1}$; and zinc, 27.0 cal. Gm.$^{-1}$ (12). Calibration coefficients and fusion temperatures obtained were as follows: gallium, 7.40 mcal. °C.$^{-1}$ in.$^{-1}$ and 29.8°; indium, 9.37 mcal. °C.$^{-1}$ in.$^{-1}$ and 156°; tin, 11.0 mcal. °C.$^{-1}$ in.$^{-1}$ and 231°; and zinc, 16.0 mcal. °C.$^{-1}$ in.$^{-1}$ and 418°. These data are plotted in Fig. 1.

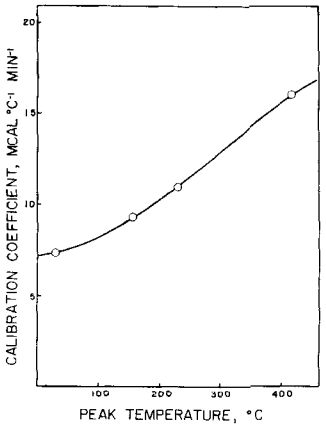

Fig. 1.—Calibration curve for the DTA calorimeter cell.

Measurement of Heats of Fusion and Transition.—Two crystal forms of sulfathiazole were obtained by the methods described by Milosovich (4). Form I, obtained by slow crystallization from warm alcohol consisted of hexagonal plates. Observed on a Kofler hotstage, these crystals underwent a transition to prisms at 155–162°, the exact temperature of the transition being dependent upon the heating rate employed. If a rapid heating rate was employed the crystals melted at 175° without undergoing a polymorphic transition. The melting point of the prismatic crystals was 201°, with decomposition. Form II was obtained by heating form I to 180° in an oven.

Form I of methylprednisolone was prepared by recrystallization from cold acetone. Form II was obtained by heating form I to 210° in an oven. Observed on a Kofler hotstage, form I was transformed to form II over the range 209–213°, with final melting occurring at 238–242°, with decomposition.

Infrared spectra of the polymorphs were taken as Nujol mulls and as potassium bromide pellets on a Beckman IR-10 spectrophotometer. Spectra of the two forms of methylprednisolone were identical with those reported by Higuchi *et al.* (3). The spectrum of sulfathiazole reproduced in the "Sadtler Standard Spectra" catalog is apparently that of form I (13).

Six samples of each polymorphic form were weighed into aluminum sample holder liners, and thermograms, graphs of differential temperature as a function of reference temperature, were obtained. The sulfathiazole samples employed weighed approximately 4.9 mg., and the methylprednisolone samples, approximately 6 mg. Typical thermograms for the four polymorphic forms investigated are shown in Figs. 2 and 3. In these thermograms, however, the y-axis sensitivity setting employed was 0.5° in.$^{-1}$ in the case of sulfathiazole and 0.2° in.$^{-1}$ in the case of methylprednisolone, whereas in the case of the thermograms from which area measurements were taken, only the fusion peaks

[1] The author is indebted to Dr. A. J. Taraszka for a gift of the methylprednisolone used in this study.

were determined at these settings. The transition peaks were determined at a higher sensitivity setting (0.2° in.$^{-1}$ for sulfathiazole and 0.1° in.$^{-1}$ for methylprednisolone) to facilitate measurement of the areas.

The temperatures of transition and fusion were determined by extrapolating the fusion endotherms to the prefusion base line and correcting this temperature for the nonlinear temperature response of the chromel–alumel thermocouples. The values of the calibration coefficients corresponding to each fusion and transition temperature were determined from Fig. 1.

Since, in the case of both sulfathiazole and methylprednisolone, transition from form I to form II occurs prior to fusion, the heat of fusion which is measured is the heat of fusion of form II. A separate determination of the heat of fusion of form II was made in each case, however, to determine whether there might be a kinetic effect which could influence the magnitude of the heat of fusion of a compound determined immediately following transition to a metastable form. Values of heats of fusion determined immediately following transition from form I to form II are listed under "Heat of Fusion, DTA, cal. mole^{-1}," while heats of fusion determined by heating form II from room temperature to fusion are listed separately. The values of the heats of transition and fusion are based on molecular weights 255.32 and 374.46 Gm. mole^{-1}, respectively, for sulfathiazole and methylprednisolone. (Table I.)

RESULTS AND DISCUSSION

Clearly there is a large discrepancy in the transition temperatures obtained by the DTA calorimetry method and those obtained by the solubility method. If a heating rate of 10° min.$^{-1}$ is employed and crystals of sulfathiazole and methylprednisolone are observed on a Kofler hotstage, transition temperatures identical with those obtained by the DTA method are observed. The transition temperature of sulfathiazole is particularly sensitive to changes in the rate of heating, as has been noted by Miyazaki (14). Inoue and Saito determined the transition temperature of sulfathiazole by a qualitative DTA method. At a heating rate of 1° min.$^{-1}$ they obtained a transition temperature of 140° (15). Milosovich (4) demonstrated that form I is converted to II at 100° in glycerin suspension, and form II is converted to I at 90°. It appears that crystals of a polymorph uncontaminated with a second form, and heated in the solid state, can be subjected to considerable overheating or underheating before phase transition occurs. In spite of these large differences in transition temperatures, the values of the heats of transition for the two compounds are not far removed from those determined by the solubility method.

One of the advantages of the DTA calorimetry method is that it also affords a means of obtaining data on the heats of fusion of the compounds investigated. The two values of the heat of fusion for sulfathiazole are clearly within experimental error. There is, however, a considerable difference in the values obtained for methylprednisolone. The heat of fusion is significantly larger for form II heated from room temperature to fusion than for the same polymorph when the heat of fusion measurement is taken immediately following transition from form I to form II. This discrepancy may be due, in part, to the fact that methylprednisolone undergoes a highly exothermal decomposition reaction

immediately following fusion. This makes the precise determination of the area of the fusion peak difficult. It is possible, however, that the difference in the measured heats of fusion may indicate that some time is required following transition from form I to form II for orientation of the molecules of the crystal to occur. Since intermolecular attractive forces are not yet completely established when the fusion temperature is reached, less energy may be required to destroy the crystal lattice.

In their discussion of the mechanism of the phase transition occurring in methylprednisolone, Higuchi *et al.* speculate that the entropy difference between the two forms is a result of greater localization of the functional groups in the side chain in form I, resulting either from intermolecular or intramolecular interactions. A comparison of the infrared spectra of the two crystal forms as potassium bromide pellets reveals that there are large differences in the spectra in the regions designated as methylene stretching and bending regions (16). It seems likely, then, that there may be significant differences in the degree of participation of the methylene groups in the ring structure in intramolecular van der Waals' interactions.

In the case of sulfathiazole, the infrared spectra of forms I and II are strikingly different in the NH— stretching and bending regions. There are strong peaks in the spectrum of II corresponding to the NH— stretching vibration of the amino group (3360, 3480 $cm.^{-1}$) (17). These peaks are shifted to lower frequencies of vibration in form I. Such a shift is indicative of an increase in intermolecular hydrogen bonding (18). In addition, the intense NH_2— bending vibration at 1625 $cm.^{-1}$ in form II is reduced to a shoulder in form I. The SO_2— asymmetric stretching band is quite pronounced in form I (1320 $cm.^{-1}$), but is shifted to a lower frequency and is less intense in form II. The symmetric stretching band at 1135 $cm.^{-1}$ is little affected by the polymorphic transition.

These differences in infrared spectra provide a basis for explaining the greater solubility of form II. There is apparently a greater tendency for intermolecular hydrogen bonding in form I than in form II. Hence, there is less tendency for the molecules of sulfathiazole in form I crystals to form hydrogen bonds with the solvent. Similar interpretations have been suggested by other workers for the differences in solubility for two forms of chloroacetamide (19), and for the spectral shifts observed to occur in the various forms of estradiol (20).

SUMMARY

DTA calorimetry is a convenient method for obtaining heats of transition and fusion of pharmaceuticals. It should be particularly useful for obtaining these data when compounds which undergo several phase transitions prior to fusion must be examined. The method can also be recommended for those compounds that do not form ideal solutions with solvents appropriate for use in the solubility method. The transition temperatures observed in this method may, however, differ appreciably from those observed in the solubility method.

Detection and Separation of Penicillins by Thin-Layer Chromatography

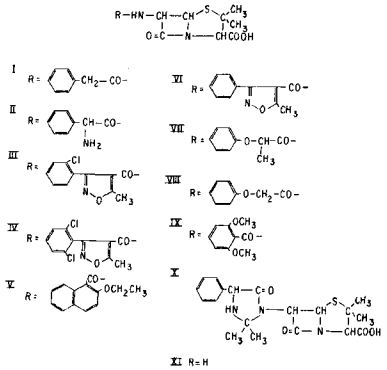
By IAIN J. MCGILVERAY and ROBERT D. STRICKLAND

Thin-layer chromatographic systems and spray reagents are described for the rapid differentiation of 10 penicillins. Comparative behavior of 18 other antibiotics under these conditions is presented together with other supporting data.

THE INTRODUCTION of new semisynthetic penicillins, two of which are official in U.S.P. XVII (1) (sodium methicillin and sodium oxacillin), has accentuated the need for convenient methods for microdetection and differentiation of members of the penicillin group. The current U.S.P. (1) and Canadian regulatory tests (2) depend upon solubility characteristics and time-consuming microbiological methods.

Paper and thin-layer chromatography have both been cited in the literature as methods for the separation of "natural" penicillins and other antibiotics (3–8). Detection techniques quoted include treatment with iodine (6, 7), iodine–sodium azide (3) and permanganate (9), and bioautography (4, 5, 8). The penicillins examined in these investigations included only those obtained from direct microbiological fermentation, although paper chromatography has been used in metabolic studies of semisynthetic analogs (10, 11). However, as far as the authors are aware, the differentiation of all the penicillins in current use—many of them manufactured by semisynthetic methods from 6-aminopenicillanic acid (6APA) (XI)—has not yet been achieved.

This paper describes some thin-layer chromatographic procedures which permit the identification of the following 10 penicillins: sodium benzylpenicillin (penicillin G) (I), sodium



ampicillin (II), sodium cloxacillin (III), sodium dicloxacillin (IV), sodium nafcillin (V), sodium oxacillin (VI), potassium phenethicillin (VII), potassium phenoxymethylpenicillin (penicillin V) (VIII), sodium methicillin (IX), and potassium hetacillin (X). Certain of these are well established clinically, while others show promise (12, 13). For purposes of comparison, the same procedures were applied to other readily available antibiotics (Table I).

EXPERIMENTAL

Preparation of Plates.—The chromatoplates (20 × 20 cm.) were coated to a thickness of 250 μ using the standard Desaga spreader. Silica Gel G (Merck) was applied according to Stahl's method (14). The plates were dried at room temperature and activated at 110° for 30 min. before use on the same day. The cellulose plates were coated with a smooth slurry prepared by stirring cellulose MN 300 without binder (Macherey and Nagel) (30 Gm.) mechanically at high speed for 15 min. with distilled water (200 ml.). They were then dried overnight at room temperature and used without preactivation.

The following systems were used. (*A*) Layer: cellulose MN 300, solvent: 0.1 *M* sodium chloride solution; (*B*) layer: cellulose MN 300, solvent: 0.3 *M* citric acid solution saturated with *n*-butanol [0.3 *M* citric acid (100 ml.) and *n*-butanol (20 ml.) were shaken and left to separate]; (*C*) layer: Silica Gel G, solvent: organic phase of isoamyl acetate–methanol–formic acid–water (65:20:5:10) (8); (*D*) layer: Silica Gel G, solvent: acetone–acetic acid (95:5) (9).

Spray Reagents.—(*a*) Ten per cent aqueous ferric chloride (20 ml.) and 5% aqueous potassium ferricyanide (10 ml.) were mixed with 20% sulfuric acid (70 ml.) and used on the day of preparation.

Received July 27, 1966, from the Research Laboratories, Food and Drug Directorate, Department of National Health and Welfare, Ottawa, Ontario, Canada.

Accepted for publication September 19, 1966.

The authors thank Dr. Leo Levi for his interest in this work, Miss K. Fitzpatrick, Biologics Control Laboratory, Laboratory of Hygiene, Department of National Health and Welfare, Ottawa, for samples of sodium ampicillin, sodium methicillin, and potassium phenethicillin (Bristol Laboratories of Canada Ltd.), sodium benzylpenicillin and griseofulvin [Glaxo-Allenbury's (Canada) Ltd.], sodium novobiocin (Upjohn Co. of Canada), and ristocetin (Abbott Laboratories). They are indebted to the following manufacturers for generous gifts of additional samples used in this study: Ayerst Laboratories Ltd. for sodium ampicillin, sodium cloxacillin, and sodium dicloxacillin; Bristol Laboratories of Canada Ltd. for potassium hetacillin and sodium oxacillin; Burroughs Wellcome and Co. (Canada) Ltd. for polymyxin B sulfate; Cyanamid of Canada Ltd. for demethylchlortetracycline hydrochloride, chlortetracycline hydrochloride, and tetracycline hydrochloride; Glaxo-Allenbury's (Canada) Ltd. for cephaloridine; Hoechst Pharmaceuticals for pyrrolidinomethyltetracycline; Eli Lilly and Co. (Canada) Ltd. for vancomycin hydrochloride; Pfizer Company Ltd. for oxytetracycline hydrochloride; E. R. Squibb and Sons of Canada Ltd. for amphotericin B; Upjohn Co. of Canada for lincomycin hydrochloride; and John Wyeth and Brother (Canada) Ltd. for sodium nafcillin and sodium phenoxymethylpenicillin.

(*b*) Ninhydrin (0.3 Gm.) in acetone (100 ml.). (*c*) Fifty per cent sulfuric acid.

Preparation of Spotting Solutions.—Samples of each of the 10 penicillin powders (10 mg.) were dissolved in methanol (10 ml.). Similarly, samples (10 mg.) of the 18 antibiotics listed in Table I were shaken with methanol (10 ml.) and the supernatants spotted. Tenfold dilutions of the penicillin solutions with methanol were made when required for determining the sensitivity of the detection method.

Chromatographic Procedure.—Samples of the methanolic solution of each penicillin salt representing 1 mcg. (1 μl.) were applied to a plate by means of a Hamilton micro-syringe. The plates were inserted in a previously equilibrated filter paper-lined tank and the appropriate solvent allowed to rise to a height of 15 cm. (approximate times taken: system, *A*, 70 min.; *B*, 120 min.; *C*, 50 min.; and *D*, 20 min.). The plates were dried thoroughly in a stream of warm air except when system *C* was used, in which case drying was accomplished by heating at 120° for 20 min. and cooling before spraying. The spots were observed as blue areas on a yellow-green background after spraying lightly with reagent (*a*). Full color development took up to 5 min., the speed depending on the nature of the penicillins.

The sensitivity of this spray reagent was determined by spotting dilutions of the 10 penicillin solutions in amounts down to 0.04 mcg. with a Burroughs Wellcome Agla syringe on plates treated in the usual way in the four systems.

A plate loaded with the 10 penicillins was chromatographed as described above with system *A*, sprayed with reagent (*b*) after drying, and heated at 100° for 5 min. Only one violet spot corresponding to sodium ampicillin (II) was observed. Similarly, a plate sprayed with reagent (*c*) revealed only two yellow spots corresponding to sodium nafcillin (V) and sodium methicillin (IX).

The behavior of the 18 antibiotics listed in Table I in systems *A* to *D* was investigated. The methanol supernatants of these substances were applied to plates and chromatographed in the usual way. The plates were sprayed with reagent (*a*) after drying.

RESULTS AND DISCUSSION

Previous chromatographic investigations of the penicillins were not concerned with distinguishing between the different acyl derivatives of 6-aminopenicillanic acid (XI), although various methods have been described for paper chromatography of penicillins G and V (3, 7, 8). Some of the solvents cited in this early work were used in trials with different thin-layer chromatographic adsorbents during the present screening program. Thus, in this study, butyl acetate–*n*-butanol–acetic acid–water (80:15:40:24) used in paper chromatography by

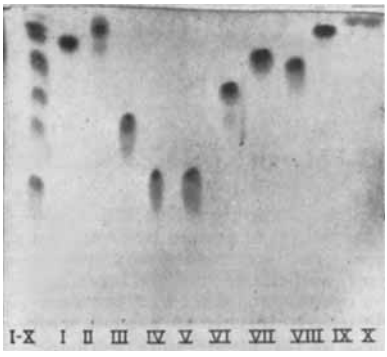

Fig. 1.—Chromatoplate of penicillins (I–X) in system *A*.

Fischer and Lautner (3), and butyl acetate–*n*-butanol–acetic acid–phosphate buffer pH 5.8–methanol (80:15:40:24:5) used by Nussbaumer in quantitative thin-layer chromatography of penicillins G and V (6) failed to separate the 10 analogs completely. Betina (8) in an extensive survey of antibiotic chromatography utilized various solvent systems for penicillins G and V and quoted 3% ammonium chloride and isoamyl acetate–methanol–formic acid–water (system *C*) as giving the best paper chromatographic separations. The authors found that 0.1 *M* sodium chloride was superior to the ammonium chloride system and system *C* was of limited value for separating the different derivatives by thin-layer chromatography.

The R_f values of the 10 penicillin salts with the four systems used are recorded in Table II. The limit of detection with spray (*a*) was found to be in the range of 0.1 to less than 0.04 mcg. System *A* was the system of choice for the separation of the analogs but failed to separate benzylpenicillin (I) from methicillin (IX); ampicillin (II) from hetacillin (X); dicloxacillin (IV) from nafcillin (V), and phenethicillin (VII) from phenoxymethylpenicillin (VIII) (Fig. 1). System *C* was found useful for the separation of I, II, IX, and X, but of all the solvent/adsorbent modifications tried, none separated penicillin IV from V or VII from VIII. However, nafcillin (V) was identified by spraying the chromatographed plate with spray reagent (*c*) when it appeared as an intense yellow spot. Methicillin was the only other penicillin which gave this color but at a very different R_f value. The use of (*a*) after this treatment, revealed the other analogs as previously described. As expected, ampicillin (II) with a primary amino group was the only penicillin to give the ninhydrin reaction which may, therefore, be applied as a confirmatory test for this substance. System *B* was a useful alternative solvent, although some of the spots exhibited variable R_f values due to streaking effects.

Ampicillin (II) and its derivative hetacillin (X) gave similar R_f values in the above systems. Hardcastle *et al.* (9) reported R_f values of 0.15 and 0.65, respectively, for these compounds as free acids in solvent system *D* and noted that dimethylformamide (DMF) should be used as the spotting solvent since hetacillin decomposes in methanol. The authors compared DMF and methanol as spotting solvents for all 10 penicillin salts in the four systems and found that the R_f values for all compounds except hetacillin were not appreciably altered by the different solvents when both freshly prepared and solutions "aged" for 1 week were used. For potassium hetacillin, there was no change in R_f when systems *A* and *B* were used. However, with systems *C* and *D* two spots were evident for the salt with both freshly prepared methanol and DMF spotting solutions. The major, faster running, spot (R_f values 0.30 and 0.64 in systems *C* and *D*, respectively) was found to be diminished in intensity while the slower running spot (R_f values 0.12 and 0.15) was found to be increased in "aged" solutions of both methanol and DMF. Thus, it would appear that hetacillin or its salts decomposed to yield ampicillin in both methanol and DMF (in which the salt is only slowly soluble) on storage and that differentiation of hetacillin from ampicillin is best accomplished using fresh solutions in system *D*. The R_f values in this system, as noted in Table II, vary markedly with changes in temperature, hence, system *D* is quoted only for the differentiation of ampicillin (II) and hetacillin (X).

A number of other solvent systems and adsorbents were tried during the course of this work. Acidic and alkaline solvent mixtures were generally found to give double spot formation and tailing (as with system *B*) probably attributable to hydrolysis. The use of ion-exchange layers such as diethylaminoethylcellulose and buffered layers proved disappointing.

The approximate R_f values of 18 antibiotics in these systems quoted in Table I indicate that these drugs do not interfere with this method of penicillin differentiation. Many of the antibiotics were only slightly soluble in methanol and with such substances the supernatant was used for spotting. The spray reagent (*a*) was much less sensitive in all cases.

These rapid diagnostic procedures will ensure that the more common penicillins are not readily substituted for the more expensive and recently introduced analogs and should also prove useful when applied to the detection of cross-contamination of pharmaceutical formulations by penicillins (15). The application of these procedures to the latter problem is currently under study in these laboratories.

Synthesis of Some Disubstituted Cyanoacetamides as Potential Anticonvulsants

By HERBERT F. SCHWARTZ, II, LEE F. WORRELL, and JAIME N. DELGADO

A series of 17 cyanoacetamides was synthesized for pharmacologic evaluation. Several synthetic methods were studied: *C*-alkylation, acylation of amines by ester, and acylation of amines by amides. The *C*-alkylation of cyanoacetamides was investigated in several solvent systems using various bases, and the results are reported. This method was adopted for the alkylation of the cyanoacetamides in a pressure-reaction vessel and utilized formamide and/or dimethylsulfoxide as solvent with potassium hydroxide as the basic reagent. Several of the compounds were obtained by the pyrolytic acylation of amine by amide.

IN AN EARLIER paper Schwartz and Doerge (1) reported the preparation and investigation of some disubstituted malondiamides. Preliminary pharmacological studies showed several of these to possess anticonvulsant activity and simultaneously to be devoid of sedative-hypnotic properties. Furthermore, the disubstituted cyanoacetamide intermediates used in the preparation of the malondiamides were observed to possess higher anticonvulsant activity and, like the malondiamides, to be devoid of sedative-hypnotic activity. Table I summarizes these pharmacological data (2).

The significant activity of 2-ethyl-2-propyl- and 2,2-diethylcyanoacetamide against both electroshock and subcutaneous pentylenetetrazol tests suggests that further molecular modification might lead to more active compounds. Such modification might serve as the basis for the study of structure-activity relationships among cyanoacetamides. Accordingly, a series of *N*-alkylated and similar *N*-cyclic derivatives from the aforementioned ethylpropyl-, and diethylcyanoacetamides was prepared by several synthetic methods which involved *C*-alkylation, aminolysis, and the acylation of amines by amides.

Since preliminary and previous laboratory experience and literature surveys indicated classical methods of *C*-alkylation and *N*-alkylation to be undesirable and impractical in the preparation of these disubstituted cyanoacetamides, alternate synthetic methods were studied.

DISCUSSION

C-Alkylation.—The *C*-alkylation of cyanoacetamides was investigated in several solvents using various bases by preparing previously known mono- and disubstituted cyanoacetamides and several related esters with the hope of finding a more suitable method.

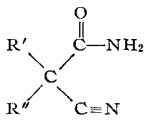
Under the conditions described under *Experimental*, cyanoacetamide has been found to act in a manner qualitatively similar to other active methylene compounds and on an acidity and reactivity basis, theoretically, may be categorized with malonic ester. The initial introduction of low molecular weight primary substituents (R-X less than 4 carbon atoms) into these types of compounds produced a mixture of monoalkylated and dialkylated product with starting material. Such mixtures are known to be difficult to purify by ordinary fractional distillation. The corresponding cyanoacetamides, although solids, are relatively water soluble and also produce a mixture which is difficult to separate by fractional crystallization.

Table II summarizes the results of this work. Since primary alkyl halides were used, dialkylation was the main side reaction detected. *N*-Alkylation was not observed.

Of the 17 compounds listed in Tables III and IV, only compound *2* (*N*-methyl-2,2-diethylcyanoacetamide) has previously been reported in the literature. Fourteen of the 16 compounds were prepared by application of the method of *C*-alkylation described above, utilizing potassium hydroxide in formamide or dimethylsulfoxide or in admixtures of these. Most of the desired compounds are derivatives of either diethyl- or ethylpropylcyanoacetamide and may be derived from their common intermediate ethylcyanoacetamide. Initially all reactions were carried out in formamide because of its lesser tendency toward dialkylation. Furthermore, when ethyl bromide was the alkylating agent, no diethylcyanoacetamide was produced and purification was easily accomplished. In earlier work, therefore, conversion to dialkylated compound was accomplished in a separate step, starting with purified ethylcyanoacetamide in formamide solution. In several instances it was possible to add the second set of reagents and to introduce the second alkyl substituent after having allowed the first stage to become essentially neutral, without separating and isolating the intermediate. Since dialkylation is of no concern when diethylcyanoacetamide is the desired product, and since dimethylsulfoxide supported a more vigorous reaction and gave excellent yields, this solvent was ultimately chosen for dialkylation in those situations when the alkyl groups were identical. When they

Received April 25, 1966, from the Pharmaceutical Chemistry Laboratories, College of Pharmacy, University of Texas, Austin 78712.
Accepted for publication September 20, 1966.
Presented to the Medicinal Chemistry Section, A.PH.A. Academy of Pharmaceutical Sciences, Dallas meeting, April 1966.

TABLE I.—PHARMACOLOGICAL DATA ON CYANOACETAMIDES STUDIED[a,e,f]



Compd.	R′	R″	Max. Tolerated Oral Dose, mg./Kg.	SED[b]	SMES[c]	RSCM[d]
2658 L	C_2H_5	C_2H_5	200	0	3+	4+

[a] The male albino rat, dosed orally, was used in all the tests. [b] SED, sedative: the ability of the compound to control the stimulating action of 30 mg./Kg. ephedrine sulfate injected subcutaneously is recorded on a kymographic record. [c] SMES, supramaximal electroshock test: the ability of the compound to abolish the hind limb extensor reflex produced by a current of 150 ma. delivered for 0.3 sec. to the brain *via* the optic pathway is recorded. [d] RSCM, rat subcutaneous pentylenetetrazol test: the ability of the compound to block completely the convulsions produced by pentylenetetrazol injected subcutaneously at a level of 70 mg./Kg. is noted. [e] Rating system: in all the tests, 0 to + indicates essentially no detectable activity of the compound to produce the desired effect. A rating of 2+ to 3+ indicates fair to good activity. A 4+ rating indicates complete control of desired effect and from an activity standpoint is the maximum attainable rating. [f] These pharmacological data abstracted from a personal communication to R. F. Doerge from R. W. Cunningham, then with Lederle Laboratories, Division of American Cyanamid Co.

were dissimilar, the usual order of alkylation for this series became ethyl- then propyl-, stepwise in the same reaction vessel, in formamide, without isolation of the intermediate.

Both *N*-methyl-2-ethylcyanoacetamide and *N*-dimethyl-2-ethylcyanoacetamide failed to react with the addition of the second portion of base and propyl bromide. Reversal of the order of introduction of the alkyl groups provided *N*-dimethyl-2-ethyl-2-propylcyanoacetamide in a slightly depressed yield but the corresponding *N*-methyl-compound was obtained in low yield and poor quality. Conversion of *N*-methylcyanoacetamide by a single molar quantity of propyl bromide gave a mixture of propyl- and dipropyl-substituted product. The desired *N*-methyl-2-ethyl-2-propylcyanoacetamide was ultimately obtained in fair to good yield by ethylating *N*-methyl-2-propylcyanoacetamide.

Generally, enolate salts appeared to be considerably less soluble in dimethylsulfoxide than in formamide, and their solubility was noted to decrease with increase in the weight of the *N* substituent. In those instances when precipitation of the enolate became troublesome, it was found advantageous to add the more polar formamide as an aid in solvation. Homogeneous solutions or satisfactory results were obtained in most instances with a 1:3 ratio of formamide to dimethylsulfoxide.

The propylation of 1-(2-cyanobutyryl)-piperidine in formamide failed until a mixture of formamide and dimethylsulfoxide was used.

Acylation of Amine by Ester.—Several of the desired members of the series arose by applying the aminolysis reaction to unsubstituted ester to obtain *N*-alkylated unsubstituted amide which was later *C*-alkylated. All of the piperidine, pyrrolidine, and morpholine derivatives were prepared in this manner. Of these unalkylated amide intermediates only 1-(2-cyanoacetyl)-pyrrolidine has not been found in the literature.[1]

[1] Compound *10* is not shown in tables.

Acylation of Amine by Amide.—The Galat-Elion acylation method (10) applied to disubstituted cyanoacetamides produced three substances not previously reported in the literature (Table IV): *N* - methyl - 2,2 - diethylcyanoacetamide,[2,3] *N*-methyl - 2 - ethyl - 2 - propylcyanoacetamide,[2] *N* - propyl - 2,2 - diethylcyanoacetamide, and *N*-propyl - 2 - ethyl - 2 - propylcyanoacetamide. Additionally, attempts were made to prepare *N* - dimethyl - 2,2 - diethylcyanoacetamide[2] and 1 - (2- cyano - 2 - ethylbutyryl) - piperidine.[2] The heating period varied from 4 to 6 hr. but occasionally, guided by the lack of precipitated ammonium chloride, the reaction time was extended overnight. The external (mantle) temperature was maintained so that the liquid appeared to be boiling gently, usually between 190° and 230°. Each reagent was melted separately and maintained in a molten condition for a period of time to insure minimal water content. Since disubstituted cyanoacetamides sublime readily, an attempt was made to counteract this loss by starting with 10% excess. Attempts to *N*-dialkylate using secondary amine salts, in a similar manner, repeatedly gave depressed yields of *N*-monoalkylated product. Considerable dealkylation apparently had taken place under these conditions (11, 12). The carbon and hydrogen analysis of *N*-methyl-2-ethyl-2-propylcyanoacetamide prepared by this method was no better than when prepared by *C*-alkylation as in Table III.

EXPERIMENTAL[4]

Unsubstituted amide intermediates were prepared from ester by a method similar to that to

[2] Preparation of this compound is possible *via* the unsubstituted ester to *N*-alkylated amide, then *C*-alkylation *via* the novel method.

[3] Known compound (9).

[4] Melting point determinations were made using a Thomas-Hoover Uni-Melt apparatus and are uncorrected. Elemental analyses were conducted by Dr. K. W. Zimmerman, University of Melbourne, Melbourne, Australia, and by Schwarzkopf Microanalytical Laboratory, Woodside, N. Y.

be given for 1-(cyanoacetyl)-pyrrolidine. Unspecified, known, *C*-alkylated intermediates were prepared by the *C*-alkylation methods below.

1 - (2 - Cyanobutyryl) - piperidine.—Potassium hydroxide (26 Gm. of 85%; 0.4 mole) and 1-(cyanoacetyl)-piperidine (61 Gm.; 0.4 mole) were added to 120 ml. of formamide contained in a 500-ml. Pyrex pressure-bottle.[5] The container was stoppered and placed on a Parr apparatus, and shaken for 1 hr. at which time ethyl bromide (48 Gm.; 0.44 mole) was added and shaking resumed. The container and cage soon became hot and potassium bromide began to precipitate. After 4 hr. of shaking, the reaction was essentially completed and had cooled. The bromide was removed and the filtrate diluted with a volume of water equal to about 1/4 of its original volume. Refrigeration (−10° to −17°) for 12 to 24 hr. gave 60 Gm. (83%) of crystals which when recrystallized from a mixture of ether and petroleum ether or from isopropanol–water had a melting point of 59–60°.

Anal.—Calcd. for $C_{10}H_{16}N_2O$: C, 66.63; H, 8.95. Found: C, 67.17; H, 8.97.

N - Dimethyl - 2 - ethylcyanoacetamide.—*N* - Dimethylcyanoacetamide (22.4 Gm.; 0.2 mole) and potassium hydroxide (13.0 Gm. of 85%; 0.2 mole) were added to 40 ml. of formamide contained in a 500-ml. Pyrex pressure-bottle. The container and its contents were shaken on a Parr apparatus for 1 hr., after which time ethyl bromide (24.0 Gm.; 0.22 mole) was added and the shaking resumed. The exothermic reaction began in a few minutes. The shaking was continued for 4 hr. during which time potassium bromide precipitated and the reaction mixture cooled. After the shaking period, the precipitate was separated, the reaction mixture and the filtrate neutralized with diluted hydrochloric acid, then transferred to a Rinco evaporator operating under vacuum and steam. After the low boiling substances had been removed, the

[a] Conrad and Zart report m.p. 102° (9). [b] Also prepared by *C*-alkylation method.

material was fractionated under reduced pressure, using a 14-cm. heated column with multiple receiver. Pure *N*-dimethyl-2-ethylcyanoacetamide distilled between 120–121° at 4 mm. pressure (n_D^{23} = 1.4616, 13.5 Gm.; 48.3%).

Anal.—Calcd. for $C_7H_{12}N_2O$: C, 59.97; H, 8.63. Found: C, 60.02; H, 8.65.

4-(2-Cyanobutyryl)-morpholine.—This compound was prepared in 69% yield from 4-(cyanoacetyl)-morpholine in the same manner as *N*-dimethyl-2-ethylcyanoacetamide above, except that the formamide solvent was increased to 80 ml. for 0.2 mole (b.p. 164–165° at 4 mm., n_D^{24} = 1.4915).

Anal.—Calcd. for $C_9H_{14}N_2O_2$: C, 59.32; H, 7.74. Found: C, 59.47; H, 7.91.

1-(2-Cyanobutyryl)-pyrrolidine.—This substance was prepared in 70–89% yield from 1-(cyanoacetyl)-pyrrolidine in an identical manner using 80 ml. of formamide for 0.2 mole (b.p. 160–161° at 8 mm., n_D^{24} = 1.4868).

Anal.—Calcd. for $C_9H_{14}N_2O$: C, 65.03; H, 8.49. Found: C, 65.18; H, 8.20.

N - Methyl - 2 - ethyl - 2 - propylcyanoacetamide.[6]—Except for the change of starting amide *N*-methyl-2-propylcyanoacetamide (56.8 Gm.; 0.4 mole) the preparation was almost identical with that for 1-(2-cyanobutyryl)-piperidine. The filtered reaction product was neutralized with a minimum of diluted hydrochloric acid. Sufficient isopropyl alcohol was then added to obtain a homogeneous solution which was chilled to produce crystals (55 Gm.; 81.8%). The melting point after recrystallization was 86.5–87.5°.

Anal.—Calcd. for $C_9H_{16}N_2O$: C, 64.25; H, 9.59. Found: C, 64.52; H, 10.38.

N - Methyl - 2 - propylcyanoacetamide and N-Methyl - 2,2 - dipropylcyanoacetamide.—Potassium hydroxide (13.0 Gm. of 85%; 0.02 mole) and *N*-methylcyanoacetamide (19.6 Gm.; 0.2 mole) were added to 60 ml. of formamide contained in a 500-ml. Pyrex pressure-bottle. The container was stoppered, placed on a Parr apparatus, and shaken for 1 hr. The dissolution was exothermic and complete, and gave an orange-colored solution. Propyl bromide (27 Gm.; 0.22 mole) was added and the two-phase mixture returned to the shaker. Within a few minutes the container and its protective cage became warm, and potassium bromide began to precipitate. The shaking was continued for 4 hr., after which time the bromide was removed and the filtrate shaken with an equal volume of hot water. The resulting two layers were separated and when chilled (−10° to −17°) for 12 to 24 hr. yielded crystals.

Alternatively, the filtrate was diluted with a volume of water equal to about 1/4 of its original volume and refrigerated as above. Extraction of the resulting crystals (16 Gm.; 57%) with hot water gave 41% of *N*-methyl-2,2-dipropylcyanoacetamide and 16% of *N*-methyl-2-propylcyanoacetamide based on starting amide. The latter was recrystallized from aqueous ethanol or from diisopropyl ether, m.p. 65.5–66.5°.

Anal.—Calcd. for $C_7H_{12}N_2O$: C, 59.97; H, 8.63. Found: C, 60.07; H, 8.55.

N-methyl-2,2-dipropylcyanoacetamide was recrystallized from hot water or hot aqueous ethanol, m.p. 111–112°.

[6] Also prepared by acylation of the amine by the amide.

Anal.—Calcd. for $C_{10}H_{18}N_2O$: C, 65.89; H, 9.98. Found: C, 66.10; H, 9.80.

N - Dimethyl - 2,2 - diethylcyanoacetamide.—*N*-Dimethylcyanoacetamide (22.4 Gm.; 0.2 mole) and potassium hydroxide (13.0 Gm. of 85%; 0.2 mole) were added to 80 ml. of solvent (formamide–dimethylsulfoxide, 1:3). At the end of 2 hr. shaking on a Parr apparatus, a small amount of basic reagent remained undissolved, and some metal enolate had precipitated. To this mixture, contained in a Pyrex glass pressure-bottle, was added ethyl bromide (24.0 Gm.; 0.22 mole) and the shaking continued. As the ethyl bromide reacted and the temperature rose, all insoluble material dissolved, and the mixture became a biphasic liquid. As the reaction progressed, potassium bromide precipitated and the liquid became homogeneous. At the end of 4 hr. insoluble bromide was removed and the filtrate returned to the reaction flask. The pattern of adding reagents was repeated: potassium hydroxide (13.0 Gm. of 85%; 0.2 mole) was added and the container shaken for 1 or 2 hr. Ethyl bromide (24.0 Gm.; 0.22 mole) was added and the mixture shaken for an additional 4 hr., after which time the insoluble bromide was removed. The filtrate was diluted with a volume of water equal to about 1/4 of its volume, neutralized with diluted hydrochloric acid, and extracted with 3 or more portions of ether. The combined ether extract was washed with water and dried over anhydrous sodium sulfate. Ether solvent was removed *via* the Rinco evaporator under reduced pressure. The residual oil was fractionally distilled under reduced pressure using a Fabco microdistillation apparatus with a heated column of about 14 cm. and a multiple receiver. Alternatively, the filtrate, after the removal of bromide, was neutralized with diluted hydrochloric acid, treated at the Rinco evaporator to remove low boiling substances, then fractionally distilled. Solvents distilled prior to the product. The yield was 48% of pure *N*-dimethyl-2,2-diethylcyanoacetamide obtained between 92–93° at 7 mm. pressure (n_D^{23} = 1.4606).

Anal.—Calcd. for $C_9H_{16}N_2O$: C, 64.25; H, 9.59. Found: C, 64.31; H, 9.77.

N - Dimethyl - 2 - ethyl - 2 - propylcyanoacetamide.—This compound was prepared in the same manner as *N*-dimethyl-2,2-diethylcyanoacetamide. Propyl bromide (27.0 Gm.; 0.22 mole) was added in the first step and ethyl bromide (24.0 Gm.; 0.22 mole) in the second. The crude yield was 44%; the pure product had a b.p. range of 111–112° at 4 mm. pressure (n_D^{23} = 1.4605).

Anal.—Calcd. for $C_{10}H_{18}N_2O$: C, 65.89; H, 9.96. Found: C, 66.31; H, 10.24.

1 - (2 - Cyano - 2 - ethylvaleryl) - piperidine and 1 - (2 - Cyano - 2 - ethylvaleryl)-pyrrolidine.—These compounds were both prepared in a manner analogous to the preparation of *N*-dimethyl-2,2-diethylcyanoacetamide except that since the starting materials were 1-(2-cyanobutyryl)-piperidine and 1-(2-cyanobutyryl)-pyrrolidine, respectively, only one step with base and alkyl halide was necessary. 1 - (2 - Cyano - 2 - ethylvaleryl)-piperidine was obtained almost quantitatively; the pure material boiled at 137–138° at 3.5 mm. pressure (n_D^{23} = 1.4829).

Anal.—Calcd. for $C_{13}H_{22}N_2O$: C, 70.23; H, 9.97. Found: C, 69.77; H, 9.93.

1 - (2 - Cyano - 2 - ethylvaleryl) - pyrrolidine (70–80% yield) distilled between 133–134° at 3 mm. pressure (n_D^{24} = 1.4810).

Anal.—Calcd. for $C_{12}H_{20}N_2O$: C, 69.19; H, 9.68. Found: C, 69.43; H, 9.73.

1 - (2 - Cyano - 2 - ethylbutyryl) - piperidine, 1-(2 - Cyano - 2 - ethylbutyryl)-pyrrolidine, and 4-(2 - Cyano - 2 - ethylbutyryl) - morpholine.—All three were prepared and isolated in essentially the same manner as *N*-dimethyl-2,2-diethylcyanoacetamide, with small differences in detail. 1-(2-Cyano-2-ethylbutyryl)-piperidine was prepared from 1-(cyanoacetyl)-piperidine by dialkylation, without isolation of the intermediate, in dimethylsulfoxide (60 ml./0.1 mole). The yield was 82–95%. The pure liquid distilled between 122–123° at 6 mm. (n_D^{23} = 1.4846).

Anal.—Calcd. for $C_{12}H_{20}N_2O$: C, 69.19; H, 9.68. Found: C, 69.00; H, 9.56.

1 - (2 - Cyano - 2 - ethylbutyryl) - pyrrolidine was prepared by monoalkylation of 1 - (2 - cyanobutyryl)-pyrrolidine in dimethylsulfoxide solvent (40 ml./0.1 mole). The vigorous reaction was moderated by chilling the enolate suspension to a solid prior to the addition of ethyl bromide. The pure substance boiled between 127–128° at 3 mm. (yield 31–47%, n_D^{24} = 1.4816).

Anal.—Calcd. for $C_{11}H_{18}N_2O$: C, 68.00; H, 9.34. Found: C, 67.84; H, 9.25.

4 - (2 - Cyano - 2 - ethylbutyryl) - morpholine was obtained by dialkylation without isolation of intermediate in formamide (43% yield, 40 ml. of solvent/0.1 mole) or in a somewhat improved yield (55%) in formamide–dimethylsulfoxide mixture (40:60; 100 ml./0.2 mole). The purified product distilled between 138–139° at 5 mm. (n_D^{23} = 1.4858) and solidified on standing, m.p. 35–36°.

Anal.—Calcd. for $C_{11}H_{18}N_2O_2$: C, 62.83; H, 8.63. Found: C, 62.93; H, 8.82.

Acylation of Amine by Ester.—*1-(Cyanoacetyl)-pyrrolidine.*—Chilled ethyl cyanoacetate (22.6 Gm.; 0.2 mole) was added to an excess of pyrrolidine (28.5 Gm.; 0.4 mole) as it was being swirled in a flask. The rate of reaction was controlled by means of an ice bath. As the reaction vigor abated, the flask was permitted to stand with an occasional shaking. Within an hour the reaction mixture solidified. The crystals were collected by filtration. Further amounts of less pure crystals were obtained by chilling the mother liquor. The crude material was recrystallized from isopropanol and after purification melted at 71.5–72.5°. The crude yield with a twofold excess of amine was 90.5%; decreasing the amine to 10% excess depressed the yield to 68%.

Anal.—Calcd. for $C_7H_{10}N_2O$: C, 60.85; H, 7.30. Found: C, 60.42; H, 7.18.

Acylation of Amine by Amide.—*N-Propyl-2-ethyl-2-propylcyanoacetamide.*—The reaction apparatus consisted of a round-bottom, 1-neck distilling flask fitted with a Standard-Taper adapter, the plain end of which passed through a large rubber stopper closing the larger end of an inverted percolator (25 cm., 250 ml.). The flask was heated using a Glas-col mantle controlled by a Powerstat; the approximate temperature of the mantle was monitored using a Fisher pyrometer.

Dry propylamine hydrochloride (28.7 Gm.; 0.3 mole) placed in the dry flask was heated to melt. Mild suction was applied to the top of the inverted percolator. 2 - Ethyl - 2 - propylcyanoacetamide (50.9 Gm.; 0.33 mole) contained in a beaker was melted separately. Both chemicals were maintained molten for a period of time to insure minimal moisture content in order to reduce the hydrolysis reaction.

After pouring the amide into the amine, the temperature was raised and maintained at about 200° for 2 to 4 hr. The partially cooled reaction mixture was diluted with isopropanol and the insoluble ammonium chloride removed by filtration. Sublimed amide and ammonium chloride and condensed amine trapped in the upper chamber of the apparatus were discarded. Evaporation of the isopropanol solution gave a 70–90% yield of crude product. Fractional crystallization employing water and isopropanol enabled the separation of unchanged amide. Pure *N*-propyl-2-ethyl-2-propylcyanoacetamide melted at 65.5–66.5°.

Anal.—Calcd. for $C_{11}H_{20}N_2O$: C, 67.30; H, 10.27. Found: C, 67.61; H, 10.47.

N - propyl - 2,2 - diethylcyanoacetamide.—This compound was prepared in approximately the same manner by heating with the *secondary* amine salt and 2,2-diethylcyanoacetamide (69–78% yield, m.p. 71–71.5°).

Anal.—Calcd. for $C_{10}H_{18}N_2O$: C, 65.89; H, 9.96. Found: C, 65.46; H, 9.85.

N - Methyl - 2 - ethyl - 2 - propylcyanoacetamide.[7]—This substance was prepared by the method above by heating the amide with the *secondary* amine salt. The *N*-methyl product was obtained in 60–62% yield. The analysis of the compound prepared by this method was unacceptable.

SUMMARY

In the course of this investigation 17 new compounds have been synthesized: *N*-methyl-2-propylcyanoacetamide;[8] *N* - methyl - 2 - ethyl - 2 - propylcyanoacetamide; *N* - methyl - 2,2 - dipropylcyanoacetamide; *N* - propyl - 2,2 - diethylcyanoacetamide; *N* - propyl - 2 - ethyl - 2 - propylcyanoacetamide; *N* - dimethyl - 2 - ethylcyanoacetamide;[8] *N* - dimethyl - 2,2 - diethylcyanoacetamide; *N*-dimethyl - 2 - ethyl - 2 - propylcyanoacetamide; 1 - (cyanoacetyl) - pyrrolidine;[8] 1 - (2 - cyanobutyryl) - pyrrolidine;[8] 1 - (2 - cyano - 2 - ethylbutyryl) - pyrrolidine; 1 - (2 - cyano - 2 - ethylvaleryl) - pyrrolidine; 1 - (2 - cyanobutyryl)-piperidine;[8] 1 - (2 - cyano - 2 - ethylbutyryl)-piperidine; 1 - (2 - cyano - 2 - ethylvaleryl) - piperidine; 4 - (2 - cyano - butyryl) - morpholine;[8] 4 - (2 - cyano - 2 - ethylbutyryl) - morpholine. The pharmacological data and structure-activity relationships of 12 of these are discussed in a separate paper to be published.

Several synthetic methods were developed and applied to the preparation of these *N*-substituted-2,2-dialkylcyanoacetamides and *N*-cyclic dialkylated cyanoacetamides. *C*-Alkylation of 2-cyanoacetamide was accomplished by a method which utilized potassium hydroxide and the appropriate alkyl halide in formamide or in dimethylsulfoxide or in mixtures of these. These exothermic reactions were

[7] Prepared also by *C*-alkylation.
[8] Not tested for anticonvulsant activity.

conducted without additional heating, in a stoppered and shielded Pyrex pressure-vessel, by shaking on a Parr apparatus. Both mono- and dialkylations were accomplished within 4 to 8 hr. The results of the influence of several solvent systems and bases on the alkylation reaction are tabulated.

Many 2,2-disubstituted cyanoacetamides prepared by the above method were converted to *N*-alkyl-2,2-dialkylcyanoacetamides by a method similar to that of Galat and Elion (10) for the acylation of amine by amide. While this method was effective for *N*-alkyl derivatives, it failed for *N*-dialkyl products when using secondary amine salts. Recourse to acylation of amine by ester, using appropriate aliphatic secondary amine (or in the instances of cyclic derivatives, pyrrolidine, piperidine, and morpholine), provided the desired amides which were subsequently alkylated at C-2.

Lawsone Derivatives III

Cyclizations Involving Side Chains

By H. MACHATZKE, W. R. VAUGHAN*, CHARLOTTE L. WARREN, and G. R. WHITE

In continuing efforts to prepare a stable 3-ω-bis-β-chloroethyl aminoalkyl-2-hydroxy-1,4-naphthoquinone the preparation and reactions of several ω-substituted alkyllawsones have been examined. The ultimate objective of the research was not achieved as a consequence of unexpectedly facile cyclizations, either of the 3-side chain to the lawsone nucleus or by macrocyclic dimerization. The nature of these cyclizations is discussed, and the structures of the cyclic products are delineated.

THE OBJECTIVES of this continuing research have been discussed in a previous paper (1), and it should be noted in this respect that lawsone derivatives have for a considerable number of years been of interest as potential chemotherapeutic agents, particularly as antimalarials (2–4) and as antitumor compounds (1).

The purpose of the present paper is to report reactions which interfere with the preparation of 3-ω-bis-2′-hydroxyethylaminoalkyl-2-hydroxy-1,4-naphthoquinones. Two types of interfering cyclizations were encountered: (*a*) a previously recognized one in which a 3-ω-chloroalkyl-side chain closes to the 2- or 4-oxygen of 2-hydroxy-1,4-naphthoquinone (lawsone), and (*b*) an unexpected dimerization of a 3-ω-carboxyalkyllawsone to a macrolactide.

* Present address: Department of Chemistry, University of Connecticut, Storrs.

DISCUSSION

Four 3-ω-chloroalkyllawsones were investigated (I) as alkylating agents for bis-β-hydroxyethylamine (diethanolamine). And in each case the reaction desired was simple alkylation of diethanolamine, but in none was this achieved. In the case of I*a* simple cyclization to the 2-hydroxyl, as reported by Moser (4), was observed. But a mixture of II and the isomeric III (8, 9-benzo-7, 10-dioxo-2-oxabicyclo-[4.4.0]deca-1[6], 8[9]-diene and 9,10-benzo-7, 8-dioxo-2-oxabicyclo[4.4.0]-deca-1[6], 9[10]-diene, respectively) was shown to be present. The structure of III is assigned on the basis of its infrared spectrum, microanalysis, and acid isomerization[1] (5) to II. The formation of III in about 10% yield was demonstrated by comparision of the infrared spectrum of the product with spectra of pure II and pure III. And when I*b* was used in place of I*a*, the yield of III increased to about 40% at the expense of II. But when I*c* was used in place of I*a* with diethanolamine a considerably more complex reaction was encountered, with production of III accounting for but 14% of the initial I*c*, and the only other readily characterizable product (IV) being the result of 1,4-addition of diethanolamine to lawsone with reduction. Scheme I represents a rationale for the

[1] *Cf.* conversion of β-lapachone to α-lapachone.

conducted without additional heating, in a stoppered and shielded Pyrex pressure-vessel, by shaking on a Parr apparatus. Both mono- and dialkylations were accomplished within 4 to 8 hr. The results of the influence of several solvent systems and bases on the alkylation reaction are tabulated.

Many 2,2-disubstituted cyanoacetamides prepared by the above method were converted to *N*-alkyl-2,2-dialkylcyanoacetamides by a method similar to that of Galat and Elion (10) for the acylation of amine by amide. While this method was effective for *N*-alkyl derivatives, it failed for *N*-dialkyl products when using secondary amine salts. Recourse to acylation of amine by ester, using appropriate aliphatic secondary amine (or in the instances of cyclic derivatives, pyrrolidine, piperidine, and morpholine), provided the desired amides which were subsequently alkylated at C-2.

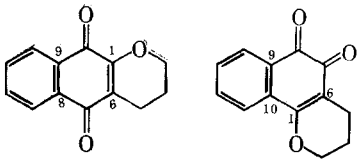
DISCUSSION

Four 3-ω-chloroalkyllawsones were investigated (I) as alkylating agents for bis-β-hydroxyethylamine (diethanolamine). And in each case the reaction desired was simple alkylation of diethanolamine, but in none was this achieved. In the case of I*a* simple cyclization to the 2-hydroxyl, as reported by Moser (4), was observed. But a mixture of II and the isomeric III (8, 9-benzo-7, 10-dioxo-2-oxabicyclo-[4.4.0]deca-1[6], 8[9]-diene and 9,10-benzo-7, 8-dioxo-2-oxabicyclo[4.4.0]-deca-1[6], 9[10]-diene, respectively) was shown to be present. The structure of III is assigned on the basis of its infrared spectrum, microanalysis, and acid isomerization[1] (5) to II. The formation of III in about 10% yield was demonstrated by comparision of the infrared spectrum of the product with spectra of pure II and pure III. And when I*b* was used in place of I*a*, the yield of III increased to about 40% at the expense of II. But when I*c* was used in place of I*a* with diethanolamine a considerably more complex reaction was encountered, with production of III accounting for but 14% of the initial I*c*, and the only other readily characterizable product (IV) being the result of 1,4-addition of diethanolamine to lawsone with reduction. Scheme I represents a rationale for the

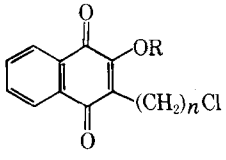
[1] *Cf.* conversion of β-lapachone to α-lapachone.

formation of the two isolated products, III and IV. The structure assigned to IV is inferred from its infrared spectrum, which shows no quinone absorption but which has a broad hydroxyl band, which in turn is confirmed as an alcohol function by preparation of a 1-napthylurethan.

It is noteworthy that a cyclization of I*c* can occur, apparently without the intervention of a base other than a hydroxylic solvent. For when an attempt was made to alkylate bis-β-hydroxyethylsulfide with I*c* by heating at reflux temperature for 10 days in 80% ethanol, a mixture was obtained which was identified as consisting of 78% III (isolation, infrared spectrum, and melting point) and about 20% II. The authors suggest the reactions outlined in Scheme II account for this phenomenon.



II III

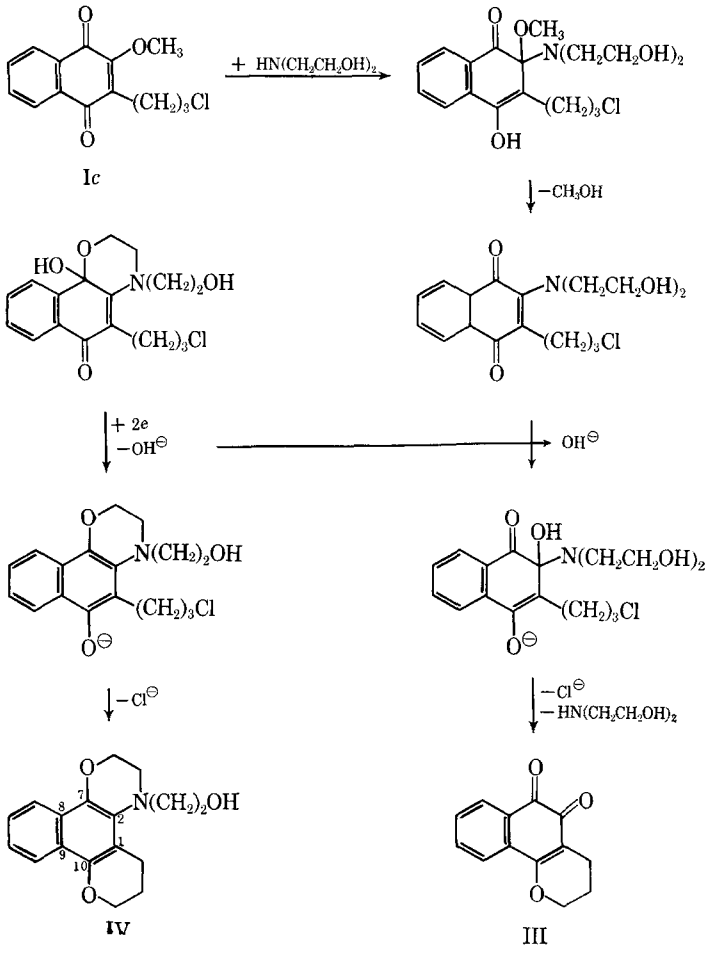


a, $n = 3$, R = H
b, $n = 3$, R = $COCH_3$
c, $n = 3$, R = OCH_3
d, $n = 4$, R = H

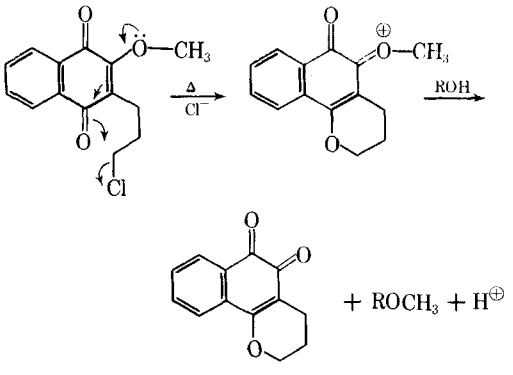
I

The conversion of III to II in the presence of an acid catalyst is an established type of reaction (*cf.* identification of III under *Experimental*). It should be noted that the production of III in the reaction of I*c* with diethanolamine, as suggested in Scheme I may in fact be the result of minor competition of the reactions of Scheme II with the conjugate addition-reduction leading to IV.

Although Fieser (6) has reported that 3-(10-bromodecyl)-2-hydroxy-1,4-naphthoquinone may be converted quantitatively to a tertiary amine by treatment with diethylamine, no characterizable product could be isolated from the reaction between I*d* and diethanolamine. Presumably reactions analogous



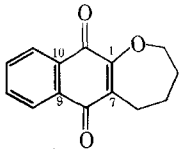
Scheme I



III

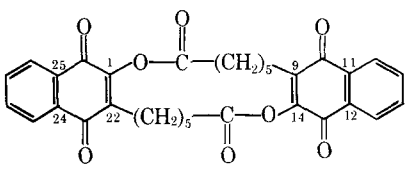
Scheme II

to those proposed in Scheme I occurred, complicated by the fact that competition between cyclizations and dimerizations is to be expected, since intramolecular cyclization would lead to seven-membered rings. That the suggested intramolecular cyclization to a seven-membered ring is not impossible is to be seen in the results of an attempt to convert *Id* to the corresponding iodide by treatment of its sodium salt with sodium iodide in aqueous solution. The only characterizable product, V (9,10-benzo-8,11-dioxo-2-oxabicyclo[5.4.0]undeca-$1^{7},9^{10}$-diene), exhibits an infrared spectrum similar to that of II.



V

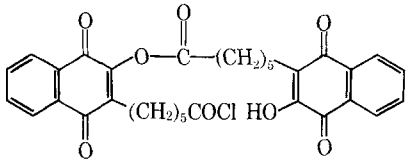
While precedent for the foregoing cyclizations was at hand, the behavior of 6-(2-hydroxy-1,4-naphthoquinon-3-yl)hexanoic acid (VI)(1) with thionyl chloride is entirely unprecedented. In initial experiments involving these two reagents there separated from the mixture a compound, VII, which analyzed for $C_{32}H_{28}O_8$. And acetylated VI (VIII) (1) also reacted with thionyl chloride to produce VII. The analysis and molecular weight of VII leave no doubt that it is the consequence of a dimeric condensation, and the infrared spectrum of VII exhibits absorptions characteristic of the 1,4-napthoquinone system as well as of a vinyl ester. Consequently, it seems most reasonable to describe VII as 11,12,24,25-dibenzo-2,15-dioxa-3,10,13,16,23,26-hexaoxotricyclo-[20,4,$0^{9,14}$]hexaeicosa-$1^{22},9^{14},11^{12},24^{26}$-tetraene (the lactide of VI).



VII

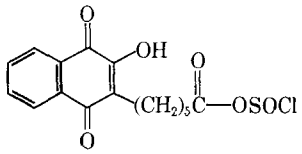
Subsequent attempts to duplicate the original experiments with both VI and VIII led to inconsistent results, and consequently a careful investigation of reaction conditions was undertaken. Of paramount importance in arriving at reproducible results was the observation that VI may be obtained in different forms which depend upon the solvent used for recrystallization: thus, one of these melts at 113° when recrystallized from benzene, another melts at 94° when recrystallized once from aqueous methanol and at 112° upon further recrystallization from the same solvent. Furthermore, the lactide (VII) apparently exists also in different crystal forms: m.p. 240° from benzene–petroleum ether (b.p. 40–60°), and m.p. 210° from benzene (which affords a nearly white product possessing the same infrared spectrum as the higher melting form, but nevertheless giving a mixed melting point with the latter of 224°). The details of this study appear in Table I.

The isolation of two compounds, the acid chloride (X) of the dimeric half ester, and what appears to be



X

the chlorosulfite of VI (XI),



XI

is to be noted (Table I and *Experimental*), but neither substance could be obtained sufficiently pure for microanalysis.

Attempts to convert VII, IX, X, and XI to the bis-β-hydroxyethylamide by reaction with diethanolamine were for the most part unsuccessful and will be reported in a subsequent paper. But by contrast, the simple amide of VI (XII) was readily obtained by refluxing VI with thionyl chloride and pouring the crude product (IX) into excess concentrated aqueous ammonia. The resultant mixture is deep blue and becomes red upon acidification. The anilide (XIII) of VI was also prepared from IX.

The preparation of VIII is readily achieved by treating VII with acetic anhydride–boron trifluoride etherate (1) and VIII may be converted to its acid chloride (albeit not in sufficient purity for analysis) by refluxing VIII with thionyl chloride using high dilution in chloroform. The identity of the product (XIV) as the acid chloride is inferred by examination of its infrared spectrum.

From the data presented here the sequence of reactions leading to production of VII may be inferred to be as follows:

$$\text{VI} + \text{SOCl}_2 \xrightarrow{(a)} \text{XI} \xrightarrow{(b)} \text{IX} \xrightarrow{(c)} \text{X} \xrightarrow{(d)} \text{VII}$$

[a] General conditions: reagents mixed and refluxed 40 min.; evaporated *in vacuo;* benzene added and distilled off. [b] A, benzene–petroleum ether (b.p. 40–60°). [c] If analytically pure, refluxing with thionyl chloride for 40 min. affords about 60% VII, m.p. 240°. [d] Freshly distilled thionyl chloride. Careful purification of the reagent in the usual manner did not change results from those obtained using redistilled commercial product. [e] Anilide (XIV) prepared. (See under *Experimental.*) [f] Chief contaminant is X (infrared spectrum and chemical behavior). [g] Infrared spectrum similar to that of IX but contains additional bands at 1770 cm.$^{-1}$ (v.s.) and 3080 cm.$^{-1}$ (W). [h] Infrared spectrum same as for X but appears to lack band at 686 cm.$^{-1}$. [i] Washed with petroleum ether. [j] Infrared spectrum identical to that of VII but mixed m.p. 224°. [k] Under "high dilution" conditions in refluxing chloroform the product appears to be XI (infrared spectrum and chemical behavior). [l] VI dissolved in 100 ml. benzene and mixture refluxed 90 min. [m] Infrared spectrum of product suggests no reaction occurred, but product "tacky."

Two of the steps in this reaction sequence (*c*) and (*d*) involve acylation of the hydroxyl group of lawsone by an acyl chloride produced *in situ* by the action of thionyl chloride upon an acid. This, of course, is not the usual manner of acylating either an alcohol or enol, and consequently it seemed desirable to obtain evidence that such a process is indeed a reasonable one, and to this end the reactions of lawsone with acetic acid and thionyl chloride were investigated.

When equivalent amounts of acetic acid and lawsone are mixed and refluxed with thionyl chloride, the product consists principally of 2-chloro-1,4-naphthoquinone. But if excess acetic acid is used and the reaction with thionyl chloride is maintained at ice-bath temperature for 3 hr. and then refluxed for 1 hr., a 67% yield of 2-acetoxy-1,4-naphthoquinone is readily obtained. Thus, it is possible to bring about the kind of reaction implied by the dimerization (*c*) and the cyclization (*d*). However, the reason why it appears to be possible to halt the reaction series at IX when the lower melting form of VI is used remains obscure. Likewise the reproducible formation of the two different crystal forms of VII from samples of VI differing in purity also remains obscure.

The bimolecular dehydration of lawsone to di-1,4-naphthoquinon-2-yl ether by dicyclohexylcarbodiimide is an interesting extension of the use of this latter reagent.

EXPERIMENTAL[2]

2-Acetoxy-3-(3′-chloropropyl)-1,4-naphthoquinone (Ib).—To a suspension of 1.0 Gm. of 2-hydroxy-3-(3′-chloropropyl)-1,4-naphthoquinone (*Ia*) (4) in 5 ml. of acetic anhydride was added 1 ml. of boron trifluoride-etherate, and after 20 min. at room temperature, the mixture was poured into water, whereupon yellow crystals separated. The product was recrystallized from aqueous methanol: 1.13 Gm. (95%), m.p. 98–99°.

[2] Melting points uncorrected. Kofler block method indicated by superscript *k* where used. Microanalyses by Spang Microanalytical Laboratory, Ann Arbor, Mich. Infrared spectra of Nujol mulls obtained with Perkin-Elmer model 21 double beam spectrophotometer. The authors are indebted to Mr. B. E. Wenzel and Mr. Gunter Schütze for preparation of certain of these spectra.

Anal.—Calcd. for $C_{15}H_{13}ClO_4$: C, 63.5; H, 4.95; Cl, 12.1. Found: C, 63.72; H, 4.91; Cl, 12.21.

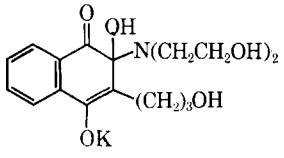
Reaction of 3-(3′-Chloropropyl)-2-hydroxy-1,4-naphthoquinone (Ia) (4) with Diethanolamine.—A solution of 1.0 Gm. of *Ia* (0.004 mole) and 0.42 Gm. of diethanolamine (0.004 mole) in 100 ml. of absolute ethanol was refluxed for 3 hr., during which time the color of the solution changed from red to yellow. Upon cooling and filtering, there was deposited 0.750 Gm. of yellow crystals, m.p. 215–216°, which were identified by mixed melting point as 8,9-benzo-7,10-dioxo-2-oxabicyclo[4.4.0]deca-1^6,8^9-diene (II). [Reported m.p. 220–221°(4).]

Evaporation of the red filtrate to about 5 ml., followed by cooling, afforded orange crystals (0.15 Gm., m.p. range > 15°). This material subsequently was shown by identity of infrared spectra to be identical with 9,10-benzo-7,8-dioxo-2-oxabicyclo[4.4.0]deca-1^6, 9^{10}diene (III) produced in the following experiment.

Reaction of 3-(3′-Chloropropyl)-2-methoxy-1,4-naphthoquinone (Ic) (1) with Diethanolamine.—A solution of 2.65 Gm. of *Ic* (10 mmoles) and 1.05 Gm. of diethanolamine (10 mmoles) in 100 ml. of absolute ethanol containing 1.40 Gm. (10 mmoles) of potassium carbonate was refluxed for 20 hr. The solution was then filtered and concentrated *in vacuo,* the residual oil being dissolved in 5 ml. of absolute ethanol. Addition of dry ether precipitated 1.5 Gm. of a brown crystalline product, m.p. 150° dec.

Anal.—Calcd. for $C_{17}H_{22}KNO_6$: C, 54.4; H, 5.90; K, 10.4; N, 3.73. Found: C, 55.8; H, 5.24; K, 12.1; N, 2.98.

This corresponds approximately to the following possible product (*cf.* Scheme I):



The filtrate from the preceding dilution was evaporated to an oil which was diluted with hydrochloric acid and extracted with ether, which upon concentration afforded orange-red crystals which were recrystallized from absolute ethanol: 0.3 Gm.

(14 %), m.p. 181–182°. The infrared spectrum is the same as that for III isolated above.

Anal.—Calcd. for $C_{13}H_{10}O_3$: C, 72.89; H, 4.71. Found: C, 72.72; H, 4.91.

Upon heating with concentrated hydrochloric acid for 0.5 hr. (5)[1] this substance was converted into II, as shown by mixed melting point (215–216°) and comparison of infrared spectra.

The acidic aqueous filtrate from the preceding isolation of III was neutralized with sodium hydroxide and the mixture then was extracted with ether from which separated a dark oil. This subsequently solidified and was then recrystallized from absolute ethanol: 0.3 Gm. (14 %), m.p. 128–129°, of 3-aza-8,9-benzo-6,11-dioxatricyclo-[8.4.$0^{2,7}$] tetradeca-1^{10}, 2^7, 8^9-triene (IV).

Anal.—Calcd. for $C_{17}H_{19}NO_3$: C, 71.60; H, 6.70; N, 4.91. Found: C, 71.40; H, 6.61; N, 4.82.

Infrared spectrum shows no carbonyl absorption but a broad band in the 3000 cm.$^{-1}$ region. The product upon reaction with 1-napthylisocyanate affords a urethan, m.p. 140–141°.

Anal.—Calcd. for $C_{28}H_{26}N_2O_4$: C, 74.00; H. 5.78; N, 6.18. Found: C, 74.04; H. 5.82; N, 6.45.

Reaction of 3-(4′-Chlorobutyl)-2-hydroxy-1,4-naphthoquinone (Id) (4) with Sodium Iodide–Sodium Carbonate.—A solution of 3.0 Gm. of Id (11.5 mmoles) and 2.0 Gm. of sodium iodide (13 mmoles) in 100 ml. of acetone containing 2.0 Gm. (20 mmoles) of sodium carbonate was refluxed for 20 hr. and then filtered. The filtrate was evaporated *in vacuo* and the residue dissolved in 10 ml. of methanol. Dilution of the methanol solution with 100 ml. of water and acidification with hydrochloric acid caused separation of an oil which crystallized on cooling in the refrigerator. Recrystallization from aqueous methanol afforded 2.5 Gm. of impure crystals, m.p. 64–70°, which could not be further purified by recrystallization. Trituration of this material with dilute sodium hydroxide, until the basic washings were colorless, left a yellow material which was then thrice recrystallized from aqueous methanol: 0. 5. Gm. (19%), m.p. 100–101°, mol. wt. (Rast) 212, 222 (calcd. 228), 9,10-benzo-8,11-dioxo-2-oxabicyclo[5.4.0]undeca-1^7, 9^{10}-diene (V).

Anal.—Calcd. for $C_{14}H_{12}O_3$: C, 73.70; H, 5.31. Found: C, 73.78; H, 5.41.

The infrared spectrum is characteristic of a 1,4-naphthoquinone.

6-(2-Hydroxy-1,4-naphthoquinon-3-yl)hexanoic Acid (VI).—This compound was prepared by a previously published procedure (1). It was usually recrystallized from benzene (m.p. 113°), but recrystallization from aqueous methanol (m.p. 112°) afforded a product which behaved differently with thionyl chloride, although no difference between the two was detectable upon infrared analysis. Two (presumably less pure) products (m.p. 94°) from aqueous methanol or from nitromethane (m.p. 104°) also appeared to behave in still another different manner with thionyl chloride. Consequently, it is important to note the source of VI in the succeeding experiments.

11,12,24,25-Dibenzo-2,15-dioxa-3,10,13,16,-23,26-hexaoxotricyclo[20.4.$0^{9,14}$]hexaeicosa-1^{22},9^{14},-11^{12},24^{25}-tetraene (VII) (Lactide of VI).—The following procedure is typical, and results of runs with VI of various origins are shown in Table I.

A mixture of VI (m.p. 113° from benzene) (288 mg., 1.0 mmole) and freshly distilled thionyl chloride (1.5 ml., 20 mmoles) was refluxed for 40 min., then evaporated under reduced pressure to dryness, the last traces of thionyl chloride being removed by addition and distillation of benzene. The solid residue (252 mg., 93.0%) was recrystallized from benzene–petroleum ether (b.p. 40–60°) to give 179 mg. (66%) of VII as yellow crystals, m.p. 244°. Mol. wt. calcd.: 540.5. Found (Rast): 515.

Anal.—Calcd. for $C_{32}H_{28}O_8$: C, 71.15; H, 5.23. Found: C, 71.41; H, 5.43.

Using essentially the same procedure for VIII, the acetyl ester of VI (1), VII was produced in 75% yield, m.p. 238–240°, with infrared spectrum identical to that of VII prepared from VI.

6-(2-Hydroxy-1,4-naphthoquinon-3-yl)hexanoyl Chloride (IX).—Most attempts to prepare IX from VI by treatment of the acid with thionyl chloride without resorting to high-dilution conditions afforded only VII. However, reactions which lead to IX from VI are recorded in Table I, the product never being obtained pure, but its existence being inferrable from infrared analysis and subsequent reaction. It should be noted that the α-methyl derivative of IX has been obtained from the α-methyl derivative of VI without the difficulties encountered in the present work (7).

6-{2-[6′-(2′-Hydroxy-1′,4′-naphthoquinon-3′-yl)-hexanoyl]-1,4-naphthoquinon-3-yl}hexanoyl Chloride (X).—This compound was not isolated in sufficiently pure condition for microanalysis. Its existence is inferred from its infrared spectrum which contains a very strong peak at 1770 cm.$^{-1}$ (vinyl ester carbonyl) and a band at 3080 cm.$^{-1}$ (hydroxyl). Otherwise the spectrum resembles the spectrum of IX. (See Table I.)

6-(2-Hydroxy-1,4-naphthoquinon-3-yl)hexanoyl Chlorosulfite (XI).—The preparation of XI employed conditions identical to those reported below for XIV, starting from VI, from 2.88 Gm. of which in 100 ml. of chloroform and 200 Gm. of thionyl chloride in 1 L. of chloroform, mixing requiring 72 hr. and refluxing being continued for 48 hr., there was obtained 4.04 Gm. of a brown intractable oil, whose infrared spectrum suggests XI. It afforded positive test for sulfur, supporting the spectrographic inference. The infrared spectrum shows bands at 3400 cm.$^{-1}$, 1745 cm.$^{-1}$, 1400 cm.$^{-1}$, and 1200 cm.$^{-1}$, the last two bands being characteristic of the —SO_2Cl group (8). There is no absorption characteristic of an acid chloride.

Reaction of crude XI (4.04 Gm.). with diethanolamine (10.5 Gm., tenfold excess) at 150° for 2 hr. afforded a dark blue product which was acidified with 200 ml. of concentrated hydrochloric acid, the resulting solution being continuously extracted with ether for 6 days. The ethereal extract was filtered, dried, and evaporated to give a dark red oil, paper chromatography of which (butanol–ethanol–water, 4:3:3) showed but one red band. The infrared spectrum is similar to that of the expected diethanolamide, to be reported in a subsequent paper.

6-(2-Hydroxy-1,4-naphthoquinon-3-yl)hexanamide (XII).—A mixture of 4.00 Gm., (1.38 mmoles) of VI and freshly distilled thionyl chloride (70 ml.) (*cf.* Table I, for preparation leading to IX) was refluxed for 40 min. and then concentrated under reduced pressure to an oil (IX) which was added

dropwise to an ice-cold ammonia solution (130 ml., sp. gr. 0.880) and then stirred overnight. Next 100 ml. of 5% hydrochloric acid was added, followed by addition of 1:1 hydrochloric acid until the pH was 7 (30 ml.). The yellow precipitate (3.51 Gm.) was filtered off and washed with 50 ml. of water, the filtrate being extracted with chloroform (six 25-ml. portions). Evaporation of the chloroform extracts and combination of the residue with the residual solid from filtration followed by recrystallization from toluene afforded 2.76 Gm. (69%) of XII, m.p. 154°.

Anal.—Calcd. for $C_{16}H_{17}NO_4$: C, 66.88; H, 6.11. Found: C, 66.95; H, 5.96.

6-(2-Hydroxy-1,4-naphthoquinon-3-yl)hexananilide (XIII).—A sample of crude IX (0.88 Gm., 0.29 mmole) was dissolved in 12 ml. of benzene to which was added 0.27 Gm. of aniline, the mixture being refluxed for 2 hr. After cooling, the solution was washed with water (three 4-ml. portions), with filtration after each wash, from a copious brown precipitate, which was recrystallized from ethanol–petroleum ether (b.p. 40–60°) to give 0.45 Gm. (44%) of XIII as yellow rhombs, m.p. 159–160°.

Anal.—Calcd. for $C_{22}H_{21}NO_4$: C, 72.71; H, 5.83; N, 3.86. Found: C, 72.45; H, 6.03; N, 3.89; ash, 0.29.

6-(2-Acetoxy-1,4-naphthoquinon-3-yl)hexanoyl Chloride (XIV).—A solution of 3.3 Gm. of VIII (0.01 mole) in 100 ml. of chloroform was dropped into a vigorously stirred refluxing solution of 100 Gm. of thionyl chloride in 1 L. of chloroform over an 8-hr. period. The solvent and excess thionyl chloride were then removed *in vacuo* and benzene added and distilled off. After filtration of the oily residue through sintered glass (residue 100 mg. of dark red crystals) it was dissolved in a solution of ammonia in ethanol and allowed to stand overnight. Upon removal of the solvent there remained a crystalline ester, m.p. 71–73° (reported 72–74°), whose infrared spectrum was superimposable upon that of the ethyl ester of VI (1).

The infrared spectrum of XII has bands at 1880–1800 $cm.^{-1}$, (acid chloride), 1790 $cm.^{-1}$ (vinyl acetate carbonyl), 1685–1695 $cm.^{-1}$ (quinone), 1185 $cm.^{-1}$ (phenolic acetate). No trace of the macrocyclic lactide (VII) was detectable.

Reaction of Lawsone with Acetic Acid in Thionyl Chloride.—A solution of 1.75 Gm. (0.01 mole) of lawsone, 10 ml. of thionyl chloride, and 3 ml. (0.05 mole) of acetic acid was stirred in an ice bath for 3 hr. and then reflxed for 1 hr. Volatile material was removed *in vacuo*, and residual thionyl chloride was removed by addition and distillation of benzene, and then the residue was triturated with cold methanol from which there was obtained on evaporation 0.45 Gm. of 2-chloronaphthoquinone (9) (infrared). The methanol-insoluble pale yellow residue was again treated with methanol, leaving 1.45 Gm., (67%) of 2-acetoxy-1,4-naphthoquinone, m.p. 127–129° K.). [Reported (10) 130°.] With less acetic acid only 2-chloro-1,4-naphthoquinone could be isolated.

Di-1,4-naphthoquinon-2-yl Ether.—To a solution of 1.74 Gm. (0.01 mole) of lawsone in 50 ml. of ethyl acetate and 10 ml. of acetone was added a solution of 0.95 Gm. of dicyclohexylcarbodiimide (0.005 mole) in 20 ml. of acetone. After stirring at room temperature for 2 hr., the solution was filtered, and the filtrate evaporated to dryness. The brown-orange residue was treated with dimethylformamide and filtered, leaving a greenish yellow material which was washed with water, methanol, and ether, and finally was dissolved in chloroform. Addition of ether precipitated 0.45 Gm. of green-yellow crystals, m.p. ~340° dec.

Anal.—Calcd. for $C_{20}H_{10}O_5$: C, 72.75; H, 3.06. Found: C, 72.79; H, 2.84.

Structure–Activity Analysis of Tetrahydrofolate Analogs Using Substituent Constants and Regression Analysis

By ELINOR MILLER and CORWIN HANSCH

The binding to dihydrofolate reductase of a series of substituted pyrimidines and triazines is shown to be dependent on the electron-contributing and lipophilic character of the substituents, as expressed by the parameters π and σ. The configuration of binding is variable, and is determined by the necessity of placing the most lipophilic substituent in a hydrophobic region of the enzyme. When two or more lipophilic substituents are present, competition between them for the hydrophobic site is dominated by the more lipophilic group, while the less lipophilic group contributes to hydrophobic bonding to a slight extent. Suggestions are made for the design of a new tetrahydrofolate analog with possible application as a nonclassical antimetabolite.

RECENT WORK has shown that biological response to congeneric drugs may be quantitatively correlated with molecular structure by means of substituent constants (1, 2). Two of the more useful parameters are Hammett's σ constant for electronic effects of substituents, and π, which is related (3) to the lipophilic character of a substituent ($\pi = \log P_X - \log P_H$ where P_X is the octanol–water partition coefficient of a derivative and P_H is that of the parent molecule). The combination of σ and π, as well as the steric parameter (4) of Taft (E_s), has been applied to a variety of compounds and systems, including the action of penicillins on bacteria (5), the relative sweetness of aromatic nitroamines (6), the binding of organic compounds by proteins (7, 8), the inhibition of photosynthesis by amides (9), the inhibitory activity of phosphate esters on cholinesterase (10), the microsomal demethylation of tertiary amines (11), and the interaction of enzymes and substrates (12).

In the present paper substituent constants and regression analysis are applied to series of substituted pyrimidines (13, 14) (Tables II and III) and triazines (15) (Table IV). These results come from the very interesting and extensive work of Baker and his co-workers on analogs of tetrahydrofolic acid designed to act as nonclassical antimetabolites (16) in the inhibition of dihydrofolate reductase. Baker's early studies were concerned primarily with steric and functional group requirements for enzyme binding (17, 18), but it has recently become apparent that hydrophobic bonding regions on the enzyme may also aid in binding the substrate (15). The purpose of this report is to show that many of Baker's deductions can be treated in a quantitative fashion, and in this way the relative importance of different substituent effects can be more precisely delineated.

Received August 19, 1966, from the Department of Chemistry, Pomona College, Claremont, Calif. 91713.

Accepted for publication September 27, 1966.

The work was supported by research grant GM-07492 from the National Institutes of Health, U. S. Public Health Service, Bethesda, Md.

The authors are indebted to Susan Anderson, Smith Kline & French Research Associate, for determining the partition coefficient of diphenhydramine.

METHOD

If ΔF°_{BR} represents the free-energy change in some biological response which can be attributed to a single physical or chemical reaction, then as a first approximation this free-energy change can be factored as follows:

$$\Delta F^\circ_{BR} = \Delta F^\circ_{L/H} + \Delta F^\circ_{\text{elect.}} + \Delta F^\circ_{\text{steric}} \sim \ln k_{BR} \quad \text{(Eq. 1)}$$

In Eq. 1, k_{BR} may represent a rate or equilibrium constant, while $\Delta F^\circ_{L/H}$ represents that portion of the free-energy change which can be attributed to hydrophobic bonding (19), $\Delta F^\circ_{\text{elect.}}$ represents the electronic contribution, and $\Delta F^\circ_{\text{steric}}$ represents the spatial demands of reactants and products on the free-energy change. The effect of substituents on the change in free energy of a reference molecule can then be represented as in Eq. 2:

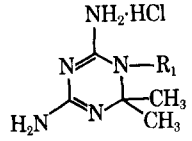
$$\delta_x \Delta F^\circ_{BR} = \delta_x \Delta F^\circ_{L/H} + \delta_x \Delta F^\circ_{\text{elect.}} + \delta_x \Delta F^\circ_{\text{steric}} \sim \delta_x \log k_{BR} \quad \text{(Eq. 2)}$$

Now substituent constants from model systems can be utilized in an extrathermodynamic approach (4) to evaluate substituent effects on k_{BR} as shown in Eq. 3.

$$\log BR \equiv \log \frac{1}{C_x} = k\pi + \rho\sigma + k'S + k'' \sim \delta_x \log k_{BR} \quad \text{(Eq. 3)}$$

In Eq. 3, C_x is the molar concentration of derivative x causing an equivalent biological response under standard conditions. π, σ, and S are extrathermodynamic constants for the respective substituent effects described in Eq. 2. The constants π and σ represent two parameters which are useful for hydrophobic and electronic effects; others can be used (3). This report will not attempt to evaluate steric effects included in S.

TABLE I.—STRUCTURE-ACTIVITY CORRELATIONS FOR TETRAHYDROFOLATE ANALOGS[a]

Pyrimidines	Compd.	Ref.	Eq.	n[b]	r[c]	S.D.[d]
	*1–16*	(13)	$\log \frac{1}{C}$[e] $= -5.002 - 5.162\sigma$ (Eq. 6)	16	0.760	1.076
	1–16	(13)	$\log \frac{1}{C} = -1.970 + 0.302\pi$ (Eq. 7)	16	0.328	1.565
	1–16	(13)	$\log \frac{1}{C} = -6.951 + 0.457\pi - 5.820\sigma$ (Eq. 8)	16	0.903	0.741
$R_3 = NH_2$	*5–16*	(13)	$\log \frac{1}{C} = -7.326 + 0.465\pi - 6.301\sigma$ (Eq. 9)	12	0.885	0.723
$R_3 = NH_2$, $\pi(R_1) = 0$	*5–16*	(13)	$\log \frac{1}{C} = -2.191 + 0.717\pi - 1.022\sigma$ (Eq. 10)	12	0.897	0.688
$R_3 = NH_2$, $\pi(R_2) = 0$	*5–16*	(13)	$\log \frac{1}{C} = -10.806 + 0.598\pi - 11.498\sigma$ (Eq. 11)	12	0.760	1.011
	5–16	(13)	$\log \frac{1}{C} = -8.144 + 0.800\pi_L$[f] $- 7.339\sigma$ (Eq. 12)	12	0.936	0.546
	5–16	(13)	$\log \frac{1}{C} = -6.686 + 0.512\pi_s$[g] $- 7.260\sigma$ (Eq. 12*a*)	12	0.735	1.054
	5–16	(13)	$\log \frac{1}{C} = -7.928 + 0.251\pi_s + 0.737\pi_L - 7.206\sigma$ (Eq. 13)	12	0.953	0.502
$R_1 = OH$, $R_3 = NH_2$	*17–26*	(14)	$\log \frac{1}{C} = -12.350 + 0.424\pi - 8.703\sigma$ (Eq. 14)	10	0.764	0.917
Omit R_2 = ethyl, *i*-amyl	*17–24*	(14)	$\log \frac{1}{C} = -17.864 + 0.103\pi - 13.724\sigma$ (Eq. 15)	8	0.899	0.523
Triazines						
						


pigeon liver	*28–39*	(15)	$\log \frac{1}{C} = -2.488 + 0.962\pi - 2.326\sigma$ (Eq. 16)	12	0.881	0.715
Omit R_1 = ethyl, *i*-amyl	*28–37*	(15)	$\log \frac{1}{C} = -2.215 + 0.861\pi - 1.724\sigma$ (Eq. 17)	10	0.930	0.499
E. coli	*27–36, 38, 39*	(15)	$\log \frac{1}{C} = -2.223 + 0.715\pi - 2.941\sigma$ (Eq. 18)	12	0.880	0.507

[a] All compounds are assayed in a pigeon liver enzyme system unless otherwise noted. [b] n is the number of points used in the regression. [c] r is the multiple correlation coefficient. [d] S.D., standard deviation. [e] C is the micromolar concentration causing 50% inhibition. [f] π_L is the π value of the most lipophilic substituent. [g] π_s is the π value of the second most lipophilic substituent.

The authors have taken σ from the compilation of Jaffé (20), making the assumption that although values for σ will change for substituents on a heterocyclic nucleus, they will do so in a parallel fashion. Using σ^+ or σ_m instead of σ_p did not give improved correlations.

While considerable evidence has accumulated to show that σ is an additive constant, an example illustrating the additive character (3) of log P and π is instructive. The experimental value of log P for a well-known antihistamine[1] is 3.07. Log P for diphenhydramine[1] can be calculated by taking advantage of the additivity of log P and π shown in I.

+ 4.26 + 0.30 −0.98 + 0.50 −0.95 = 3.13 calcd.

I

[1] Marketed as Benadryl by Parke-Davis Co., Detroit, Mich.

In I, log *P* for benzene (21) is taken as 2.13. Hydrogen is 0. The trisubstituted CH is given the value of 0.30 which is obtained by subtracting 0.50 for each methyl group in the isopropyl (π = 1.30) moiety. The value of CH_3 or CH_2 is 0.50. The value of −0.98 is that for an aliphatic methoxy

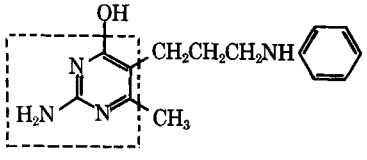
group (3). The figure of −0.95 is that for an aliphatic dimethylamino fragment (3). The good agreement between observed and calculated log P exemplifies the additive character of π.

For the work in hand one does not have or need to use log P for the pyrimidine or triazine unit. Since π is an additive constant when strong group interactions are absent, partition coefficients may be estimated from previously determined values for functional groups.

$$\log P = \pi_1 + \pi_2 \ldots + \pi_i$$

where π_i represents logs of partition values for the components of a molecule. In series of compounds where a portion of the molecule is held constant, that portion may be disregarded and $\Sigma\pi$ for the substituents is then used for the correlation. For example, $\Sigma\pi$ for the molecule in II (number 1 in Table II) was calculated as shown in II and Eqs. 4 and 5.



constant

II

$$\Sigma\pi = \pi OH + \log P\ C_6H_5NH_2 + 3\pi CH_2 + \pi CH_3 \quad \text{(Eq. 4)}$$

$$\Sigma\pi = -0.61 + 0.90 + 3(0.50) + 0.50 = 2.29 \quad \text{(Eq. 5)}$$

$\Sigma\sigma$ was calculated for each molecule by adding the individual σ values. π for the H_2N group was taken as −1.15. For groups such as $C_6H_5CH_2CH_2CH_2$— and $C_6H_5NHCH_2CH_2CH_2$— it was assumed that the phenyl and phenylamino functions would be sufficiently insulated from the ring so that they played no electronic role. Taft's σ^* values (4) were used for the nonaromatic substituents in Table IV. The use of σ from the benzene system is an approximation which is particularly bad for the OH group since in the nitrogen heterocycles keto–enol tautomerism is so important. From the data in Tables II, III, and IV the equations in Table I have been derived by the method of least squares using an IBM 360/40 computer.

DISCUSSION

Rather good correlations were found to result using simple two-parameter equations employing only π and σ. In no instance did a significant improvement in correlation result when either a π^2 or σ^2 term or both π^2 and σ^2 were added. This is what one would normally expect (12) in an *in vitro* system using purified enzymes.

Baker and his colleagues have concluded (13) that the dihydrofolate reductase inhibitors are bound to the enzyme by the interaction of ring electrons with an electron-deficient site, and by hydrophobic interaction of one or more side chains. The equations in Table I strongly support these conclusions. All of the equations have positive coefficients for π, indicating that the more lipophilic the side chain, the more effective the compound is as an inhibitor. The negative coefficient associated with σ means that the more electron-releasing the substituent (the more it tends to increase the electron density on the ring), the more effective the derivative is as an inhibitor. The importance of the use of the two parameters is best seen by considering Eqs. 6–8 in Table I. The two single-parameter equations account for only 58% ($r^2 = 0.58$) and 11% of the variance in the data, while the two-parameter equation accounts for more than 81% of the vari-

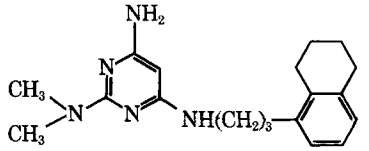
ance. In deriving these equations, only one compound [R_3=OH, R_2=$C_6H_5(CH_2)_4$, R_1=n-C_3H_7] was not used because it gave a poor fit in relation to the other data. The correlation obtained for the other 16 different derivatives in which changes were made in three different substituents is surprisingly good, especially when one considers no account has been taken of steric interactions of substrate and enzyme which classical enzyme theory has characterized as being so highly important (lock and key theory).

In order to evaluate more precisely the role of hydrophobic bonding, the 12 derivatives were taken in which changes were made only in R_1 and R_2. Equation 9 gives the result, treating the substituents R_1 and R_2 in simple additive fashion. First the hypothesis was tested that substituents in only one of the positions (R_1 or R_2) could fit into the hydrophobic area of the enzyme and thus contribute to inhibitory power of the derivative. This was done by setting R_1 equal to zero in Eq. 10, and R_2 equal to zero in Eq. 11. The higher correlation obtained with Eq. 10 would seem to confirm Baker's feeling (18) that the 6-position substituent is unable to contact the hydrophobic bonding area. However, the fact that one obtains essentially the same correlation with Eqs. 9 and 10 seems inconsistent. If, in fact, 6-position substituents contribute nothing to binding, an equation which includes their π values would include a varying and meaningless addition to π and should show a poor correlation. This inconsistency makes doubtful the theory that only one conformation is possible, but the relatively high correlations obtained suggested that hydrophobic binding may be *primarily* controlled by the larger lipophilic substituent. Inspection of the groups in positions 5 and 6, as shown in Table II, reveals that position 5 has more of the larger substituents. This could account for the fact that Eq. 10 gives a better correlation than Eq. 11. Equation 12 gives the best correlation. The hypothesis underlying Eq. 12 implies that substituted pyrimidines bind to dihydrofolate reductase in any of several conformers and that the choice of conformer is determined by the necessity of placing the most lipophilic group in contact with the hydrophobic bonding region of the enzyme. The most lipophilic group thus provides the dominating force in determining the binding configuration. Equation 12 confirms this hypothesis by rationalizing 87% of the variance in the data. Equation 12*a* shows that the contribution to the binding by the second most lipophilic substituent correlates about 50% of the variance in the data. However, when these two terms are included in a single equation (Eq. 13), the slight improvement in correlation is not statistically significant (F test).

Equations 14 and 15 correlate a series of trisubstituted pyrimidines which differ from the previous group chiefly in having an OH group in place of the lipophilic function at R_1. They appear to be intrinsically less active (the intercepts are more negative). Although this series appears very similar in structure to that considered in Eqs. 6–13, combining the two sets of data resulted in a very poor correlation (r = 0.776), indicating that the two series have different modes of binding. The coefficients of Eq. 15 indicate an increased dependence on σ and a decreased importance of π, which might result from a greater dependence on hydrogen bonding. In Eq. 15 the ethyl and isoamyl groups which were poorly correlated have been omitted. The ethyl group was about 30 times less active than predicted and the isoamyl was about 10 times more active than predicted. Why these groups are not adequately accommodated by the correlation is not clear. However, a reasonable suggestion by Baker (14) is that a conformational change may be caused in the enzyme in proceeding from ethyl to n-butyl. This brings out one of the great advantages of regression analysis, however, since the spotting of such exceptional structures indicates areas for further research. This same characteristic of the ethyl and isoamyl groups is apparent again in the substituted triazine series.

The coefficients in the best equations for pyrimidines (Eq. 12) and for the triazines (Eq. 17) are quite similar to each other. Hydrophobic bonding in the triazines seems to be somewhat more important, as indicated by the larger coefficient of π, and electronic bonding is somewhat less important as indicated by the smaller coefficient of σ. In general, the 90% confidence limits on the σ terms are much greater, no doubt because the differences in σ values are small compared to the experimental error in measuring σ. F tests also indicate lower significance for σ terms in the triazines. Of the more than 20 derivatives tested by Baker, the authors have not been able to treat those in which a phenyl group was attached directly to the ring nitrogen because of the uncertainty in electronic interaction. Delocalization of the lone pair electrons on nitrogen by the phenyl ring can greatly affect the lipophilic character (21) of the molecule, as well as the electron density on the ring which appears to react with an electron-deficient species. For the substituents which were considered, species differences in enzymes appear to be rather small (*cf.* Eqs. 16 and 18), although in some instances Baker has found quite marked differences. The species differences mentioned by Baker are, however, supported by the authors' finding that response for isoamyl and ethyl substituents are moderately well predicted for the *E. coli* enzyme (Eq. 18) but not for the enzyme from pigeon liver (Eqs. 14–17).

The equations in Table I should enable one to design more active inhibitors. Greater activity should result from compounds having larger positive $\Sigma\pi$ and more negative $\Sigma\sigma$. To increase the electron density on the ring, one could move the amino group Baker has incorporated into the side chain to a ring position in the 5- or 6-position and attach the largest possible lipophilic substituent to it. The possibility in III seems most logical.



III

In the variation of Baker's general type of inhibitor (III), the authors have added the quite lipophilic cyclohexyl moiety to the phenyl ring, hoping, of course, that the enzymic hydrophobic area is large enough to accommodate it. Another approach

would be to use a pentamethyl- or pentachlorophenyl group on the side chain. Placing methyl groups on one of the amino groups would lower affinity for the aqueous phase, even though hydrophobic bonding in the direct sense might not be possible at this position. We have indicated attachment of the side chain at the 6-position to make maximum use of the electron-releasing effect of the amino function. Since a better correlation was obtained using σ_p rather than σ_m, it is assumed that it is the high electron density on the 1,3,5-positions which is most important. This may not be the case, however. Since so few strong electron-releasing groups were tested, it is not possible to isolate this factor with confidence. In any case, it would be advantageous to separate the two functions so that steric interactions do not twist either of the nitrogen atoms out of the ring-plane and thus prevent effective overlapping of p-orbitals.

While the above design might be very effective in *in vitro* work, such a highly lipophilic compound would probably not make the best drug. For *in vivo* use, one would first have to determine π_0 (2) and then work close to this value, making maximum use of σ, in designing derivatives. The problem of penetration of the blood-brain barrier which appears to be a limiting factor in the clinical use of the tetrahydrofolate analogs, aminopterin and amethopterin (22), could be circumvented by proper lipophilic design of the drug (23).

The good correlations obtained for the structure-activity relationships of these varied series of compounds show that the additive nature of π makes it a useful and reliable parameter in drug design. The large reduction in variance obtained by using the linear combination of σ with π confirms the value of the use of σ constants in heterocyclic systems, even though the values were obtained from benzene. Although it is likely better correlations would be obtained if pKa values for the drugs in question could be used, the values of Jaffé's σ are probably good enough for practical purposes. If one wished to isolate as precisely as possible the steric factors, it would then be essential to determine pKa values. The rather good mathematical correlation the authors have obtained with the wide variety of bulky substituents used by Baker is further evidence for the importance of the role of flexibility in enzyme action (24) which in recent years has become so apparent. The authors' correlations provide a mathematical basis for the essential conclusions of Baker's studies and reinforce these conclusions by deriving them in an independent way.

Analysis of Promethazine Hydrochloride in Syrups

By ALBERT R. SPERLING

An improved method for the determination of promethazine hydrochloride in official syrups is presented. Column chromatography has been used to separate the active ingredient from those of its degradation products that interfere with the present official analysis. Determination and identification are by ultraviolet and infrared spectrophotometry, respectively. The procedure is rapid and accurate. One of the major breakdown products of promethazine hydrochloride in aqueous solution is identified.

THE U.S.P. XVII (1) assay for promethazine hydrochloride syrup is not adaptable to all commercial products. The viscosity of some syrups prevents efficient extraction, and the results of analysis are poor. Another disadvantage of the assay is that certain degradation products of promethazine hydrochloride which may be present will interfere with the analysis. No provision has been made for the separation or removal of these materials. Steele (2) attempted an analysis of various phenothiazine derivatives by using a strongly acidic ion-exchange resin. Good results were obtained on pure materials but the application to dosage forms was less successful. Turi (3) used a diatomaceous earth[1] chromatographic column with 1% tartaric acid as the stationary phase to separate promethazine hydrochloride and other phenothiazines from mixtures containing other therapeutic agents. Only tablet and capsule dosage forms were studied.

The present paper describes a simple method for the chromatographic separation, on diatomaceous earth columns, of promethazine hydrochloride from official syrups, and the removal of interfering degradation products. The active principle is determined and identified by ultraviolet and infrared spectrophotometry, respectively. Also identified is the major degradation product from an aqueous solution of promethazine hydrochloride.

METHOD

Apparatus.—A Beckman DK-2 recording spectrophotometer and chromatographic columns, 20 × 200 mm., were used.

Received July 29, 1966, from the Spectrophotometric Research Branch, Division of Pharmaceutical Chemistry, Bureau of Science, Food and Drug Administration, U. S. Department of Health, Education, and Welfare, Washington, D. C. 20204.

Accepted for publication October 5, 1966.

[1] Marketed as Celite 545 by Johns-Manville Corp., New York, N. Y.

Reagents.—Chloroform, A.C.S., reagent grade; chloroform, A.C.S., reagent grade saturated with water, containing 1% v/v acetic acid; ether U.S.P., saturated with water; 1 *N* sulfuric acid solution; 1 *N* sodium hydroxide solution; diatomaceous earth.

Preparation of Chromatographic Column.—Place a pledget of glass wool at the bottom of a chromatographic column. To 4 Gm. of diatomaceous earth, add 1 ml. of 1 *N* sulfuric acid, and mix well. Transfer to the column and tamp down moderately.

Preparation of Standard Solution.—Dissolve 6 mg. of U.S.P. promethazine hydrochloride reference standard, accurately weighed, in 200 ml. of water-saturated chloroform containing 1% v/v acetic acid.

Preparation of Sample Solutions.—For syrups containing 1 to 2 mg./ml. of active ingredient, dilute the syrup with an equal volume of water in a volumetric flask. For syrups containing about 5 mg./ml. of active ingredient, dilute 1 part of syrup with 4 parts of water in a volumetric flask. To measure the viscous syrup more easily, pipet the appropriate volume of water into the flask and then bring to volume with syrup.

Procedure.—*Assay.*—Transfer a 10-ml. aliquot of sample solution to a 125-ml. separator and allow the pipet to drain well. If necessary flush the pipet with a small amount of water (less than 2 ml.). Extract the solution with three 45-ml. portions of chloroform and filter the extracts through a pledget of glass wool. Evaporate the filtrate to dryness on a steam bath with the aid of a stream of air. Remove immediately from the steam bath, add 2 ml. of water to the residue, and mix well. The entire residue will not dissolve. To this mixture add 3 Gm. of diatomaceous earth and mix thoroughly. Transfer this diatomaceous earth-sample mixture to the previously prepared chromatographic column, tamp moderately, and add a pledget of glass wool. Wash the column with 150 ml. of water-saturated ether and discard this eluate. Rinse the sample beaker and elute the column with water-saturated chloroform containing 1% v/v acetic acid; collect the eluate in a 200-ml. volumetric flask. Dilute to volume with chloroform. Determine the absorbances of the chloroform solutions of the sample and standard solutions in

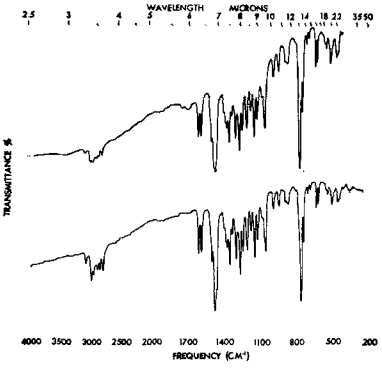

Fig. 1.—Infrared spectra of promethazine standard (bottom) and promethazine isolated from the sample (top).

1-cm. cells at the wavelength of maximum absorption at about 302 mμ and at the wavelength of minimum absorption at 360 mμ, using water-saturated chloroform containing 1% v/v acetic acid as a blank. Calculate the quantity of promethazine hydrochloride in milligrams by the formula

$$\frac{C(A_u^{302} - A_u^{360})}{V(A_s^{302} - A_s^{360})} = \text{mg./ml. of syrup}$$

where A_u and A_s are the absorbances of the unknown and standard solutions at the specified wavelengths, C is the concentration of the standard solution in mg./200 ml., and V represents the volume of syrup present in the 10-ml. aliquot of the sample solution.

Identification.—Transfer a volume from both standard and sample chloroform solutions, equivalent to about 1 to 2 mg. of promethazine, to 125-ml. separators. Wash each solution successively with 10 ml. of 1 *N* sodium hydroxide and 10 ml. of water. Evaporate each chloroform layer to dryness in an agate mortar and dry the residue for 30 min. in a vacuum desiccator over phosphorus pentoxide. Prepare a potassium bromide disk of the residue. Identify the sample by comparing the infrared absorption spectrum of the sample with that of the standard (Fig. 1).

RESULTS AND DISCUSSION

Table I gives the recoveries of U.S.P. reference standard promethazine hydrochloride which was added to a simulated and a commercial syrup. The recoveries agree within 1.4% of the amounts added. Table II shows the average results of analysis of various commercial samples. Samples *A*, *B*, *C*, *E*, and *F* are declared to contain 1.25 mg./ml. and sample *D* 5 mg./ml. Very low results were obtained when syrups *B* and *F* were analyzed by the U.S.P. method, but after dilution with an equal volume of water, results were satisfactory. All of the results agreed within 3.2% of the declared content except sample *A*, which assayed only 70% of the declared amount. Preliminary investigation showed that this low result was due to partial decomposition of the syrup. When an attempt was made to analyze this syrup by the present U.S.P. (1) method, degradation products

interfered with the analysis because no provision had been made for their removal or separation. This interference (Fig. 2, curve 2) can be seen by the change in the ultraviolet spectrum from that of the reference standard (Fig. 2, curve 1). An interfering peak occurs at about 335 mμ and the main peak is shifted to about 292 mμ with an increase in absorptivity. With the proposed procedure, the promethazine is trapped on the diatomaceous earth in the sulfuric acid layer while the ether wash removes the interfering degradation products. The eluate is then determined and identified.

According to Waaler (4) the thermal decomposition products of promethazine in aqueous solution are 10-methylphenothiazine, acetaldehyde, and dimethylamine. Yamamoto and Fujisawa (5) report the same decomposition when a 0.5% solution is

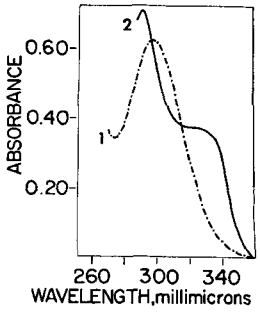

Fig. 2.—Ultraviolet spectra of promethazine in 0.1 *N* acid (curve 1) and in the presence of degradation products (curve 2).

exposed to 20-w. cool white fluorescent light in the presence of air, for a period of 2 or 3 days. In the course of this investigation it has been found that when an aqueous solution of promethazine hydrochloride of similar concentration is exposed to sunlight for longer periods of time, phenothiazine is one of the major degradation products. After extraction of the aqueous solution, this compound was identified by thin-layer chromatography and by its infrared spectrum.

SUMMARY

A procedure has been developed for the analysis of promethazine hydrochloride in syrups. Column chromatography is combined with extraction to separate the active ingredient from interfering degradation products and excipients. Phenothiazine has been identified as one of the degradation products of promethazine.

Evaluation of the Suitability of Butadiene–Acrylonitrile Rubbers as Closures for Parenteral Solutions

By J. SHANKER, M. GIBALDI*, J. L. KANIG, A. P. PARKER†, and L. LACHMAN

The sorption, leaching, tensile, and other properties of a series of butadiene–acrylonitrile rubbers from the medium-high acrylonitrile group were evaluated to determine the suitability of this copolymer system as elastomer closures for multiple-dose vial injectable preparations. These elastomers were found to exhibit considerable sorption of antibacterial preservatives from solution and leaching of extractives to the solutions when compared with a butyl rubber control. Partial identification of the leached materials was possible by chemical analysis. By reducing the amount of accelerator in one of the elastomer formulations by 25 per cent, a 35 per cent reduction in the amount of extractive leached from the elastomer resulted. This rubber formulation also exhibited a lower tensile strength and greater ultimate elongation. The butadiene-acrylonitrile elastomers possessed very low porosity and exhibited a low degree of water vapor transmission.

THERE HAS been considerable development in elastomer chemistry and technology during the last two decades, and a variety of synthetic elastomers are now in common use. A few of the more important uses of elastomers by the pharmaceutical industry are as packaging materials, surgical gloves, tubing for medical use, and vial closures.

These materials make excellent closures for multidose vials containing parenteral solutions because of their unique combination of properties—namely, pierceability and resealability (1). Unfortunately, the favorable qualities are also accompanied by various undesirable characteristics. It has long been known that rubber closures may yield substances to the preparation for which it is used as a stopper, a property known as leaching (2, 3). The closure can also sorb components from the preparation (3). In addition, it has been reported that materials can be lost by vapor transmission through the closure, chemical incompatibility between the product and closure could take place, physical instability of the elastomer could result, and coring or cutting away of rubber particles by the hypodermic needle is a frequent occurrence (1, 4, 5–7).

It is evident from the foregoing brief literature review that most of the studies appearing in the

[a] In addition to the components listed above, sodium and potassium salts, mercaptans, sulfates, peroxides, fatty acids, amines, and disproportionated rosins are present in these copolymers in amounts of 1% or less. [b] 2,6-Ditertiary butyl *p*-cresol.

literature to date have dealt with factors affecting sorption, leaching, and various other properties of several natural and synthetic elastomeric products (1–12). Recently, some information has been presented concerning the influence of mylar, silicone, and epoxy linings on the sorption and leaching tendencies of closures (1, 13). However, except for these reports, there has been very little information presented in the literature regarding the development of rubber closures that would meet the broad and diversified requirements of the pharmaceutical industry.

The present study was undertaken to evaluate the sorption, leaching, and physical properties of a group of elastomers not commonly used as closures for parenteral multiple-dose containers. It was also the intent of this study to explore ways to improve the properties of these elastomers by formulation modification, if the results indicated certain shortcomings for use as closures for multiple-dose vials. The long-range objective of the investigational program is to develop a closure which will possess the major characteristics demanded by the pharmaceutical industry, namely, be nonadditive, nonsorptive, nonreactive, and yet possess the requisite physical properties needed for satisfactory use as a closure for multiple-dose parenteral preparations.

EXPERIMENTAL

Materials

Elastomers.—The elastomers selected belong to the nitrile rubber group and are butadiene–acrylonitrile copolymers.[1] Four of these formulations, coded 1008, 1009, 1010, and 1011, were employed. These were identical in composition, except for the antioxidants and emulsifying agents which are different in each case (Table I). A representative formula is as follows: butadiene–acrylonitrile copolymer, zinc oxide, sulfur, channel black, di-(2-ethyl hexyl)phthalate, diethylene glycol, tetraethylthiuram disulfide,[2] tetramethylthiuram disulfide,[3] stearic acid.

[1] Marketed as Hycar by the B. F. Goodrich Chemical Co., Cleveland, Ohio.
[2] Marketed as Ethyl Tuads by the R. T. Vanderbilt Co., New York, N. Y.
[3] Marketed as Methyl Tuads by the R. T. Vanderbilt Co., New York, N. Y.

The respective nitrile rubber present in each elastomer compound is as follows:

Elastomer Compd.	Nitrile Rubber No.
1008	1022
1009	1032
1010	1042
1011	1002
1008′[4]	1022

The nitrile rubber constitutes the bulk of the elastomer compound. The other ingredients which act as reinforcing agents, colorants, accelerators, plasticizers, and fillers are present in much smaller amounts.

Butadiene–Acrylonitrile Copolymers.—The nitrile rubbers are the basic crude polymers. They are spongy, yellowish-white solid materials. The composition of each polymer is recorded in Table I.

Solvents.—Alcohol U.S.P.; chloroform, certified reagent (Fisher Scientific Co.); petroleum ether (40–60) (Sargent and Co.), double distilled before use; polyethylene glycol 300 (Ruger Chemical Co.).

Components of Elastomer Compounds.—Butadiene–acrylonitrile rubber and di-(2-ethyl hexyl) phthalate (B. F. Goodrich Chemical Co.), a mono- and dioctylated diphenylamines mixture,[5] tetraethylthiuram disulfide, tetramethylthiuram disulfide; sulfur (Olin Mathieson Chemical Corp.); channel black (J. M. Huber, Inc.); diethylene glycol (Carbide and Carbon Co.); stearic acid and zinc oxide (National Bureau of Standards).

Miscellaneous Reagents and Chemicals.—Benzyl alcohol, certified reagent and anhydrous sodium sulfate, certified reagent (Fisher Scientific Co.); *p*-chloro-β-phenylethyl alcohol (Ciba Pharmaceutical Co.); zinc diethyldithiocarbamate[6] and zinc dimethyldithiocarbamate;[7] anhydrous calcium sulfate;[8] epoxy adhesive sealant.[9]

Standard Solutions.—Benzyl alcohol 1.0% (w/v solution) in standard citrate–phosphate buffer (0.275 *M*), pH 4; *p*-chloro-β-phenylethyl alcohol 0.3% (w/v solution) in standard citrate–phosphate buffer (0.275 *M*), pH 4; standard phosphate buffer solutions (0.2 *M*), pH 4–9.

Equipment.—Micro Kjeldahl steam distillation

[4] Elastomer 1008′ is a modified form of 1008. It contains 25% less of tetraethylthiuram disulfide and tetramethylthiuram disulfide, respectively.
[5] Marketed as Age Rite Stalite by the R. T. Vanderbilt Co., New York, N. Y.
[6] Marketed as Ethyl Zimate by the R. T. Vanderbilt Co., New York, N. Y.
[7] Marketed as Methyl Zimate by the R. T. Vanderbilt Co., New York, N. Y.
[8] Marketed as Drierite by the W. A. Hammond Drierite Co., Xenia, Ohio.
[9] Marketed as Hysol by the Hysol Corp., Olean, N. Y.

unit; Beckman ultraviolet spectrophotometer, model DB; Perkin Elmer infrared spectrophotometer, model 421; Beckman pH meter, model Zeromatic; Instron Universal Testing Equipment, model TM; Aminco Winslow Mercury Porosimeter; Hotpack constant humidity chambers; hydraulic cutting press for ASTM tensile studies.

Sorption of Preservatives

Preparation of Samples.—The vulcanizates were obtained in sheets of uniform thickness (0.4 cm.). These were cut into small pieces of uniform dimensions (0.4 × 0.5 × 1.0 cm.^{3}) using a paper cutter. The cut pieces were washed by immersion in a 1% solution of sodium lauryl sulfate using continuous agitation for 10 min. The detergent solution was decanted and the sample was washed repeatedly with fresh warm water. Fifteen to 20 washings were used. The sample was finally washed with 10 successive quantities of distilled water. The washed samples were dried in a hot air oven between 60–70° and stored at room temperature.

Sorption Properties.—Sorption of *p*-chloro-β-phenylethyl alcohol (0.3% solution in citrate–phosphate buffer) and benzyl alcohol (1.0% solution in citrate–phosphate buffer) was investigated. An amount of the prepared vulcanized samples (elastomer compounds 1008, 1009, 1010, 1011, and butyl rubber stoppers[10]) equal to 2.5 Gm. was transferred to a 25-ml. conical flask containing 10 ml. of the preservative solution. Triplicate samples of each elastomer compound were prepared for each preservative solution, and control solutions were run simultaneously. The samples were stored at room temperature and shaken once or twice daily to remove the air bubbles which settle on the elastomer samples. At the end of the experimental period (1–3 weeks) solutions from all the samples were withdrawn. The preservative content was ascertained by spectrophotometric absorbance measurement at 257 mμ and 267 mμ for benzyl alcohol and *p*-chloro-β-phenylethyl alcohol, respectively.

Direct absorbance measurement was not possible due to the presence of leached materials from the several samples. A reasonable degree of purification was obtained by steam distillation of the solutions using a micro Kjeldahl distillation unit. One or 2 ml. of solution was transferred to the distillation unit. The distillate was collected directly in a 25-ml. volumetric flask. About 20 ml. of the distillate was collected each time and the final volume was adjusted to 25 ml. with distilled water. The butyl rubber was found to possess some steam volatile materials, and a correction factor was applied according to the method suggested by Lachman *et al.* (14).

Leaching of Extractives

Leaching behavior of the samples was investigated by allowing the prepared elastomer samples to stand in contact with the selected solvents. Duplicate samples of each of the elastomer compounds and their basic nitrile rubber polymers were prepared by transferring 2.5 Gm. of the sample in a 25-ml. conical flask. To each flask, 10 ml. of distilled water, 10% ethyl alcohol, or 50% aqueous polyethylene glycol 300 were added. The flasks were sealed and stored at room temperature (23–28°) and shaken once or twice daily. At the end of the experimental period (1–6 weeks) solutions containing the leached materials were withdrawn and filtered through a sintered-glass funnel of medium porosity. Their absorbance was checked in the visible and ultraviolet range.

Effect of Surface Area.—Since elastomer compounds 1008, 1009, 1010, and 1011 were found to be less porous than the butyl rubber, it was considered of interest to investigate the effect of surface area on the leaching behavior. Sample 1008 was selected for the study. The investigation was conducted in two ways. In one set of experiments, the weight of the samples was kept constant at 2.0 Gm. and they were cut into large, small, and very small pieces to obtain a small (6.5 cm.^{2}), medium (8.9 cm.^{2}), and large (10.2 cm.^{2}) surface area, respectively. In the other set of experiments, samples weighing 1 Gm., 1.5 Gm., and 2 Gm., respectively, were cut in calculated sizes to obtain the same surface area. All the samples were tested in distilled water at room temperature in accordance with the procedure described earlier.

Effect of pH.—In order to evaluate the effect of pH on the leaching properties of the nitrile rubber vulcanizates, two of the samples which showed the lowest degree of leaching were selected. Butyl rubber was used for comparison. The procedure followed was identical to that in the determination of leaching in the pure solvents. The pure solvent was replaced with the same amount of standard phosphate buffer solution (0.2 *M*) at pH 4, 5, 6, 7, 8, and 9, respectively.

Identification of the Leached Materials

Spectrophotometric Analysis.—Ultraviolet absorption spectra of all the materials used in the synthesis of the basic nitrile rubber polymers and in the several elastomer formulations were obtained in distilled water, 10% ethyl alcohol, and 50% aqueous polyethylene glycol 300. Most of the ingredients are only sparingly soluble in these solvents. Consequently, saturated solutions were prepared by allowing 5 Gm. or 5 ml. of the compound to stand with 25 ml. of the solvent for 48 hr. with occasional shaking. The solutions were filtered through a medium porosity sintered-glass funnel and diluted wherever necessary. The ultraviolet absorption spectra of these solutions was compared with the absorption spectra of the leached material from the basic nitrile polymers and vulcanized elastomer formulations.

Chemical Analysis.—One-hundred grams of elastomer compound 1008 was cut in small pieces. It was washed and dried according to the procedure described previously. The dried sample was transferred to a glass refluxing assembly and refluxed for 2 hr. with 400 ml. of distilled water. The aqueous extract so obtained was transferred, while still hot, to a 1-L. beaker. The remaining elastomer compound was washed twice with 50-ml. portions of hot distilled water. The washings were combined with the first portion. The combined aqueous extract appeared milky with a white colloidal material dispersed in it. The extract was allowed to cool to room temperature. A portion of the extract settled

[10] Butyl Rubber Stoppers manufactured by West and Co., Inc., were used for comparative evaluation.

out as a thin white precipitate, but the rest of it remained suspended. The dispersed material was not retained on ordinary filter paper.

The aqueous extract was transferred to a 1-L. separator. It was extracted with successive 100-ml. portions of petroleum ether by shaking for 25 min. each time. The extraction was continued until 1 ml. of the petroleum ether portion did not leave any observable residue on evaporation to dryness. A total of five extractions was required. All the petroleum ether portions were combined and washed twice by shaking with 50-ml. portions of distilled water. The petroleum ether extract was then dried by allowing it to stand in contact with 50 Gm. of anhydrous sodium sulfate for 24 hr. with occasional shaking. The dried extract was filtered through filter paper, and the solvent was distilled off. The residual solvent was removed by keeping the extract in a vacuum desiccator for 24 hr. The final residue weighed 15 mg. and was a pale viscous liquid. An infrared absorption spectrum of the material was obtained.

The aqueous extract left after extraction with petroleum ether was heated at 80° to remove the residual petroleum ether. It was allowed to cool to room temperature and was extracted repeatedly with 100-ml. portions of chloroform until 1 ml. of the chloroform portion left no residue on evaporation to dryness. A total of four extractions was sufficient. The chloroform extract was washed, dried, and the solvent was removed as described above for the petroleum ether extraction.

The final residue weighed 17 mg. and occurred as a brownish amorphous mass. This was redissolved in a small amount of fresh chloroform. Most of the material dissolved, but a small portion of the insoluble brown residue separated out. Infrared absorption spectrum of the insoluble residue was taken in liquid petrolatum[11] and that of the soluble portion in chloroform.

The aqueous extract left after extraction with petroleum ether and chloroform was distilled under reduced pressure to approximately 50 ml. This was evaporated to dryness and heated strongly on a direct flame. The residue did not decompose or char, indicating that it was an inorganic material. This residue was further analyzed for inorganic components according to standard semimicro techniques.

Physical Testing of Rubber Samples

Water Vapor Transmission and Sorption.—Preparation of Samples.—The vulcanized elastomer compounds were cut into circular disks of uniform diameter (1.8 cm.) from sheets of uniform thickness (0.4 cm.) using an electric cork borer. These disks were washed by immersing them in a 1% solution of sodium lauryl sulfate and stirring for 10 min. The detergent solution was decanted and the sample washed repeatedly with fresh warm water. Final washing was performed with 10 successive quantities of deionized water. The washed samples were air dried (25–28°) and stored at room temperature in a desiccator.

Evaluation of Moisture Sorption.—The prepared disks were individually tied with a thin copper wire and with a portion of the wire, a hook was formed by which the disks were hung in a 90% ± 3% relative humidity cabinet set at 26°. The individual samples were removed from the relative humidity chamber after 1, 2, 3, and 4 hr. and 3, 5, 7, 11, and 71 days and weighed.

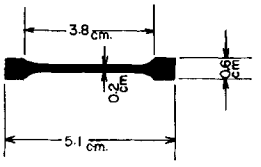

Fig. 1.—Dimensions of dumbbell samples used for the determination of tensile properties.

Evaluation of Water Vapor Transmission.—To 10-ml. glass vials, approximately 5 Gm. of anhydrous calcium sulfate was added. The disks of the elastomer formulations were sealed along the top rim of the vials with an epoxy adhesive sealant and allowed to set for 20 min. The vials were then crimped with three-piece aluminum vial caps. The outer and center portions of the aluminum seal were detached, exposing a uniform surface area of rubber beneath the cap. The sample vials were weighed (0 time sample) and placed into a 90% relative humidity chamber at 26°. Another set of 10-ml. glass vials, which did not contain calcium sulfate, was sealed in the same manner with the four different rubber disks and placed into the relative humidity chamber as controls. Samples with and without anhydrous calcium sulfate were removed from the relative humidity chambers at 1, 2, 3, and 4 hr. and 3, 5, 7, 11, and 71 days and weighed.

Tensile Properties.—The vulcanized sheets were cut into uniform "dumbbell" shaped samples having the dimensions shown in Fig. 1, by use of a hydraulic cutting press. These were tested for tensile strength, ultimate elongation, and tension set in accordance with modified ASTM procedures (15). The modification consisted of altering the minimum distance between grips (bench marks) at the start of the test from that recommended by the ASTM. For all samples with the exception of 1008′, a 2-cm. distance was used, while for 1008′ 0.5 cm. was employed. Using the recommended bench mark distances of the ASTM with the model TM Instron which has a maximum travel of 60 cm. for its tensil fixture, no break could be obtained with any of the samples. Consequently, it was necessary to reduce bench mark distances until a point of rupture within the travel distance of the equipment was obtained. The rate of jaw separation for each of these measurements was 50 cm./min.

The *tensile strength* of a material may be defined as the force required to rupture a dumbbell sample of unit area. It may be calculated as follows:

$$\text{tensile strength} = \frac{\text{force at rupture } (F)}{\text{cross sectional area of unstretched sample } (A)}$$

The *ultimate elongation* (E) of a sample can be defined as the maximum elongation immediately prior to sample rupture and is expressed as follows:

$$E(\%) = \frac{L - L_0}{L_0} \times 100$$

[11] Marketed as Nujol by Plough Laboratories, Memphis, Tenn.

where L = observed distance between stretched bench marks at point of rupture,
L_0 = original distance between unstretched bench marks.

The bench mark for the rubber dumbbell samples is the distance between the jaws clamping the sample.

The *tension set* is determined by stretching the sample at a uniform rate of speed (0.6 cm./sec.) for 15 sec. The sample is held in this stretched position for 10 min. At the end of the 10-min. period, the sample is released and allowed to rest for an additional 10 min. with no external force applied. At the end of the rest period, the distance between the bench marks is again measured. *Tension set* is defined as the extension remaining after a sample has been stretched and allowed to retract in a specified manner, expressed as a percentage of original length.

Porosity Studies.—The vulcanized samples of the butadiene–acrylonitrile copolymer compounds were cut into small cubical pieces (0.4 cm. × 0.4 cm. × 0.4 cm.) and the porosity determined by mercury diffusion using the Aminco-Winslow porosimeter (16).

Each sample is placed in the penetrometer which is in turn attached to the porosimeter. A vacuum pump evacuates the system and fills the penetrometer with mercury. Pore sizes of 17 μ or larger in diameter can be determined under these conditions.

TABLE II.—SORPTION OF *p*-CHLORO-β-PHENYLETHYL ALCOHOL

Sample	Preservative Absorbed, % 1 Wk.	2 Wk.	3 Wk.
Butyl	14.5	15.6	16.9

1011	31.9	35.5	36.2
1008′	34.5	35.0	35.0

[a] The values were obtained after applying correction for the steam volatile impurities leached by the butyl rubber. Corrected absorbance, $A_c = A_{257} - (A_{253} - A_{263})$ (14).

The penetrometer is then transferred to the pressure chamber of the porosimeter where pressures up to 5000 p.s.i. can be applied to the mercury and where pore sizes down to 0.035 μ in diameter can be measured. As the pressure is increased, mercury is forced into smaller and smaller pores, the volumes of which are continuously indicated by the level of mercury in the graduated stem of the penetrometer.

RESULTS AND DISCUSSION

Sorption of Preservatives.—The results of the sorption study are presented in Tables II and III. All the butadiene–acrylonitrile copolymer compounds show considerable sorption of *p*-chloro-β-phenylethyl alcohol and benzyl alcohol from buffered aqueous solutions of the preservatives. There is very little difference in the loss of preservative after 2 or 3 weeks, indicating equilibrium has been attained at 2 weeks or sooner. The amount of *p*-chloro-β-phenylethyl alcohol sorbed is almost twice the amount of benzyl alcohol during the same period of time. Elastomer compound 1008′, the modified sample, showed a degree of sorption similar to that of the rest of the samples belonging to the acrylonitrile group. In comparison to the butyl rubber, the formulations under investigation caused considerably more sorption of the preservatives.

The sorption properties of elastomers is a direct consequence of their ability to "dissolve" other materials. The extent to which a preservative would be sorbed from an aqueous solution would thus depend on the partitioning tendencies of the preservative between water and the elastomer. The long chain, high molecular weight organic molecules of the elastomers preferentially sorb hydrophobic organic materials from aqueous systems. A nonpolar substance, with a limited water solubility, would usually be more soluble in the elastomer composition than in water. Thus, it is reasonable to expect greater sorption of *p*-chloro-β-phenylethyl alcohol than benzyl alcohol which is more polar than the former and has greater water solubility.

It has been proposed that sorption is a function of the basic polymer and is not influenced by the fillers to any considerable extent (17). All the samples evaluated in this investigation showed a remarkably similar degree of sorption as would be expected with acrylonitrile–butadiene ratios in the same relative range. This similar degree of sorption displayed by these formulations suggests that the difference in the molecular structure of the particular

basic nitrile rubber polymers is not large enough to alter significantly their affinity for the preservative molecules.

Leaching of Extractives.—The polymers show a considerable degree of leaching at room temperature in distilled water, 10% ethyl alcohol, and 50% aqueous polyethylene glycol 300. Leaching was observed both from the basic polymers (*i.e.*, the butadiene–acrylonitrile copolymers) and the finished elastomer formulations. The absorption patterns of the leached materials from the butadiene–acrylonitrile copolymers differed from one another as is evident from the ultraviolet absorption maxima presented in Table IV.

The leached materials from the various vulcanized elastomer compounds, unlike the material leached from the butadiene–acrylonitrile copolymers, had identical absorption patterns in all three solvents (Table IV). The degree of absorbance, however, was different with sample 1008 exhibiting the least leaching.

The leached materials from the butadiene–acrylonitrile copolymers could be identified by a comparison of their ultraviolet absorption spectra with that of the component ingredients. The leached materials from all four samples were found to be single ingredients and their identification was relatively simple. A comparison with the wavelengths of maximum absorbance of the component ingredients, presented in Table V, led to the identification of the leached materials. These are recorded in Table VI. The materials leached in distilled water and 10% ethyl alcohol were found to be the same as in 50% polyethylene glycol 300 in the case of basic nitrile rubber polymers 1002 and 1032. In the case of basic nitrile rubber polymers 1022 and 1042, the materials leached in 50% ethyl alcohol and in water could not be identified.

Although the absorption pattern of the leached materials from the various vulcanized elastomer compounds was identical in all three solvents, it was not similar to the absorption pattern of any of the pure component ingredients, and no identification was possible by their comparison. A bulk extract was, therefore, prepared and fractionated into different solubility groups by solvent-solvent extraction. Three different fractions were obtained, namely, a petroleum ether extract, a chloroform extract, and an inorganic portion. The residue from the petroleum ether extract was examined for its infrared absorption in its original form. This gave an indication of the presence of phenyl groups (at 702, 740, 1575, and 1595 $cm.^{-1}$) and ester groups (at 1710–1720 $cm.^{-1}$). The only component in the elastomer formulations containing these groups is di-(2-ethyl hexyl) phthalate. Its presence was confirmed by taking an infrared spectrum of the pure compound which was found to coincide with the petroleum ether extractive.

The residue from the chloroform extract occurred as a brownish mass and appeared to be impure as it did not go into solution completely upon the addition of chloroform. The insoluble residue did not show any identifiable group on the infrared spectrum besides a hydrocarbon chain and could not be identified. The chloroform soluble portion gave an indication of the presence of —C=S groups. One source of these could be the thiuram-type accelerators, *i.e.*, the tetraethyl thiuram disulfide and the tetramethyl thiuram disulfide. However, an infrared spectrum of the pure compound did not resemble that of the extract. It was, therefore,

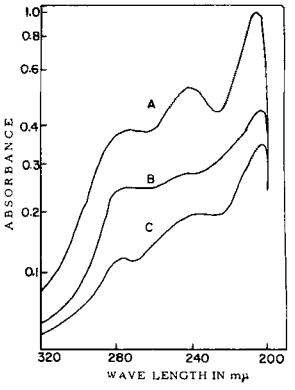

Fig. 2. — Ultraviolet absorption spectra of the aqueous extract of elastomer 1008 and zinc diethyldithiocarbamate. Key: A, aqueous extract diluted with 50% aqueous polyethylene glycol 300; B, saturated solution of zinc diethyldithiocarbamate in distilled water; C, aqueous extract diluted with distilled water.

suspected to be a reaction product of these materials and was identified as a mixture of zinc diethyl/methyl dithiocarbamate. These products are known to be formed during vulcanization process (18). These appear to be the primary leached components responsible for strong absorbance in the ultraviolet region. An ultraviolet absorption spectrum of the aqueous extract obtained after large dilution was in excellent agreement with the absorption spectrum of the dithiocarbamates (Fig. 2). The inorganic portion was identified to be zinc sulfide which is also formed during the vulcanization process.

Based on these findings, elastomer formulation 1008 was modified by reducing the concentration of tetraethyl and tetramethyl thiuram disulfide 25%. This sample, now called 1008′, demonstrated a 35% reduction in the degree of leaching. Figures 3, 4, and 5 represent the results of the leaching study over a period of 6 weeks in distilled water, 10% ethyl alcohol, and 50% aqueous polyethylene glycol 300, respectively. As is evident from the figures, the degree of leaching of the acrylonitrile rubbers is much higher than the butyl rubber samples. Furthermore, the degree of leaching in 50% aqueous polyethylene glycol 300 was much higher than in distilled water or 10% ethyl alcohol.

Leaching of extractives by the elastomers is much more complex than might appear initially. Attempts to prevent or reduce leaching by modification of the formulation most likely has received considerable attention by the rubber stopper manufacturers, but since this has not been reported in the literature, it is difficult to assess the progress made. The degree of reduction in leaching achieved by the modification of the formulation in the present investigation is by no means adequate; nevertheless, the results are quite encouraging, particularly in view of the fact that a reduction of the tetraethyl and tetramethyl thiuram disulfides alone brought about a 35% reduction in leaching. It may be possible to further reduce leaching by decreasing the di-(2-ethyl hexyl) phthalate and zinc oxide which have also been found to be leached from the rubber. There is, however, a finite limitation to the extent of reduction beyond which the physical

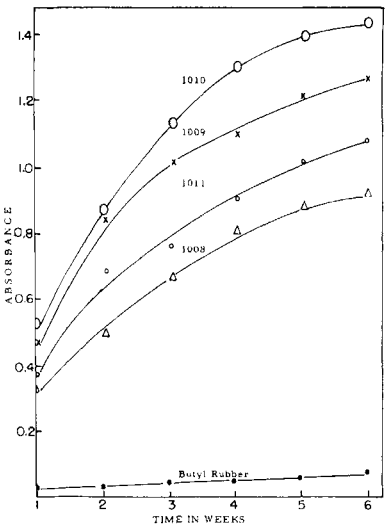

Fig. 5.—Relative leaching from elastomer samples in 50% aqueous polyethylene glycol 300 at room temperature.

properties of the elastomer may be adversely affected.

Effect of Surface Area and pH on Leaching.—The amount of leaching was found to be directly proportional to the surface area and completely independent of weight as illustrated by the graphs in Fig. 6. The leaching increased as the surface area of rubber exposed to the solvent was increased, even though the weight of the sample was maintained constant. On the other hand, samples with the same surface area, but of different weights, had the same degree of leaching. An increase in the surface area of the samples allows greater contact with the solvent, resulting in a faster rate of dissolution. The fact that leaching was not a function of the mass employed indicates that the leaching process in the butadiene–acrylonitrile copolymer compounds is essentially a surface phenomenon.

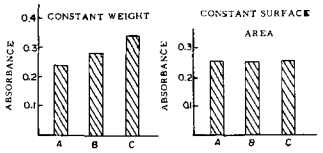

Fig. 6.—Effect of surface area on leaching. Weight: A, 1.0 Gm.; B,1.5 Gm.; C, 2.0 Gm. Surface area: A, 6.5 cm.²; B, 8.9 cm.²; C, 10.2 cm.².

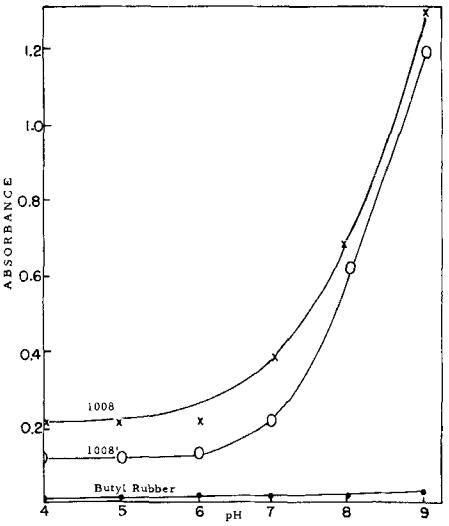

Fig. 7.—Effect of pH on leaching.

This may be a consequence of the low porosity of the samples.

The pH of the solvent had a profound effect on leaching. In the acidic range, the degree of leaching is relatively low. As the pH value increases, an increase in the degree of leaching is observed (Fig. 7).

Water Vapor Transmission.—The data summarized in Table VII indicate that for the storage period of the test, elastomer formulation 1011 shows the greatest tendency for water vapor permeation, while elastomer formulation 1008′ the least.

Water Sorption.—The results from the water sorption studies are summarized in Table VIII. It is evident from these data that the five elastomer formulations show sorption of about the same magnitude. However, it would appear that the relationship found for the water vapor transmission studies exists here too, but the magnitude of the differences are not so great.

Tensile Properties.—It is evident from the data in Table IX that a reduction in the tetraethyl and tetramethyl thiuram disulfide concentration by 25% in formulation 1008′ over formulation 1008 results in a considerably less tight cure (undercure) as evidenced by the lower tensile strength and greater ultimate elongation. From the curves in Fig. 8, illustrating the Hooke's law relationship of the five rubber formulations, this is further substantiated by the lower slope of the curve for formulation 1008′ as compared to formulation 1008. It would be expected that elastomer formulation 1008′ would exhibit higher coring, could be more difficult to insert into vials, and possibly exhibit greater seizure with the glass wall of the vial, and very objectionable compression set.

Porosity Studies.—Porosity measurements performed on the five rubber formulations using the mercury porosimeter at a maximum of 5000 p.s.i. showed essentially no porosity down to 0.035 μ in diameter. This can possibly explain why low water vapor transmission was found for these rubber samples in the water vapor transmission studies discussed earlier. In addition, this low porosity could also be the reason why leaching was found essentially to be a surface phenomenon and not influenced by the weight of the rubber sample.

SUMMARY AND CONCLUSIONS

The information gained from this study may be summarized as follows.

1. Considerable sorption of preservative was found to take place for each of the five elastomer formulations evaluated.

2. The magnitude of the loss of preservative was found approximately the same for the several formulations.

3. Significant extractive was leached from each of the formulations and were identified.

4. A reduction of 25% in the concentration of tetraethyl and tetramethyl thiuram disulfides in elastomer formulation 1008 resulted in a 35% reduction in extractives leached from the elastomer.

5. Water vapor transmission and sorption studies indicated that elastomer formulation 1008′ gave the best results and formulation 1011 the poorest.

6. A reduction of 25% in concentration of tetraethyl and tetramethyl thiuram disulfides in formulation 1008 gave a rubber formulation which exhibited two-thirds the tensile strength and about three and a half times the ultimate elongation. It would be anticipated that closures made from this formulation would not function satisfactorily because of probable undercure.

7. All the elastomer formulations in the study exhibited a very low degree of porosity and small pore size.

Instrumented Rotary Tablet Machines I

Design, Construction, and Performance as Pharmaceutical Research and Development Tools

By E. L. KNOECHEL, C. C. SPERRY, H. E. ROSS, and C. J. LINTNER

Two conventional rotary tablet compressing machines, the Stokes models 540-35 and BB2-27, have been instrumented to measure both compressional and ejectional forces. This was accomplished by attaching strain gauges to key components of the presses and displaying the electrical outputs of the strain gauges on a dual-beam oscilloscope fitted with a camera. The compressional and ejectional forces developed during the tableting operation are thus obtained under dynamic conditions. The design, construction, and performance of these instrumented rotary tablet machines (IRTM) are described and illustrated.

ALTHOUGH COMPRESSED tablets have been in use for many years, fundamental research concerning tableting was initiated only little more than a decade ago. Since that time, attempts have been made to isolate and evaluate the effects of many of the variables involved in the complex process of producing a tablet. Some of the most significant information has been obtained with instrumented single punch tablet machines where the compressional and ejectional forces involved in the tableting operation could be accurately detected, recorded, measured and, if necessary, reproduced.

The instrumentation of single punch compressing machines was first described by Brake in 1951 (1) and later by Higuchi, Nelson, and Busse (2), Gagnon (3), Markowski (4), and most recently by Shotton and Ganderton (5).

By attaching strain gauges to the upper punch of a single stroke Colton 4B press,[1] Brake (1) was able to measure and record the compressional force exerted in the tableting process.

Higuchi and co-workers (2) modified a Stokes model A3 tablet machine[2] and attached strain gauges and load cells directly to the press. This instrumentation permitted the simultaneous recording of any two of the following variables as functions of compression time: (*a*) the absolute force exerted by the upper punch; (*b*) the absolute force transmitted to the lower punch; and (*c*) the absolute displacement of the upper punch. They were also able to determine the force of ejection.

Gagnon (3) attached strain gauges to the lower punch of the instrumented press used by Brake. This enabled Gagnon to detect and measure the lower punch compressional force. Markowski (4) further refined this system to measure the ejectional forces as well as upper and lower punch forces.

Shotton and Ganderton (5) attached strain gauges to the upper punch and lower punch holder of "a Lehman single punch eccentric tableting machine, driven at a constant speed through a Kopp Variator." They were able to measure the upper and lower punch compressional forces as well as the ejectional force.

The value of these instrumented single punch tablet machines in investigating fundamental aspects of tableting has been clearly established (1–21). However, single stroke machines are usually used only for research and pilot batches, for small volume production items, or for large size specialty tablets such as boluses. Today, rotary tablet machines are the conventional type of compressing equipment in the pharmaceutical industry. It was felt that methods were needed to measure and record the compressional and ejectional forces involved in the preparation of tablets on high speed rotary presses under production conditions.

This paper discusses the instrumentation of two widely used rotary tablet presses, a Stokes model 540-35 and a modified Stokes model BB2-27.[2] The instrumentation permits the simultaneous detection and recording of (*a*) the compressional forces during the formation of the tablets in their dies and (*b*) the ejectional forces during the removal of the tablets from their dies. This communication describes and illustrates the design, construction, and performance of these machines.

REQUIREMENTS OF DESIGN

In instrumenting rotary tablet machines, two distinct problems were encountered: (*a*) finding the means of detecting the compressional and ejectional forces and (*b*) finding an adequate method of moni-

Received May 16, 1963, from the operating units of Product Research and Development and Mechanical Engineering, The Upjohn Co., Kalamazoo, Mich.
Accepted for publication August 5, 1966.

toring (*i.e.*, amplifying, displaying, recording, and measuring) the detected forces.

Force Detecting System.—To detect the forces, a system was required that: (*a*) could be readily attached to a conventional high speed rotary tablet press; (*b*) could operate over a wide range of thickness, die fill, overload, and speed settings; (*c*) would not interfere with the normal operations of the press; (*d*) would permit the detection of individual forces for each station; (*e*) would permit the use of any size or shape punches and dies; (*f*) could be readily transferred to other machines of the same type.

Commercially available strain gauges were selected as the force sensors. Because of the simplicity, sensitivity, reproducibility, reliability, versatility, durability, and short recovery time of strain gauges, the first three requirements were fulfilled.

It was obvious, however, that if the punches of each station were to be instrumented in a manner similar to that used to gauge the single punch machines, complex electronic arrangements would be required to "pick up" and transmit the impulses from each set of gauges. If some portion of the press remotely linked to the punches could be gauged to detect the desired forces as they occurred at each station, requirements (*d*) and (*e*) would be achieved. The last requirement would also be fulfilled if the members selected for gauging were conveniently transferable to another machine. Since cast iron and similar materials do not exhibit constant values of the modulus of elasticity[3] and Poisson's ratio,[4] the gauges would have to be attached to steel portions of the press.

Monitoring System.—To monitor the detected electrical impulses, a system was required that: (*a*) could follow at least two simultaneous or exceedingly rapid, consecutive events (*e.g.*, the compression and ejection events); (*b*) could respond to a tablet production rate of at least 2,000 tablets per minute (TPM); (*c*) would follow and record either individual or a consecutive series of compression and/or ejection events; (*d*) could respond to and measure compressional forces ranging from 200 to 10,000 lb.; (*e*) would be sensitive enough to amplify and measure the lower magnitude ejectional force impulses. As the ejectional forces are usually smaller than compressional forces, the electrical output of the gauges would be lower; (*f*) would allow some sort of permanent record to be readily obtained at any time if desired; (*g*) would be versatile, relatively easy to operate, and yet would not interfere with or limit the normal operation of the press; (*h*) would be stable, durable, portable, and self-contained (*i.e.*, not dependent upon a wide variety of associated equipment or procedures, such as photographic development, etc.).

The monitoring system meeting the above requirements consists of a high sensitivity dual-beam oscilloscope, such as a Tektronix model 502 fitted with a Tektronix model C-12 camera.[5] The camera, equipped with a *f*/1.9 lens having a 1 to .9 object-to-image ratio, is fitted with a Polaroid roll film back.

[3] Modulus of elasticity in compression is the constant which expresses the ratio of unit stress to unit deformation for all values of unit stress not exceeding the proportional limit of a material.

[4] Poisson's ratio, also known as the factor of lateral contraction, is the ratio of lateral unit deformation within the elastic limit.

[5] Tektronix, Inc., Beaverton, Oreg.

The electronic traces of two events can be displayed simultaneously on this oscilloscope. Each beam can be adjusted separately over a wide range of vertical sensitivity settings (20 v./cm. to 200 μv./cm.). Because the sweep range selection is large (5 sec./cm. to 1 μsec./cm.), either an individual or a series of impulses can be displayed. The persistency of the image on the screen is controlled by the intensity setting of the beam, and a green filter can be inserted to prolong the image. Impulse heights can be estimated directly from the graticule which is calibrated in 1-cm. divisions with 2-mm. markings at the baselines.

With the camera attached to the oscilloscope, a permanent record can be obtained at any time without interfering with the visual observation of the screen by taking a picture through the beam splitting mirror. The photographic prints, which are obtained in less than 30 sec., reproduce the graticule markings as well as the electronic traces to $^{9}/_{10}$ their original size. Fast speed film permits the capture of very rapidly occurring events or sequences with extremely good resolution. Film which produces high contrast transparencies can also be used.

Portability of the entire monitoring system is obtained by mounting the camera, oscilloscope, batteries, and Wheatstone bridge circuits on a wheeled cart (see Fig. 5).

INSTRUMENT DESIGN AND CONSTRUCTION

This phase of the investigation consisted of selecting the proper press components to be gauged, installing the gauges on the selected components, and confirming that the gauges were responsive to the stresses produced.

The Stokes model 540-35 was the first rotary press to be instrumented in our laboratory.

540-35 Press.—The essential features of the system to detect compressional forces for this press are shown in Fig. 1. The mechanical design of the press overload system is such that oil under preset pressure forces one end of a lever system against an adjustable stop screw. The opposite end of the lever supports the upper compression roll. As tablets are compressed, the force on the punches operates through

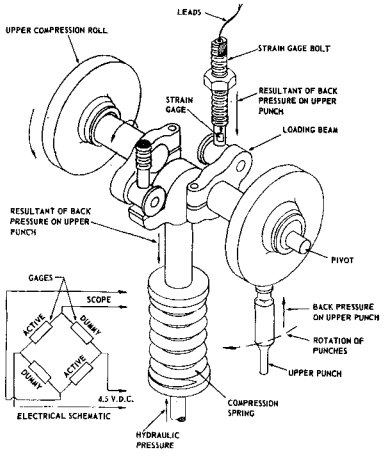

Fig. 1.—Instrumentation of 540-35 press. (Detection of compressional force.)

the upper compression roll and the lever to reduce the force applied to the adjusting screw. To detect compressional forces for this press, semiconductor type strain gauges were attached directly to the lower end of a specially fabricated adjusting screw of the overload system. The gauges, which were attached on opposite sides of the screw, reflect the tablet compressional force as a function of the reduction of force on the screw. The plane passing through the strain gauges must be perpendicular to the axis of the roller on the overload system.

Modifications to the screw included a uniform "necked-down" section for application of the gauges and a hole running axially through the center of the screw to convey the lead wires from the machine. These alterations also increased the sensitivity of the strain gauged area of the screw to stress. The gauges were attached to the screw by the Kulite-Bytrex Corp., Newton, Mass., whose calibration of the screw indicated that an output of 7.5 μv. was generated per input volt per pound of applied force. The geometry of the release mechanism causes a ninefold reduction in detected stress, *i.e.*, 9 lb. of force on the punch reduces the force on the gauged screw by 1 lb. As indicated in the electrical schematic drawing (Fig. 1) for the compressional force instrumentation of the 540-35 press, the input voltage of the Wheatstone bridge circuit is 4.5 v. Thus, with this arrangement an absolute force of 270 lb. applied to the punches will generate a gauge output of 1.0 mv.

When the gauges are connected to the upper beam of the oscilloscope, the force of compression in pounds can be determined for each of the 35 stations as tablet formation occurs. The force of compression is an absolute force at the point of measurement. However, the indicated compressional force values include the friction in the upper punch guide and overload system. This frictional value could not be discerned when the signal on a strain gauged slug in the die cavity and the indicated force on the instrumented machine screw were compared. In this experiment the generation of a known load of 5000 lb. in the die cavity produced an equivalent reading on the instrumented screw.

The instrumentation of the ejection system for this press is shown in Fig. 2. A steel bracket was made to hold the two specially fabricated bolts to which semiconductor strain gauges were attached by the Kulite-Bytrex Corp. This bracket was mounted directly below the ejectional track or cam so that this track was supported .002 in. above the track bed by the strain gauged bolts. The track, although held in position by its original mounting bolts, was free to move vertically. When the track was struck by a lower punch in pushing a tablet from its die, the strain gauged bolts supporting the track detected this event.

Although the gauges were calibrated in terms of millivolts of output per volt of input per pound of applied force (1 mv./4.5 v./25 lb.), the ejectional force determined is a relative measurement of the actual force involved. Because a lever system is involved, an absolute equivalency would be possible only if the punches always struck the ejectional track at the exact same point and accomplished complete ejection when they did. Unfortunately, these conditions cannot be fulfilled because of the following reasons. (*a*) The contact point is changed

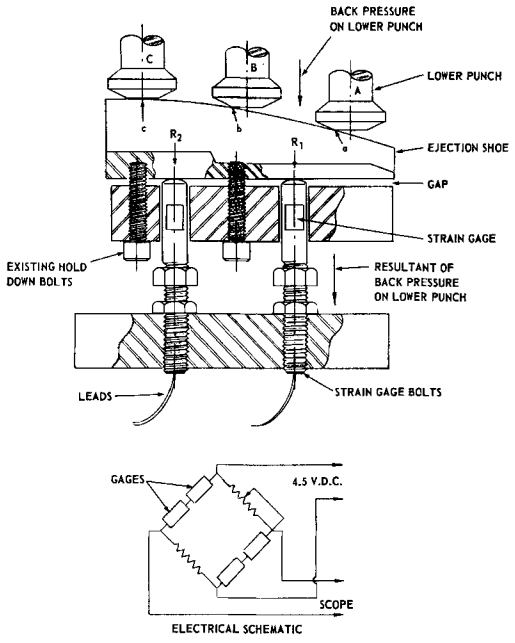

Fig. 2.—Instrumentation of 540-35 press. (Detection of ejectional force.)

when the machine settings, which vary with the formulation being compressed, are altered. (*b*) Random variations in the dimensions of the tools and press components also displace the contact point. (*c*) Complete ejection does not occur instantaneously at the initial point of contact.

When the gauges are connected by a Wheatstone bridge circuit to the lower beam of the oscilloscope (see Fig. 2), an ejectional force impulse will be detected as a single punch "A" strikes the track at point "a." This impulse represents the force of the contact which was applied to the entire track and created a reaction R_1 and R_2 in the two strain gauges. Disregarding the minimal horizontal shear force due to the angle of approach, the sum of R_1 and R_2 equals the applied force of ejection. Therefore, irrespective of the locus of this force on the track, the algebraic sum of the two reactions will always equal the force applied to the track by the punches.

Since two to three punch heads are in contact with the track at any time, the detected electrical impulse is a summation of the forces resulting at various points along the surface of the ejectional track. The literature pertaining to the instrumentation of single stroke presses (2, 4–7, 12, 13, 15) indicates that the force required to propel the tablet from its die is smaller than the force initially required to "break" the tablet loose from the die wall. If this is so, then the force applied by punch "A" as it first contacts the track will be much larger than the forces applied by punches "B" and "C" as they slide across the track. Our studies showed that this is the case. When ejection occurs, the oscilloscopic trace produced shows a sharp initial peak that slowly decreases until the next peak is generated (see Fig. 6).

Since the ejection event occurs somewhat later than the compression event for a given station, the

peak ejectional force impulse is not displayed on the oscilloscope's screen directly below the compressional force impulse for that tablet. Rather, the ejectional impulse is displaced from its compressional impulse by five impulses for the 540-35 press.

One "side" of this 540-35 press was instrumented and thus only the compressional and ejectional forces occurring during this half of the revolution can be monitored. Obviously, the components of the opposite side of the press could be instrumented in a similar manner if desired.

Model BB2-27.—One of the major advantages of the 540 press—its high tablet production rate—unfortunately becomes a distinct drawback in research and development work. Although the press can be slowed to produce as few as 700 TPM, a great deal of tablet stock is still required for a satisfactory run. For this reason a tablet press with a lower tablet output was sought.

A Stokes model 538 press coating tablet machine was converted to a single stage rotary tablet press. The design of this press was originally based on the standard BB2-27 press. By changing the lower cam track design, the converted press performs like one-half of a standard BB2-27 machine. Thus, tablets are made on this press (termed $^1/_2$ BB2-27) in the conventional manner during one-half of the cycle. During the remainder of the cycle following ejection, the punches remain elevated with the lower punches level with the bed surface and the upper punches held in their uppermost position until the rear pull-down tracks are reached. The die filling, compressing, ejecting, and take-off sequence was not altered. Although this press has a capacity of only 375–750 TPM, the operation of this press and a standard Stokes BB2 press are identical. So that speed selections could be standardized, a tachometer was also attached to the press. This machine, then, is a very useful tool for tablet research and development studies and was instrumented in a similar manner to that used for the 540-35 press.[6]

A diagrammatic sketch showing the instrumentation and the electrical schematic outline for the compressional force detecting and monitoring system is shown in Fig. 3. Force applied to the lower punch during tablet formation is transmitted through the lower compression roll and the lever arm to produce a strain on the eyebolt of the pressure regulatory mechanism. The first step to instrument this press was to detach the entire lower, threaded portion of this cast iron eyebolt and to replace it with a specially fabricated steel section. This new part was threaded at the lower end as usual to accept the adjusting wheel and reduced in cross-sectional area at the upper end to increase its sensitivity to stress. Metal foil type strain gauges attached to this "necked-down" area measure the compressional force as tablet formation occurs. Our calibration of the gauges and our calculation of the mechanical advantage indicated that a force of 3,000 lb. on the

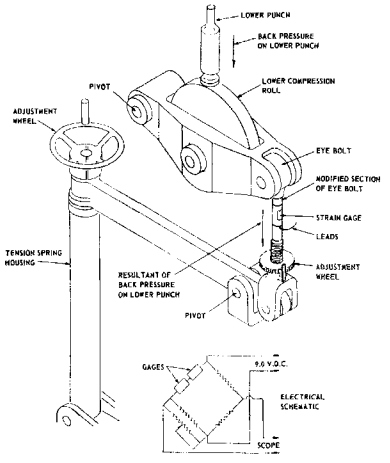

Fig. 3.—Instrumentation of BB2-27 press. (Detection of compressional force.)

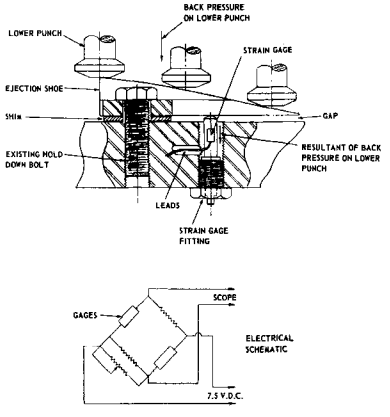

Fig. 4.—Instrumentation of BB2-27 press. (Detection of ejectional force.)

lower punch produced a 1 mv. output by the gauges with 9 v. applied to the Wheatstone bridge circuit.

The installation of detectors to measure the ejectional force for the $^1/_2$ BB2-27 press was similar to that of the 540-35 press. Figure 4 shows this instrumentation and the electrical schematic diagrams for the monitoring system. The standard ejection track was shimmed to .002 in. above the track bed and the existing hold-down screw was used to secure it at the rear end. A bolt to which metal foil strain gauges were attached was positioned to support the front half of the ejectional track. Thus, the force generated when a punch hits the track while ejecting a tablet is transmitted to the bolt. Our calibrations indicated that, at a point directly above the gauged bolt, a force of 250 lb. was required to generate a gauge output of 1 mv. when 7.5 v. were applied to the Wheatstone bridge circuit. At a point near the leading edge of the track, the same force generates twice this electrical output, or 2 mv. However, because two to three punches are always in contact with the track at any given time, the electrical display is a composite of the forces being produced by these punches. Thus, as with the

[6] Subsequent to our developments, the authors found that Brake (1) had briefly explored the partial instrumentation of a Stokes B2 rotary tablet press. Although Brake's instrumentation of the single stroke machine has been mentioned in the literature, to our knowledge no previous reference has been made to his work concerning the measurement of compressional forces on a rotary tablet press. Another investigator working with a B2 press (22) claimed that "during the tableting process the pressures exerted on the punches were measured and increased twice." Unfortunately, just how this was accomplished was not explained. The forces measured ranged from only about 1500 to 4000 lb.

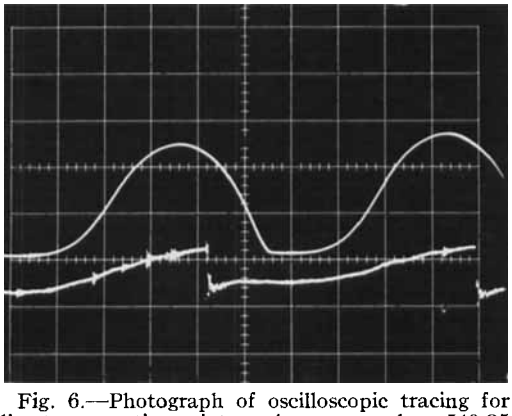

Fig. 6.—Photograph of oscilloscopic tracing for direct compaction mixture *A* compressed on 540-35 IRTM with Force-Flo-Feeder operating at 1000 TPM using 35-$^{7}/_{16}$ in. full oval punches. Calibration: upper trace (C.F.), one large division = 2700 lb.; lower trace (E.F.), one large division = 25 lb.; sweep, 20 msec./large division; left to right.

540-35 IRTM, only a relative measure of the ejectional force is obtained with this system.

Again, the dual-beam oscilloscope was used to amplify and display the generated impulses, and the camera was used to record the oscilloscopic displays for the studies. With this press the ejectional force impulse trailed the compressional force impulse by three impulses.

Both "sides" of two standard production BB2-27 presses have been instrumented in the described manner to measure compressional and ejectional forces. These IRTM's are in routine production use today (see Fig. 5). Furthermore, the eyebolts and ejectional tracks of a Manesty Bicota[7] have been instrumented in a manner similar to that shown in Figs. 3 and 4.

TYPE AND NATURE OF DATA OBTAINABLE

Figure 6 is a photograph of the compressional and ejectional force traces produced during tableting of a direct compaction mixture, *A*, containing three active ingredients with the 540-35 IRTM. The upper trace records the compressional force impulses and the lower trace records the ejectional force impulses. The latter is inverted, *i.e.*, its magnitude increases in a downward direction. For this photograph the horizontal sweep of the beams was increased so that only two consecutive compression and ejection events are shown. The compressional force for the first tablet (impulse to the left side of the photograph) is about 6480 lb. For the second tablet it is 7020 lb. For the first ejectional event displayed, the initial peak height represents a force of about 27 lb., while a force of about 32 lb. is registered for the ejection of the second tablet. As explained, the ejection events shown do not correspond to the compressional curves depicted.

By decreasing the horizontal sweep and making a time exposure, the photograph shown in Fig. 7 was obtained. In this run, however, the upper punches were removed from stations 31 and 33, accounting for the "blanks" in both tracings. It can be observed that an ejectional force impulse is displaced to the right by five impulses from its compressional force counterpart. The usual variation in both the compressional and ejectional force impulse heights was accentuated because the experimental direct compaction mixture *A* being compressed did not flow well. The uniform compressional pulse heights at the right side of the picture occurred because the press "unloaded" as the tablets were compressed, *i.e.*, the development of excessive pressures was automatically prevented by the hydraulic-mechanical overload system of the press. When this occurs, there is a plateau in the individual compressional force curve since additional force cannot be applied to the tablet or punches.

The oscilloscopic displays obtained from the $^{1}/_{2}$ BB2-27 IRTM are similar to those shown for the 540-35 IRTM. An example is shown in Fig. 8 where the horizontal sweep has been increased on the left half to show the characteristics of individual impulses and then decreased on the right half to

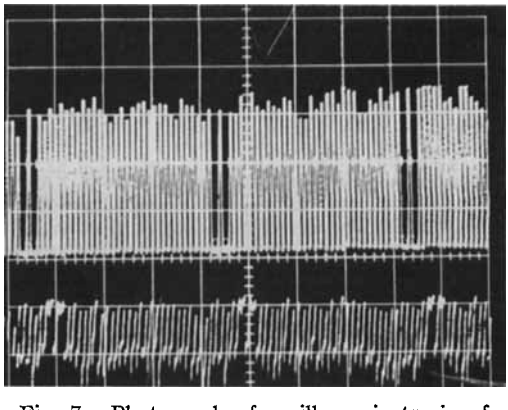

Fig. 7.—Photograph of oscilloscopic tracing for direct compaction mixture *A* compressed on 540-35 IRTM with Force-Flo-Feeder operating at about 1000 TPM using 35-$^{7}/_{16}$ in. full oval punches (upper punches removed from stations 31 and 33). Calibration: upper trace (C.F.), one large division = 2700 lb.; lower trace (E.F.), one large division = 25 lb.; sweep, 1 sec./large division; left to right.

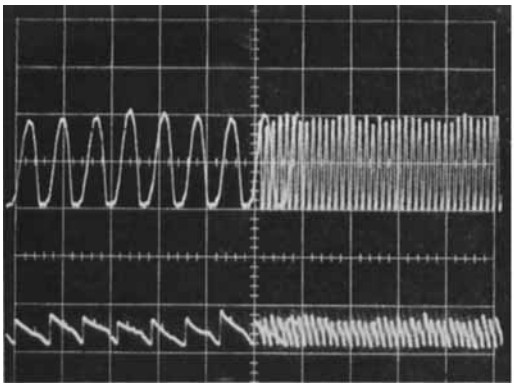

Fig. 8.—Photograph of oscilloscopic tracing for direct compaction mixture *B* compressed on BB2-27 IRTM with Force-Flo-Feeder operating at a speed of about 430 TPM using 27-$^{7}/_{16}$ in. full oval punches. Calibration: upper trace (C.F.), one large division = 3080 lb.; lower trace (E.F.), one large division = 125 lb.; left sweep, 0.2 sec./large division; right sweep, 1 sec./large division; left to right.

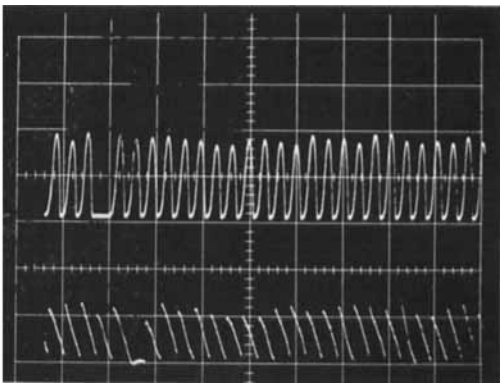

Fig. 10.—Photograph of oscilloscopic tracing of conventional granulation D compressed on BB2-27 IRTM operating at about 400 TPM using 26-$^{7}/_{16}$ in. full oval punches (upper punch removed from station 1). Calibration[8]: upper trace (C.F.), one large division = 2360 lb.; lower trace (E.F.), one large division = 83 lb.; sweep, 0.5 sec./large division; left to right.

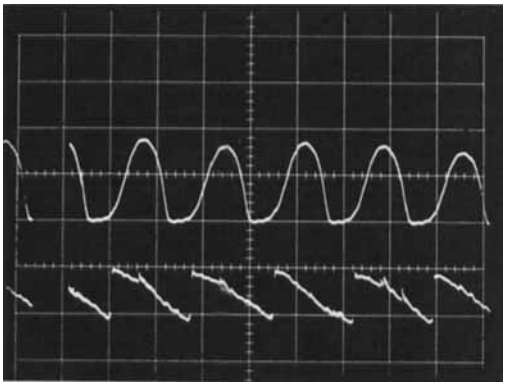

Fig. 9.—Photograph of oscilloscopic tracing for conventional granulation D compressed on a BB2-27 IRTM operating at about 400 TPM using 27-$^{7}/_{16}$ in. full oval punches. Calibration[8]: upper trace (C.F.), one large division = 2360 lb.; lower trace (E.F.), one large division = 83 lb.; sweep, 0.1 sec./large division; left to right.

"squeeze" the series of impulses together. These compressional force impulses are quite uniform. One explanation is that this particular direct compaction mixture *B*, containing the same three active ingredients as *A*, flowed extremely well. The ejectional force tracings are not inverted in Figs. 8, 9, and 10; hence, the magnitude of the force increases in an upward direction.

Figures 9 and 10 are photographs obtained while a conventional granulation D containing the same three active ingredients was being compressed on the $^{1}/_{2}$ BB2-27 IRTM.[8] Figure 9 shows the individual impulses, while Fig. 10, obtained by decreasing the sweep and removing the upper punch from one station, shows the displacement of the ejectional force impulse to the right of the corresponding compressional force impulse by three impulses. There was more compressional force uniformity for this granulation than there was for the poorly flowing direct compaction mixture *A* shown in Fig. 7. However, the good flowing direct compaction mixture *B* pictured in Fig. 8 showed the most nearly uniform compressional force impulse heights of the three.

Various methods can be used to measure the individual heights for a series of impulses. Photographic prints or transparencies can be projected onto a calibrated grid or measured directly by a specially scaled transparent ruler. The mean of a series of impulse heights can be determined and used to calculate the force involved in the preparation of that sample of tablets. For example, in Fig. 8 the mean pulse height for the left side of the picture was found to be 1.71 cm. Since 0.9 cm. is equivalent to 3080 lb., the average compressional force generated during the compression of these tablets is 1.71 × 3080 ÷ 0.9 or about 5850 lb. The average ejectional force calculated in a similar manner is 0.52 × 125 ÷ 0.9 or about 72 lb. Compressional and ejectional force data can be obtained in this manner to define or describe an individual tableting run. All force measurements can be converted into pressure values by simple calculation involving the area of the punch faces. It is important to remember that the compressional force measurements are in terms of absolute force at the point of measurements and include any slight friction components of the upper punch guide and overload systems. The ejectional force measurements are relative values with respect to the machine, the machine settings, and the tools. The ejectional force is related to the stock, the size and shape of the punches, the depth of compression, and the size or weight of the tablets being produced.

The material presented describes the type and nature of data that can be obtained with instrumented rotary tablet machines. Some of the ways that

[8] The calibrations differ between Figs. 9 and 10 and Fig. 8 because deliberate alterations to the circuitry and cross-sectional area were made to increase the sensitivity of the system. Presently, by adjusting the circuitry, the sensitivity has been further increased for the BB2-27 IRTM.

such data have been used to study a variety of tableting problems will be presented in part II of this series (26).

SUMMARY

The proposed design requirements to measure and monitor compressional and ejectional forces developed on rotary tablet machines have been fulfilled by the two instrumented presses described here. The forces are detected by strain gauges attached to strategic components of the press remotely located from the sites of action. The detected forces are monitored on a dual-beam oscilloscope connected through Wheatstone bridge circuits to the individual compressional and ejectional force sensing strain gauges. Diagrams are included to show the strain gauging and electrical circuits. Permanent records are obtained by taking pictures of the transmitted displays with a Polaroid-backed oscilloscope camera. Photographs are used to illustrate the type and nature of compressional and ejectional force data obtainable from the instrumented presses.

Thus, two instrumented rotary tablet machines, the Stokes models 540-35 and 1/2 BB2-27, are now available for research and development projects. Other tablet machines, similarly equipped, have been used to monitor routine tablet production runs.

ADDENDUM

Since the time this paper was prepared and presented at the annual meeting of the AMERICAN PHARMACEUTICAL ASSOCIATION in May 1963, additional studies on the instrumentation of rotary tablet machines have been reported.

Shotton and co-workers (23) bonded strain gauges to the shanks of one upper and one lower tablet punch and used radio telemetry to transmit the compressional force to the recorder. The press was a Manesty D-3, 16 punch, rotary tablet machine in which all of the tablet punches had been removed except for a single punch and die set. The machine had to be hand turned.

Fuhrer (24) discussed the pressure distribution in tableting with a study on compression curves in rotary tableting presses.

Recently, Wray *et al.* (25) reported on an instrumented Stokes BB2 rotary tablet machine similar to that described in this paper. These workers were able to monitor simultaneously the upper and lower compressional forces from both a set of instrumented punches and instrumented upper and lower compression rolls and ejection forces from an instrumented lower punch and a redesigned ejection cam.

The rotary tablet machine instrumented by Shotton is a research tool incapable of operating at high speeds. The instrumented rotary tablet machines described in this paper and the one subsequently modified by Wray may be utilized to study typical tablet development and production problems under dynamic conditions.

Instrumented Rotary Tablet Machines II

Evaluation and Typical Applications in Pharmaceutical Research, Development, and Production Studies

By E. L. KNOECHEL, C. C. SPERRY, and C. J. LINTNER

The instrumented rotary tablet machines (IRTM's) previously described have been used to study many phases of the tableting process. The performance of rotary tablet machines with respect to compressional force generated at various settings of the machine controls and to the tablets produced was analyzed and graphically described. Additional studies established the specific relationships between the dimensions and physical properties of the tablets and the compressional forces used to prepare them for a number of different tableting mixtures. These findings are compared with similar relationships obtained by others who used instrumented single punch tablet presses, specialized "static" compression methods, or empirical methods of measuring compressional force. In most cases the results obtained for rotary machines were similar to those previously reported, but in a few instances contradictory behaviors were observed. It was concluded that the excessive amount of punch-to-punch and cycle-to-cycle variation in compressional and ejectional forces that was unexpectedly found to exist for rotary tablet machines is primarily due to unequal filling of the individual dies with stock. Some applications where IRTM's were used to investigate typical tablet development and production problems are described.

THE INSTRUMENTATION of conventional rotary tablet machines so that compressional and ejectional forces can be determined under dynamic, production-type conditions has been described in the first paper of this series (1). Along with the details of their design and construction, the type and the nature of the data which can be obtained from instrumented rotary tablet machines (IRTM's) were also presented.

In the present report a series of experiments evaluated the performance of rotary tablet machines with respect to the tablets and the compressional force levels produced over the entire range of the various machine settings.

Following these investigations, another series of experiments examined the relationships between compressional force and the physical properties of the tablets produced from a variety of different tableting mixtures. These findings were compared to those previously found by others working with instrumented single stroke tablet machines (2–18), static compressional devices (19–24), empirical methods of measuring "compression" (25–29), and rotary presses (2, 30, 31).

When the basic performance of the rotary presses had been established, the IRTM's were used to study some typical tablet development and production problems.

Data from specific tableting runs as well as general observations from the studies are presented to describe the various ways that the IRTM's were used.

EXPERIMENTAL

Materials.—Since the main purpose of this paper is to describe the value of the IRTM, the details of the formulations and their preparation are being omitted. However, a variety of experimental and standard production granulations as well as a number of experimental direct compaction mixtures were studied. All formulations contained therapeutic concentrations of physiologically active ingredients. As a result, data on the compressional characteristics of actual production-type materials were collected.

Methods of Measurement and Equipment.—(*a*) Hardness values are the average for 5 to 20 tablets determined on a Strong-Cobb hardness tester[1] operated from a compressed air line.

(*b*) Fracture resistance values are also the average for 5 to 20 tablets determined by using the modified anvil and plunger for the Strong-Cobb hardness tester previously described by Endicott *et al.* (32).

(*c*) Friability values are the weight loss in per cent determined after 20 tablets were rotated in the Roche Friabilator for 4 min. at 25 r.p.m. (33).

(*d*) Disintegration times, determined by U.S.P. procedure, apparatus, and official plastic disks, are reported either as the average time or the total time required for six tablets to disintegrate. In some cases the disks were not used. Generally, the fluid used was 750 ml. of deionized water at ~37°; when a different fluid was used, this is indicated.

(*e*) Dissolutive rates, expressed in terms of the

Accepted for publication September 8, 1966.

Presented to the Scientific Section, A.PH.A., Miami Beach meeting, May 1963.

Instrumentation of rotary tablet machines is claimed in U. S. pat. 3,255,716 (June 14, 1966).

The authors acknowledge the technical assistance of D. D. Noble, Jane Patterson, and C. Hine, and the members of the Tablet Production Unit and Statistical Section of the Scientific Administration Staff during the course of these studies.

Previous paper: Knoechel, E. L., Sperry, C. C., Ross, H. E., and Lintner, C. J., *J. Pharm. Sci.*, **56**, 109(1967).

[1] Strong-Cobb & Co., Inc., Cleveland, Ohio.

time required for a given percentage of the drug(s) to be dissolved (*e.g.*, $T_{50\%}$) from the tablet, were determined either by using the procedures and equipment described previously by Schroeter *et al.* (34) or by using the "automated dissolution rate apparatus" described by Schroeter and Wagner (35).

(*f*) Mean tablet weights were obtained by weighing 90 to 100 tablets on torsion balances and performing the appropriate calculations. Individual tablet weights were determined to the nearest 0.1 mg. on a Mettler Gramatic balance.[2]

(*g*) Mean tablet thicknesses were obtained either by measuring the total length (to the nearest 0.01 in.) of a column of 60 to 100 tablets stacked face to face in a V-shaped trough (one side of which was a 2 ft. steel ruler) and making appropriate calculations or by measuring individual tablets with dial micrometers[3,4] (estimated to the nearest 0.0005 or 0.0001 in., respectively) and averaging the values obtained.

(*h*) Compression ratios (CR), a measure of a tablet's apparent density, were calculated either by dividing the weight of the individual tablet by its own thickness or by dividing the mean weight by the mean thickness for a tablet sample and expressing the results in "mg./in." (27, 29). The term compression ratio is used here because of its historical significance and widespread usage. To convert to mg./mm., divide the compression ratio in mg./in. by 25.4.

(*i*) Compressional and ejectional force values were obtained from the Stokes 540-35 IRTM, the Stokes 1/2 BB2-27 IRTM, or the instrumented ejectional track of the Manesty Bicota machine and the associated electronic and photographic equipment described previously (1). Mean values were determined by averaging 50 to 130 individual impulse heights (estimated to the nearest millimeter) from the photograph obtained for the determination and making appropriate calculations as described previously (1).

(*j*) Settings for the press controls were designated as follows.

Speed Settings.—These were determined either by reading the press tachometers (calibrated in tablets/min. (TPM) for the 540-35 and 1/2 BB2-27 presses) or by measuring the r.p.m. of the head and converting this to TPM for the conventional BB2-27 press.

For a 540-35 press the rate ranges from 700 to ~2400 TPM (2 tablets/station/revolution). For the 1/2 BB2-27 press the rate ranges from ~350 to 700 TPM (1 tablet/station/revolution). Since the conventional BB2-27 press produces two tablets/station/revolution, it has twice the rate (700 to 1400 TPM) of the 1/2 BB2-27 press.

Weight Cam Settings.—These were expressed in terms of "notches of weight added." For both the 540-35 and the BB2-27 presses one complete rotation of this control equals 40 notches.

Thickness Settings.—These were expressed in terms of revolutions of the appropriate control for the 540-35 press on which pointers and specially calibrated dials were installed. For the BB2-27 presses the settings were in terms of "notches;" these were converted to degrees of rotation by the factor, 7 notches = 45°, or 56 notches = one complete revolution.

(*k*) Punches and dies were regular production tools. However, the length of each punch was measured with a platform dial micrometer[5] and the diameter of each punch and die was determined by using the Sheffield Precisionaire Gage.[6] Each individual tool was labeled and its dimensions recorded. The tools were then arranged so that upper and lower punches and dies with uniform clearances were obtained for each station. These were installed so that the total length of upper and lower punches first decreased from and then increased back to the total length of the punches in the first station.

Procedures.—*Evaluation of Rotary Tablet Machine Performance.*—For these studies the general procedure for conducting the runs was as follows.

All control settings were made, checked, and "locked-in." Hopper(s) were filled to a preselected level. The press was run at the desired settings for at least 2 min. before tablets were collected or photographs taken. Then at least 125 tablets were collected (only from the instrumented side of the 540-35 IRTM) while the time exposure was being made of the oscilloscopic tracings. These tablets were bottled and labeled and the photograph identified. Then the press control being evaluated was readjusted to the next setting—with no changes being made to the others—and the entire procedure was repeated. For the "speed" control study the upper and lower limits were those of the press itself. For the weight cam and thickness control studies the upper limit occurred when the press "unloaded" because it had reached its mechanical capacity, while the lower limit was reached when tablets became too fragile to handle.

After the collections were finished for all the runs, the various measurements on the tablets and photographs were performed.

Establishment of Relationships Between Physical Properties of Tablets and Compressional Force.—Essentially the same procedure as described above was used to carry out these studies. Only the thickness control setting was adjusted to produce the compressional force changes. Except as noted, all tablet measurements were made within a short time after their compression.

Applications for Tablet Development and Production Studies.—The various procedures used for these studies will not be described in detail in this section since they will be evident when the results of the individual studies are discussed.

RESULTS AND DISCUSSION

Evaluation of the Performance of Rotary Tablet Machines.—These studies, designed to quantify the general rules of thumb that tablet men have long used in working with rotary presses, established the relationship between specific settings of the speed, weight cam, and thickness controls of the presses and of the compressional force generated.

Figures 1 and 2 typify the photographs obtained

[8] See run 9 in Table IV.

In this manner the effects of various press adjustments were determined for this granulation and other tablet formulations. It was found that these effects are related mainly to the mechanical aspects of the presses and not necessarily to the composition of the formulations.

Speed Control.—The data listed in Table I were obtained when only the speed control setting of an IRTM was adjusted (by 200 TPM increments) during the compression of a previously slugged and granulated conventional granulation F. Figure 3 shows plots of the press speed *versus* (*a*) the mean tablet weight and (*b*) the mean compressional force developed. As the speed increased, the die fill decreased, the tablet weight diminished, and the compressional force being generated decreased. The apparent density and thickness of the tablets also decreased as the press speed increased. In fact, for this run the decrease in thickness was directly proportional to the decrease in weight. Furthermore, the relationship between tablet weight and compressional force approaches linearity.

In another study the weight of tablets produced and the compressional forces generated were determined for each setting when the press speed was increased by increments. Appropriate adjustments were then made to the weight cam control to obtain tablets of the initial weight at that particular speed. In all cases the compressional force being generated returned to the initial level when tablets with the proper weight were made. It should be pointed out, however, that although the compressional force levels remained constant, the dwell time (*i.e.*, the actual time that the tablet stock was subjected to the compressional force) became increasingly shorter as the press speed increased.

Weight Cam Control.—The data in Table II were obtained when the weight cam control of an IRTM was adjusted by "4 notch" increments to produce heavier tablets from conventional granulation D. In Fig. 4 it will be observed that as the fill weight cam setting was advanced, the actual weight of the tablet produced increased linearly with the setting. Figure 4 also shows that as the weight cam setting was adjusted the compressional force increased until the capacity of the press was reached (~4

tons). Less than 1.5 rev. of the weight cam control produced the entire range of fill weights (448.7 to 615.2 mg.) and compressional forces (825 to 8,235 lb.). As the weight of the tablets increased, their thickness and apparent density also increased, even though the thickness control setting was not altered during the run.

Furthermore, it can be seen that a significant portion of the curve which would be obtained with a plot of weight *versus* compressional force would be linear. This points out that the compressional force generated is apparently dependent upon the weight of the tablets or the die fill. Brake (2) and Rehberg (31) anticipated this possibility for rotary presses, and similar relationships were reported by others (8, 10, 11, 15) in their work with instrumented single stroke presses.

Thickness Control.—Regulation of the thickness control to bring the upper and lower punches closer together or farther apart at the instant of compression is the usual way that a press is adjusted to control the properties of the tablets to be made once the desired fill weight is obtained. The press speed is usually optimized and is not ordinarily used to control the properties of the tablets. The data in Table III were collected when tablets were compressed at different thickness settings from an experimental granulation I on an IRTM. The two plots in Fig. 5 show the relationships between thickness control setting and (*a*) the thickness of the tablets produced and (*b*) the compressional force generated. Adjusting the thickness control to "apply more pressure"

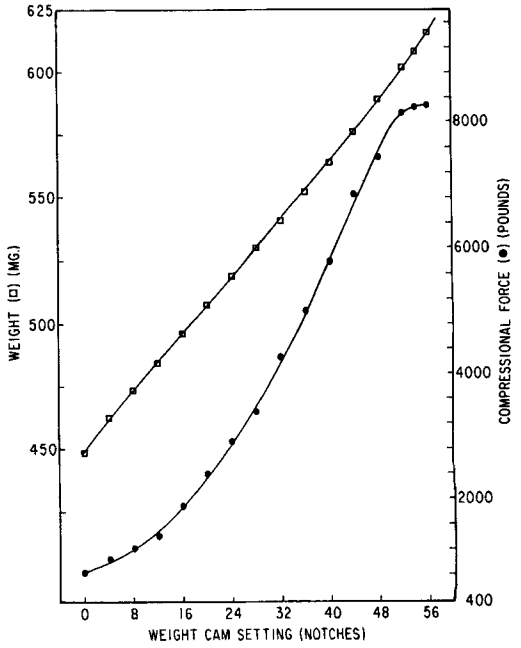

Fig. 4.—Weight cam setting *versus* weight (mean) (□) and compressional force (mean) (●).

resulted in thinner tablets being compressed at higher force levels.

The entire range of compressional forces was attained with less than 2 rev. of the thickness control. The compressional force did not change uniformly throughout the range of the thickness settings. The last 160° of rotation to the control produced as much a change in force as did the first 440°. Thus, adding a notch of "pressure" to the thickness control is not equivalent to adding a constant increment of force to the compression.

Another important observation is that the thickness decreased rapidly at first, and then leveled to a constant value, even though the pressure applied to the mass continued to increase. Since the weight of the tablets remained relatively constant during the run, the apparent density of the tablets thus increased to an asymptotic value as the thickness control was continually adjusted to produce thinner tablets. The significance of this phenomenon will be discussed later.

On the basis of these and other experiments, relationships for the press settings can be generally summarized as follows.

Increasing the press speed causes the die fill to decrease, a factor which causes the tablet weight and compressional force being generated to decrease. The tablets, therefore, become successively thinner and less dense and are ejected with a decreasing amount of force.

Adjusting the weight cam control setting to increase the die fill results in successively higher compressional and ejectional forces being generated while thicker and denser tablets are also produced. In support of these findings, Nelson *et al.* (5) showed that for a single stroke press the ejectional force

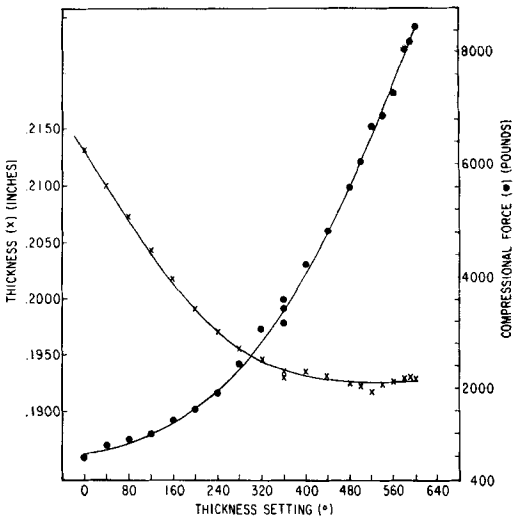

Fig. 5.—Thickness setting *versus* thickness (mean) (×) and compressional force (mean) (●).

increased linearly with an increase in tablet weight (and resulting thickness) when the compressional force was maintained constant.

Adjusting the thickness control setting to bring the punches closer together for the punching event causes successively thinner and denser tablets to be produced up to a point. The compressional and ejectional forces developed increase continuously throughout the entire range of press settings, even though the thickness decreases and the density increases, until each attains a nearly constant level.

Correlation of Compressional Force and Physical Properties of the Tablets.—For all the materials studied, nonlinear, but generally reproducible, relationships were found to exist between the relative setting of the thickness control and the generated compressional force. However, in attempting to correlate the physical properties of the tablets with the force used to compress them, two distinct types of behavior, predictable and nonpredictable, were found to exist for all the materials.

(*a*) The relationship between certain physical dimensions of the tablets, *e.g.*, thickness and apparent density, as well as the force required for ejection and the compressional force used in their preparation, are relatively independent of the actual material being compressed. Since all the materials behaved similarly, the compressional force profiles with respect to these properties are usually predictable.

(*b*) The relationship between certain other physical characteristics of the tablets, *e.g.*, hardness, friability, disintegration, and dissolutive rate values and the force used to compress them, are more dependent on the composition of the particular stock being tableted. Since compositions vary greatly between formulas, the effect that different levels of compressional force will have on the properties of the tablets is unpredictable. The compressional force profile must be determined for each material.

General or Predictable Relationships.—A specific case typifying predictable behavior is depicted by the data in Table IV and the plots shown in Fig. 6

[a] Controls: constant settings for weight cam and speed (360 TPM) adjustments. Material: conventional granulation E. Punches: 7/16 in. full oval. Machine: 1/2 BB2-27 IRTM. [b] Measured in terms of "notches" of control setting; 7 notches = 45° or 56 notches/rev. At 0° the punches were farthest apart at time of compression; at 720° the punches were nearest to each other.

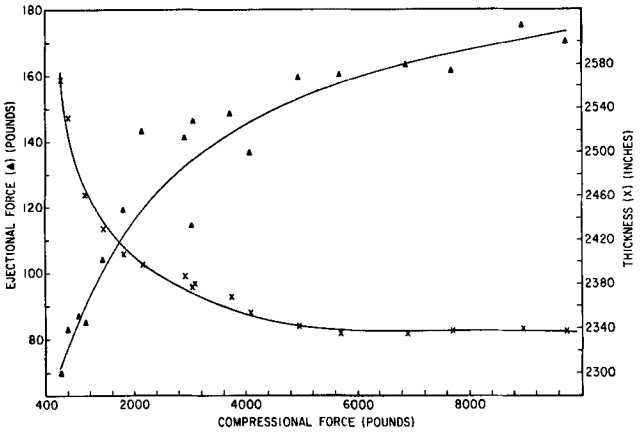

Fig. 6.—Compressional force (mean) *versus* ejectional force (▲) and thickness (×).

of compressional force *versus* (*a*) ejectional force and (*b*) mean tablet thickness. Here a conventional granulation E was compressed at various compressional force levels on an IRTM.

Higher compressional forces were generated as thinner (and consequently denser) tablets were produced. Note that the tablet thickness hardly changed as the compressional force increased from 5000 to almost 10,000 lb. Thus, although the compressional force almost doubled, the apparent density of the tablets (*i.e.*, CR α1/thickness) did not increase beyond a certain asymptotic value.

The results were in general qualitative agreement with those previously found by investigators who worked with "static" methods of compression (20–22) or instrumented single stroke machines (14, 16, 18). These workers empirically plotted the density (real or apparent) or porosity *versus* the logarithm of compressional force to obtain linear relationships at all but the higher force levels. Similar semilogarithmic plots using our data are also more linear, except where tailing occurs at higher compressional force levels.

The apparent density and thickness of the tablets tend to approach constant values as the compressional force is increased. The common practice used to determine the correct degree of compression for a given tablet is to measure a few tablets as they are made and compare their thickness to a previously set standard. This procedure should be questioned since tablets with the "correct" thickness could be compressed over a wide range of compressional forces if the "acceptable standard" was within the plateau region. Certain tablet properties may be more dependent on the actual force at which the tablets were compressed than they are on the thickness or apparent densities of the tablets. The value of being able to measure the actual force of compression with an IRTM during a tableting operation, rather than attempting to determine these values by indirect methods, is obvious.

As the compressional force increased, the force

[a] Controls: constant settings for weight cam and speed (700 TPM) adjustments. Material: previously slugged granulation F containing phenacetin, aspirin, and caffeine. Punches: 7/16 in. full oval. Machine: 540-35 IRTM. [b] Tablets from these runs were designated by these letters in *Reference 34*. [c] Average time for 6 tablets to disintegrate with disks in pH 1.3 fluid (HCl–NaCl, $\mu = 0.1$). [d] These values were determined about 6 months later than others (after storage at room temperature). [e] Average times required for the 2 tablets tested individually. Fluid used was HCl–NaCl, pH 1.3 with $\mu = 0.1$.

required to eject the tablets also increased even though the tablets became thinner (Fig. 6). An apparent linear relationship was obtained when the ejectional force was plotted against the logarithm of the compressional force. Shotton and Ganderton (16), working with an instrumented single stroke press, found a similar relationship for unlubricated sodium chloride crystals.

If tablet thickness is plotted *versus* ejectional force, a curvilinear relationship with a negative slope is obtained; this is the converse of that reported by Nelson *et al.* (5) and discussed earlier. These anomalous findings are apparently explained because a higher force of compression increases the ejectional force more than a smaller tablet thickness reduces it (23). Furthermore, Nelson used an unlubricated granulation with a single stroke press and kept the compressional force constant while varying the tablet weight to change the thickness. In the present study where a lubricated granulation was

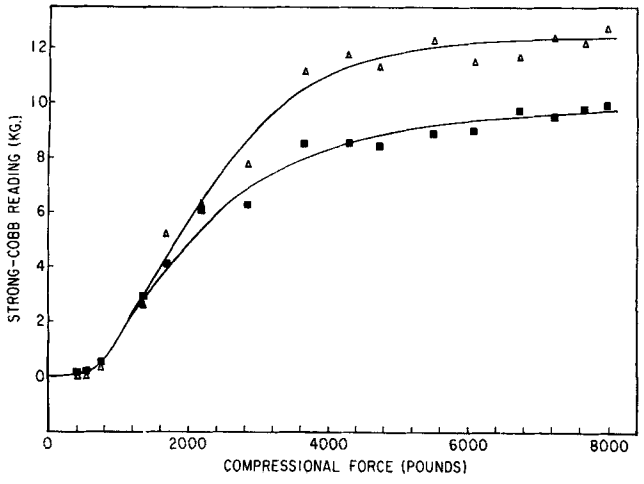

Fig. 7.—Compressional force *versus* hardness (△) and fracture resistance (■).

run on a rotary machine, the weight was held constant but the compressional force varied as the tablet thickness was changed.

For all the materials studied, the thickness and apparent density of the tablets level off even though the compressional and ejectional forces continue to increase. Because different materials reach their density plateaus at different compressional forces or with less absolute change in density, the rate of increase of tablet density with increasing compressional force possibly may be used as a measure of the bonding strength of the tablet. Elowe *et al.* (22) suggested that this in turn might be a criterion of the ease with which tablets can be compressed and reflects on the physical properties of the tablets after compression. No attempt has been made in these studies to test the validity of this proposal.

Specific or Unpredictable Relationships.—As indicated, general relationships between the compressional force and the physical properties of the tablets, such as hardness, friability, disintegration time, and dissolutive rate, were not found for the various materials studied. The specific compressional force profile for a material, or the exact way in which properties vary with compressional force, is often unpredictable and must be determined for each tableting mixture.

The following illustrates the establishment of such specific compressional profiles for one of the mixtures studied. The data in Table V were obtained when an experimental mixture containing aspirin, phenacetin, and caffeine, which had been previously wet granulated and slugged, was compressed on an IRTM. As usual, as the thickness setting was successively adjusted "to increase the pressure," thinner and denser tablets were produced—up to a point—but the compressional force generated increased continuously. Figure 7 shows that the values for tablet hardness and fracture resistance also increased to plateaus when they were plotted against compressional force. This finding confirms similar ones reported previously for "static" compression methods (20–22) and instrumented single stroke machines (15, 16, 18). Plots of the hardness or fracture resistance *versus* the logarithm of compressional force would also be linear except at the higher force levels where tailing occurs. Linear relationships would also be found for the tablets of this series if their apparent densities were plotted against either their hardness or fracture resistance values; similar findings have been reported for a specialized single stroke press (20) and a rotary press (31).

Although the thickness, apparent density, hardness, and fracture resistance values for the tablets of this run reach plateaus, the disintegration times (determined with and without plastic disks) and the $T_{50}\%$ and $T_{90}\%$ values for dissolutive rates continued to increase as the compressional force increased. These relationships are shown in Fig. 8. Tablets compressed with a force of about 5,800 lb. had a compression ratio of about 2,353 mg./in. and a thickness of .2517 in. while tablets compressed at about 7,600 lb. had similar values. The tablets compressed at the lower force required 40 min. for 90% of their ingredients to dissolve while those made at the higher force needed over 60 min. to release the same proportion of their ingredients. Furthermore, their disintegration times were somewhat different (28 *versus* 36 min.), yet there was very little difference in the hardness and fracture resistance values of the two samples.

For this series of tablets significant linear correlations were established between the various values for disintegration times and dissolutive rates (34). Obviously, linear correlations can also be obtained between any of these values and the compressional forces used to prepare the tablets.

Others (27, 29) have also shown that the disintegration time for certain tablets continues to increase as the compressional force is increased, even though the compression ratio of the tablets has reached a maximum. Similarly, in separate studies, Higuchi *et al.* found semilogarithmic relationships between the distintgration time and the compressional force for certain tablets made by static compression methods (20, 21) despite the fact that their porosities approached asymptotic values.

Unfortunately, the friability values for these tablets were determined quite some time after the tablets were prepared. Since compressed

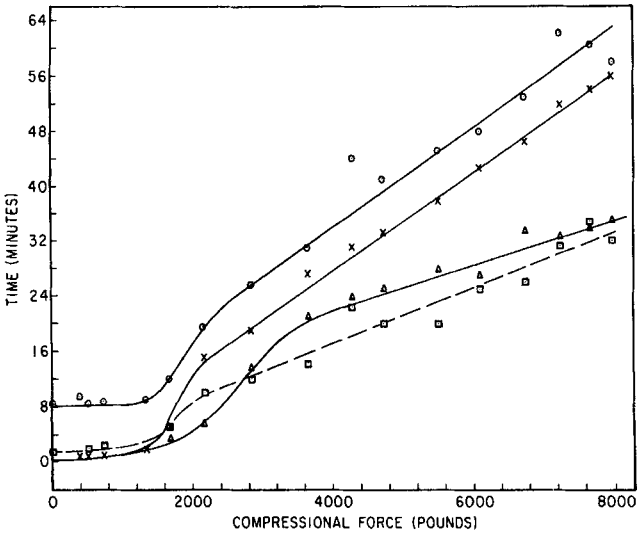

Fig. 8.—Compressional force (mean) *versus* $T_{90}\%$ (O) disintegration time w/o disks (×), disintegration time with disks (△), and $T_{50}\%$ (□).

tablets, especially those made from wet granulations, have a tendency to "set-up" upon storage (28, 29), the values listed do not reflect the true friabilities of the tablets at "time zero." Initially, the tablets made at compressional forces of less than 2,000 lb. were quite fragile.

As indicated, the above relationships were specific for the particular material in question. Different relationships with respect to the compressional force used to prepare the tablets were found for the other materials studied. For example, as the compressional force was increased over the range of 500 to 9,000 lb., the properties of the tablets were found to vary as follows.

The *hardness* values may increase continuously; increase and then level off; increase, level off, and then increase again, or increase to a maximum and then decrease. Similarly, the *fracture resistance* values may increase continuously; increase and then level off; increase to a maximum and then decrease; or not necessarily parallel the hardness values. The *friabilities* may decrease sharply from high values to plateau at lower ones; decrease more slowly from high values to plateau at lower ones; decrease to a minimal value and then increase again; or not necessarily be correlated with the hardness or fracture resistance values.

The *disintegration times* (with disks) may increase continuously; increase continuously with only a short plateau; increase only slightly and level off over a wide range; increase to a maximum and then decrease; decrease slightly, then increase continuously; or not necessarily be correlated with hardness or friability. The *dissolutive times* may increase from low values to level off at high values; increase from very short times to level off at only slightly longer times; vary randomly at intermediate values with no apparent relation to compressional force; increase from moderately long times to level off at very long times; increase to a maximal time and then decrease again; or not necessarily be correlated with disintegration times.

A unique finding of these studies was that for one of the conventional tablet granulations E, maxima were found for the hardness, fracture resistance, and disintegration and dissolutive times with respect to compressional forces. The friability reached a minimal value. As the compressional force increased, however, the hardness, fracture resistance values, and disintegration and dissolutive times decreased while the friability values increased.

Examples of many of these different types of behaviors have been reported previously by other investigators using a variety of methods to measure tablet properties and the degree or force of compression for single stroke machines (2–12, 15–18), specialized static compressional methods (19–23), empirical methods of varying compression (24–29), and in three cases, rotary machines (2, 30, 31).

Thus, for all materials, although tablets cease to become thinner or more dense when the compressional force is increased beyond a given point, predictions cannot always be made regarding the relationships between the compressional force and other physical properties of the tablets. Certain characteristics, *e.g.*, hardness, fracture resistance, disintegration time, dissolutive rate, and friability, may be affected more by the nature of the formulation or the medicaments than they are by the compressional force used to prepare them. This fact has not always been clearly established in the literature.

Interdependency of Tablet Uniformity and Force Variations.—For the foregoing studies the mean values from a large number of individual measurements and determinations were used to establish the various relationships. However, some general statements can be made regarding the individual compressional and ejectional force values observed during the runs.

Usually rotary tablet machines are thought to provide more uniform compression than do the single stroke machines. Contrary to expectations, however, large punch-to-punch and cycle-to-cycle variations in compressional and ejectional forces were found to exist. Brake also mentioned that the individual compressional forces varied more than expected during the exploratory work with his partially instrumented rotary tablet machine (2). Rehberg (31) also anticipated this possibility.

The degree of variation found in this study was not the same for all runs; for some the compressional force variation was observed to be as high as ±40% of the mean. In other runs much greater uniformity was displayed. Furthermore, the variation is usually larger at the lower compressional force levels and smaller at the higher compressional force levels because "unloading" of the press occurs at some stations; this tends to eliminate the high peaks that otherwise would be observed. For instance, in Fig. 1 the variation in compressional force is about ±18%, but in Fig. 2, at the higher compressional force level, the variation is only about ±5%.

The variation observed is also smaller when good flowing granulations or direct compaction mixtures are compressed with the aid of mechanical die filling equipment. Some of the most "uniform" compressional force tracings were observed when direct compaction mixtures made up of essentially lubricated spray-dried lactose were compressed.

It has been shown in Figs. 3 and 4 that the compressional force developed is directly related to the weight of the tablets being compressed. These data, the above observations, and previous findings by other workers who used single stroke (2, 8, 10, 11, 15) or rotary (2, 31) tablet presses indicate that the prime reason for the tablet-to-tablet and cycle-to-cycle variation in compressional force levels noted with a rotary tablet machine is apparently that the individual dies are being filled unequally. Rehberg (31) found that the weight variations of tablets made with rotary presses were normal distributions. Although compressional forces were not measured, Rehberg postulated that the compressional force was proportional to the weight of the tablet made. Thus, anything which causes more uniform filling of the dies should produce a more uniform compressional force impulse picture. Because the finer mesh particles of direct compaction mixtures fill the dies more uniformly than the coarser material of the conventional granulations, more uniform compressional force impulse heights are observed when the former materials are compressed (8, 36–38). (See Figs. 12 and 13 also.)

In addition to the fact that unequal die filling affects compressional force uniformity, evidence from these studies suggests that small differences

in the punch and die dimensions may also be a contributing factor by influencing not only the volume of fill (tablet weight) but the degree of compression (tablet thickness) as well. A die fitted with a short lower punch should receive a larger charge than a die fitted with a long one; thus, this station would deliver a heavier tablet. A long upper punch will always exert a higher compressional force than a short one when opposed by lower punches of the same length with dies filled with equal charges. Obviously, in sets of tools for presses with 16 to 51 stations a wide variety of combinations is possible. When the effect of the variations in die and punch diameters is introduced, the problem becomes even more complex. Others have pointed out that such variations exist within a set and from set to set as well (40–42).

The punch-to-punch and cycle-to-cycle variations in ejectional force occur for at least two reasons, because variations in compressional force occur and because variations in the lengths and the clearances of the tools exist for almost every set-up. In addition, tools wear unevenly (40, 42). It can be seen in Fig. 9 (where this was demonstrated for two different compressional force levels) that compression at uniform force levels (by adjusting the "overload" setting point to a lower value) does not produce tablets which are ejected with uniform forces. As expected, a higher ejectional force was required for the tablets produced at the higher compressional force level.

Results from some preliminary work as well as literature supplied by equipment manufacturers suggest that, if the overload system of the press were set so that the press continuously "unloaded" and all the tablets were compressed at the same force, tablets with uniform densities would be obtained. It has also been reasoned that tablets with uniform densities would have uniform physical characteristics, *i.e.*, disintegration times, dissolutive rates, hardness values, and friabilities. Less tablet-to-tablet variation in a lot would be observed. However, when this was attempted experimentally, there was no dramatic increase in uniformity of tablet densities or other properties because such a procedure does not improve the uniformity of flow or die filling. Actually, the presses could be damaged unless they were equipped with specialized "unloading" systems.

However, it is obvious that tablet-to-tablet variations as well as lot-to-lot variations with respect to the physical properties of the tablets may be due in some cases to the variation in compressional force used in their preparation. Since weight variations contribute mainly to the compressional force variations, the former may also be considered to influence greatly the physical properties of the individual tablets (8, 11, 15, 30, 31, 39). In the study mentioned previously, Rehberg (31) showed that for a series of three different tablet formulations compressed on a rotary press at constant settings, their thickness, density, hardness, and disintegration time all increased linearly as the tablet weight increased. He concluded that this occurred because heavier tablets were compressed at higher forces. Brake also suggested that hardness and disintegration might be correlated with the compressional force used to prepare the tablets (2). Thus, anything that can be done to insure compression of equal die fills at uniform and reproducible force levels will contribute greatly to the production of tablets which are uniform within a lot and from lot to lot (7, 8, 11, 31, 36, 37, 43, 44).

Applications of the IRTM for Tablet Development and Production Studies.—The foregoing material described the use of the IRTM for some types of basic or research studies. An extension of these studies led to the use of IRTM's to study both developmental and production tableting problems on the "floor" rather than at the bench. Some of these uses are described below. Where applicable, references to previously published investigations of a related nature are included in the discussions.

Tablet Development Studies.—(*a*) The IRTM has been used to determine the optimum lubrication system for a given stock by screening lubricants and

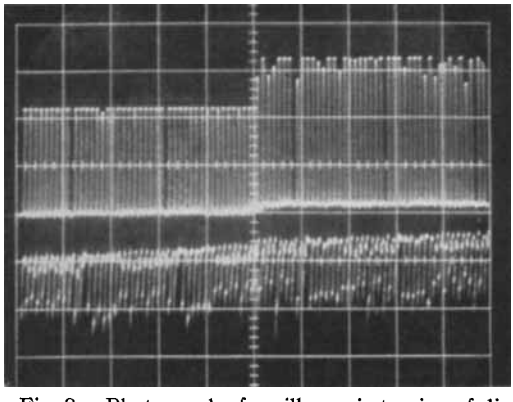

Fig. 9.—Photograph of oscilloscopic tracing of direct compaction mixture *A* compressed on 540-35 IRTM with Force-Flo-Feeder (FFF) at about 1000 TPM using 17-$^{7}/_{16}$ in. full oval punches. The upper punches were removed from every other station. Calibration: upper trace (C.F.), one large division = 2,700 lb.; lower trace (E.F.), one large division, = 25 lb.; sweep, 1 sec./large division, left to right. Overload setting on left side, 3 tons; on right side, 4 tons.

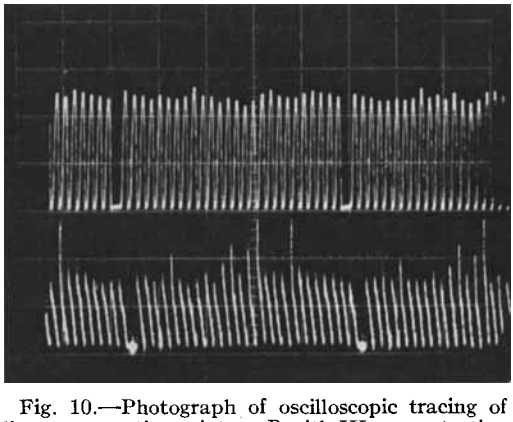

Fig. 10.—Photograph of oscilloscopic tracing of direct compaction mixture *B* with IX concentration of lubricant compressed on $^{1}/_{2}$ BB2-27 IRTM with FFF at about 660 TPM using 26-$^{7}/_{16}$ in. full oval punches (upper punch removed from one section). Calibration: upper trace (C.F.), one large division = 1540 lb.; lower trace (E.F.), one large division = 125 lb.; sweep, 0.5 sec./large division, left to right.

lubricant concentrations (3–5, 9–11, 13, 14, 17, 24). Figure 10 shows the compressional and ejectional forces generated for a given direct compaction mixture *B*. When the lubricant concentration was doubled with all the other variables being kept constant, the force required to eject the tablet was reduced to the level shown in Fig. 11. Note that with the increase in lubricant, the ejectional force impulses also became more uniform. When the lubricant concentration was tripled, only a slight additional decrease in ejectional force was observed. Thus, on the basis of ejectional force level, the optimum lubricant concentration for this formulation was considered to be between 2 to 3 times the initial concentration.

(*b*) The IRTM has been used to study and compare the relative flowability of various tableting mixtures. One way to evaluate how well a particular stock flows is to determine the weight variation of a collected sample of tablets. When the mixture flows well, the individual tablet weight variation is usually low; but if the flowability is poor, the individual weight variation will be high. As previously indicated, since the compressional force is directly proportional to the tablet weight or die fill, the degree of uniformity of the compressional force impulses should be a measure of the relative flowability of the mixture being tableted.

This is demonstrated by the following experiment in which 500-mg. tablets of a direct compaction mixture *C* and a conventional granulation E containing the same three active ingredients were each compressed on an IRTM. About 125 tablets were collected as the photographs of the compressional force impulses were being made during each run. One hundred tablets from each sample were weighed individually to the nearest 0.1 mg. The tablets compressed from the direct compaction mixture were found to have a lower weight variation than the tablets made from the standard granulation (coefficient of variation 0.52% *versus* 0.92%).

Figure 12 is the photograph obtained during the compression of the direct compaction mixture while the photograph in Fig. 13 was made when the conventional granulation was compressed. Data from these photographs show that the coefficient of variation for the compressional force impulses is less for the direct compaction mixture (4.49% *versus* 6.15%).

Both with respect to weight variation of individual tablets and compressional force impulse variation, the flowability of the direct compaction mixture was found to be superior to that of the conventional granulation.

Thus, the IRTM provided an instantaneous and continuous indication of the relative flowability of a tableting material in contrast to the more time-consuming method of weighing a representative number of individual tablets after a run has been finished (31, 36, 37, 39, 43, 44).

(*c*) The IRTM has been used to compress similar

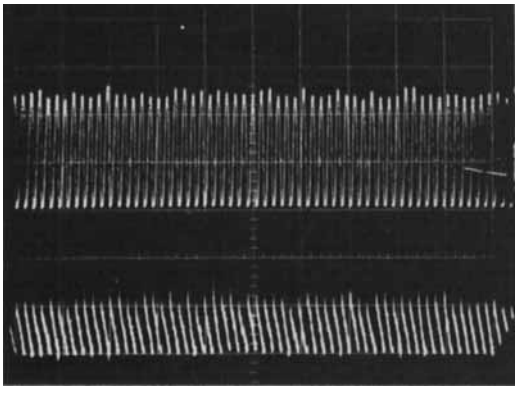

Fig. 11.—Photograph of oscilloscopic tracing of direct compaction mixture *B* with 2X concentration of lubricant compressed on $^1/_2$ BB2-27 IRTM with FFF at about 660 TPM using 26–$^7/_{16}$ in. full oval punches (upper punch removed from one section). Calibration: upper trace (C.F.), one large division = 1540 lb.; lower trace (E.F.), one large division = 125 lb.; sweep, 0.5 sec./large division, left to right.

formulas at constant and preselected compressional force levels. In this manner the real effects of an added ingredient or modified manufacturing procedure can be definitely determined (5, 7, 8, 12, 27). For example, during the development of a tablet prepared by a direct compaction process, the various formulations were compressed at the same force to determine the effects of both a dry binder-disintegrant and a flow promoting agent on the physical properties of the tablet. Some of the results obtained are shown in Table VI.

The flow promoting agent was so effective that the dry binder-disintegrant was no longer required because firmer tablets with acceptable disintegration times could be produced at lower compressional forces. Since there was less weight variation, there was also more uniformity in physical properties of the tablets; thus, individual units which were too soft or too hard were avoided. The mean ejectional force required was also reduced ~20% from 125 to 100 lb.

In another study involving a standard production granulation, it was found that by changing both the lubricating and disintegrating agents as well as their concentrations and using a finer mesh granule, the compressional force required to produce tablets with an acceptable hardness, friability, and dissolutive rate could be reduced from more than 5000 lb. to less than 2500 lb. The ejectional force required was concurrently reduced, too, not only because the compressional force level was decreased, but also because better lubricants were included.

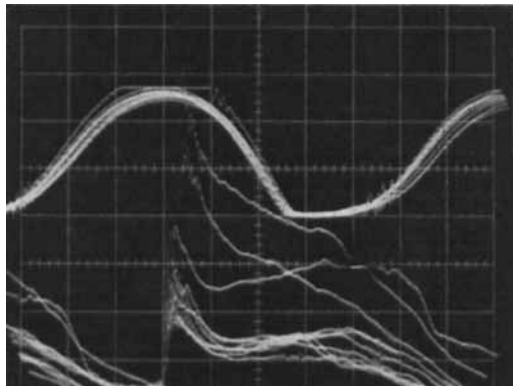

Fig. 15.—Photograph of oscilloscopic tracing of conventional granulation G compressed on 540-35 IRTM at 1500 TPM using 35-$^{15}/_{32}$ in. quarter oval punches. Calibration: upper trace (C.F.), one large division = 2700 lb.; lower trace (E.F.), one large division = 25 lb.; sweep, 10 msec./large division, left to right. Overload setting ~3.5 tons.

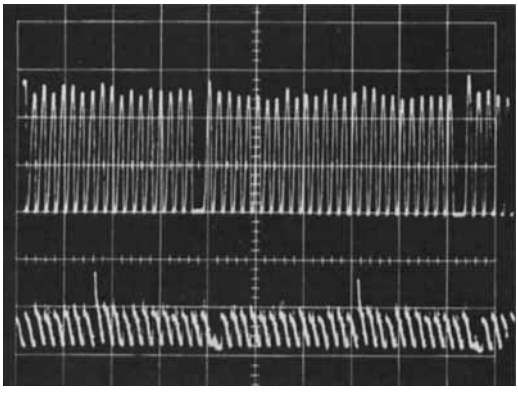

Fig. 14.—Photograph of oscilloscopic tracing of direct compaction mixture *B* compressed on $^1/_2$ BB2-27 IRTM with FFF at 600 TPM using 27-$^7/_{16}$ in. full oval punches (upper punch removed from station No. 1). Calibration: upper trace (C.F.), one large division = 3080 lb.; lower trace (E.F.), one large division = 125 lb.; sweep, 0.5 sec./large division, left to right.

Lower compressional and ejectional force requirements in rotary tablet machines mean reduced wear and longer life for punches, dies, and machine components, *e.g.*, cam tracks, compression rolls, and bearings (41, 42).

Production Activities.—(*a*) The IRTM has been useful in detecting and locating a malfunction of the machine or tools earlier than this can usually be accomplished by conventional methods. Observation of the oscilloscope gives an instantaneous picture of machine performance.

For example, as shown in Fig. 14, one punching

station was repeatedly responsible for an abnormally high ejectional force impulse (6). By removing the upper punch from station No. 1 and thus causing no tablet to be formed and no ejectional impulse to be produced for this station, the troublesome station was determined to be No. 16. Upon close examination, the lower punch in this station was found to have a deformed tip. When another lower punch was substituted, the high impulses disappeared.

Recently, an operator experienced difficulty in maintaining the desired tablet weight for a normally well-running granulation. Unfortunately, by using traditional methods, quite some time was required to trace the difficulty to a lower punch with a broken tip. Since the tip would not always drop completely, the die would not obtain the correct fill, and thus tablets with an incorrect weight were made at least two times per revolution. If, however, an IRTM had been in use, the trouble would have been located much more rapidly with less loss of granulation.

The use of the IRTM to detect a machine malfunction is illustrated in Fig. 15 where a combination of a time exposure and a rapid oscilloscopic sweep captured a number of successive compression and ejection events (23). Although one punch "unloaded," a relatively uniform compressional force level is shown. (Note the characteristic plateau in the compressional force curve for this tablet that is produced with the 540–35 IRTM.) The compressional forces ranged from 6500 to 7300 lb. (equivalent to pressures of 36,600 to 42,300 p.s.i.). However, there is an extreme variation in both initial peak height and shape of the ejectional force tracings for three of the tablets. The profiles for the other tablets are lower and relatively uniform. The complete profile of one of the "high peak" tracings (the lowest of the three) differs from the other two by the display of a plateau followed by a sharp drop to the baseline. This indicates that there was a considerable force required to keep the tablet (or punch) moving in the die until ejection occurred. For these tablets forces up to three to four times the "normal" ejectional force were observed. The normal ejectional pressure was about 290 p.s.i. while the binding tablets required pressures ranging from 870 to 1160 p.s.i. to eject them. The incidence of a higher impulse corresponded to a tendency for the punches to bind during the actual run.

Application of suitable amounts of lubricants to the lower punch shafts reduced the binding tendencies and eliminated the "high peak" tracings previously observed. Concurrently, the squeaking which had been heard was eliminated.

(*b*) Another use of an IRTM was to determine whether the ejectional forces required for a regular double press coated tablet (DPCT) made on a Manesty Bicota (triple turret) tablet press were actually excessive to the point of causing a breakdown of the press. Pictures of the ejectional force tracings were taken and compared for tablets compressed at 10 to 12 different thickness settings for six different standard production granulations (using only the

third turret) as well as for the entire DPCT formula. Other formulations tested included granulations for three press coated tablet (PCT) coatings, a chewable vitamin, an APC combination, and a sulfonylurea compound.

It was concluded that the forces required to eject the entire DPCT or the tablets made of its coating granulation alone on the third turret were not any higher than those required to eject tablets of the same size made (on the third turret) of the other granulations studied at equivalent thickness settings. Thus, the lubrication of the DPCT formulation was apparently not responsible for the excessive wear to certain members of the Manesty press (3–5, 9–11, 13, 14, 17, 24).

(*c*) The IRTM was used to provide a type of "set-up" and "in-process" control for a specific product on a routine production basis (7, 43, 44). For this purpose a standard Stokes BB2–27 press was "instrumented" by transferring to it the strain gauged eyebolt from the 1/2 BB2–27 IRTM. The system was used to adjust the thickness control so that a preselected force level was obtained for consecutive laboratory scale-up and pilot lots of a new formulation. Previously, it had been found that tablets compressed at a force of 4500 lb. from a specific direct compaction mixture possessed certain desirable physical properties (Table VI). The runs were then monitored to maintain this compressional force level by using the IRTM.

The data in Table VII will attest to the success attained by controlling this variable more closely than heretofore has been possible.

The physical properties of the tablets for the various runs were very similar and exhibited no marked variation from lot to lot. Note that, for two of the large size lots, it was necessary to compress the tablets at somewhat higher force levels to obtain tablets with the desirable characteristics. These formulations were somewhat drier than the others reported and this may be the reason higher pressures were required to produce the necessary bond.

Not all of the tablets of run 12 were compressed when the stock was first prepared. The remaining material was compressed into tablets 2 months later. Note that the physical properties of the tablets (run 12R), except for the hardness values, are quite similar to those found initially in run 12 (Table VII).

If, during the run, the compressional force level shifted markedly from the norm, the tablet operator usually found that heavier or lighter than theoretical weight tablets were being prepared. Appropriate adjustments to the weight cam control brought the force level back to normal. Thus, the IRTM provided not only a way of reproducing batches of uniform tablets from consecutive runs, but also a means of in-process control. Perhaps it was equipment and methods like this that Swintosky, Kennon, and Tingstad visualized when they prophesied in their 1955 paper, "These data suggest that by (a) judicious selection of disintegrant, (b) suitable choice of tablet composition, and (c) *regulation of the compressional force to precise and known values, the rates of tablet disintegration and drug release may be controlled*," (7) (emphasis added).

As a result of these investigations, two conventional BB2-27 presses have been instrumented to measure both compressional and ejectional forces for both sides. These presses are now used routinely in the production of the new formula and are also available for other production oriented studies. (See Fig. 5, *Reference 1.*)

The foregoing examples have served to describe and demonstrate the use and usefulness of the IRTM at this time. These will in turn suggest many more studies in which the IRTM can be used to obtain valuable data to resolve other tableting problems. Some of these studies have already been carried out in this laboratory and future communications will cover in greater detail some of these as well as those only briefly mentioned in this report.

SUMMARY

The use and usefulness of instrumented rotary tablet machines to study a variety of tableting problems, both fundamental and applied, were described and discussed.

Using the two IRTM's and a variety of tablet formulations, fundamental information concerning the performance of rotary tablet machines was obtained. General relationships were established between the relative settings of the three press controls (speed, thickness, and weight cam) on the one hand, and certain physical characteristics of the tablets (thickness, weight, and density) and the compressional and ejectional forces generated in their preparation on the other.

General relationships between the force of compression and the physical properties of the tablets, such as weight, thickness, density, and the force required to eject them, were found to be relatively independent of the material being compressed and quite similar for all materials studied.

As others have found by using different methods to measure the variables, certain other physical characteristics of the tablets, such as hardness, friability, disintegration time, and dissolutive rates, were apparently affected by the nature of the formulations or the medicaments as well as by the compressional force involved in their preparation. Contrasting behaviors for different formulations were described.

It was concluded that the relatively large punch-to-punch and cycle-to-cycle variations in compressional and ejectional force levels, which were unexpectedly found to exist during tableting on rotary presses, were apparently due to unequal filling of the dies. When formulations were run which flowed well or which were induced to flow into the dies by mechanical means, compressional, and ejectional force impulse heights became more uniform and weight deviations decreased.

Descriptions of the manner in which the IRTM's were useful in studying typical development and production tableting problems included their use to: (*a*) screen and compare lubricants and lubricant concentrations; (*b*) determine and compare the relative flowabilities of tablet formulations; (*c*) compress experimental and developmental formulas at constant and preselected force levels; (*d*) detect and locate press or tool malfunction more rapidly than by conventional means; (*e*) determine whether the degree of lubrication for a given formulation was adequate to permit compression on a specific tablet press; (*f*) provide a means of "set-up"

and "in-process" control to obtain routinely both tablet-to-tablet and lot-to-lot uniformity for a production formulation.

Antagonism of Propoxyphene Poisoning in Albino Mice with Nalorphine HCl, Methylene Blue, and Tolonium Chloride

By DAVID E. MANN, JR.

The intraperitoneal administration of propoxyphene HCl to albino mice at a dosage level of 200 mg./Kg. ($LD_{99.5}$) was lethal to 98 per cent of the controls. The prophylactic subcutaneous administration of nalorphine HCl alone, or in combination with either methylene blue or tolonium chloride, significantly increased the number of survivors with the greatest degree of protection being afforded by the nalorphine–dye combinations.

HARPEL AND MANN (1) recently demonstrated the antidotal effectiveness of subcutaneously administered nalorphine HCl and methylene blue, alone and in combination, prior to lethal doses of propoxyphene HCl in mice. The greatest amount of protection against the lethality of the analgesic occurred when nalorphine and methylene blue were administered 5 min. before propoxyphene HCl.

The purpose of this investigation was to confirm the results previously obtained with nalorphine and methylene blue in mice and to determine whether tolonium chloride (toluidine blue), a dye chemically related to methylene blue, also possessed antidotal qualities.

Received July 5, 1966, from the Department of Pharmacology, School of Pharmacy, Temple University, Philadelphia, Pa.
Accepted for publication September 19, 1966.
The author is indebted to Dr. J. M. McGuire, Eli Lilly and Co., Indianapolis, Ind., for supplying propoxyphene HCl (Darvon) and to Dr. Ronald F. Gautieri and Mr. Howard Harpel, Jr., for their valuable assistance.

EXPERIMENTAL

Three hundred and fifty adult male albino mice (Huntingdon Farms, HTF strain), weighing between 20 and 25 Gm., were used in this study. Prior to treatment, the animals were caged in groups of 25 for several days and had access to laboratory chow (Purina) and water *ad libitum*.

The following solutions were prepared with distilled water: propoxyphene HCl, 2.0%, and methyl-

and "in-process" control to obtain routinely both tablet-to-tablet and lot-to-lot uniformity for a production formulation.

[a] Drug administered to groups of 50 mice 5 min. prior to propoxyphene HCl. [b] Animals which survived 24 hr. after propoxyphene HCl. [c] χ^2 test, $P < 0.05$. [d] χ^2 test, $P < 0.001$.

ene blue and tolonium chloride, 1.0%, respectively. Ampuls of nalorphine HCl, 5 mg./ml., were obtained from the manufacturer.

The experimental procedure has been previously described (1). In contrast to the former investigation, however, the end point of survival after propoxyphene HCl was extended from 17 min. to 24 hr.

The intraperitoneal LD_{50} of propoxyphene HCl, determined by the method of Litchfield and Wilcoxon (2), was formerly shown to be 118 (106 to 131) mg./Kg. (1). Based upon these data, a dose of 200 mg./Kg. was selected as the lethal amount to be used in future antidotal studies in mice with propoxyphene HCl because theoretically it should produce death in 99.5%.

The treatment schedule consisted of injecting subcutaneously either methylene blue or tolonium chloride (1.0 mg.) into the upper left abdomen, nalorphine HCl (0.1 mg.) or an equivalent volume of distilled water (0.02 ml.) into the upper right abdomen, or nalorphine HCl first (0.1 mg.) followed immediately with either dye (1.0 mg.). Five minutes after prophylactic treatment, propoxyphene HCl (200 mg./Kg.) was injected intraperitoneally and the mice were then placed in individual cages for close observation. Survival time extended from the moment of propoxyphene HCl injection to the cessation of respiration. To determine the precise time of death, the number of animals under observation at one time never exceeded four.

The data obtained from the seven groups of control and treated animals (50 per group) are reported in Table I.

The significance of the per cent survival in the treated group with respect to the control group was estimated by the χ^2 test (3). Probability values greater than 0.05 were considered nonsignificant.

RESULTS

The intraperitoneal administration of 200 mg./Kg. of propoxyphene HCl ($LD_{99.5}$) was fatal to 98% of the controls. The subcutaneous injection of distilled water in a volume equivalent to that employed for nalorphine HCl (0.02 ml.), followed in 5 min. with the intraperitoneal administration of 200 mg./Kg. of propoxyphene HCl, killed 96% of the animals, although the mean survival time (580 sec.) for this group closely approximated that of the controls (583 sec.).

The subcutaneous administration of nalorphine HCl (0.1 mg.) 5 min. prior to propoxyphene HCl resulted in survival of 12% of the mice and extended the mean survival time of the remainder to 852 sec. Interestingly enough, the mean survival time of the controls and nalorphine HCl in the earlier paper is considerably lower than that recorded in this study, yet the increase is approximately the same (256 and 269 sec., respectively). A decrease in the per cent survival after nalorphine HCl from 18.4 to 12 is to be expected because the criterion for survival was changed from 17 min. to 24 hr. These results confirm the earlier observation that definite antagonism of propoxyphene HCl by nalorphine HCl occurs in mice and are in agreement with similar reports in rats (4, 5).

The administration subcutaneously of either methylene blue or tolonium chloride (1.0 mg.) 5 min. prior to propoxyphene HCl did not increase significantly the per cent of survivors (6 and 8, respectively). On the contrary, tolonium chloride increased the convulsant episodes to such an extent that a marked decrease in mean survival time occurred (480 sec.). However, when nalorphine HCl (0.1 mg.) and either methylene blue or tolonium chloride (1.0 mg.) were given together 5 min. prior to propoxyphene HCl, the per cent of survival was significantly increased to 38 and 30, while the mean survival time increased 279 and 437 sec., respectively, beyond that of the controls.

The earlier observation that nalorphine HCl alone or in combination with methylene blue significantly protected mice against lethal doses of propoxyphene HCl has been confirmed under more stringent experimental conditions. In addition, tolonium chloride, a dye chemically related to methylene blue, when administered together with nalorphine HCl, has been shown to enhance the protective activity of the narcotic antagonist in a manner quantitatively similar to its congener.

Effect of a Pantothenic Acid-Deficient Diet on Monoamine Oxidase (MAO) and Deoxyribonucleic Acid (DNA) in Rat Liver

By KANTI G. BHANSALI* and JOHN L. LACH

Livers of rats maintained for 20 days on a pantothenic acid-deficient diet plus a molecular antagonist showed lower MAO activity and higher DNA content than those of the rats receiving a basic diet plus pantothenic acid. The biochemical changes reported are not understood.

DURING the course of investigation on MAO activity and DNA content in human liver the opportunity arose to assay MAO in the livers of Sprague-Dawley rats that had been maintained on a diet devoid of pantothenic acid (1). Pantothenic acid is an important constituent of coenzyme A (CoA); its deficiency in laboratory animals causes disorders of carbohydrate, fat, sterol, and steroid metabolism and produces lesions of the skin, adrenals, nerves, spinal cord, and entire gastrointestinal tract (2).

To assure that the effect of any indigenous pantothenic acid was eliminated, experimental rats received a molecular antagonist, ω-methyl pantothenic acid (3). Control rats were fed the basic diet plus pantothenic acid. The animals were sacrificed after 20 days and their livers immediately placed in the cold until analyzed. MAO activity was determined on liver homogenates by the method of Sjoerdsma *et al.* (4), a method based on the colorimetric determination of substrate (tyramine) disappearance. DNA content was assayed by the method of Webb and Levy (5), a colorimetric procedure based on the reaction of DNA with *p*-nitrophenylhydrazine. The data obtained from the analysis of the liver specimens are given in Table I. Statistical evaluation was by Student's *t* test.

TABLE I.—NORMAL AND PANTOTHENIC ACID-DEFICIENT RAT LIVERS

	MAO Units[a]	DNA, mcg./Gm. Liver
	Normal Livers	
1	3225	2008
2	2925	2681
3	3105	2146
4	3165	2597
5	3450	2666
6	3015	2239
Mean	3147.5	2389
S.D.	±182	±294
	Pantothenic Acid-Deficient Livers	
1	2385	3777
2	2115	3556
3	2220	3468
4	2145	3596
5	1860	3369
6	1650	3268
Mean	2062	3506
S.D.	±250	±179
	$P < 0.001$	$P < 0.001$

[a] One unit is amount of MAO causing the disappearance of 1 mcg. tyramine/Gm. tissue/hr.

The liver of the rat maintained on the pantothenic acid-deficient diet plus ω-methyl pantothenic acid shows a significantly lower MAO activity and significantly higher DNA content than the normal rat liver. This relationship of low MAO activity and high DNA content in normal and pathological human liver has been also observed (1). Under pantothenate deficient conditions, CoA of rat liver has been shown to be reduced to 35–40% of normal after 9 weeks and CoA of duck liver has been observed to be depleted 40% of normal after 5 days (6). Lipmann *et al.* (7) demonstrated that pantothenic acid is a constituent of CoA. The present data suggest that pantothenic acid might also be a part of MAO.

As the determination of MAO activity and DNA content is based on Gm. of liver tissue, the higher content of DNA might be attributed to the dehydration of pathological liver (that is, a greater number of cells/Gm. of liver tissue than is normal). However, if the above is true, MAO activity of pathological liver should be more than the normal. The data reported in the paper indicate that this is not so.

Since the DNA content per cell is known to remain constant (8), the increased DNA content suggests an increase in the number of liver cells, possibly as a natural defense mechanism. Increased numbers of liver cells have been observed in other pathological states, such as in inflammation.

Since MAO as yet has not been isolated in pure form, its chemical structure is unknown, and hence, the biochemical changes involved in the presently reported phenomenon are not understood.

Gas Chromatographic Determination of Ethanol in Pharmaceuticals. Comparison of the Flame Ionization and Thermal Conductivity Detectors

By MILTON ELEFANT and JOSEPH M. TALMAGE

The use of a flame ionization detector has been investigated as a means of reducing the time necessary for the analysis of ethanol. Results obtained are in complete agreement with those found using a thermal conductivity detector.

GAS CHROMATOGRAPHY has been reported as an analytical tool for the determination of ethanol in wine (1), cosmetics (2), mixed solvents (3), and pharmaceuticals (4, 5). In a collaborative study sponsored by the Pharmaceutical Manufacturers Association (6), gas chromatography was found comparable in accuracy and precision to the official U.S.P. and N.F. distillation method for the determination of ethanol. Subsequently, the gas chromatographic procedure was adopted in the N.F. XII (7).

All of these methods specified a thermal conductivity detector which necessitated the elution of water from the column before injection of the next sample. Even with efficient columns which reduced or eliminated the tailing of water, most chromatograms required at least 12 min. It is interesting to note that in N.F. XII First Supplement (8) no detector is specified.

The use of a flame ionization detector would considerably reduce the analytical time, but the presence of water diminishes the flame detector's over-all sensitivity (9). The need to keep the flame ionization detector at constant sensitivity is the basis for obtaining results that would compare favorably with those using a thermal conductivity detector. By designing a column which gives efficient separation of acetone (internal standard) and ethanol while allowing the water to bleed off, it was found possible to use the flame ionization detector with constant sensitivity. This water bleeding phenomenon was probably responsible for the excellent results obtained by Parker *et al.* (10), in the determination of ethanol in blood using the flame ionization detector.

EXPERIMENTAL

Flame Ionization Detector

Apparatus.—Perkin-Elmer model 801 flame ionization gas chromatograph.

Column Packing.—A 6 ft., 1/4-in. o.d., copper column packed with 20% polyethylene glycol 4000[1] on Gas Pack RP 60/80 mesh (Applied Science Laboratory, State College, Pa.).

Operating Conditions.—Column temperature, 115°; injector temperature, 150°; detector temperature, 150°; He flow rate, 40 ml./min. Figure 1 illustrates a typical chromatogram.

Received June 9, 1966, from the Pharmaceutical Research and Development Laboratories, Warner-Lambert Research Institute, Morris Plains, N. J. 07950.
Accepted for publication August 24, 1966.

[1] Marketed as Carbowax by the Union Carbide Corp., New York, N. Y.

Thermal Conductivity Detector

Apparatus.—Perkin-Elmer model 154C gas chromatograph equipped with thermistor detector.

Column Packing.—A 6-ft., 1/4-in. o.d., copper column packed with 20% polyethylene glycol 4000 on 60/80 mesh Gas Pack F (a perfluorocarbon impregnated diatomaceous earth, Chemical Research Services, Inc., Addison, Ill.).

Operating Conditions.—Column temperature, 110°; injector temperature, 150°; He flow rate, 80 ml./min. Figure 2 illustrates a typical chromatogram.

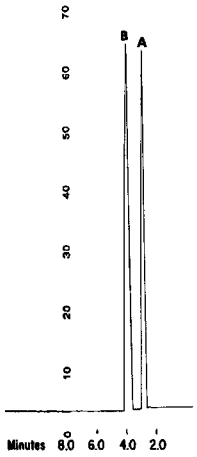

Fig. 1.—A typical chromatogram. (Flame ionization detector.) Key: A, acetone; B, ethanol.

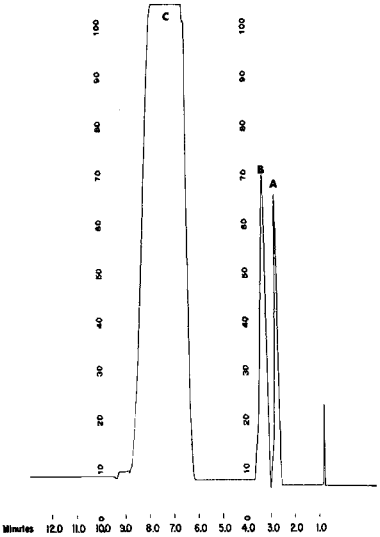

Fig. 2.—A typical chromatogram. (Thermal conductivity detector.) Key: A, acetone; B, ethanol; C, water.

Quantitation was performed, following the procedure outlined in the collaborative study of the Pharmaceutical Manufacturers Association (6).

RESULTS AND DISCUSSION

In order to demonstrate that the flame ionization detector technique was comparable to thermal conductivity detector technique, six repetitive analyses were done by each method on an experimental mouthwash product. The results obtained are summarized in Table I.

It is obvious from Table I that both methods give comparable results.

Previously during a 5-hr. period, 20 ethanol analyses could be done. Now, using a flame ionization detector, 60 analyses can be run in a 5-hr. period.

Anticonvulsants III. Alkyl Esters of 4-Bromo-2-sulfamoylbenzoic Acid and 4-Chloro-2-sulfamoylbenzoic Acid

By GLENN H. HAMOR and BERNARD L. REAVLIN

In addition to steric factors, electronic effects may also be important in the anticonvulsant activity of alkyl *o*-sulfamoylbenzoates and related compounds. To further explore the relationship between electronic properties and antielectroshock activity, three esters of 4-bromo-2-sulfamoylbenzoic acid and four esters of 4-chloro-2-sulfamoylbenzoic acid were prepared by the alcoholysis reaction of passing hydrogen chloride into a refluxing solution of 6-bromo- or 6-chlorosaccharin in the appropriate alcohol. The following alkyl 4-bromo- and 4-chloro-2-sulfamoylbenzoates were thus obtained: methyl; ethyl; *i*-propyl; and *sec*-butyl. In these compounds the bromine or chlorine atom is in the 4-position *para* to the alkoxycarbonyl group; thus, they do not possess the steric interactions between the large halogen atom and the ester moiety, which are believed to be necessary in the anticonvulsant activity of the related, potent *ortho*-substituted alkyl 6-chloro-2-sulfamoylbenzoates. Preliminary pharmacological results indicate that isopropyl 4-bromo-2-sulfamoylbenzoate lacks antielectroshock effects in mice.

RECENT WORK has shown that alkyl esters of 2-sulfamoylbenzoic acid, 4-amino-2-sulfamoylbenzoic acid, and 6-chloro-2-sulfamoylbenzoic acid (I) possess marked anticonvulsant activity as indicated by their prevention of the effect of strychnine or maximal electroshock in mice (1–5).

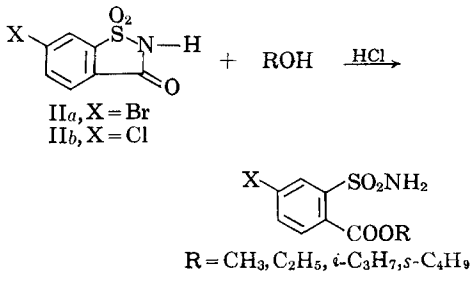
[a] Analyses were performed by Elek Microanalytical Laboratories, Torrance, Calif. [b] Infrared analysis of selected compounds corresponded to the indicated structures. [c] Melting points were taken with a Fisher-Johns melting point apparatus and are uncorrected. [d] Reported m.p. 142–144° (1).

It has been proposed that the activity of these sulfamoylbenzoates is related to their resistance to hydrolysis (5). To support this concept, data correlating anticonvulsant potency with increased chain branching of the alkyl portion of the ester were presented (5). Apart from the steric factors noted, a relationship also appears to exist between the anticonvulsant activity of these esters and the electronic effects of substituents attached to the benzene ring. The pharmacological properties reported in Table I for five previously synthesized isopropyl sulfamoylbenzoates show that the presence of electron-donating substituents *para* to the alkoxycarbonyl group tend to increase the activity, while electron-withdrawing substituents tend to decrease it. Thus, the *para* amino analog (compound *1*, Table I) possesses greater antielectroshock activity than does the desamino compound *2*, with the *para* nitro compound *3* being considerably less active.

In an effort to further explore the relationship between electronic effects and anticonvulsant activity, a number of esters containing a bromine or a chlorine atom *para* to the alkoxycarbonyl group were prepared. The three alkyl 4-bromo-2-sulfamoylbenzoates and the four alkyl 4-chloro-2-sulfamoylbenzoates synthesized are listed and their properties given in Table II, and have the formula shown



IIa, X = Br
IIb, X = Cl

VII

Scheme II

below (III). These compounds were prepared by the alcoholysis reaction of passing hydrogen chloride into a refluxing solution of 6-bromosaccharin or 6-chlorosaccharin in the appropriate alcohol, as pictured in Scheme I (4, 5).

6-Bromosaccharin (II*a*) and 6-chlorosaccharin (II*b*) were synthesized by the reaction sequence shown in Scheme II. Chlorosulfonation of the *p*-halotoluene (IV) by the procedure of Huntress (6) followed by treatment with aqueous ammonia gives 5-halo-2-methylbenzenesulfonamide (VI). Alkaline potassium permanganate oxidation of VI by the method of Noyes (7) gives the known 6-bromosaccharin (VII) (8) and 6-chlorosaccharin (VII) (8).

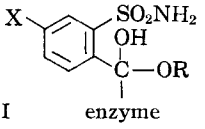
Preliminary pharmacological results indicate isopropyl 4-bromo-2-sulfamoylbenzoate,[1] (compound *11*, Table II), lacks antielectroshock effects when administered intraperitoneally, in suspension form, to mice at a dose of 100 mg./Kg. (0/10 mice protected). The compound was also inactive at doses of 200 mg./Kg. i.p. and 250 mg./Kg. p.o. The LD_{50} is greater than 800 mg./Kg. (0/10 mice i.p.). It is of interest to note that isopropyl 4-chloro-2-

[1] The authors thank Riker Laboratories, Northridge, Calif. for performing the pharmacological testing.

sulfamoylbenzoate has previously been reported to be less active than the deschlorocompound isopropyl 2-sulfamoylbenzoate, but no pharmacological data were given (1).

DISCUSSION

One possible explanation for the greatly reduced activity of the *p*-bromo-, *p*-chloro-, and *p*-nitro-substituted *o*-sulfamoylbenzoates when compared with the *p*-amino and desamino compounds may be obtained by considering that these esters are undergoing nucleophilic attack in a manner that approximates alkaline hydrolysis ($B_{AC}2$) in a chemical system (9). Alkaline hydrolysis of esters has been shown to be quite sensitive to the electronic effects of substituents on a benzene ring. One might then postulate that during the hydrolytic process these sulfamoylbenzoates are forming an enzyme–ester intermediate analogous to the tetrahedral intermediate demonstrated in $B_{AC}2$ hydrolysis (10). If this is the case, then electron-attracting substituents by increasing the polarization at the ester carbonyl group promote the formation of the enzyme–ester complex (VIII) and thus increase the rate of hydrolysis leading to pharmacologically inactive compounds.



VIII enzyme

Isopropyl 6-chloro-2-sulfamoylbenzoate (Table I, compound *5*), in which the chlorine atom is *ortho* to the ester moiety, has antielectroshock activity intermediate between that of the unsubstituted compound isopropyl *o*-sulfamoylbenzoate (compound *2*) and the compounds with electron-attracting group *para* to the alkoxycarbonyl group. The electron-withdrawing properties of the *ortho* chlorine atom, which would tend to labilize the ester to hydrolysis, are opposed by a steric hindrance to hydrolysis as a result of the steric effects of the chlorine atom. It may be of interest to note that correlation of antielectroshock activity of some 12 selected sulfamoylbenzoates with substituent effects by subjection to regression analysis according to the method of Hansch[2] (11), shows that electronic, steric, and hydrophobic factors are all important.

EXPERIMENTAL

4-Bromo- and 4-Chloro-2-sulfamoylbenzoic Acid Esters.—These esters were prepared by acidic alcoholysis of 6-bromosaccharin (II*a*) and 6-chlorosaccharin (II*b*). The known saccharins were synthesized by chlorosulfonation of the corresponding *p*-halotoluene (IV) (6), followed by treatment with aqueous ammonia which gave the 5-halo-2-methylbenzenesulfonamide (VI). The subsequent alkaline potassium permanganate oxidation of (VI) by the method of Noyes (7) yielded the desired 6-bromo- and 6-chlorosaccharins.

The esters synthesized are listed and their properties given in Table II. The alcoholysis procedure used will be illustrated by the following account of the preparation of isopropyl 4-bromo-2-sulfamoylbenzoate (compound *11*). Five grams (0.02 mole) of 6-bromosaccharin [m.p. 213–214°; reported m.p. 217° (12)] was placed in a two-necked flask fitted with a reflux condenser protected by a calcium chloride tube, and a gas inlet tube. To this was added 100 ml. of dry 2-propanol; the saccharin dissolved at the reflux temperature. The refluxing was continued while a continuous current of dry hydrogen chloride gas was passed through the solution for 2.5 hr. The passage of hydrogen chloride gas was discontinued and the reflux condenser removed; the solution was then heated for several minutes to expel hydrogen chloride. After partial evaporation, the cooled solution gave 1.8 Gm. (28.5%) of crystalline isopropyl 4-bromo-2-sulfamoylbenzoate (compound *11*), m.p. 151–153°.

Mouse Preparation for Pharmacodynamics Studies

By G. E. DEMAREE, R. L. MUNDY, M. H. HEIFFER, E. H. HERMAN, and D. P. JACOBUS

A method is described for recording an essentially undamped arterial pulse pressure in the mouse using methyl-2-cyanoacrylate physiological adhesive to secure a 22 gauge needle shaft in the carotid artery for cannulation. A miniaturized pneumotachograph screen for recording respiratory exchange in the mouse is described. Pulse pressure, ECG, and respiratory exchange tracings are shown.

PREVIOUS methods for recording directly the arterial pulse pressure of the mouse have been handicapped by low frequency response of the hydraulic and electronic systems utilized (1–6). Through the use of a large bore, hard plastic cannula, and a small displacement strain gauge pressure transducer in conjunction with rapid response electronics, an essentially undamped pulse pressure was obtained.

This report deals with simple techniques and instruments adapted for the direct recording of physiological measurements in the anesthetized mouse.

Preparation.—Female ICR mice from the Walter Reed colony weighing 25–35 Gm., aged 6–7 weeks, were used. Sodium pentobarbital (75 mg./Kg.) was administered intraperitoneally for anesthesia. The mouse was secured to the operating surface in a supine position using masking tape at each appendage and either side of the muzzle to secure the ears and whiskers to the table. The left femoral vein was exposed. A 27-gauge needle shaft, attached to a 15 μl. polyethylene cannula, was inserted into the vein and secured in position using methyl-2-cyanoacrylate monomer[1] as an adhesive. Drugs were introduced into this cannula in volumes of 10 μl. or less and flushed into circulation with 30 μl. of 0.9% NaCl solution. Additional doses of anesthetic (150–300 mcg.) were administered as needed through this cannula.

Cannulation of the Trachea.—The ventral neck area was exposed by a 3 cm. longitudinal incision. The strap muscles were exposed by separating the submaxillary glands by blunt dissection. (The fused ends of melting point capillaries worked well as dissecting probes.) The trachea was exposed by blunt dissection of the strap muscles. A tracheotomy was performed below the larynx, and a polyethylene tube large enough to fit snugly was inserted into the trachea.

Carotid Artery Cannulation.—The right carotid artery was visualized through the tissue and isolated to include the vagus nerve and as much fascia as possible using curved forceps for blunt dissection. The artery, nerve, and supporting fascia were stabilized using a single backtie which was secured to the table with beeswax. The exposed artery was supported by a melting point capillary. A 22-gauge needle shaft attached to a saline-filled vinyl cannula (B. D., No 442T) was inserted into the artery. The arterial wall was fixed to the cannula tip with the monomer adhesive.

All operative procedures were carried out with the aid of an illuminated magnifier.

ECG Leads.—Recording needle electrodes were implanted in the left hind leg and right foreleg; a needle electrode was implanted in the right hind leg as a ground lead.

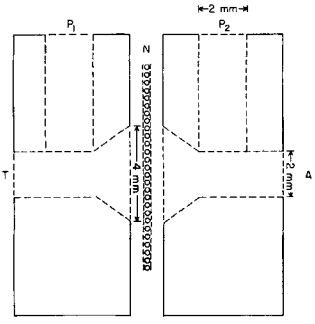

Fig. 1.—Diagram of pneumotachograph screen. Broken lines outline axes and size of holes bored in 4 mm. thick acrylic plastic. Nylon woven screen (N) in cemented between plastic halves. P_1 and P_2 lead to transducer. T leads to mouse tracheal cannula. A opens to ambient pressure. Over-all dimensions: 8 × 8 × 8 mm.

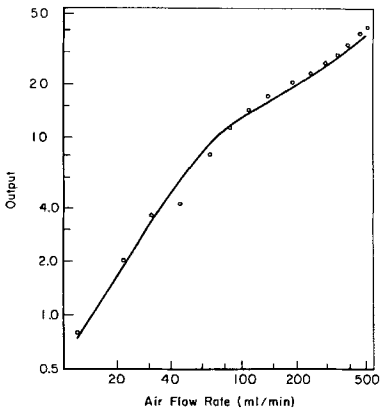

Fig. 2.—Calibration curve of pneumotachograph screen. Output voltage is in arbitary units.

Received July 22, 1966, from the Pharmacology Department, Walter Reed Army Institute of Research, Washington, D. C. 20012.

Accepted for publication August 15, 1966.

A portion of this work dealing with direct measurement of arterial pressure was reported in *Federation Proc.*, **24**, 365(1965).

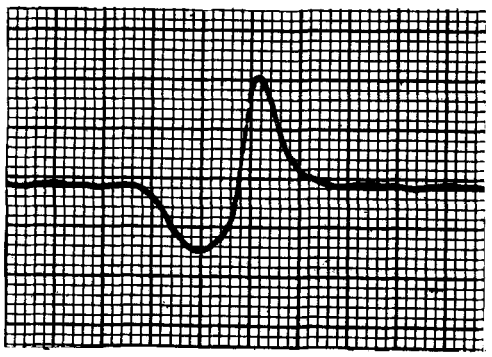
[1] Supplied through the courtesy of Ethicon, Inc., Somerville, N. J. For a description of the properties of this material see: Coover, H. W., Joyner, F. B., Shearer, N. H., and Wicker, T. H., *Soc. Plastics. Eng. J.*, **15**, 413(1959).

Respiratory Exchange Measurements.—The tracheal cannula was attached to a pneumotachograph screen which was made from a nylon screen cemented between two pieces of acrylic plastic. (See Fig. 1.) The two chambers of the pneumotachograph screen were connected by polyethylene tubing to the two sides of a Sanborn 270 differential gas pressure transducer which was activated by a Sanborn 350-1100 carrier preamplifier.

Arterial Pulse Pressure Measurements.—The arterial cannula was attached to a Sanborn 267B differential pressure transducer which was activated by a Sanborn 350-1100 carrier preamplifier.

ECG Recording.—The ECG impulses were amplified by a Phipps and Bird balanced biological preamplifier. The output of this first stage amplification was fed into a Sanborn 350-3200 ECG preamplifier.

All recordings were made on a Sanborn 964 polygraph at 50 mm./sec. and monitored on a fast sweep oscilloscope.



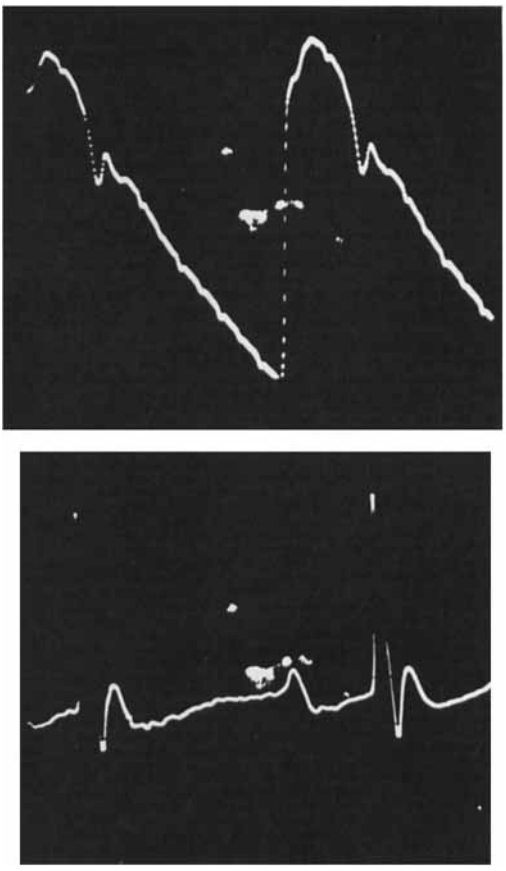


Fig. 3.—Tracings of physiological measurements of the mouse. Key: Bottom left, respiratory exchange cycle (chart speed: 50 mm./sec.); peak inspiration reached 55 ml./min.; peak expiration rate was 80 ml./min. Top right, pulse pressure curve (sweep time: 200 msec.); diastolic pressure is 60 mm. Hg; systolic pressure is 90 mm. Hg; heart rate is 550/min. Bottom right, ECG tracing (sweep time: 200 msec.).

The calibration curve of the improvised pneumotachograph screen-transducer assembly is shown in Fig. 2. A typical recording of respiratory cycle is shown in Fig. 3 (bottom left). Pulse pressure and ECG oscilloscope tracings are shown in Fig. 3, top right and bottom right, respectively.

Isolation of Two Bisbenzylisoquinoline Alkaloids from the Rhizomes and Roots of *Xanthorhiza simplicissima*

By JOSEPH E. KNAPP*, FAWZY T. HUSSEIN†, JACK L. BEAL, RAYMOND W. DOSKOTCH, and TOSHIAKI TOMIMATSU‡

The alkaloids obamegine and oxyacanthine were isolated from the tertiary alkaloid fraction of the rhizomes and roots of *Xanthorhiza simplicissima*. The tertiary alkaloids were separated from the quaternary fraction using a chromatographic column of a polyamide (nylon 66). The mixture of obamegine and oxyacanthine was separated by partition chromatography.

DURING THE course of the investigation of the quaternary alkaloids of the rhizomes and roots of *Xanthorhiza simplicissima* Marsh., a quantity of tertiary alkaloid material was isolated (1). This investigation was undertaken to isolate and identify the alkaloids in the tertiary fraction.

EXPERIMENTAL[1]

Plant Material.—The rhizomes and roots of *X. simplicissima* Marsh. used in this investigation were obtained in granulated form from S. B. Penick and Co. (lot B-19753).

Extraction.—Twenty kilograms of the plant material was extracted with ethanol U.S.P. by percolation at room temperature. Extraction was continued until the extractive failed to give a positive test with Valser's solution (2). Evaporation of the ethanol *in vacuo* at 40° or less yielded 1.7 Kg. of residue which was dissolved in 5% hydrochloric acid solution and filtered. The filtrate was basified to pH 8–9 (indicated by pHydrion paper) with 10% ammonium hydroxide solution and extracted with ethylene dichloride. After drying over anhydrous sodium sulfate the ethylene dichloride was removed *in vacuo* to yield 19.6 Gm. of crude tertiary alkaloids. Thin-layer chromatography on Silica Gel G,[2] using a solvent system of benzene–acetone–ammonium hydroxide (32:32:1) indicated the presence of only two tertiary alkaloids in the mixture; a spot at the origin was also evident indicating the presence of quaternary alkaloids in the mixture. The alkaloid spots were detected with Dragendorff's spray reagent (3). By means of a modification of a spot test for phenols (4) it was possible to determine on the thin-layer chromatogram that both tertiary alkaloids were phenolic. This was performed by spraying the developed chromatogram with a 2% solution of phosphomolybdic acid in 50% aqueous acetone and then exposing the chromatogram to ammonia fumes. Phenolic compounds will give a blue to black color with this treatment.

Separation of the Quaternary from the Tertiary Alkaloids.—The small quantity of quaternary alkaloids present in the crude tertiary alkaloid fraction were removed by utilizing a chromatographic column prepared with a polyamide (nylon 66) powder.[3] Two glass chromatographic columns (4 × 40 cm.) each containing 200 Gm. of the polyamide powder were prepared. One column was prepared by the slurry method in water while the other by the slurry method in benzene. The crude alkaloid mixture (19.6 Gm.) was dissolved in chloroform and adsorbed onto about 5 Gm. of the polyamide powder followed by evaporation of the solvent. The powder was placed on the column prepared with water and the column eluted with water. Several colored, fluorescent bands were eluted and were shown by thin-layer chromatography to be traces of quaternary alkaloids. The column was next eluted with methanol and the effluent reduced in volume and again adsorbed onto about 5 Gm. of the polyamide powder as before. The resulting powder was placed on the column prepared with benzene and the column eluted with benzene until the eluate was alkaloid free (as indicated by Valser's test). Evaporation of the benzene from the effluent, *in vacuo*, yielded 12.3 Gm. of semicrystalline material. This material was shown by thin-layer chromatography to consist mainly of the two phenolic alkaloids.

Separation of the Tertiary Alkaloids by Partition Chromatography.—The two tertiary alkaloids were purified by partition chromatography according to the procedure of Brown and Kupchan (5). The solvent system consisted of methanol–water (5:1, v/v) as the stationary phase and ethylene dichloride–Skellysolve F (1:2, v/v) as the mobile phase with a diatomaceous earth[4] serving as the inert support. Bromothymol blue was incorporated into the stationary phase to detect the alkaloid bands as they moved through the column. A chromatographic column (2 × 90 cm.) was prepared as follows. The solvent mixture of Skellysolve F, 1600

[1] Melting points were determined with a Thomas-Hoover Uni-Melt capillary melting point apparatus. The infrared spectra were taken in chloroform and as KBr pellets on a Perkin-Elmer model 237 infrared spectrophotometer. The ultraviolet spectra were determined on a Perkin-Elmer model 4000 Spectracord.

[2] Made by E. Merck (Darmstadt, West Germany); obtained through Brinkmann Instruments, Inc., Cantiague Road, Westbury, N. Y.

[3] Obtained as Polypenco Powder from the Polymer Corp., Pittsburgh, Pa.

[4] Marketed as Hyflo Super-Cel by Johns-Manville Corp., New York, N. Y. Purified by suspending in 4 *N* HCl, with occasional agitation, for 24 hr. It was then filtered on a Büchner funnel and washed successively with distilled water, methanol, chloroform, benzene, and finally methanol again. After air-drying it was dried in an oven at 105° and stored in an air-tight container. Skellysolve F is a petroleum ether fraction, b.p. 30–60°. Ethylene dichloride C.P., Union Carbide Co., methanol A.R.

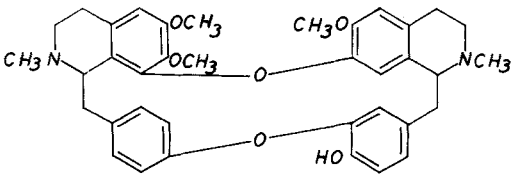
ml.; ethylene dichloride, 800 ml.; methanol, 300 ml.; and distilled water, 60 ml., was shaken well and allowed to equilibrate overnight. Two hundred grams of diatomaceous earth in a 1-L. glass-stoppered flask was treated with 132 ml. of the stationary phase (lower phase) of the solvent mixture, in which 60 mg. of bromothymol blue was dissolved. The flask was vigorously shaken to remove all lumps and the mixture then packed into the column in about 1-cm. increments. The mobile phase was then passed through the column until all the air had been displaced and the column was a uniform yellow color. A solution of 1.0 Gm. of the alkaloid mixture in 25 ml. of the mobile phase (upper phase) was added to the column. When the last portion of the alkaloid mixture had passed into the top of the column, elution was begun at a rate of about 100 ml./hr. The alkaloids were observed as two blue bands advancing down the column and were collected separately. The first band was labeled "alkaloid I" and the second "alkaloid II." Both bands were shown by thin-layer chromatography to consist of only one alkaloid. In this fashion, the remainder of the alkaloid mixture was separated.

Identification of Alkaloid I as Oxyacanthine.—The total effluent fractions containing alkaloid I were evaporated *in vacuo*. The residue was dissolved in ether and washed several times with a 10% sodium carbonate solution followed by distilled water. The ether solution was dried over anhydrous sodium sulfate followed by evaporation *in vacuo* to yield a residue of 4.75 Gm. which resisted all attempts of crystallization of the free base. The alkaloid was crystallized as the hydrochloride salt from a 5% hydrochloric acid solution. It was recrystallized from water, after saturation with sodium chloride, to give needles melting above 280° dec.

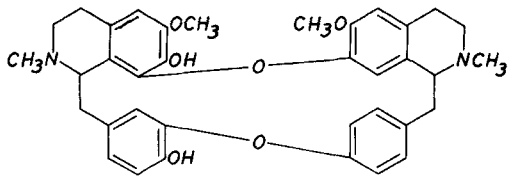
An aqueous solution of 1.4 Gm. of the hydrochloride salt was made basic with ammonia and extracted with chloroform. After drying over anhydrous sodium sulfate and removal of the chloroform *in vacuo*, a residue was obtained which crystallized from petroleum ether (b.p. 30–60°) as rosettes, m.p. 212–214°. $[\alpha]_D^{29}$ + 285.6° (c = 0.5, $CHCl_3$). The ultraviolet absorption spectrum was indicative of a benzylisoquinoline nucleus, having a $\lambda_{max.}^{MeOH}$ 283 mμ (log ε 3.95) (6). The infrared absorption spectrum in chloroform indicated a hydroxyl function ($\nu_{max.}$ = 3510 cm.$^{-1}$) in the molecule. The NMR spectrum in deuterochloroform gave indications of two *N*-methyl groups (7.40 and 7.45 τ, 3H each) and three *O*-methyl groups (6.25, 6.40, and 6.85 τ, 3H each) which suggested an oxyacanthine-type alkaloid with methoxyl groups at 6, 6′, and 7 positions, respectively, of the bisbenzylisoquinoline nucleus (7). The compound was identified to be oxyacanthine (I) on the basis of melting point, optical rotation, NMR data, and comparison of ultraviolet and infrared absorption spectra with an authentic sample of oxyacanthine.[5]

Identification of Alkaloid II as Obamegine.—The total effluent fractions containing alkaloid II were combined and treated in the same manner as for alkaloid I to yield 2.1 Gm. of residue. The material crystallized readily from benzene as colorless needles, m.p. 163–168° dec. $[\alpha]_D^{29}$ + 99° (c = 0.5, $CHCl_3$). The infrared spectrum in chloroform indicated the presence of hydroxyl function ($\nu_{max.}$ = 3525 cm.$^{-1}$). The ultraviolet spectrum gave $\lambda_{max.}^{MeOH}$ 280 mμ (log ε, 3.19).

The NMR spectrum[6] in deuterochloroform showed two *N*-methyl groups (7.6 and 7.75 τ, 3H each) and two *O*-methyl groups (6.3 and 6.4 τ, 3H each) which suggested a berbamine-type alkaloid with methoxyl groups at the 6 and 6′ positions of the molecule (7). The alkaloid was identified as obamegine (II) on the basis of melting point, optical rotation, NMR data, and comparison of infrared and ultraviolet absorption spectra with an authentic sample of obamegine.



I



II

DISCUSSION

X. simplicissima is an example of a plant which when investigated with the advantage of more modern techniques such as chromatography was found to contain several more alkaloids than reported in the older literature. In 1862, Perrins (8) reported the isolation of berberine from the rhizomes and roots of the plant; Jones (9), in 1886 verified the presence of berberine and suggested the presence of a second alkaloid. Two additional quaternary alkaloids, jatrorrhizine and magnoflorine (1), were isolated in 1963. This investigation has shown that the rhizomes and roots contain the tertiary bisbenzylisoquinoline alkaloids oxyacanthine (1) and obamegine (II), thus bringing the total to five alkaloids reported to be isolated from *X. simplicissima* Marsh.

Oxyacanthine, first obtained in crystalline form by Spath and Kolbe in 1925 (10), has been found previously in eight species of the genus *Berberis* (*Berberidaceae*), seven species of the genus *Mahonia* (*Berberidaceae*), and in the species *Cocculus leaeba* (*Menispermaceae*) (11).

Obamegine was first isolated by Tomita and Kugo (12) in 1959 from *Berberis tschonoskyana* and recently by Tominatsu and Beal (13) from *Thalictrum rugosum* (*Ranunculaceae*). This is the third report of the isolation of this compound.

[5] The authors thank Dr. E. Fujita, Institute for Chemical Research, Kyoto University, Takatsuki, Osaku-fu, Japan, for an authentic sample of oxyacanthine.

[6] The authors thank Dr. David R. Dalton for determining the NMR spectra of obamegine and oxyacanthine. These were determined on a Varian A-60 NMR spectrometer.

Ion-Exchange Separation and Ultraviolet Determination of Phenylephrine, Codeine, and Selected Antihistamines

By K. O. MONTGOMERY, P. V. JENNINGS, and M. H. WEINSWIG

A method for the isolation and determination of phenylephrine, codeine, or an antihistamine as a single active ingredient is presented. Also, a method is presented for the separation and determination of an antihistamine and codeine or an antihistamine and phenylephrine in pharmaceutical products containing these combinations. All of the amines are extracted with a strong cation-exchange resin, AG 50W-X4. The phenylephrine or codeine is eluted with 1 *N* hydrochloric acid in 60 per cent methanol in water. The antihistamine is then eluted with 3.5 *N* hydrochloric acid in 40 per cent methanol in water. The compounds are determined by subjecting the eluates to ultraviolet spectrophotometry. The assay is used successfully on several commercial products.

A LARGE NUMBER of pharmaceuticals are presently marketed for treatment of the common cold and other respiratory disorders. These products use a large variety of active ingredients but for the most part they are, chemically, basic amines. These amines are in the form of vasoconstrictors, antitussives, and antihistamines.

Phenylephrine is widely used as a vasoconstrictor in these products. The assay for this compound in liquid pharmaceuticals has been difficult because of the water solubility of phenylephrine even as the base. The U.S.P. (1) describes the time honored bromination procedure. This procedure is ineffective when oxidizable substances are present because of their reactions with bromine. Reducing sugars are a good example of this type of interference. The reactions of phenols with ferricyanide and 4-aminoantipyrine has been proposed by several workers (2, 3). Chafetz (4) oxidized phenylephrine and other phenylethanolamines to their aromatic aldehydes, extracted with organic solvents, and determined the ultraviolet absorption. Clark and Rosenberg (5) reported phenylephrine separation using a Levine column with acetylation on the column. The phenylephrine was determined in the eluates. Auerbach (6) used a diazotization technique where phenylephrine acted as the coupler. Kelly and Auerbach (7) utilized ion-exchange chromatography in a method similar to that presented in this paper.

Codeine, which is a very popular antitussive, has been the subject of extensive analytical study for many years because of its wide usage. Nonaqueous titrimetry has been utilized by several workers (8–10). Artamonov and Bugreeva (11) applied the techniques of high frequency titration for the determination of codeine.

Several colorimetric methods have been proposed (12, 13) as well as fluorimetry (14, 15), refractometry (16), and spectrophotometry (17, 18).

Various types of chromatographic procedures have been used for codeine analysis. Izmailov and co-workers (19) used paper chromatographic techniques to separate codeine from other poppy extract alkaloids. Adsorption columns of silicic acid were utilized by Andreeva and Figurovskii (20). The more recent techniques of gas chromatography (21) and thin-layer chromatography (22) have also been reported.

The common methods of assay for antihistamines include nonaqueous titrimetry (23, 24), ultraviolet spectrophotometry (25), and reineckate salt formation with subsequent colorimetric determination of the acetone solution (26). A widely used colorimetric method, specific for compounds containing the 2-pyridyl group, is based on the König reaction with cyanogen bromide and aniline. This was described by Jones and Brody (27) and later modified by Hudanick (28). Gas chromatography has been used successfully by Celeste and Turczan (29) and by Fontan and co-workers (30).

This paper utilizes strongly acidic cation-exchange resins to separate the amines from common dosage form ingredients. The amines are then eluted separately from the resin using specific concentrations of hydrochloric acid. The amines are deter-

mined in the eluate by ultraviolet spectrophotometry.

EXPERIMENTAL

Apparatus.—Glass column 20 cm. × 1 cm. with stopcock made of Teflon and containing built in needle valve for control of flow rate. The column is also fitted with a reservoir with a capacity of 250 ml.

A suitable recording ultraviolet spectrophotometer such as the Beckman DK-2A or Spectronic 505 which records in absorbance units.

Reagents.—Cationic exchange resin AG 50W-X4 100–200 mesh in hydrogen form available from Bio-Rad Laboratories, Richmond, Calif. Enough resin, about 3 Gm., is added in the form of a slurry to the glass column and rinsed with water.

Hydrochloric acid, 0.05 *N* in 50% methanol in water. Hydrochloric acid, 1.0 *N* in 60% methanol in water. Hydrochloric acid, 3.5 *N* in 40% methanol in water.

Standard Solutions.—Prepare the following standard solutions using U.S.P., N.F., or other suitable reference standards.

(*a*) Phenylephrine hydrochloride, 10 mg./200 ml., 1.0 *N* hydrochloric acid in 60% methanol in water. (*b*) Codeine phosphate, 20 mg./200 ml., 1.0 *N* hydrochloric acid in 60% methanol in water. (*c*) Chlorpheniramine maleate, 4 mg./200 ml., 3.5 *N* hydrochloric acid in 40% methanol in water. (*d*) Pheniramine maleate, 6 mg./200 ml., 3.5 *N* hydrochloric acid in 40% methanol in water. (*e*) Promethazine hydrochloride, 12.5 mg./200 ml., 3.5 *N* hydrochloric acid in 40% methanol in water. (*f*) Methapyrilene hydrochloride, 4 mg./200 ml., 3.5 *N* hydrochloric acid in 40% methanol in water.

Sample Treatment.—Use 10-ml. samples of each product except antihistamines *A*[1] (5 ml.), *B*[2] (20 ml.), and *C*[3] (20 ml.). Pipet the sample into the reservoir, rinse the pipet with distilled water, and add to the reservoir.

Add distilled water to the sample to make the volume approximately 100 ml. and mix well.

Allow the sample solution to flow through the resin bed at the rate of 2–3 ml./min. Wash the column by adding 100 ml. of distilled water and allow it to flow through the resin at the rate of 5 ml./min.

Traces of aromatic amines from flavors or coloring agents are removed by allowing 50 ml. of 0.05 *N* hydrochloric acid in 50% methanol in water to flow through the column at 5 ml./min.

For products containing phenylephrine or codeine as a single active ingredient, place a 200-ml. volumetric flask under the column and add 190 ml. of 1.0 *N* hydrochloric acid in 60% methanol in water to the reservoir. Allow this to flow through the column at the rate of 3 ml./min. The volume is adjusted with 1.0 *N* hydrochloric acid in 60% methanol in water.

For products containing an antihistamine as a single amine active ingredient, position a 200-ml. volumetic flask under the column and add 190 ml. of 3.5 *N* hydrochloric acid in 40% methanol in water to the reservoir. Allow this to flow through the column at the rate of 4 ml./min. The volume is adjusted with 3.5 *N* hydrochloric acid in 40% methanol in water.

For products containing either phenylephrine or codeine in addition to an antihistamine, follow the same procedures outlined above eluting the phenylephrine or codeine first with 1.0 *N* hydrochloric acid in 60% methanol in water, then eluting the antihistamine from the same column using 3.5 *N* hydrochloric acid in 40% methanol in water.

Determination.—Quantitatively dilute the sample eluates, if necessary, so that the theoretical concentrations are as close as possible to the standard concentrations. Record the ultraviolet spectra of the final sample dilutions and the standard solutions using a suitable spectrophotometer. Absorbance units should be used.

Using the base line technique, determine the absorbance for each sample and standard at the particular maximum. Calculate the amounts of each compound present in each sample from the values obtained for the standard solutions.

DISCUSSION AND RESULTS

Standard solutions, when subjected to the above procedures, gave the results shown in Table I. These results are derived from 10 determinations for each compound. These data indicate that the method is accurate to within 1% of the true values and are reproducible to ±1.5% at 95% confidence limits. The data for the analyses of marketed products are shown in Tables II and III.

A slightly raised base line was noted with some products where a small portion of the coloring agent was held and eluted with the sample. This did not cause any problem since the base line technique was used in the calculations.

When the maleate salt of a compound is used for a standard, there is a small difference in the base line caused by ultraviolet absorbance of the maleic acid

radical. This also is overcome for the most part by the use of the base line technique.

One deviation from the described procedures was necessary for antihistamine *D*[4]. Since terpin hydrate is precipitated on dilution with water, the sample dilution prior to column application and the washing of the column were performed using 50% methanol in water instead of distilled water.

The proposed method was successful in the presence of normal syrup and elixir components in addition to other materials such as menthol, glyceryl guaiacolate, terpin hydrate, ammonium chloride, tartar emetic, potassium guaiacolsulfonate, and chloroform.

SUMMARY

A method of assay for liquid dosage forms containing phenylephrine, codeine, or an antihistamine has been presented. Also included was an assay method for combinations of phenylephrine or codeine with an antihistamine. The procedures have been used successfully on commonly available products with accurate and reproducible results.

Double Isotopic Labeling in Toxicological Analysis I. Strychnine in Blood—A Preliminary Report

By R. A. WILEY* and J. L. METZGER

Initial results in the development of toxicological assays based on double isotopic labeling methodology are presented. It has been found that strychnine can be analyzed more accurately by this method than by more conventional procedures.

Among accepted analytical procedures for strychnine in biological fluids and tissues, probably the most commonly used is the spectrophotometric method, which ordinarily follows ethylene dichloride extraction (1). This method appeared to be the best available, but suffered from the serious disadvantage that recovery of strychnine from samples containing known amounts was never higher than 75%, and was most commonly in the 40–60% range. Since very sensitive radiochemical assays using double isotopic labeling have been reported (2) for aldosterone and other steroids, the authors were prompted to investigate the applicability of these methods to strychnine analysis.

In the steroid procedures, it is usual to add a quantity of the ^{14}C-labeled steroid to be assayed, allow the total sample to react with a tritium labeled reagent, purify the steroid derivative of interest chromatographically, and count the ^{14}C and tritium. Using ^{14}C recovery to evaluate losses during purification, it is then possible to calculate the total tritium activity, thus the concentration of the desired steroid, in the sample.

Since ^{14}C-labeled strychnine is not readily available, it was necessary to prepare a suitable ^{14}C-labeled derivative of strychnine. The planned assay envisioned allowing strychnine present in the sample to react with methyl iodide, so it was obvious that the derivative of choice would be ^{14}C-labeled strychnine methiodide. This would be added to the sample at the outset, following which the total sample would be allowed to react with ^{3}H-labeled methyl iodide. The resulting double-labeled strychnine methiodide would be purified chromatographically, and strychnine estimated by calculating the total tritium content of the sample as in the steroid case.

Thin-layer chromatography seemed well suited to the planned assay, due to its speed and simplicity. Numerous reports of recovery of radioactive substances from thin-layer plates can be found, but in this case strychnine methiodide was so firmly bound to the adsorbent that effective elution and counting were not possible. Paper chromatography was next investigated, and a number of experiments indicated that, although strychnine methiodide could not be eluted from the paper, immersion of small pieces of paper containing the radioactive material into standard fluor solutions enabled ^{14}C and ^{3}H to be counted with efficiencies of 60.3 and 21.4%, respectively. Counting efficiency was reasonably reproducible with all samples of paper used. In counting double-labeled samples, the authors found that it is a simple matter to insure that all activity due to tritium is confined to the tritium channel. However, it is never possible completely to eliminate activity due to ^{14}C from the tritium channel, so that a correction for this factor must be applied. It was found that the ratio ^{14}C c.p.m. in ^{3}H channel/^{14}C c.p.m. in ^{14}C channel exhibited sufficient variation with different pieces of filter paper that it was not possible to calculate a single correction factor for use in all assays. Instead, it was necessary to apply a spot of ^{14}C-labeled strychnine methiodide to each chromatogram and to calculate this factor independently for each run. Observed radioactivity appeared to be independent of the positioning of filters in the counting vials.

Suitable chromatographic procedures having been found, it was necessary to establish conditions ensuring 100% reaction between strychnine and methyl iodide-^{3}H. Initial attempts, using a 100:1 *M* excess of methyl iodide-^{3}H and making no particular effort to remove the water from the reaction mixture, indicated that the reaction had proceeded to about 30% completion. On increasing the molar ratio of methyl iodide to about 1000:1 and removing most of the water initially present by evaporation in the presence of a large excess of ethanol, quantitative reaction was achieved. Results, including complete calculations, for a typical assay of strychnine in aqueous solution are presented in Table I, where it is seen that recovery is essentially quantitative.

No particular difficulty was encountered in applying the method to analysis of strychnine in blood, for which results from one run are shown in Table II. Blood was selected as the biological specimen to be used because in our experience it is the most difficult fluid from which to obtain good analytical results, since it contains many compounds of all chemical types. As can be seen in Table II, blood yielded

quite high blank values, but the analytical results show that the method is capable of yielding much better recoveries than the spectrophotometric procedure, despite this complication.

It is believed that the results presented here are sufficient to establish the feasibility of the method. Although an insufficient number of assays has been run to present the usual estimates of accuracy and precision over a range of concentrations, results obtained in several duplicate assays lead the authors to believe recoveries of at least 80% may be routinely achieved. In principle, the sensitivity of the method is limited only by the specific activity of the reagents. As strychnine concentrations decrease, it will probably be necessary to perform two or more chromatographic separations on each sample in order adequately to purify the strychnine methiodide for counting. In these initial studies, relatively substantial quantities of strychnine were employed in order to minimize the required specific activity of the reagents. The authors will continue to explore the method with respect to accuracy, precision, sensitivity, and applicability to other substances of toxicological interest which are assayed only with difficulty by other methods.

EXPERIMENTAL

Preparation of Strychnine Methiodide-^{14}C.—Strychnine (430 mg.) was dissolved in 50 ml. of absolute ethanol, and a twofold molar excess of methyl iodide-^{14}C in absolute ethanol was added. The mixture was heated under reflux for 2 hr., at which time a thin-layer chromatogram indicated the reaction to be complete. On cooling the solution in dry ice, a precipitate appeared, which was collected, washed, and dried, affording 170 mg. of strychnine methiodide. Evaporation of the solvent yielded an additional 270 mg. of product. Both fractions were again checked by TLC and found to be homogeneous. The specific activity of the strychnine methiodide was found to be 20.9 μc./mmole.

Preparation of Strychnine Methiodide-^{3}H.—In order accurately to determine the specific activity of the methyl iodide-^{3}H to be used, strychnine methiodide-^{3}H was prepared in a similar fashion from 105 mg. of strychnine. Its specific activity was found to be 12.6 μc./mmole.

Preparation of Strychnine Stock Solution.—Strychnine (8 mg.) was added to 5 ml. water, and 5 drops of 0.1 *N* HCl was added to dissolve the alkaloid. Five drops of 0.1 *N* NaOH was then added, and the solution made to a volume of 25 ml. Its pH was found to be 8.2, and the solution was stored in a refrigerator for not more than 1 week.

Assay Procedure.—Strychnine stock solution and/or water was added to 1 ml. human citrated blood to make a total volume of 2 ml., followed by addition of 0.2 ml. (9600 dpm) of a solution of strychnine methiodide-^{14}C in absolute ethanol. After addition of 2 ml. of absolute ethanol, the mixture was evaporated at 60° on a rotary evaporator under water pump vacuum nearly to dryness. After addition of about 20 ml. of ethanol, the mixture was again evaporated nearly to dryness. One milliliter of a solution of methyl iodide-^{3}H in absolute ethanol (0.1 Gm. or about 30 μc./ml.) was then added, and the mixture was sealed in a glass tube. After heating at 60° for 4 hr., the tube was opened, and excess methyl iodide and ethanol evaporated in an efficient hood, until the final volume of solution was approximately 0.1 ml. This was transferred to Whatman No. 1 chromatography paper. Two control spots were also applied to each chromatogram. First, in order to be sure of the location of strychnine methiodide, "cold" strychnine methiodide was spotted. After development of the chromatogram, the edge on which this spot had run was cut off and sprayed with potassium iodoplatinate reagent to locate the strychnine methiodide. A band of the chromatogram corresponding to the R_f displayed by this strychnine methiodide was used for counting. Second, a spot containing a total of 2400 dpm of strychnine methiodide-^{14}C was applied in order to be sure of quenching corrections, as previously detailed. The chromatogram was developed by the descending technique with ethyl acetate–absolute methanol–28% NH_4OH (100:10:5). The band of the chromatogram found to contain the strychnine methiodide from each spot was then cut out and inserted in a counting solution consisting of 10 ml. of a toluene fluor solution containing 0.5% PPO and 0.04% dimethyl POPOP and 5 ml. of toluene. The amount of ^{14}C and ^{3}H contained in each spot was then determined, using a Beckman liquid scintillation spectrometer. Using the percentage recovery of ^{14}C to correct for losses during workup, the amount of strychnine methiodide-^{3}H, thus the amount of strychnine, in the original sample was calculated.

Baeocystin, a Mono-Methyl Analog of Psilocybin from *Psilocybe baeocystis* Saprophytic Culture

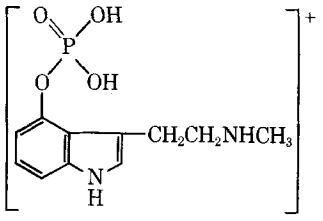
Sir:

The occurrence of psilocybin and/or psilocin in *Psilocybe baeocystis* Singer and Smith has been reported (1–3). During the authors' investigations of the indole derivatives of this fungus, an unknown compound was observed by thin-layer chromatography (3) in extracts of wild carpophores and of mycelial pellets formed in submerged culture. The compound, named baeocystin, exhibited the same color reactions with Ehrlich's reagent and with a modified phosphate reagent (4) as did psilocybin. The R_f values of psilocybin and baeocystin were similar but the compounds were separable using a two-dimensional technique (3). Baeocystin was not detected in extracts of carpophores of *Psilocybe strictipes* Smith, *Ps. caerulipes* Peck, *Ps. pelliculosa* Smith, or *Ps. atrobrunnea* (Lasch) Gillet.

The organism was grown in submerged culture, the mycelial tissue freeze-dried, and extracted as described previously (3). The extract was evaporated to dryness and chromatographed on a powdered cellulose column using 1-butanol saturated with water as the eluant. Fractions richest in psilocybin and baeocystin were combined, concentrated to dryness, and the residue was crystallized from hot methanol. This crystalline material was rechromatographed on a silicic acid column using 1-propanol–5% ammonium hydroxide (5:2) as the eluant. Fractions containing psilocybin and those containing baeocystin were concentrated to dryness and the residues were crystallized from hot methanol. From 23 Gm. of freeze-dried tissue, 10 mg. of psilocybin and 6.5 mg. of baeocystin were isolated.

Baeocystin (m.p. 254–258° dec.) showed a U.V. spectrum identical with psilocybin, indicating it to be a 4-substituted indole derivative (5), yet different from psilocin (6). The I.R. spectrum exhibited primary or secondary amine absorption bands at 3275 cm.$^{-1}$ and 1640 cm.$^{-1}$ which are absent in the I.R. spectrum of psilocybin (6).

The mass spectrum[1] showed a weak molecular ion peak at m/e = 270, corresponding to I, a



I

strong peak at m/e = 190, which corresponds to the dephosphorylated species, and a strong peak at m/e = 44 [$CH_2{=}\overset{+}{N}HCH_3$]. The mass spectrum of psilocybin showed a weak molecular ion peak at m/e = 284 and both psilocybin and psilocin showed strong peaks at m/e = 204 and m/e = 58 [$CH_2 = \overset{+}{N}(CH_3)_2$].

Apart from these differences, all three compounds showed similar fragmentation patterns with prominent peaks at m/e = 160, 159, 146, 130, and 117 in their mass spectra, the structures of which have been postulated.

Thin-layer chromatography and color reactions, U.V., I.R., and mass spectra indicate that baeocystin is the monomethyl analog of psilocybin. This report constitutes the first on its isolation from nature. The pharmacology and clinical applications in mental disease await future investigations.

Details of the isolation and characterization procedures will be reported at a later date.

A New Antifungal and Antibacterial Agent, Methyl 5(*or* 4)-(3,3-dimethyl-1-triazeno)imidazole-4(*or* 5)-carboxylate

Sir:

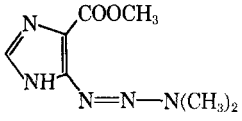
The relative scarcity (1–3) of useful antifungal drugs in comparison with the many antibacterial agents of microbial and synthetic origins emphasizes the potential importance of new compounds and structures that display potent antifungal activity. The need for more and better antifungal agents has become more urgent because of the increasing incidence and severity of fungal infections associated with debilitating diseases, such as neoplasia, and with the administration of antibiotics, corticosteroids, and antineoplastic drugs (4–8). The few medicinal antifungal agents, such as nystatin, amphotericin B, and griseofulvin, are essentially devoid of antibacterial activity; and, conversely, antibacterial drugs are generally ineffective against pathogenic fungi. A new compound, methyl 5(or 4)-(3,3-dimethyl-1-triazeno)imidazole-4(or 5)-carboxylate (I, NSC-87982), with pronounced activity *in vitro* against a broad spectrum of both fungi and bacteria is reported here. This compound is structurally related to 5(or 4)-(3,3-dimethyl-1-triazeno)- and 5(or 4)-[3,3-bis(2-chloroethyl)-1-triazeno]imidazole-4(or 5)-carboxamide, both of which have antileukemic activity (9, 10).

The triazenoimidazole methyl ester (I) was prepared by diazotizing methyl 5(or 4)-aminoimidazole-4(or 5)-carboxylate with sodium nitrite and hydrochloric acid and then introducing a 25% aqueous solution of dimethylamine into the diazotization mixture. The product (I) was extracted with chloroform and, after evaporation of the chloroform, was twice dissolved in methanol and treated with activated carbon. Evaporation of methanol after the second decolorization gave I as a white solid that was homogeneous by thin-layer chromatography (silica gel, 9:1 chloroform–methanol), m.p. 163–165° dec. $\lambda_{max.}^{methanol}$ in mμ 233 (ε 10,500) and 328 (ε 16,700).

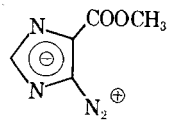
Anal.—Calcd. for $C_7H_{11}N_5O_2$: C, 42.64; H, 5.63; N, 35.52. Found: C, 42.56; H, 5.64; N, 35.23.

By extracting the diazotization reaction mixture with chloroform, the intermediate, methyl 5-diazoimidazole-4-carboxylate (II), may also be isolated as a crystalline solid, m.p. 95–96°, $\lambda_{max.}$ in mμ, 314 (ε 9400) and 270 (sh) in phosphate buffer (pH 7); $\bar{\nu}$ in cm.$^{-1}$: 2180 (N_2^+), 1700 (C=O).

Anal.—Calcd. for $C_5H_4N_4O_2$: C, 39.48; H, 2.65; N, 36.84. Found: C, 39.81; H, 2.98; N, 36.51.



I (NSC–87982)



II

Antimicrobial evaluation of NSC-87982 *in vitro* was performed by the paper disk–agar diffusion method previously described (11). NSC-87982 inhibits the growth of numerous strains of various microorganisms; the data shown in Table I illustrate its inhibitory action against representative yeasts, filamentous fungi, and Gram-positive and Gram-negative bacteria. Zones of inhibition produced by NSC-87982 in most of the fungal tests were comparable to, or greater than, those given by amphotericin B or by nystatin under similar conditions (12). It is less toxic to mice than certain 1,2,5-selenadiazoles that also have antifungal and antibacterial activity (13).

NSC-87982 significantly increased the lifespan of BDF_1 mice bearing lymphatic leukemia L1210. The average survival time of leukemic mice receiving chronic, intraperitoneal treatment (q.d. 1–30 days or to death) with NSC-87982 at 31 mg./Kg./day was approximately 160% of that of untreated leukemic mice. Inhibitory

activity against fungi, neoplastic cells, and bacteria by a single compound is of special interest because of the danger of fatal fungal infections in cancer patients (4–6).

Books

REVIEWS

Principles of Regulatory Drug Analysis. By Daniel Banes. Association of Official Analytical Chemists, P.O. Box 540, Benjamin Franklin Station, Washington, D. C. 20044, 1966. vi + 157 pp. 15.5 × 23.5 cm. Price $5.00 domestic, $5.25 foreign.

This book was written especially to point out the importance of chemical analysis in the effective enforcement of drug laws, regulations, and standards. The first chapter discusses the purpose of modern drug laws and the chemical evidence necessary to enforce them. The role of the U.S.P. and N.F. in establishing drug standards is also included. The remaining chapters are devoted to methods used in regulatory drug analysis using specific groups of drugs. The majority of the tests and assay procedures included are those appearing in the pertinent N.F. or U.S.P. or are those used by the FDA. Some discussion of methods which appear in "Official Methods of Analysis" of the A.O.A.C. is also given. The chemical principles upon which a particular test or assay is based are considered. Following each chapter, the author has included questions especially thought-provoking for students. The drug categories included are nonaddicting analgesics and antipyretics, barbiturates and related amides, sympathomimetics, antihistamines, estrogens, sulfonamides, and antibiotics.

Chemical Data Book. 2nd ed. Edited by G. H. Aylward and T. J. V. Findlay. John Wiley & Sons, Pty. Ltd., Sydney, Australia, 1966. viii + 88 pp. 15 × 24.5 cm. Paperbound. Price $2.95.

This small handbook serves as a source of data covering most of the chemical systems encountered by senior high school and first year college students. Included are properties of elements, inorganic, and organic compounds, some crystal forms, thermochemical data, and small tables of various constants and properties using only a few selected compounds.

NOTICES

Essentials of Biological Chemistry. 2nd Ed. By J. L. Fairley and G. L. Kilgour. Reinhold Publishing Corp., 430 Park Ave., New York, N. Y. 10022, 1966. xvii + 314 pp. 15.5 × 23.5 cm. Price $9.

Biochemistry: An Introduction to Dynamic Biology. By Ernest R. M. Kay. The Macmillan Co., 866 Third Ave., New York, N. Y. 10022, 1966. ix + 374 pp. 16 × 24 cm. Price $7.95.

Chemical Kinetics in Homogeneous Systems. By M. Ritchie. John Wiley & Sons, Inc., 605 Third Ave., New York, N. Y. 10016, 1966. viii + 115 pp. 14 × 21.5 cm. Price $2.95. Paperbound.

Outlines of Biochemistry. 2nd Ed. By Eric E. Conn and P. K. Stumpf. John Wiley & Sons, Inc., 605 Third Ave., New York, N. Y. 10016, 1966. x + 468 pp. 15.5 × 23.5 cm. Price $9.50.

activity against fungi, neoplastic cells, and bacteria by a single compound is of special interest because of the danger of fatal fungal infections in cancer patients (4–6).

SUMMARY 167
REFERENCES 167

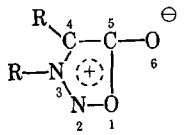
THE MESOIONIC COMPOUNDS possess structural features which have been of considerable interest to these laboratories as well as to other medicinal chemists. Their potential value as biologically active substances is found in their planar aromatic character, their relatively small size, the variation in electron density around the ring, and the possibility of selecting different patterns of electron density by selecting different mesoionic systems. Their highly charged, yet net neutral electrical character, and some of their chemical properties are also valuable assets in their potential usefulness as medicinal agents. Some biological studies have already been made or initiated with several mesoionic systems. It is, therefore, the purpose of this review to summarize the properties and the known biological activities of these systems and to discuss the relationships observed between the two.

Received from the Medicinal Chemistry Group, Battelle Memorial Institute, Columbus Laboratories, Columbus, Ohio 43201.

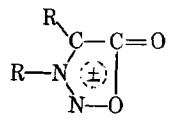
* College of Pharmacy, University of Nebraska, Lincoln.

MESOIONIC COMPOUNDS

The term "mesoionic" was first suggested by Simpson (83) to describe a type of molecule which defied covalent representation. Schönberg (82) was the first to have recognized the existence of such compounds in his consideration of the reagent "nitron." The generality of this term became apparent when the structure of the sydnones (I) became known.



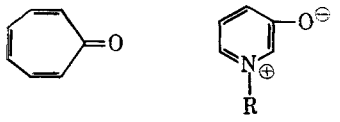
Ia



Ib

The definition of the term, given by Baker and Ollis (7) is as follows. (*a*) A five or six-membered heterocyclic aromatic ring which is not capable of being represented by a covalent structure. (*b*) All atoms of the ring furnish π-electrons to form a delocalized sextet. (*c*) The ring has a partial positive charge which is balanced by a corresponding negative charge on an exocyclic atom or group. (*d*) The ring must be planar or nearly so and must possess considerable resonance energy.

The definition precludes tropone (II) since a covalent representation is possible.



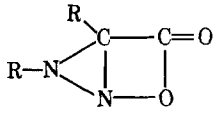
II III

Also the betaines (III) are not so classified since, in these cases, a high degree of charge fixation exists and the compound may be satisfactorily represented by the dipolar structure. Conventionally, mesoionic systems are depicted as in I*a* or I*b*. The atoms thus far encountered in rings have been carbon, oxygen, nitrogen, and sulfur. Bieber (12) has calculated that this combination of atoms could give possibly 288 five-membered mesoionic ring systems. The number of 5-membered rings actually synthesized to date is less than 20.

In this review, the authors will consider only those mesoionic ring systems for which any biological studies have been reported. The chemistry of mesoionic compounds has been reviewed by Baker and Ollis (7) and more recently by Ohta and Kato (75) in Japanese. Our objective is to discuss only the chemical and physical properties which may relate to, or may shed some light on, reported biological activity.

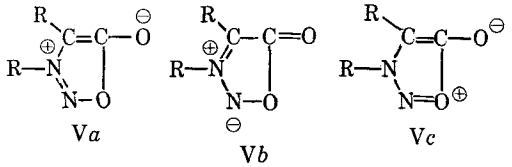
SYDNONES

Chemistry.—The first sydnone was prepared in 1935 by Earl and Mackney (33), who suggested structure IV for the product. Baker and Ollis

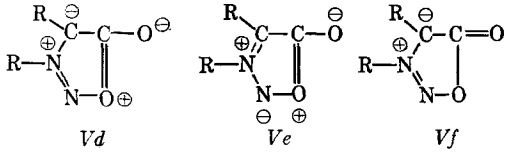


IV

(3) regarded this structure as unacceptable and proposed that the sydnones were resonance hybrids of numerous dipolar and tetrapolar forms (V).



Va *Vb* *Vc*



Vd *Ve* *Vf*

The proper evaluation of the contribution of the resonance forms to the structure is extremely difficult, pointing out an inherent defect in classical resonance or valence bond theory. The possibility that molecular orbital theory might be more illuminating as far as the sydnone electronic structure led Hill, Sutton, and Longuet-Higgins (50), Orgel, Cottrell, Dick, and Sutton (76), and later Bochvar and Bagaturyants (14) and Paoloni and Givmanini (99) to perform simple Hückel molecular orbital (MO) calculations. More recently, Kier and Roche (67) have performed MO calculations on the sydnones using the improved Hückel procedure known as the ω-technique, which takes into consideration some electron correlation. The parameters used were derived from ionization potentials and modified to give self-consistent values which would reproduce meaningful charge densities and relative energies (63, 64). From these values, the dipole moments of 3-phenyl- and 3-methylsydnone were calculated quite closely, and the ultraviolet absorption maxima were correlated with suitable MO calculated energies (67). The structures calculated are shown in Figs. 1 and 2.

Several observations can be made from these ground state structures.

(*a*) The exocyclic oxygen atom bears a high negative charge density. In comparison with the comparable oxygen atom of butyrolactone, the sydnone oxygen atom has a charge density higher by 0.15 of an electron. This indicates a more polarized carbonyl group, but the bond

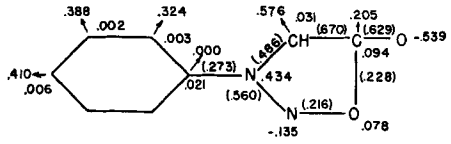


Fig. 1.—Molecular orbital calculated properties of 3-phenylsydnone from *Reference 67*. (The numbers in parentheses are bond orders, the numbers at the arrowheads are free valencies, and the other numbers are charge densities.)

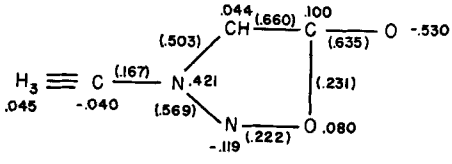

Fig. 2.—Molecular orbital calculated properties of 3-methylsydnone from *Reference 67*. (The numbers in parentheses are bond orders, and the remaining numbers are charge densities.)

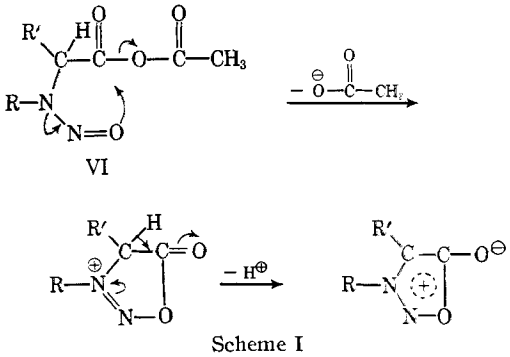
order suggests more double bond character than single bond character. This is consistent with X-ray diffraction bond length measurements by Bärnighausen, Jellinck, and Vos (8, 9), who found the C—O bond length to be 1.20 Å., close to a normal carbonyl bond length.

(*b*) The No. 3 nitrogen atom bears a high positive charge. The highest ring bond order is between the two ring carbon atoms while low bond orders exist between the ring O—N bond and the ring O—C bond. This suggests a significant contribution of canonical form V*a* to the structure of the sydnone, in a valence bond consideration.

(*c*) The sydnone ring is an electron-withdrawing substituent on the phenyl ring in 3-phenylsydnone, deactivating it at all positions. Inasmuch as ground state properties mirror excited state reactivities, this indicates that electrophilic substitution would be retarded on the benzene ring. This is borne out by experiment. Substitution reactions on 3-phenylsydnone invariably favor the 4-position of the sydnone ring (7).

The sydnones are derivatives of the 1,2,3-oxadiazole ring system, hence were named by Baker, Ollis, and Poole (4) as Ψ-5-keto-3-methyl-3,5-dihydro-1-oxa-2,3-diazole, using 3-methylsydnone as an example. The symbol Ψ reflects the uncertain electron distribution—hence, the inability to write formal covalent or single polar structures. As an alternative, Katritsky (59) has proposed a name based on a theoretical betaine representation; hence 3-methylsydnone becomes anhydro-5-hydroxy-3-phenyl-1-oxa-2,3-diazolinium hydroxide. In the opinion of the authors, the former name is superior since it does not attempt to invoke the use of a single canonical or polar form but is adaptable to a new electronic pattern in a heterocycle, one of uncertain electron distribution. Even within variously substituted sydnones, the electronic distribution would be quite variable depending on the substituents in the 3 and/or 4-position. *Chemical Abstracts* employs the use of the trivial name "sydnones" for these compounds, a name taken from the University of Sydney, where they were first made (33).

The original method of synthesis, described by Earl and Mackney (33), has not been significantly improved upon. It involves the treatment of an *N*-nitroso-α-amino acid with an anhydride such as acetic anhydride or trifluoroacetic anhydride (5). The latter reagent results in a completed reaction in seconds, while with acetic anhydride, standing for days may be necessary. Thionyl chloride (5) and phosgene (45) have also been used to close the ring. The possible substituents are alkyl or aryl but not hydrogen on the 3-position, and aryl, alkyl, or hydrogen on the 4-position. Baker, Ollis, and Poole proposed a mechanism for the formation, involving an intermediate mixed anhydride (VI) which they independently synthesized (5). (Scheme I.)



VI

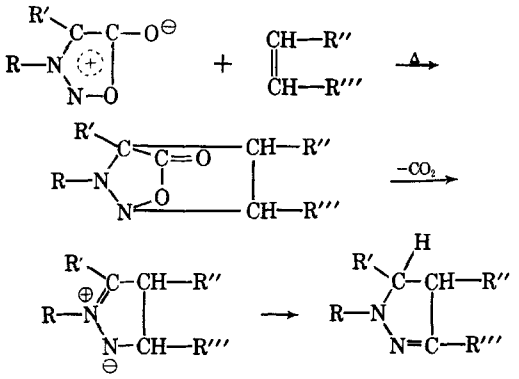
Scheme I

The chemistry of the sydnone ring has been studied extensively and reviewed recently by Nöel (72), Stewart (87), and Ohta and Kato (75). It is the authors' intention to discuss briefly only those reactions having any possible biological significance.

An argument for the aromatic character of the sydnone ring is its stability and ability to undergo electrophilic substitution at the No. 4 carbon atom (7). Examples include halogenation (11) with chloride (5), bromine (4, 58), and iodine (71), mercuration (71), deuteration (95), nitration (45), acylation (98), formylation (90), and sulfonation (94). The 4-bromo derivative has been used as an intermediate to 3-phenyl-4-carboxysydnones (58) and 3-alkyl-4-carboxysydnones (62). Attempts to put electron-donating groups in the 4-position have been unsuccessful to date (58, 96).

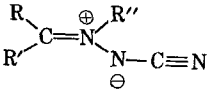
Baker, Ollis, and Poole (5) observed the unreactivity of the phenyl ring of 3-phenylsydnone to electrophilic substitution. This is predicted by the MO calculations of Kier and Roche (67) discussed earlier. On the other hand, it has been observed that a phenyl group in the 4-position of the sydnone is disposed to electrophilic attack, such as nitration (84).

An interesting reaction of the sydnones is their ability to add alkenes, alkynes, and nitriles to give pyrazole or pyrazoline derivatives with elimination of CO_2 (92, 54). Huisgen proposed Scheme II as the mechanism for the reaction (54). Huisgen (55) has compared this reaction of the



Scheme II

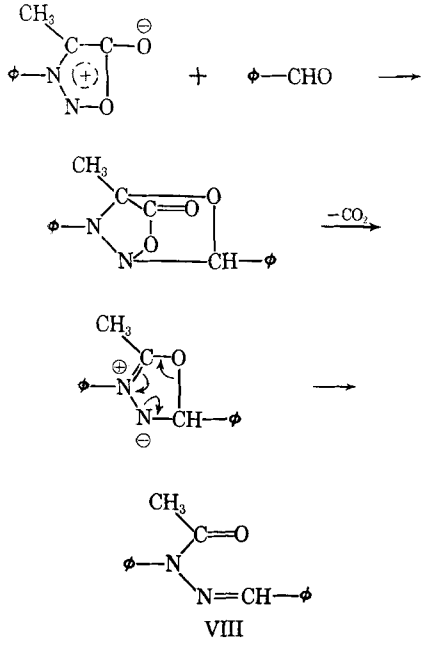
sydnones with the behavior of the azomethine imines (VII) which undergo similar addition reactions quite readily.



VII

The proposal has been made that resonance contributions (*Vb* and *Vf*) are more prominent in the ultimate structure of the sydnone than had been previously supposed (85). Addition 1,3 of a carbonyl group has also been observed (55), but a different sequence is followed to give an α-acyl hydrazine azomethine (VIII). (Scheme III.)

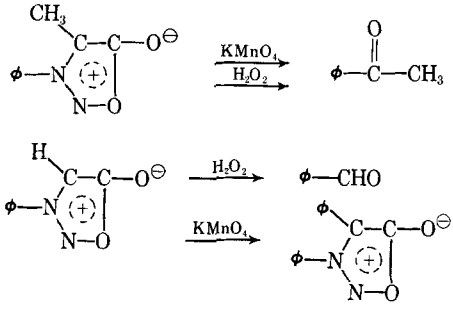
An extremely interesting reaction with an



VIII

Scheme III

as yet unresolved mechanism is the oxidation of sydnones. Hashimoto and Ohta (46) observed the products shown in Scheme IV.



Scheme IV

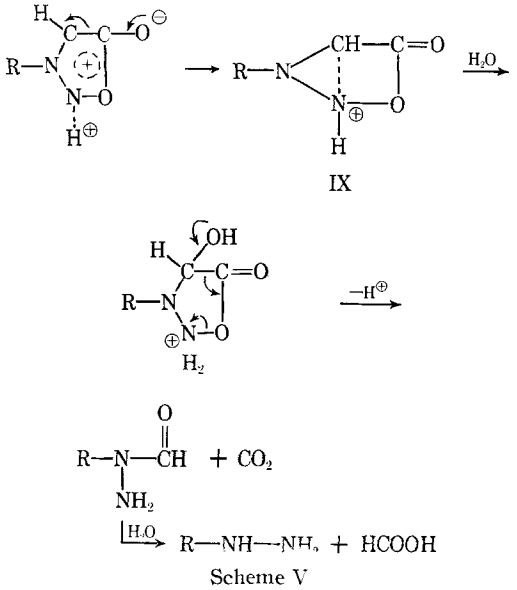
They suggested the formation of a phenyl radical from decomposition of the ring, followed by attack of the radical on an intact sydnone ring at position 4 to produce the products shown. Molecular orbital calculations show the value for the free valence at position 4 to be quite favorable for such a radical attack. (See Fig. 1.)

Acid hydrolysis of sydnones yield a substituted hydrazine, a carboxylic acid, and CO_2 (32, 33). Garrett (40) has studied the kinetics of this hydrolysis and found the order of decreasing rate in a series of 3-alkyl sydnones to be *tert*-butyl > isopropyl > methyl. He proposed, on the basis of his calculated entropies of activation, that the observed order was due to a decreasing negative charge on the ring due to a decreasing alkyl inductive effect. However, recent molecular orbital calculations (68) indicate that the alkyl groups cause insignificant perturbations in the electron distribution in the ring, an observation borne out by the fact that all of the 3-alkyl sydnones absorb at essentially the same wavelength (44, 60).

Garrett proposed a mechanism of acid hydrolysis (40) based on initial protonation of the nitrogen at position 2. This position was also predicted as the most energetically favorable position for protonation from molecular orbital calculations of protonation energies (68). The proposed mechanism of Garrett's further included the formation of an "incipient 2,4 bond or a quasidiazomethane" (IX). (Scheme V.)

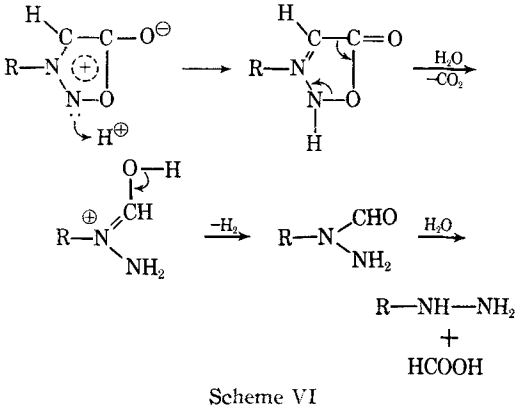
An alternate mechanism proposed by Garrett (40) involved the unlikely addition of H_2O across the 2,4 atoms, involving attack of $OH^{\ominus}$ at the N_2 position.

These two proposals seem unlikely on the basis of steric and electronic considerations. The quasidiazomethane ring structure was eliminated early in the sydnone studies (3). The attack by $OH^{\ominus}$ on the No. 2 nitrogen is predicted to



Scheme V

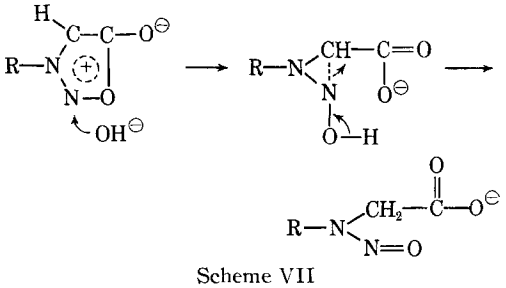
be, energetically, the least likely point of attack based on molecular orbital calculations of anion localization energies (68). A likely mechanism of acid hydrolysis would be Scheme VI (68), which is an expansion of the mechanism proposed by Baker and Ollis (7).



Scheme VI

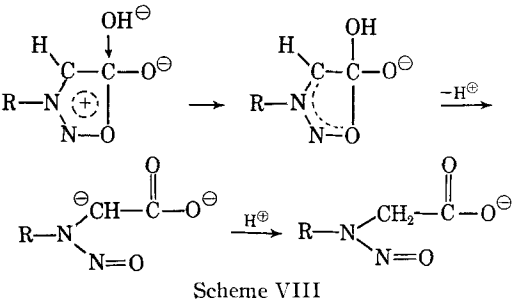
Acid hydrolysis of sydnone derivatives has become a general method for the synthesis of monoalkyl hydrazines that are difficult to obtain from more direct means (96).

Base-catalyzed hydrolysis of sydnones has been reported to regenerate the starting *N*-nitrosoaminoacid salt (32). Garrett (40) studied the kinetics of this reaction, and found the decreasing order of the rate of hydrolysis of 3-alkyl sydnones to be methyl > propyl > isopropyl > *tert*-butyl. The proposed mechanism of this hydrolysis (40) involved initial attack by $OH^{\ominus}$ on the No. 2 nitrogen, followed again by the formation of the intermediate "incipient 2,4 bond or quasidiazomethane." (Scheme VII.)



Scheme VII

This mechanism appears quite unlikely from the standpoint of valence bond reasoning. Furthermore, anion localization energies from molecular orbital calculations argue against this point of attack by $OH^{\ominus}$ (68). Energetically, the carbonyl carbon is the preferred point of attack by a reagent with a pair of electrons. Localization energies of the 3-alkyl sydnones predict the experimental order of hydrolytic rates and suggest the mechanism shown in Scheme VIII (68).



Scheme VIII

Physical Properties.—The assignments of carbonyl and carbon-hydrogen stretching frequencies in the infrared spectra of numerous sydnones have been made. A number of representative compounds are listed in Table I. The ν CO assignment of 1720–1770 cm.$^{-1}$ is consistent with the γ-lactone CO absorption at 1740 cm.$^{-1}$. The C—H absorption at 3190–3140 cm.$^{-1}$ is quite characteristic for this bond and has been used to detect the absence of a 4-substituent in sydnones (86).

The presence of an intense absorption band in the ultraviolet spectra of sydnones at 290–340 mμ ($\epsilon \sim$ 6000–8000) has been used as evidence of the aromatic character of the ring (7). Conjugation of the ring results in displacement to lower energy, *i.e.*, higher wavelength. Thus, 3-phenylsydnone absorbs at 310 mμ (44), 3-methyl-4-phenylsydnone at 317 mμ (86), and 3,4-diphenylsydnone at 340 mμ (35). (See Table II.) Kier and Roche (67) have calculated

the energy levels by MO methods for 10 substituted sydnones with $\lambda_{max.}$ values ranging from 290 to 340 mμ. They have shown a correlation between the frequency maxima of the longest wavelength high intensity absorption and the energy difference between the highest filled and lowest empty MO's, characteristic of a $\pi \rightarrow \pi^*$ electronic transition.

The dipole moments of the sydnones are quite large compared to most organic compounds. Hill and Sutton (51, 52) and Earl, Leake, and LeFevre (34) studied a large number of sydnone moments and interpreted them. The moment is directed toward the exocyclic oxygen atom, and support was derived from these studies in the formulation of these compounds as mesoionic. An attempt to reproduce the dipole moment by calculation from MO charge densities led Orgel, Cottrell, Dick, and Sutton (76) to a total moment that was high by a factor of 1.6. Coulson (23) scaled the charge densities calculated by Hill, Sutton, and Longuet-Higgins (50) for phenylsydnone to conform to the experimental dipole moment. Calculations by Kier and Roche (67), using MO procedures and parameters previously described (63, 64), produced charge densities from which dipole moments for 3-methyl- and 3-phenylsydnone were calculated. These values corresponded quite closely to experimental values. (See Table III.)

Two studies on the proton magnetic resonance spectra of sydnones have appeared in the literature. Stewart and Danieli (85) observed an unexpectedly high field for the ring proton of several sydnone derivatives. They concluded that this occurrence was difficult to reconcile with the mesoionic formulation since the positive charge associated with the ring nitrogen adjacent to this position should markedly deshield this proton. A partially delocalized azomethineimine system was proposed in which some negative charge could be generated at the sydnone 4 carbon to contribute some diamagnetic shielding to the attached proton.

Lawson, Brey, and Kier (69) found essentially the same chemical shift for the sydnone ring proton. However, they concluded that this is a downfield shift from the normal resonances for olefinic hydrogens due either to the anisotropic effect of the aromatic sydnone ring, or to

the electron withdrawing effect of the positive nitrogen. The resonance location of the ring proton is not sufficient evidence to support or discard theories concerning the aromaticity of the sydnone ring. (Table IV.)

A further look at the chemical shifts of the hydrogens attached to the carbon α to the sydnone ring in 3-alkyl sydnones uncovered some interesting evidence dealing with the electronic structure of the sydnone ring (69). These protons show downfield shifts of about 1.8-2.1 τ units from their normal resonance positions in alkyl benzene derivatives and alkyl amines. The downfield shifts from their normal aliphatic positions are about 3.2 τ units. The strong deshielding of these protons has been interpreted (69) as being due to the combined effects of the ring current in the sydnone ring and the electronegativity of the positively charged 3 nitrogen of the sydnone nucleus which bears these substituents.

Another interesting phenomenon discovered by Lawson, Brey, and Kier (69) is the concentration dependency of the chemical shift of the sydnone ring proton in $CDCl_3$ solution. As the concentration of sydnone decreases in these solutions, the sydnone proton resonance shifts upfield. This has been attributed by these authors (69) to aggregation of the sydnone in concentrated solutions. The intermolecular interaction of sydnone rings will withdraw electron density and cause the proton to appear at comparably low field. As the concentration of solvent ($CDCl_3$) increases relative to that of the sydnone, hydrogen bonds could be formed presumably with the exocyclic oxygen atom, and thus bring about the break-up of the aggregates. The interaction of the sydnone with solvent would result in less electron withdrawal than sydnone–sydnone interaction; therefore, the ring hydrogen shifts upfield. This mechanism is supported by the fact that the solvent peak for sydnone concentrations of from 0–50% in $CHCl_3$ shifts from 2.74 to 2.25 τ. The indication here is that the solvent is forming hydrogen bonds with the solute.

There is also evidence that sydnone derivatives with larger side chains have their aggregates disrupted more easily than those derivatives with smaller side chains. This concentration effect is not nearly so pronounced in acetone solution due to the fact that the solvent cannot form the hydrogen bond necessary to cause the destruction of the sydnone aggregates.

The complexing ability of sydnones was first observed by Yamada and Kazima (93), who observed a carbonyl infrared absorption shift with iodine which was found to form a 1:1 complex with the sydnone, and the conclusion was drawn

that the carbonyl oxygen was involved in the complex. Lawson, Brey, and Kier (69) observed a tendency to aggregate in solution with a series of 3-alkyl sydnones as was described in the NMR discussion. Gentile and Mao (41) studied metal halide complexes with a large number of sydnones and found complexation with strong Lewis acids such as $TiCl_4$, $SbCl_5$, $SnCl_4$, $FeCl_3$, $ZnCl_2$, and $TeCl_2$. They found that bonding occurred with the exocyclic oxygen in a 1:1 ratio in the solid state. These complexes dissociated completely in solution.

Biological Activity.—The earliest reported consideration of sydnones as biologically important agents was made by Brookes and Walker (17) in 1957 when they prepared several 3-methyl-4-alkyl sydnones as potential amino acid antagonists. Their compounds were tested against several microorganisms, including *Streptococcus haemolyticus*, *Staphylococcus aureus*, *B. coli*, *L. mesenteroides*, and filarial infections. No activity was observed. Davis, Becker, and Rogers (29) pursued the concept of the sydnones being analogs of amino acids. They tested a number of 3-substituted sydnones, mostly 3-aryl, against two fungal infections of plants. (See Table V.) The observed disease reduction appears not to be a function of where the phenyl ring substituent is, but rather what it is, in the case of controlling wheat rust. Specifically, the presence of chlorine at any position usually imparts activity to some extent. The same generalization can be made for the control of bean rust with the addition that 3-phenyl-4-substituted sydnones with no substituent on the phenyl ring also showed activity. Interestingly, the sydnones studied did not inhibit the fungal growth *in vitro*. This suggests that the sydnones perhaps function by increasing resistance to disease by a mechanism which renders the host tissue unfavorable to disease development. This is the role that the sydnones as possible amino acid antagonists might play (29).

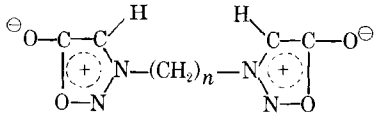
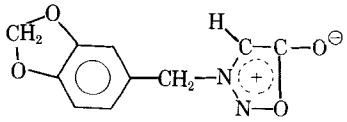
Pütter and Wolfrom (78), in a series of patents, claimed ascaridal activity for a number of substituted 3-phenylsydnones. The claim was made that the compounds were particularly effective against mites resistant to phosphorus-containing insecticides. Tien and Hunsberger (90) synthesized *N*-(3-pyridyl)sydnone and subjected the compound to a general screen against tuberculosis, several bacteria, cancer, and other chemotherapy assays. The results reported were all negative.

A number of sydnones have been examined in the search for anticancer agents. Daeniker and Druey (24) synthesized a number of polymethylene-bis-sydnones, and reported some antitumor activity for the ethylene homolog.



In a more recent antitumor study of sydnones and sydnonimines, Greco, Nyberg, and Cheng (42) reported activity against carcinoma 755 in mice with 3-(*p*-methoxybenzyl)sydnone. The same compound was inactive against sarcoma 180 and leukemia 1210 systems. An analog of this compound, 3-piperonylsydnone (X), was reported by Nyberg and Cheng (73) to be an active agent in preliminary antimalarial evaluation. At a dose of 10 mg./Kg. it was found to



X

be active against *Plasmodium berghei* in mice. It was active either orally or subcutaneously and was found to be nontoxic at a dose of 500 mg./Kg. The acid and base hydrolysis products, piperonylhydrazine (XI) and *N*-nitroso-*N*-piperonylglycine (XII), respectively, were also tested and found to be inactive, suggesting that the intact ring is the active substance.

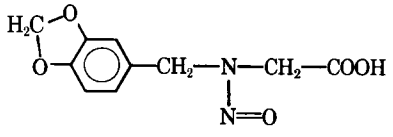
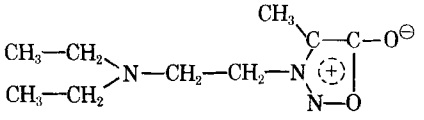
XI



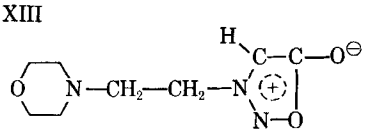
XII

A number of 3-alkyl sydnones were found by Kier and co-workers (61) to be potent central nervous stimulants. The 3-*sec*-butylsydnone was found to be a powerful respiratory stimulant in a heavily barbitalized dog. The stimulation appeared to be predominantly central, as there was little decrease of activity after vagotomy or denervation of the carotid sinus. The respiratory activity was superior to that produced by the same dose of pentylenetetrazol.[1] Kier and Dhawan (31, 60) studied the relationship between the partition coefficients of several mono and dialkyl substituted sydnones. It was observed that there was a correlation between partitioning into an oil phase and convulsive potency in the case of the 3-alkyl sydnones. (See Table VI.) In the case of the 3,4-dialkyl sydnones, the convulsive potency was found to be greater and independent of the partition coefficient. It is possible that in the case of the 3-alkyl sydnones, the absolute lipid solubility is sufficiently low so that the partition coefficient becomes a limiting factor concerning the amount of drug reaching the CNS. With the disubstituted sydnones, the absolute lipid solubility may be appreciably high so that in spite of a less favorable partition coefficient in some compounds, there is a sufficient concentration in the biolipid phase to permit an active level of sydnone to reach the site of action. Another explanation is that the intrinsic activity of the 3,4-dialkyl sydnones is significantly higher than that of the 3-alkyl sydnones, so that a less favorable partition coefficient would not mitigate against a high level of activity (31). The basic hydrolysis products of these sydnones did not elicit the same activity. Bruzzese and co-workers (18) synthesized a number of 3-aminoalkyl sydnones and noted essentially the same CNS stimulation previously observed (60), although a few were mild depressants. They also observed an analgesic action in most cases, particularly with the 3-diethylaminoethyl-4-methylsydnone (XIII) and 3-morpholinylethylsydnone (XIV). They also noted a hypoglycemic activity for several compounds. Bruzzese and his co-workers (19) hydrolyzed the 3-aminoalkyl sydnones to the corresponding hydrazines and subjected these products to the same tests. They found a dif-

[1] Marketed as Metrazole by Knoll Pharmaceutical Co., Orange, N. J.



XIII

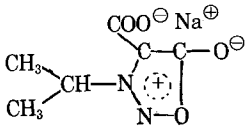


XIV

ferent pattern of activities from the sydnone precursors in most cases.

It is noteworthy that products of acid or base hydrolysis of sydnones failed to give the biological activities seen for the intact sydnone, suggesting that it is the ring itself, rather than an *in vivo* degradation product, which is the active species. This would tend to minimize the early suggestion of an amino acid antagonist (17, 29).

Fregly, Kier, and Dhawan (38) studied the diuretic and hypotensive properties of 3-*sec*-butylsydnone, 3-butyl-4-ethylsydnone, and 3-*iso*-propyl-4-sodium carboxylate sydnone (62) (XV). With comparable doses, 3-butyl-4-ethylsydnone was the most active with respect to urinary sodium output. (See Fig. 3.)



XV

The 3-*sec*-butylsydnone reduced rat blood pressure 5 to 10% over a 10 to 20 mg./Kg. dose range. The sydnone acid was inactive against blood pressure while the dialkyl sydnone was convulsive at low enough doses so that

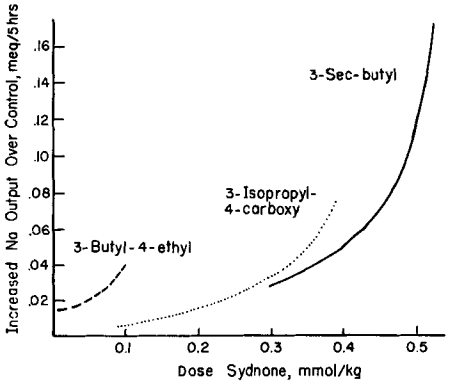


Fig. 3.—Comparison of urinary Na output by the three sydnones. (*Reference 33.*)

blood pressure measurements were interfered with.

Oehme and co-workers (74) conducted an extensive pharmacological study of a large number of 3-phenylsydnones. They found that these compounds were significantly less toxic than the 3-alkyl sydnones (60) though the toxic manifestations were quite similar. (See Table VII and compare with Table VI.) They noted that at subtoxic doses in the rat a marked change occurred in the blood picture characterized by diminution of erythrocytes as well as formation of methemoglobin. They noted an analgesic effect $^1/_{30}$ of the effectiveness of morphine with the 3-(*o*-tolyl)- and the 3-(*m*-tolyl)sydnones.

The sydnones studied were found not to have hypnotic effect themselves, but they did influence hexobarbital narcosis even in small doses. Particularly effective were the 3-(*o*,*m*, and *p*-tolyl)-sydnones, the 3-(*p*-methoxyphenyl)-, and the 3-phenyl-4-isopropylsydnones, which more than doubled the sleeping time. Substituents in the 4-position generally diminished this effect. They noted, in the case of the 3-(*m*-tolyl)sydnone, that the hexobarbital level in the rat brain, after sydnone pretreatment, was doubled. This suggested an interference with the microsomal decomposition process of the barbiturate as the cause of prolongation of the hexobarbital narcosis. This conclusion was reached when it was observed that 3-(*m*-tolyl)sydnone did not prolong sleeping time due to ethylbarbital, which is not metabolized by the rat.

In contrast to the convulsive activity found for the 3-alkyl sydnones (61), Oehme and co-workers (74) found considerable anticonvulsive activity for the 3-aryl sydnones. The 3-(*o*-tolyl)sydnones were the most active of the compounds tested. (See Table VII.) On isolated rat duodenum and guinea pig ileum, the sydnones studied had no effect. Finally, they observed that 3-methylsydnone did not inhibit glutamic acid decarboxylase. Furthermore, 3-methylsydnone and a number of 3-aryl sydnones did not inhibit monoamine oxidase, suggesting that conversion of the sydnones to the corresponding hydrazines is not involved.

In some recent work on four 3-phenyl-4-acyl sydnones (43), a modest hypotensive activity was noted when administered i. v. in dogs. There was quantitatively little differences between the compounds tested (acetyl, propionyl, isobutyryl, butyryl), the average blood pressure drop being about 10% at 10 mg./Kg. The action was of short duration.

It is evident that the 3-aryl sydnones generally

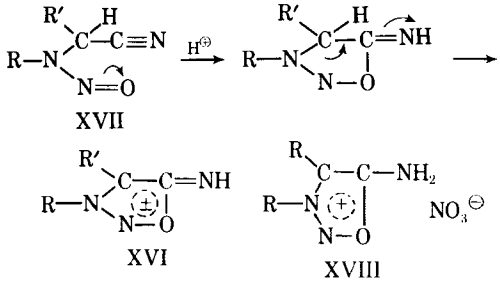
exert a depressant type of CNS response while the 3-alkyl sydnones exert a convulsive response. This dichotomy of action is not unlike barbiturates and hydantoins, depending on the presence of or absence of certain substituents on the nitrogen atoms of these compounds. This analogy has been noted and commented upon (61). A glance at the ground state electronic structures of 3-phenyl- and 3-methylsydnones (see Figs. 1 and 2) reveals some differences in the charge density patterns around the rings of these two modifications. These differences are possibly involved in determining the type of CNS action elicited.

SYDNONIMINES

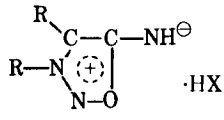
Chemistry and Physical Properties.—Brookes and Walker (17) first reported the synthesis of a sydnonimine (XVI) from the reaction of an *N*-methyl-*N*-nitroso-α-amino-nitrile (XVII) with nitric acid. (Scheme IX.) The salt in this case was the nitrate (XVIII). The sydnonimines have also been reported to be formed with hydrogen chloride (25, 57, 91) and dilute hydrochloric acid (25). The free sydnonimine (XVI) does not exist and removal of the acid causes ring opening (17).

The structure of sydnonimine salts has not been settled. Structure XVIII is usually used to represent the imine salt; however, the infrared



Scheme IX

spectrum of this compound shows absorption at 1588–1606 cm.$^{-1}$ and 1671–1770 cm.$^{-1}$, which Yashunskii (97, 98) ascribes to a $=\overset{\oplus}{N}H_2$ and a C=N group, respectively. This raises the possibility that a better representation for a sydnonimine salt may be structure XIX with a closely associated molecule of acid. Ohta and Kato (26) point out that structure XVIII does not give the usual amino group reactions such as diazotization or alkylation; hence, this structure



XIX

may not be an adequate model for the sydnonimine salt. Other derivatives of the imine salt can be formed such as the *N*-nitroso (57), *N*-nitro

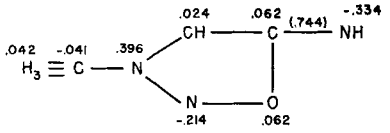


Fig. 4.—Molecular orbital calculated properties of 3-methylsydnonimine from *Reference 67*. (Number in parenthesis is a bond order. The remaining numbers are charge densities.)

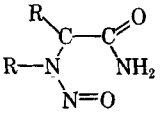
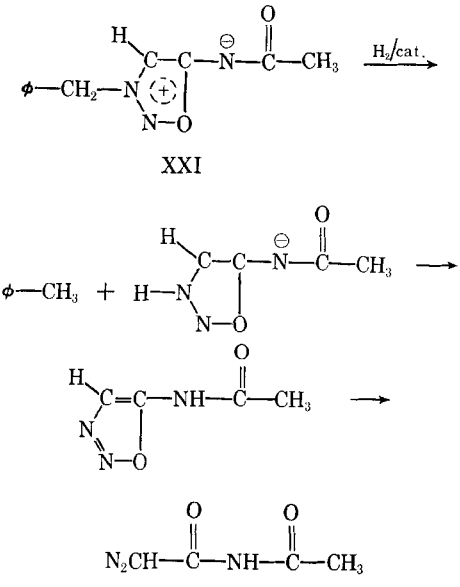
(17), *N*-acyl (57), *N*-phenyl-carbamoyl (26), and *N*-benzene-sulfonyl (27). The aromatic nature of the ring is illustrated by the fact that the 3-phenyl-*N*-acetyl-sydnonimine can be brominated and mercurated in the 4-position. Also, the NMR spectrum of the proton at position 4 supports ring aromaticity (26).

A molecular orbital treatment (68) (Fig. 4) lends support to structure XIX as being more truly representative of the sydnonimine structure. The exocyclic NH group bears a distinct negative charge density, while the C—NH bond is decidedly more of a double bond than the C—NH bond depicted in structural representation XVIII. The trisubstituted ring nitrogen bears a high positive charge density, though it is lower than the corresponding atom in methylsydnone.

Sydnonimines, unlike sydnones, are stable to acid (26). In alkali they suffer ring opening to give the nitrosoamides (XX). Prolonged exposure to hot concentrated acid cleaves the ring (25) but does not give a hydrazine derivative, in contrast to the behavior of the sydnones. Catalytic hydrogenation of sydnonimines and derivatives gives aliphatic amides with the exception of the 3-benzyl-*N*-acetylsydnonimine (XXI) which debenzylates to give α-diazoacetylacetamide (XXII) (28). Ohta (75) reported the same product from the treatment of the hydrochloride salt with acetic anhydride. (Scheme X.)



XX



XXI

XXII

Scheme X

The ultraviolet absorption of the sydnonimines closely resembles that of the sydnones. The alkyl derivatives absorb at about 290 mμ (ε ~ 8500), while the aryl derivatives are shifted to lower energy, *i.e.*, 306 mμ (ε ~8100) for 3-phenylsydnonimine HCl, and 323 mμ (ε ~ 8700) for 3,4-diphenylsydnonimine HCl (25). Molecular orbital calculations on 3-methylsydnonimine (68) predict an absorption maxima, using the correlation equation of Kier and Roche (68), of 300 mμ in fair agreement with the experimental value.

The NMR spectra of sydnonimines (25) exhibits a low field singlet for the proton on C-4. (See Table VIII.) The position of this peak is very strong evidence of π-electron delocalization in this sytem. The induced ring current causes a magnetic anisotropic shift of the proton to lower field than benzene protons. It is further interesting to note the very large downfield shift of the C-4 proton in the 3-phenyl derivative. This may be due to a combined anisotropic effect of the two aromatic rings. The magnitude of the downfield shift for the ring proton in the 3-alkyl sydnonimines also appears to be greater by more than 1 τ than the corresponding chemical shift in 3-alkyl sydnones.

Biological Activity.—Interest in the potential biological activity of sydnonimines stems from the first reported testing of salts of 3-methyl-4-isopropyl and 3-methyl-4-isobutylsydnonimines (17). They showed no activity in experimental filarial infections. Daeniker and Druey (26) and subsequent patents (10) described the analgesic, antipyretic, anti-inflammatory, antiallergenic, and hypotensive effect of sydnonimines, with the 3-benzylsydnonimine salt being particularly active. Greco, Nyberg, and Cheng (42) synthesized a number of 3-alkyl sydnonimine salts for anticancer screening and reported no activity.

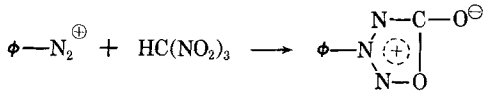
Oehme and co-workers (74) made a detailed pharmacological study of a number of sydnonimine salts. They found the sydnonimine salts studied to be more toxic than a series of sydnones studied at the same time. (See Table IX and compare with Table VII.) Deaths occurred with marked convulsions. The analgesic effects were not significant. The sydnonimines have no hypnotic effect themselves but a number of them did potentiate hexobarbital sleeping time. (See Table IX.) The compounds unsubstituted at position 4 were the most active, a situation comparable to the sydnones. The sydnonimines had no effect as anticonvulsants against pentylenetetrazol or electroshock at 0.1–0.4 mmole/Kg.

The sydnonimines tested by Oehme (74) showed spasmolytic effects in the rat duodenum and the guinea pig ileum. They noted a decrease in acetylcholine and histamine-induced contractions. They also noted a decrease in barium-induced spasms, with 3,4-diphenyl- and 3-*p*-tolyl-4-phenylsydnonimine salts. The strength of the effect corresponded to that of papaverine. The sydnonimines were hypotensive only in high doses, the effect not being pronounced (74). They did not inhibit the enzyme glutaminic acid decarboxylase *in vitro*.

There appear to be some fundamental differences in the activities of the sydnonimines and the sydnones. While the sydnones appear to act more by central mechanisms, the sydnonimines act more strongly on isolated organs.

PSEUDOÖXATRIAZOLES

Chemistry and Physical Properties.—The Ψ-oxatriazoles (XXIII) are a group of mesoionic compounds formed by replacing a ring carbon atom in the sydnone with a nitrogen. The nitrogen atom donates one electron to the 6 π-electron sextet, hence the two classes of heterocycles are isoconjugate. Quilico (79) and Ponzio (77) reported the synthesis of this ring system when they observed the reaction of phenyldiazonium salt with nitroform. (Scheme XI.)



XXIII

Scheme XI

They prepared the phenyl and *p*-nitrophenyl derivatives. Boyer and Cantor (15) reported the synthesis of the first alkyl-Ψ-oxatriazole using the appropriately substituted semicarbazide (XXIV) as the starting material. Boyer and Cantor proposed as the intermediate in the nitrosation step, the *N*-nitrososemicarbazide (XXV) a proposal subsequently confirmed by Boyer and Hernandez (16), who isolated the intermediate nitrososemicarbazide at low temperature. (Scheme XII.) Hashimoto and Ohta (49) reported the synthesis of methyl pseudoöxatriazole from the reaction of phosgene on *N*-nitroso-*N*-methylhydrazine (XXVI). They proposed an isocyanate intermediate (XXVII) although the carbamylchloride (XXVIII) is a possibility. (Scheme XIII.) Farrar (37) has prepared the phenyl derivatives by reacting potassium diazomethanedisulfonate (XXIX) with phenyldiazonium salt to form potassium hydrazono-

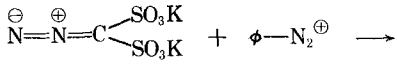
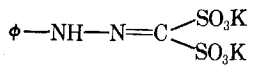
methanedisulfonate (XXX). (Scheme XIV.) Reaction of this compound with nitrous acid gave phenyl-Ψ-oxatriazole.



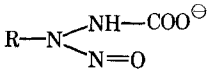
XXIX



XXX

Scheme XIV

Practically nothing is known about the chemistry of this mesoionic heterocycle. Boyer and Hernandez (16) noted that cyclohexyl-Ψ-oxatriazole resisted dilute acid, but with 80% sulfuric acid at 75° gave cyclohexanol, CO_2, and NH_3. The Ψ-oxatriazoles are considerably less stable in base (68) yielding a base-soluble product which gives a positive nitroso test. A likely structure for this compound is XXXI. This would be analogous to the base hydrolysis product of the sydnones.



XXXI

Molecular orbital calculations (68) give the ground state charge densities and bond orders shown in Fig. 5. Using the localization energy technique (81) the predicted point of protonation is the No. 2 nitrogen atom. It is interesting to note that the charge density of the Ψ-oxatriazole exocyclic oxygen is lower than that calculated for the corresponding atom of 3-methylsydnone. By contrast, the No. 3 nitrogen atom of methyl-Ψ-oxatriazole is substantially higher in positive charge then the corresponding atom of 3-methylsydnone.

Using the correlation equation derived from sydnones by Kier and Roche (67) relating U. V. absorption frequency with the MO calculated energy difference between the highest filled and lowest empty molecular orbitals (corresponding to a $\pi \rightarrow \pi^*$ spectral transition), the calculated $\lambda_{max.}$ for methyl-Ψ-oxatriazole is found to be 264 mμ, which agrees very closely with the experimental value of 260 mμ (68). The calculated value for phenyl-Ψ-oxatriazole is 277 mμ, which is very close to the experimental value of 275 mμ (37).

The infrared absorption band due to the carbonyl group lies between 1780 and 1800 cm.$^{-1}$. The ultraviolet absorption maximum is at 260 mμ ($\epsilon \sim 9000$) for alkyl derivatives and at 275 mμ ($\epsilon \sim 13{,}500$) phenyl (37).

Biological Activity.—Kier (65, 66) studied a number of alkyl substituted Ψ-oxatriazoles in the hope of finding an enhanced hypotensive activity previously noted for the isoconjugate sydnones (38). The compounds studied (see Table X) were free from toxicity at doses of 200 mg./Kg. in mice. Doses of 20 mg./Kg. i. v. in anesthetized dogs gave very prompt depressor effects in each case. The more potent hypo-

tensive compounds exhibited prolonged activity, in some cases lasting several hours. Other signs such as respiration, EKG pattern, heart rate, and gross and general appearance remained normal during this period of hypotension. The hypotensive effect ranged from approximately a 10% drop in blood pressure for methyl-Ψ-oxatriazole to about a 40% decrease for *tert*-butyl-Ψ-oxatriazole. Hypotensive activity was observed in the spinal cat, indicating that activity in the cat is not centrally mediated. Pretreatment in dogs with atropine or tripelennamine did not block the hypotensive effects, indicating that cholinergic effects or histamine release are unlikely causes of the hypotensive effects. Pressure responses in the dog to DMPP and epinephrine or norepinephrine were not reduced by the Ψ-oxatriazoles, indicating that ganglionic or α receptor blockade are also unlikely causes. On isolated rabbit ileum and rat ileum or uterus, the Ψ-oxtriazoles produced a prompt inhibition of smooth muscle activity in low concentrations. The hypotensive activity of these compounds may well be due to the relaxation of smooth muscle at the periphery. The order of potency found by Kier (66) was *tert*-butyl > *sec*-butyl $\cong$ 3-pentyl $\cong$ isopropyl > ethyl > methyl. This is in the order of increasing mesomeric contribution to the ring, suggesting that a minimization of π electron contribution enhances hypotensive activity.

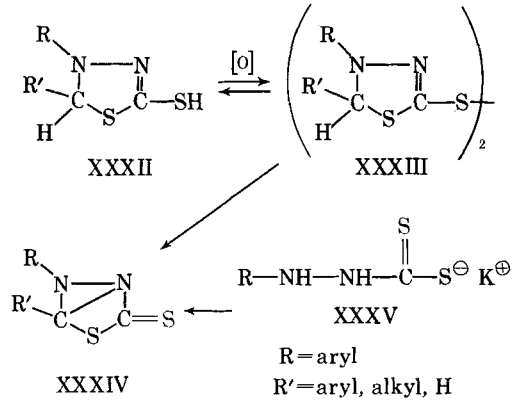
A comparison of three groups of mesoionic compounds which have shown hypotensive activity—namely, the Ψ-oxatriazoles (66), the 4-acyl sydnones (43), and the alkyl sydnones (38)—revealed the decreasing order of hypotensive potency as Ψ-oxatriazoles > 4-acyl sydnones > 3-alkyl sydnones. A comparison of the π-charge densities of the No. 3 nitrogen atom of each series reveals a decreasing positive charge, +.476, +.448, +.421, respectively. Thus, the involvement of this portion of the ring as a cationic moiety with a receptor was suggested (66). It is interesting to note that the calculated charge density of the No. 3 nitrogen of phenyl-Ψ-oxatriazole is +.484 (68) which, if the previous correlation holds, should lead to the prediction that it is a more potent hypotensive agent than the alkyl Ψ-oxatriazoles. No tests have been reported on this compound.

MESOIONIC 1,3,4-THIADIAZOLES

Chemistry and Physical Properties.—In 1895, Busch (20) noted that a thiadiazolinethiol (XXXII), oxidized to its disulfide (XXXIII), underwent a disproportionation to give the original compound (XXXII) plus a new compound postulated as XXXIV. Busch later synthesized the same compound by reaction of the potassium salt of an aryldithiocarbazinic acid (XXXV) with an acid chloride (21). (Scheme XV.) In this latter procedure, the compound in which R′ = H was made by using ethyl

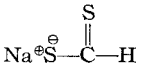
$CH_3—CH_2—O—CH{=}NH \cdot HCl$

XXXVI



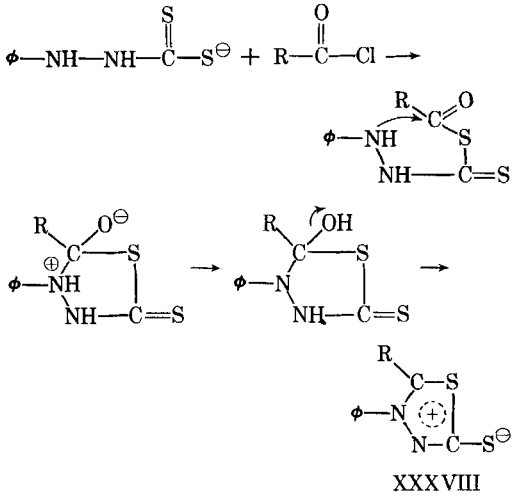
Scheme XV

formamidate hydrochloride (XXXVI) as the reagent (22). A more recent synthesis of this compound utilizes sodium dithioformate (XXXVII) with XXXV (6). The mechanism



XXXVII

of the reaction forming the mesoionic thiadiazoles is unknown. Baker (6) suggested a mixed anhydride as an intermediate. Stewart and Kier (89) proposed a mechanism employing this mixed anhydride intermediate. (Scheme XVI.)



Scheme XVI

In 1938, Schönberg (82) suggested that the compound (XXXIV), synthesized by Busch, would be better represented by a hybrid structure involving several charged forms. These are now known to be a member of the mesoionic family of aromatic heterocycles and are conventionally represented as XXXVIII.

The question of proper nomenclature is still unsettled. According to Katritzky (59) these compounds would be named anhydro - 4,5-disubstituted - 2 - thio - 1 - thia - 3,4 - diazolinium thiol, and according to Baker (6), Ψ - 4,5 - disubstituted - 2,4 - dihydro - 2 - thio - 1 - thia - 3,4 - diazole. As a matter of expediency, we have referred to these compounds as mesoionic 1,3,4-thiadiazoles in print or as "pseudothiadiazoles" in conversation.

These compounds are high melting, yellow to orange solids. They are not dethionated by HgO in boiling benzene but at elevated temperatures and pressures the diphenyl derivative decomposes to several products including *N*-, *N*′-dibenzophenylhydrazine (22). With HgO in boiling ethanol, the ring cleaves to give a dithiocarbazinic acid (XXXV) (22). Oxidation with potassium permanganate results in the formation of benzanilide from the diphenyl compound. In hot base, the ring opens to reform the dithiocarbazinic acid salt (XXXV).

The diphenyl and the 4-phenyl-5-methyl compounds have dipole moments of 8.8 D in benzene (56) characteristic of mesoionic compounds. Stewart and Kier (89) reported an absorption band at 1325–1355 cm.$^{-1}$ for a number of mesoionic thiadiazoles, which they assigned to the thiocarbonyl group. (See Table XI.) In the same study they reported a U. V. absorption maximum of high molar absorptivity at about

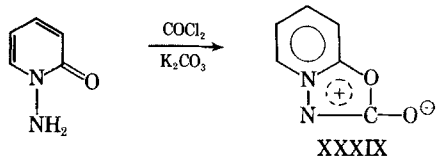
358 mμ for the 4-phenyl-5-alkylthiadiazoles and an absorption at about 400 mμ for the diaryl derivatives. (See Table XI.) It is interesting to note that the presence of an *ortho* substituent on the 5-phenyl group (4-phenyl-5-*o*-chlorophenylthiadiazole) must provide sufficient steric bulk to twist the ring out of coplanarity with the mesoionic ring, thereby isolating the two from maximal conjugation. This results in a shift of the $\lambda_{max.}$ to higher energy (lower wavelength). (See Table XI.)

Biological Activity.—Kier and Stewart (88, 89) tested a series of 4-phenyl-5-substituted mesoionic thiadiazoles against Gram-positive *Staphylococcus aureus*, *Diplococcus pneumoniae*, and Gram-negative *Escherichia coli*. Activity was observed with the 5-methyl, 5-ethyl, 5-isopropyl, and 5-propyl derivatives. Compounds with longer chains or greater bulk in this position had lower activity. The compounds were not active against the Gram-negative *E. coli*.

In other pharmacological tests, Stewart (88) observed that the LD_{50} exceeded 500 mg./Kg. i. p. in mice with each of the compounds in Table XII. The 5-alkyl compounds produced moderate convulsions in rats at higher doses. In anesthetized dogs, a number of compounds produced a fairly rapid lowering of blood pressure with a varying effect on the pulse rate. (See Table XII.) A direct cardiac effect or a peripheral vasodilation was assumed to be implied by the increase in pulse pressure with the 5-*p*-chlorophenyl compound as well as the production of extra systoles with the onset of the hypotensive effect.

ISOSYDNONES

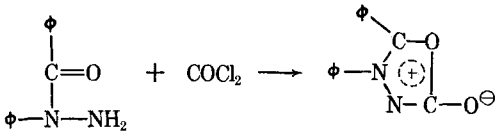
Chemistry and Physical Properties.—A modification of the sydnone ring, in which the lactone moiety is reversed, has been referred to as an isosydnone (XXXIX) (1). Hashimoto and Ohta (48) have named these Ψ-2,4-dihydro-4,5-disubstituted 2-keto-1-oxa-3,4-diazoles, while *Chemical Abstracts* indexed the compounds as 5-hydroxy-2,3-disubstituted-1,3,4-oxadiazolium hydroxide inner salts. This ring system was first reported by Hoegerle (53), who synthesized a number of bicyclic isosydnones (XXXIX). (Scheme XVII.) Using this



XXXIX

Scheme XVII

same method, Hashimoto and Ohta synthesized the first monocyclic isosydnone (48) (XL) from an α-acylhydrazine (XLI). (Scheme XVIII.)

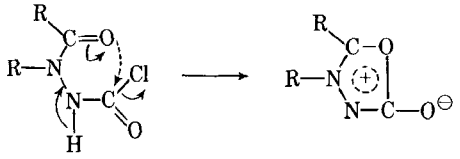


XLI XL

Scheme XVIII

The same authors attempted the synthesis of 4-methyl-5-phenylisosydnone but were not able to isolate enough of their products to fully characterize it. Ainsworth (1) succeeded in synthesizing and characterizing the 4-methyl-5-phenyl compound using phosgene in dioxane. Two 4,5-dialkyl isosydnones were first reported by Roche and Kier (80) using essentially the same synthesis, thus establishing the stability of a completely nonaromatic substituted isosydnone.

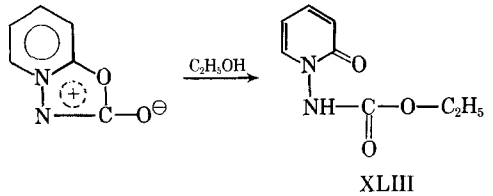
Ainsworth (1) has suggested the mechanism of formation starting with chloracylation of the hydrazine (XLII) followed by ring closure.



XLII

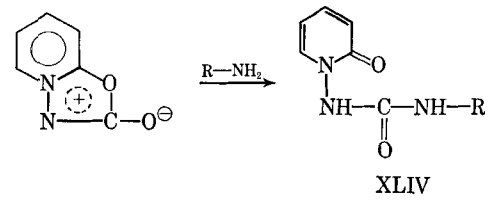
Scheme XIX

(Scheme XIX.) Hoegerle (53) noted that the ring was unstable when warmed in ethanol, yielding the substituted ethylurethane (XLIII). (Scheme XX.) Similarly, he noted the formation of the substituted urea XLIV, upon warming with NH_3 or an aliphatic amine. (Scheme XXI.) This behavior was confirmed by Hashimoto and Ohta (48) in the monocyclic isosydnone. Hashimoto and Ohta (48) observed that the product of acid hydrolysis of diphenylisosydnone was the starting material *N*-benzoyl-*N*-phenylhydrazine. They proposed a mechanism for the reaction. (Scheme XXII.) They observed that alkaline hydrolysis of the same compound led to phenylhydrazine and benzoic acid. They proposed the intermediate *N*-carboxy-*N'*-benzoyl-*N'*-phenylhydrazine (XLV) in the reaction.



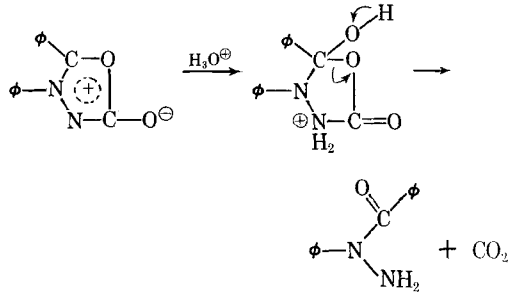
XLIII

Scheme XX

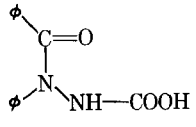


XLIV

Scheme XXI



Scheme XXII



XLV

The isosydnones possess high dipole moments, characteristic of the high charge separations found in mesoionic compounds. Ainsworth (1) reported a dipole moment of 7.58 ± 0.06 D for 4-methyl-5-phenylisosydnone in benzene at 25°. Bishop (13) in Ollis' laboratory reported dipole moment values for several aryl isosydnones, all at least 1 D higher than similarly substituted sydnones.

The infrared spectrum revealed a band at 1750–1760 cm.$^{-1}$ (1, 47, 53) which undoubtedly is due to the exocyclic C—O group. This is quite close to the typical value for the same group in the sydnones. The ultraviolet absorption maximum occurs (1, 53) at 290–325 mμ with high molar absorptivity. This is probably due to the isosydnone ring and is again comparable to the sydnone ring absorption.

Molecular orbital calculations using the methods described by Kier and Roche (67) give some insight into the electronic structure of the isosydnones. (See Fig. 6 for the calculation of 4-methyl-5-phenylisosydnone.) The charge den-

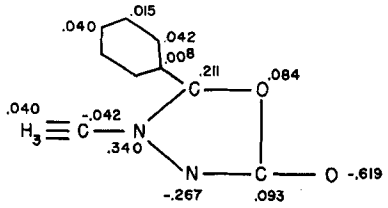


Fig. 6.—Molecular orbital calculation of 4-methyl-5-phenylisosydnone from *Reference 68*. (The numbers refer to charge densities.)

sity on the exocyclic oxygen atom is almost 0.1 electron higher than on the corresponding atom of the sydnone. This higher charge density indicates a higher calculated dipole moment than for sydnones, a prediction confirmed by the value of Ainsworth (1) of 7.58 D for 4-methyl-5-phenylisosydnone. The positive charge on the trisubstituted ring nitrogen is substantially lower than that of the sydnones, while the No. 5 ring carbon bears a much higher positive charge than the similarly placed ring carbon atom of the sydnone. Using the correlation equation derived from sydnones by Kier and Roche (67) relating U. V. absorption frequency with the energy difference between the highest filled and lowest vacant molecular orbital (corresponding to a $\pi \rightarrow \pi^*$ spectral transition), the calculated $\lambda_{max.}$ for 4-methyl-5-phenylisosydnone is found to be 296 mμ which corresponds very well to Ainsworth's experimental value of 294 mμ (1).

Biological Activity.—Interest in the isosydnones arose because of their isomeric relationship with the sydnones. In some preliminary studies Ainsworth reported (2) that 4-methyl-5-phenylisosydnone was inactive in an antibiotic screen at 25 mcg./ml. against 19 organisms representing animal pathogens, saprophytes, and bacterial and fungal plant pathogens. It was also inactive in entomology screening at 500 p.p.m. In a mouse behavior screening test, the pattern of activity suggested that the compound may be a cholinergic agent. The 4,5-diphenylisosydnone was found to give the same results against microorganisms.

SUMMARY

Much remains to be explored concerning the biological activity of mesoionic compounds. The work done to date clearly indicates significant activity and a potential as useful medicinal agents in several compounds. That the mesoionic compounds possess marked activity is not surprising, in the view of the authors. These ring systems are composed of delocalized π electrons which have been appreciably perturbed by the cores from which they arise. This perturbation is sufficient to deny the use of conventional, classical structural representations, and leads to the definition and depiction of a new class of heterocycle, the mesoionics. This perturbation results in a common structural feature found in the systems just reviewed and in many other mesoionic systems, that is, an oppositely charged dipolar segment at the extrema of a four-atom chain.

$$\overset{+\delta}{\text{—N—X—Y—}}\overset{-\delta}{\text{O}}$$

The extent of these partial charges is not obvious from classical resonance considerations, but emerges only after molecular orbital treatments, pointing out the tremendous value and utility of this technique to the medicinal chemist.

This charged four-atom segment is the hallmark of many pharmacologically active classes of drugs. Its significance perhaps lies in its ability to electrostatically interact with two complementary partially charged positions on a receptor macromolecule such as a protein helix.

A second structural feature of the mesoionic systems which suggests potential value is the fact that, although the molecules are internally charged and possess high dipole moments, they are over-all electrically neutral, therefore soluble to a much greater extent in nonpolar or lipoid solvents. Thus, *in vivo*, we have the capability of crossing lipoid barriers with a molecule which internally is appreciably ionic. This circumvents the problem found with quaternary salts and molecules rich in polar groups such as carbohydrates, which are usually constrained in their action to a water compartment, being generally unable to pass through a lipoid barrier.

Finally, the mesoionic rings are comparatively small in size, about 16 Å.^{2} for methylsydnone, and are planar, thus eliminating conformational problems and permitting the relatively close approach of all ring atoms to a receptor surface.

As the chemistry and electronic structures of more of these ring systems are studied and elucidated, more obvious relationships between these properties and their biological activities will be revealed, and the direction of future research on these compounds will be indicated.

Computer Program for a Double Exponential Equation to Determine Biological Constants

By WERNER LOWENTHAL and BARBARA L. VITSKY

A new computer program in Fortran II (with Format) for the equation, $C = \frac{a_0 k_a}{V_d(k_a - k_d)} \cdot (e^{-k_d t} - e^{-k_a t})$, has been written. This program overcomes the problems of the previous programs published. A grid method was used to search for the constants and a method to handle exponential overflow was included. Applicability of the equation and the computer program was demonstrated on the IBM 1410 computer system with eight different sets of data from the literature. The data represented a variety of drugs, *i.e.*, sulfaethylthiadiazole, aspirin alone or with additives, oxazepam, penicillin salts, and trimeprazine, in a variety of dosage forms. The conclusions of the authors were verified by the calculated constants. In some instances the conclusions of the originators of the data could be expanded by the use of the calculated constants.

As our techniques become more sophisticated and our understanding of biological systems becomes greater, the mathematical interpretation of the data can become more refined.

Teorell's work (1) stands as a landmark in the field of kinetics of drug absorption, distribution, and excretion. Teorell's equation 25 is a simplification of the kinetics of drug absorption, distribution, and excretion. It describes the kinetics of drug appearance in the blood and its disappearance from the blood when the drug is administered by any route other than i.v. The constant k_d is a combination of various rate constants due to tissue absorption, drug release from tissues, metabolism, and excretion by all organs.

$$C = \frac{k_a a_0}{V_d(k_a - k_d)} (e^{-k_d t} - e^{-k_a t}) \quad \text{(Eq. 1)}$$

a_0 = drug dose in mg./Kg.,
C = blood drug concentration in mcg./ml.,
t = time in hours,
k_a = the apparent first-order absorption rate constant in hr.$^{-1}$,
k_d = the apparent first-order drug disappearance rate constant from the blood in hr.$^{-1}$,
V_d = the specific apparent volume of drug distribution in L./Kg.

Equation 1 also neglects any effect due to excretion of the drug in the bile and reabsorption by the intestine. Teorell assumed apparent first-order kinetics for drug appearance and disappearance in the blood, which has been shown many times before to be a valid assumption. The absorption and excretion of certain drugs and dosage forms may not follow apparent first-order kinetics, *e.g.*, some sustained-release dosage forms or when metabolism of the drug is the slowest step.

In spite of the limitations of this equation, it may yield useful information about the rate of drug absorption, indirectly about the process of absorption, and the rate of drug disappearance from the blood.

It is the purpose of this paper to describe a new computer program used to solve Eq. 1, and to illustrate the application of this equation and computer program.

This program is different from the one previously reported (2) because a simpler, more rugged search routine is used to determine the constants, a method is included to handle exponential overflow, and the number of search grids is not limited. In addition, one less parameter is calculated, increasing speed and accuracy. A value for a_0/V_d is determined rather than for V_d only.

COMPUTER PROGRAM

Using the following:

$$\frac{a_0}{V_d} = \gamma, \text{ and } k_a - k_d = \delta$$

Received August 4, 1966, from the Department of Pharmacy and the Department of Biometry, Medical College of Virginia, Richmond 23219.
Accepted for publication October 14, 1966.
This investigation was supported in part by grant P07-FR-00016-04 from the National Institutes of Health, U. S. Public Health Service, Bethesda, Md.
The suggestions and assistance given by Mr. Samuel E. Ketner, Department of Biometry, concerning the grid search routine and its program, are acknowledged.
The flow diagram for the program shown in Fig. 2 is available from the authors on request.

Eq. 1 may be rewritten as:

$$C = \frac{\gamma k_a}{\delta} (e^{-k_d t} - e^{-k_a t}) \qquad \text{(Eq. 2)}$$

Rearranging

$$C = \frac{\gamma}{\delta} k_a e^{-k_a t} (e^{\delta t} - 1) \qquad \text{(Eq. 3)}$$

Taking natural logs

$$\ln C - \ln(e^{\delta t} - 1) = \ln \left(\frac{\gamma}{\delta} k_a\right) - k_a t \quad \text{(Eq. 4)}$$

Equation 4 may be calculated by means of the least squares procedure. The program calculates the best values for the constants by finding the curve with the minimum variance.

The program in Fortran II (with Format) is divided into three main parts: (*a*) the data input statements 1–70, (*b*) the search for minimum variance, statements 75–360, and (*c*) the printing of the final results, statements 360–480.

The first card of the input data contains the title of the data (up to 80 positions). The second card is the number of observations (N) and the print control k_1. If the value of the print control k_1 is anything other than a zero or blank, the minimum variance and corresponding k_a, k_d, and k_d/k_a will be printed after each grid search. This was included in the program to give greater versatility if one is interested in seeing the results of each search. The third card contains the estimated values of k_a and for the ratio k_d/k_a. These estimates were made from literature values for similar drugs or just estimated. These estimates could vary by a factor of 10 or more and still obtain a proper solution to the equation. If the initial estimates of k_a and k_d differ from the final calculated values by a factor greater than 10, the computations would take about 45 min. The computer will continue to compute until it has calculated the best values. The fourth card begins the observations, one time value, and the corresponding concentration per card.

The second portion of the program begins using the input to obtain a variance. The initial estimates of k_a and k_d/k_a become the center for a 2^3 factorial ($\times$ in Fig. 1). The initial incrementing value of 0.1 is added or subtracted from the estimates of k_a and k_d/k_a giving eight new estimates for which variances are computed. A new factorial is built around the minimum variance of the eight computed. The current estimates of k_a and k_d/k_a are incremented and decremented in steps of 0.1 until the current minimum variance computed is larger than the previous one, or until k_a or k_d/k_a become zero or less than zero by subtraction of 0.1. The 0.1 incrementing value is then reduced to 0.05. The grid search routine continues alternately reducing the increment values by 0.005 each time the currently computed minimum variance exceeds the previous minimum variance, until the value of k_a increment reaches zero. The values for k_a and k_d/k_a are essentially incremented and decremented independently.

In this manner, the program converges on the minimum variance, which is assumed when the k_a increment reaches zero.

A simplified grid search routine is presented in Fig. 1.

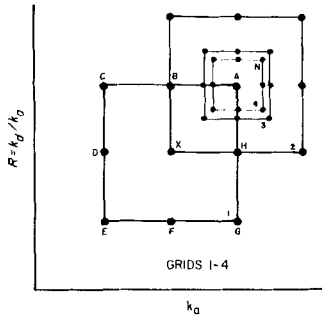

Fig. 1.—Grid search routine. Key: $\times$, initial intersection, the first estimates of k_a and k_d/k_a; A–H, first eight values to calculate variances. First minimum variance at A. The eight variances in grid 2 were greater than the one at A, so that the increments were reduced to 0.05 giving grid 3. For the purpose of this example both k_a and k_d/k_a were reduced simultaneously. In the program they are incremented and decremented independently. In grid 3 the new values of k_a and k_d/k_a gave larger variances than in A, so that the 0.05 increments were reduced by 0.005 (new increment = 0.045), giving grid 4. Again for simplification both constants were reduced simultaneously. A new minimum variance was found at N. The eight values in a grid using grid 1 as an example are: A: R + increment, k_a + increment; B: R + increment, k_a; C: R + increment, k_a − increment; D: R, k_a − increment; E: R − increment, k_a − increment; F: R − increment, k_a; G: R − increment, k_a + increment; and H: R, k_a + increment.

The final portion of the program computes and prints calculated concentrations at 15-min. intervals through the maximum time of the observed data. Following this, the values for δ, a_0/V_d, k_a, k_d, k_d/k_a, and the variance are printed.

A routine is set up in the program to avoid exponential overflow. This is done by checking the value of $-k_a t$. The exponential value ($e^{-k_a t}$) approaches zero as time increases. Absorption should be complete after many hours (*e.g.*, 24 hr.), so that if the value of $k_a t$ is greater than 50, the rate of absorption into the blood is negligible and the effect due to absorption is set to zero.

The approach using input of k_d/k_a is taken rather than using a constant for k_d because it is more accurate to work with this ratio.

The program was written for an IBM 1410 computer system, and due to the small core usage, it may be adopted to almost any computer system using Fortran. This program is fairly lengthy, dependent in part on the accuracy of the initial estimates for k_a and k_d/k_a and in part due to running the program concurrently with an interruptible telecommunications monitor. The procedure takes from 5 min. to 45 min. per set of data.

The complete program for Fortran II (with Format) is presented in Fig. 2.

RESULTS AND DISCUSSION

Most blood concentration *versus* time data in the literature could not be fitted by this equation because of: (*a*) poor spacing of time intervals, (*b*)

insufficient number of data, and (*c*) data were not collected over a sufficiently long period of time. These shortcomings of the data usually meant that the experiments were not designed for kinetic studies. Most of the usable data were found in the pharmaceutical literature where experiments were often designed for rate studies.

If the data showed an initial "lag phase" and only two points on the ascending portion of the curve, then the program may fail. Dropping the data for the lag phase and solving the equation would reduce the variance but may still give a poor fit due to lack of data. If the observed data give a high, sharp peak, the program would calculate a line below the peak and give a relatively poor estimate of the concentrations representing the peak.

Obviously, if the data do not follow apparent first-order kinetics, the equation would not fit the

Fig. 2.– Computer program in Fortran II (with Format) for double exponential equation.

observed data. Symmetrical curves on rectangular coordinates are an indication of non-first-order rates.

If the data for each subject were used instead of averages, then additional steps may be added to the program to calculate the variation about each point on the observed curve. With the present program separate tests must be made to determine the goodness of fit of the calculated curve. The χ^2 test,

$$\chi^2 = \frac{(C_{obs.} - C_{calcd.})^2}{C_{calcd.}}$$

can be used. The χ^2 values obtained are compared with the table of χ^2 values. It was found that the computer calculated variance was just as good an indicator of goodness of fit as the χ^2 test.

The following is a brief discussion of several sets of data obtained from the literature. The constants are presented in Table I.

The disappearance rate constant for sulfaethylthiadiazole (SETD) calculated by Swintosky *et al.* (3) was verified. Using averages of the published data, the k_d calculated by the computer is 0.0856 hr.$^{-1}$ and that reported was 0.073 hr.$^{-1}$ (average of four values). The k_a calculated is 2.68 hr.$^{-1}$, indicating a much more rapid absorption than disappearance from the blood. The a_0 was calculated from the 2.0-Gm. dose divided by the average weight of the subjects.

[a] 0.073 hr.$^{-1}$ reported. [b] 0.09 hr.$^{-1}$ reported for 1 patient. [c] 0.05 reported. [d] a_0/Vd values are not given because patient weights were not reported.

Later Swintosky *et al.* (4) reported blood concentrations from SETD given in 1.0, 2.0, 3.0, and 4.0-Gm. doses. These data could not be fitted by Eq. 1 using the previous program (2). There is an apparent "lag time" in the initial absorption of the drug before absorption becomes an exponential process, so that the concentration at 20 min. was omitted. This resulted in better fitting the observed data by the calculated data, and the variance was decreased by about one-half. The omission of the data at 20 min. resulted in only small increases in the values on the constants. The dose a_0 was calculated as indicated above. The present equation would require an additional term to fit the initial "lag time." This "lag time" is important in determining length of time for absorptive process to occur.

The constants calculated from these data differ considerably from those calculated from the first set of data described above. There is essentially no difference in the k_a for 1.0, 2.0, and 4.0-Gm. doses, and for k_d for 1.0 and 2.0-Gm. doses. The V_d for 1.0 and 2.0-Gm. doses are similar, as are those for 3.0 and 4.0-Gm. doses. The k_a and k_d for the 3.0-Gm. dose are smaller than those for the other doses. Some of the discrepancies are due to the fact that the calculated data cannot reproduce the high peaks in the 1.0 and 2.0-Gm. doses, so the computer-calculated k_a could be smaller than those reported by Swintosky *et al.* (3) in their earlier work. Also, if the data had been collected for longer than 4 hr., a different k_d might have been obtained. The k_d for the 3.0-Gm. dose may be only an estimate because of the lack of data to properly calculate the k_d. For the 4.0-Gm. dose, the calculated concentrations did not go so high as the observed concentrations. In the other three cases the calculated data appear to give a good approximation of the experimental data. Since the 3.0-Gm. dose gives different constants, the 4.0-Gm. dose a relatively small V_d, and the V_d for the 3.0 and 4.0-Gm. doses differ from the 1.0 and 2.0-Gm. doses, it is possible that different rate-limiting steps become important at the 3.0-Gm. dose and greater.

Nicholson *et al.* (5) compared blood levels due to SETD in plain tablets and as sustained-release tablets. The data were averaged and the computer calculated constants found in Table I verify the constants for rate of disappearance from the blood reported by Nicholson and co-workers. The k_a did not vary significantly between the plain tablets and the sustained-release tablets, although the rates of absorption vary. The decrease in k_d for the sustained-release tablets is accompanied by an increase in V_d indicating wider distribution or more SETD in the fluids which would be expected from Eq. 1. The smaller k_d indicates slower disappearance from the blood.

Liberman and Wood (6) compared three different aspirin formulations and reported serum salicylate levels up to 2.5 hr. The three formulations

were: *D*, aspirin, dihydroxyaluminum glycinate, and magnesium carbonate; *E*, commercial aspirin–starch granulation; and *L*, a commercial aspirin tablet. The constants for formula *E* could not be calculated by the previous program (2). The data showed higher and earlier peak of salicylate in serum with formula *D*. This can be seen from the k_a which is 3 to 4 times greater than the k_a for the other two preparations, a smaller k_d and a larger V_d, indicating a more rapid absorption and a slower loss from the blood.

The constants for the data of Walkerstein *et al.* (7) could not be calculated by the previous program but were satisfactorily calculated by the new program. Plasma levels of ^{14}C-oxazepam given orally to dogs were reported from 0.5–120 hr. The calculated constants are shown in Table I.

Juncher and Raaschou (8) gave 400,000 units of penicillin acid and various penicillin salts to 10 subjects, either fasting or after a standard meal. Blood levels were measured from 0.25 to 6 hr. The fasting subjects had higher blood levels and the calcium and potassium salts of penicillin V gave the highest blood levels. The authors' conclusions are verified by the calculated constants. The data from subjects which had fasted gave much higher k_a, indicating higher rates of absorption than the data from subjects who ate a standard meal. The rate of decline in the blood levels was about the same for all preparations.

Wood and Syarto (9) compared buffered aspirin to aspirin coated with different ratios of ethyl- and methylcellulose; for formula 138 the ratio was 100:1; for 152, 82.5:17.5; for 134B, 75:25; and for 134C, 25:75. The workers did not calculate any rate constants, but stated plots of cumulative *in vivo* release fit apparent first-order better than zero-order kinetics. The same amount of aspirin was used in all the formulas. Blood levels were obtained from 0.5 to 24 hr. The constants shown in Table I indicate that the absorption rate for buffered aspirin is much greater than for the other preparations. The rate of decrease in blood for all the preparations is similar; also V_d does not change very much with formulation changes. As the ethylcellulose content of the coatings decreases, the rate of aspirin absorption increases and the apparent specific body volume decreases. Therefore, the amount of ethylcellulose in the coating affects the rate of aspirin absorption.

Johnson and Masters (10) gave ^{35}S-labeled trimeprazine tartrate orally to patients. Serum levels up to 48 hr. were used to compare a 5-mg. dose, a 15-mg. dose, a 5-mg. dose given 3 times a day, and a 15-mg. dose sustained-release preparation. These workers reported the characteristic differences expected between a 5-mg. dose and a 15-mg. dose, and that 5 mg. given 3 times a day and the 15-mg. sustained-release product gave similar blood levels. The constants shown in Table I indicate that the rate of disappearance of the drug from the blood given by the various dosage regimens and the V_d closely agree. The V_d for the 5-mg. dose is smaller because there is only one-third the amount to be distributed in the body compared to the other 15-mg. doses. The V_d for the other three preparations are similar. The k_a for the 15-mg. dose is about 1.86 times greater than the k_a for the 5-mg. dose; assuming instantaneous availability for both dosages, this could indicate k_a is dose dependent. The more drug exposed to absorbing surfaces, the more rapid the absorption. The k_a for the 5-mg. dose given 3 times a day and the 15-mg. sustained-release preparation appear the same, the k_d are similar, and the V_d appear the same, indicating the divided dose therapy and the sustained-release preparation are similar.

Isolation of Cantharidin from *Epicauta pestifera*

By WILBERT G. WALTER and JOHN F. COLE

Epicauta pestifera Werner (*Meloidae*) is a species of blister beetle which is found in North America and contains a powerful irritant and vesicant. This paper reports the isolation, quantitative determination, and identification of the active principle responsible for this activity. Employing standard practices of analysis, which involved infrared and NMR spectroscopy, thin-layer chromatography, elemental analysis, and determination of physical constants, the substance was identified as cantharidin.

THIS PAPER reports the isolation and quantitative determination of cantharidin from a species of blister beetle, *Epicauta pestifera* Werner (*Coloptera, Meloidae*) which is found in North America and occurs commonly in Mississippi. This particular specie of blister beetle has not been previously investigated for its vesicating principle. Cantharidin, as it was determined in this investigation, is the substance responsible for the strong irritating and vesicating effects. This compound has also been isolated from several other species of beetles of the genera *Epicauta* of Asia, Indonesia, and South America.

Investigators have reported previously that cantharidin occurs in *E. pilmus* Porter (1), which is found in Chile, in concentrations ranging from 1.7% to 3.5%; in *E. gorhami* Marseul (2), from 0.4% to 1.75%; in *E. waterhousei* (3), which is found in Formosa, from 1.02% to 1.26%; and *E. ruficeps* Ill. (4), which is found in Java, and *E. odspersa* (5), found in Brazil, in concentrations of 2.5%. Shimano *et al.* (2) showed that the substance is present in *E. gorhami* in the head (2.5%), thorax (1.2%), abdomen (94%), and legs (2%), which is contrary to general belief that it is confined principally to the abdomen where it may be secreted from between the segments of the underside. The cantharidin content varies considerably from one genera and species to another but is found usually in concentrations of approximately 1% and has been reported as high as 3.5% in *Epicauta gorhami* (2). In this investigation, cantharidin was found to be present in *E. pestifera* in the amount of 1.09% by weight.

Received April 25, 1966, from the Department of Pharmacognosy, School of Pharmacy, University of Mississippi, University.

Accepted for publication September 29, 1966.

Presented to the Pharmacognosy and Natural Products Section, A.PH.A. Academy of Pharmaceutical Sciences, Dallas meeting, April 1966.

The authors acknowledge support of this work by the Research Institute of Pharmaceutical Sciences, Natural Product Division, School of Pharmacy, University of Mississippi.

The authors express their appreciation to Dr. Richard B. Selander, Department of Entomology, University of Illinois, Chicago, who identified the beetle, for his encouragement and assistance.

DISCUSSION

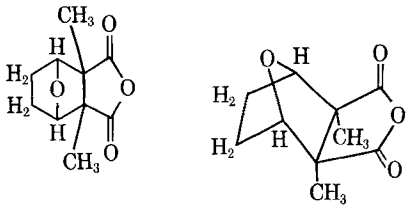
E. pestifera is, in the United States, often referred to as the common margined blister beetle of potatoes. It has been called *E. solani* Werner and *E. marginata* Fabr. The latter may sometimes be used in reference to *E. cinera* Forster. *E. pestifera* is widely scattered throughout North America and the U. S. but occurs principally from the Atlantic Coast to the Rocky Mountains. The seasonal range of the adult beetles is July to September. They are regarded as garden pests and are known to attack garden vegetables in addition to the potato plant. However, Werner (6) points out that the margined blister beetle of potatoes does have a grey form and that they occur on *Clematis* species of plants rather than potatoes, and furthermore, that they are actually an *Epicauta* species distinct from that found on potatoes. This and related species have been found on plants of the *Ranunculaceae, Solanaceae, Leguminosae,* and *Compositae* familes. One is referred to studies conducted by Werner (6–9) and Selander (10–13) on the *Meloidae*, genera *Epicauta*, for plants from which particular species were collected.

The *Meloidae*, or blister beetle family, are centered mostly in the arid and semiarid areas of the world, and at the present time, this family comprises approximately 75 genera and some 2000 described species (14). More than three-fourths of the North American entomological literature on the *Meloidae* deals with members of *Epicauta*. Werner (6–9) and Selander (15, 16) have made major contributions to the collection and entomological data of the genus *Epicauta* and the *Meloidae* in North America and Mexico, while MacSwain (14) and Blackwelder (17) have compiled comprehensive classification check lists on the Colepterous insects.

Because of its toxicity and irritation properties, cantharidin is little used in human medicine, although it was once used extensively as a vesicant. Today, its use is confined to veterinary medicine as an irritant and stimulant for hair growth. Among the uses that have been reported for this substance are: aphrodisiac, anticarcinogenic, antihypertensive, herbicide, insecticide, vesicant, hair growth stimulant, diagnostic agent in leprosy, and agent to remove warts. Several cases (18–21) of poisoning from cantharidin have been reported.

Cantharidin (cantharidine) (exo-1,2-*cis*-dimethyl-3,6 - epoxyhexahydrophthalic anhydride) has been assigned structure I by Gadamer (22) and his collaborators (23). It is optically inactive,

nonresolvable, and exists naturally as the *cis*-isomer.



I

Further proof of this structure was made by Woodward and associates (24), who synthesized desoxycantharidine (cantharidin lacking the oxide bridge). Stork and his associates (25) reported the first total synthesis of cantharidin in 1952. However, other investigators also contributed significantly toward the chemistry and synthesis of this compound; worthy of mention, they are Schenck *et al.* (26), Paranjape (27), Pai *et al.* (28), Iyer *et al.* (29), and Ziegler *et al.* (30). Physical and chemical characteristics of cantharidin may be found in the literature (31, 32). In this investigation, 1 Gm. of cantharidin was found to be soluble in 50 ml. of dimethylsulfoxide at room temperature (28°).

The isolation of cantharidin from blister beetles has been studied extensively, particularly in an attempt to improve upon previous methods of separation. It occurs partly free and partly combined in the insect; the nature of the combination is unknown. This unknown complex adds to the difficulty of extraction and quantitative determination. In general, the methods employed for separation utilize continuous extraction with chloroform, acetone, or ethanol, alone or in the presence of an acid (HCl or HNO_3). The extract is concentrated *in vacuo* and treated with petroleum ether or benzene to remove lipid material, then crystallized from a mixture of petroleum ether and ethanol (1:9). Further purification may be obtained by repeated recrystallization or sublimation.

In this study, cantharidin was extracted from *E. pestifera* in a Soxhlet extractor using acetone, cooled, the insoluble material collected, the extract evaporated *in vacuo*, then submitted directly to sublimation. Pure cantharidin was obtained. The quantitative analysis was conducted using the procedure outlined in the "United States Pharmacopeia XI" (33). Infrared and NMR spectra, elemental analysis, physical constants, and thin-layer chromatography of isolated cantharidin when compared to the pure substance showed the two compounds to be identical.

EXPERIMENTAL

Approximately 200 Gm. of *E. pestifera* beetles were collected for this study during July and August of 1965 near Hattiesburg, Miss., and stored in a refrigerator (10°) in a closed jar to which a few drops of chloroform were added to prevent microbial deterioration. They were found on the ornamental vine, *Clemenatis paniculata*.

Isolation of Cantharidin.—The beetles (100 Gm.) were placed in a Waring blender and 150 ml. of acetone was added. The mixture, after being blended for 5 min., was decanted into a Soxhlet thimble and extracted for 18 hr. with acetone. The olive colored solution, on cooling, yielded a heavy dark brown precipitate and a white flocculant precipitate which settled on top of the brown syrupy material. The white substance (0.22 Gm.) was easily decanted from the heavy gummy material and sublimed directly at 110° with vacuum using a sublimation apparatus (McCarter, Nester Faust). The crystalline needle-like sublimate gave a melting point of 217–218° uncorrected. A mixed melting point with pure cantharidin showed no change. The infrared spectrum of the isolated cantharidin was obtained using a Perkin Elmer spectrophotometer in KBr pellets (Fig. 1) and was identical to the pure material.

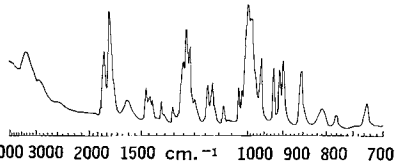


Fig. 1.—Infrared spectrum of cantharidin in KBr pellet.

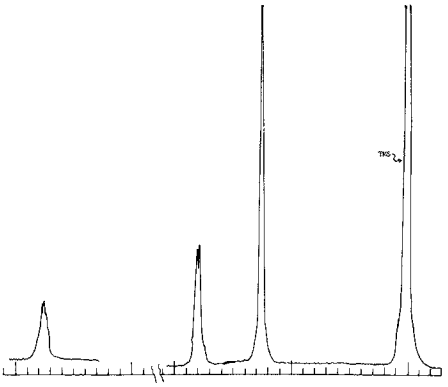

Fig. 2.—NMR spectrum of cantharidin in $CDCl_3$. Solvent, $CDCl_3$; temperature, 37°; filter bandwidth, 4 c.p.s.; R. F. field, 0.04 mg.; sweep time, 250 sec.; sweep width, 500 c.p.s.; sweep-offset, 0 c.p.s.; spectrum amp, 25; 10; integral amp, 625 →; remarks, 500 ←.

NMR Spectroscopy.[1]—Nuclear magnetic resonance (NMR) spectra were obtained with a Varian A-60A spectrometer and were in agreement with the expected chemical shifts, multiplicity, and intensities. Samples were prepared as 10% solutions in $CDCl_3$ and were not degassed. Tetramethylsilane (TMS) was used as internal reference standard. The NMR spectra of pure cantharidin and the isolated substance (Fig. 2) consisted of the following: (*a*) a sharp singlet at $\tau = 8.74$, relative intensity 3, assigned to the methyl protons of the methyl groups *cis* to the oxide bridge; (*b*) a doublet, $J = 2$ c.p.s., centered near $\tau = 8.21$ with relative intensity of 2 assigned to the adjacent pairs of protons on the cyclohexane ring; (*c*) a broad, low field absorption

[1] Acknowledgment is made to Mr. J. L. McClanahan, and Mrs. J. M. Settine, Chemistry Department, University of Mississippi, for their assistance in measuring and interpreting the spectra.

centered near τ = 5.25, relative intensity 1, assignable to tertiary protons of the type at the oxide bridge. The absorption peaks at τ = 2.70 are assigned to a $CHCl_3$ impurity in $CDCl_3$ and at τ = 10 to the reference standard, TMS.

Anal.—Calcd. for $C_{10}H_{12}O_4$: C, 61.21; H, 6.17; O, 32.62. Found: C, 61.29; H, 6.27; O, 33.52.

Thin-Layer Chromatography.—Thin-layer chromatography was conducted on acetone solutions of cantharidin prepared from *E. pestifera* and of the pure substance. Chromagram sheets (Eastman, K301R2) and prepared Silica Gel G plates were used in the tests with comparable results. Shimano (2) has reported the use of paper chromatography for analyzing mixtures containing cantharidin.

Several detection systems were tested with satisfactory results: iodine; bromocresol green, 0.1% in isopropanol with NaOH added until appearance of blue color; 50% aqueous sulfuric acid solution with a trace of chromium trioxide. In the case of iodine the chromatogram was placed in a closed container containing iodine crystals. Cantharidin with bromocresol green gave a yellow coloration. A contrasting white spot revealed the presence of cantharidin when sprayed with the sulfuric acid solution.

Development of the chromatogram can be made with either acetone, chloroform, or an acetone–benzene (1:9) mixture. All systems showed relative movement of cantharidin: acetone (R_f = 0.74–0.75); chloroform (R_f = 0.61 to 0.59); acetone–benzene mixture (R_f = 0.50).

The R_f values and chemical response to the indicators for pure cantharidin and isolated cantharidin were sufficiently close to conclude these data as further confirmation that the isolated substance was indeed cantharidin.

Quantitative Determination.—A quantitative estimation of cantharidin and *E. pestifera* was determined by the method outlined in the U.S.P. XI (33). The dried beetles (15 Gm.) were ground to a coarse powder and placed in a round-bottom flask. A mixture (150 ml.) of benzene and petroleum ether (2:1) which contained 2 ml. of HCl was added. The flask was stoppered, shaken, and allowed to stand for 24 hr. at room temperature (28°). It was then heated to 40° and maintained at this temperature for 3 hr. with frequent shaking. After cooling, a portion of the mixture, 100 ml. representing 10 Gm. of beetles, was decanted and filtered into a tared beaker. The solution was evaporated to a volume of approximately 5 ml. using a stream of nitrogen gas and 5 ml. of chloroform added. The solution was evaporated to dryness. Ten milliliters of a wash mixture of equal volumes of petroleum ether and absolute ethanol which had previously been saturated with cantharidin was added to the residue to remove coloring and lipid materials. This mixture was allowed to stand for 15 min., then decanted through a pledget of purified cotton. This step was repeated until approximately 40 ml. of the wash solution had been used. The crystals which had collected on the cotton were then washed in the same manner with 25 ml. of petroleum ether which had been saturated with cantharidin. The crystals were white and free of coloring and lipid materials. Chloroform (10-ml. portions) was passed over the cotton to remove any cantharidin adhering to the cotton. This washing was returned to the tared beaker. The solvent was evaporated, and the crystalline residue dried for 0.5 hr. at 60°. The 100 ml. of original extract, representing 10 Gm. of beetles, yielded 0.1092 Gm. of cantharidin or approximately 1.09% by weight of dried beetles.

Further work is being conducted on the structure–activity relationship of the cantharidin molecule and the specific structure of certain derivatives of which past investigators have expressed some reservation.

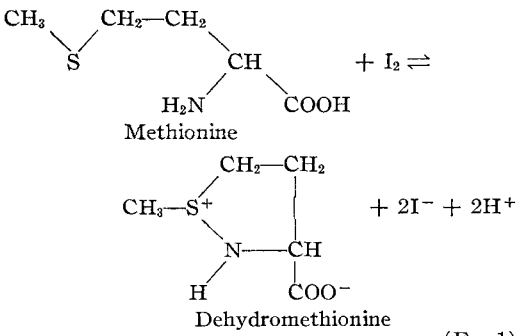
Kinetic Investigation of Reversible Reaction Between Methionine and Iodine

Improved Iodometric Determination of Methionine

By KARL-HEINZ GENSCH* and TAKERU HIGUCHI

Rate studies of reactions discovered by Lavine involving reversible oxidation of methionine to dehydromethionine with iodine are presented. The data suggest that the initial iodine attack may occur either on the nitrogen or on the sulfur. The hydrolytic rate of dehydromethionine to the corresponding sulfoxide appears to be sufficiently fast to cause some inherent errors in the original method of assay for the amino acid.

ALTHOUGH methionine has been determined by a number of iodometric methods (1–5), the chemistry involved has not been clearly established. A method of assay was proposed by Lavine (1) in 1943 based on the following reaction:



(Eq. 1)

Methionine reacts reversibly with iodine to form a cyclic sulfonium compound which Lavine called dehydromethionine (1). According to the method, methionine is allowed to react in a buffered neutral solution with an excess of iodine for 20 min. After removal of the unreacted iodine by careful addition of sodium thiosulfate solution, sufficient potassium iodide and hydrochloric acid (to pH 0.5 to 1.0) are added to reverse the reaction. The liberated iodine is finally titrated with a standardized sodium thiosulfate solution from which the amount of methionine can be calculated. This method suffers from two important disadvantages: (*a*) it is time consuming because of several operations, and (*b*) it cannot theoretically yield stoichiometrically correct results as will be shown later. Several modifications of the original Lavine method have been proposed, but they also require relatively long times for analysis (2–5).

The present study was undertaken to elucidate the microscopic chemistry of this interesting reaction and to provide possible leads for improvement in the method. As parts of these investigations the dependences of the reaction rates in both directions on pH, iodide-ion concentration, and iodine concentration have been determined. The hydrolysis of the cyclic oxidation product has also been studied. A possible improved method of analysis of the acid is proposed as a result of this investigation.

RESULTS AND DISCUSSION

Rate of Oxidation of Methionine.—*Forward Reaction.*—The rate of oxidation of methionine with iodine to form dehydromethionine can be conveniently followed spectrophotometrically at 353 mμ, the absorbance peak of I_3^-. From pseudo first-order rate constants obtained in presence of excess methionine and essentially constant iodide and hydrogen-ion concentrations, observed second-order rate constants for the forward reaction, $k_{f(obs.)}$ can be readily calculated by dividing by the concentration of the amino acid. Or

$$-\frac{d[I_2]_T}{dt} = k_{f(obs.)}\,[Me]_T[I_2]_T \quad \text{(Eq. 2)}$$

where Me represents methionine, and the subscript, T, designates the total concentration of both the titratable iodine and methionine.

In Fig. 1 the observed second-order rate constants obtained at pH 7 in this manner have been plotted against the reciprocal of the iodide concentration. It is evident from the observed linear relationship that the forward rate is inversely proportional to the iodide concentration in the system. This behavior can be best rationalized on the basis that free iodine is involved in this mechanism since, according to the equilibrium in Eq. 3, the concen-

$$I_2 + I^- \underset{}{\overset{K_I}{\rightleftharpoons}} I_3^- \quad \text{(Eq. 3)}$$

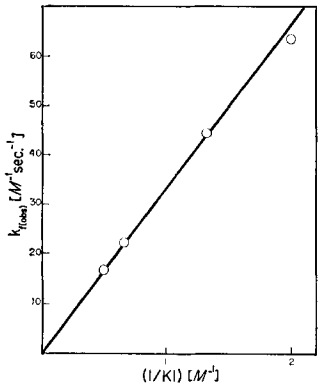

Fig. 1.—Observed second-order rate constants *vs.* (1/KI) for the oxidation of methionine with iodine at pH 7.2. Initial $C_5H_{11}NO_2S$ = 6.82 × 10^{-4} *M*; initial total I_2 = 10^{-4} *M*; phosphate buffer = 0.02 *M*; ionic strength = 2.05 (adjusted with KCl); temperature = 25.0°.

tration of free iodine is inversely proportional to that of iodide at higher iodide concentrations.

In Fig. 2 the product of observed second-order rate constants obtained in the above fashion and the iodide concentration for each run have been plotted as a function of the pH of the system. Different iodide concentrations were used to adjust the observed rate to a convenient range. From the profile, it is evident that the rate is essentially inversely proportional to the hydrogen concentration in the range between pH 4 and 8. Above pH 8 the curve levels off, the observed second-order rate constant at pH 10 being approximately twice that at pH 9. Since the pKa_2 of methionine in this system is approximately 9, the observed pH dependence strongly suggests that the free amino group is involved in this reaction.

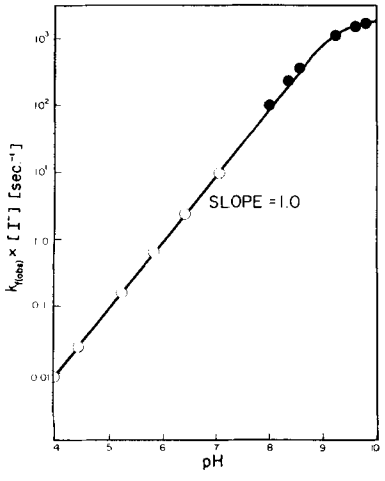

Fig. 2.—Products of observed second-order rate constant and iodide concentration *vs.* pH for the oxidation of methionine with iodine. Initial $C_5H_{11}NO_2S$ = 5 × 10^{-4} *M*; initial total I_2 = 10^{-4} *M*; phosphate or phthalate buffer = 0.02 *M*; ○ = $k_{f(obs.)}$ measured in 0.1 *M* KI, ● = $k_{f(obs.)}$ measured in 1 *M* KI; temperature = 25.0°.

On the basis of the results presented in Figs. 1 and 2 the following rate law can be written:

$$\frac{-d[I_2]_T}{dt} = k_{f(obs.)}\,[Me]_T\,[I_2]_T$$

$$= k_f[Me^-]\,[I_2] \quad \text{(Eq. 4)}$$

where Me^- represents the anionic methionine species and k_f is the second-order rate constant for the species Me^- and I_2 of the forward reaction. Considering Eq. 2 and the dissociation of methionine as expressed by

$$Ka_2 = \frac{[Me^-]\,[H^+]}{[Me]} \quad \text{(Eq. 5)}$$

we can write the forward rate as

$$\frac{-d[I_2]_T}{dt} = \frac{k_f Ka_2\,[Me]_T[I_2]_T}{([H^+] + Ka_2)\,(1 + K_I[I^-])} \quad \text{(Eq. 6)}$$

and for the observed second-order rate constant as follows

$$k_{f(obs.)} = \frac{k_f Ka_2}{([H^+] + Ka_2)\,(1 + K_I[I^-])} \quad \text{(Eq. 7)}$$

From Eq. 7 and the data as shown in Figs. 1 and 2, a mean value for k_f at 25° was determined to be 6.5 × 10^5 M^{-1} sec.$^{-1}$.

Rate of Reduction of Dehydromethionine.—*Reverse Reaction.*—The reduction of the cyclic species by iodide was readily followed spectrophotometrically by the appearance of the I_3^- species. Pseudo first-order rate constants, for the reverse reaction, $k_{r(obs.)}$, were obtained from such data in either of two ways. For fast reaction at constant pH and excess iodide concentration, pseudo first-order rate constants were obtained by plotting log $(A_\infty - A)$ against time. If the rate was expected to be slow, a relatively high concentration of dehydromethionine was used, and the initial rate of formation was measured. Based on previously determined values for the molar absorptivity of iodine in the particular system, the initial rate of reaction was converted to pseudo first-order rate constants by dividing through by the initial dehydromethionine concentration.

Pseudo first-order rate constants obtained in this fashion at different pH values are shown plotted *versus* pH in Fig. 3. From the resulting pH profile it is evident that above pH 4.5 the rate is directly proportional to the hydrogen-ion concentration, while in the more acidic region the order of the over-all reaction with respect to the hydrogen concentration is larger than 1.

The dependence of the reverse pseudo first-order rate constant on the iodide concentration at pH of 5.02 is evident from the log-log data plotted in Fig. 4. The line which closely fits the experimental points was drawn with a slope of 2. On this basis, it would appear that the kinetic dependence with respect to iodide is 2. Similar determinations at pH 2.48, however, yielded a log-log plot with a slope of 1.52 also shown in Fig. 4. From these studies it would appear that the responsible reaction pathway in the acidic region may differ at least in part from that operating at neutral pH. If we assume that the protonated dehydromethionine requires an attack by only a single iodide anion in the rate-determining step while the

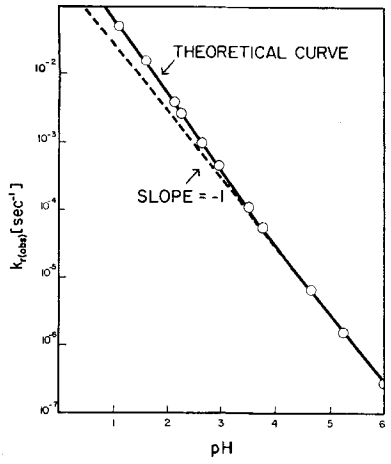

Fig. 3.—Observed first-order rate constant *vs.* pH for the reduction of dehydromethionine. KI = 0.1 *M*; $C_5H_9NO_2S$ = 8.3 × 10^{-5} to 10^{-2} *M*; phosphate or acetate buffer = 0.016 *M*; the theoretical curve was calculated from Eq. 10. The constants were determined by trial and error to be k'_r = 27 [M^{-3} sec.$^{-1}$], k''_r = 3 × 10^{-3} [M^{-2} sec.$^{-1}$], Ka = 3 × 10^{-3} [*M*] at 25.0°.

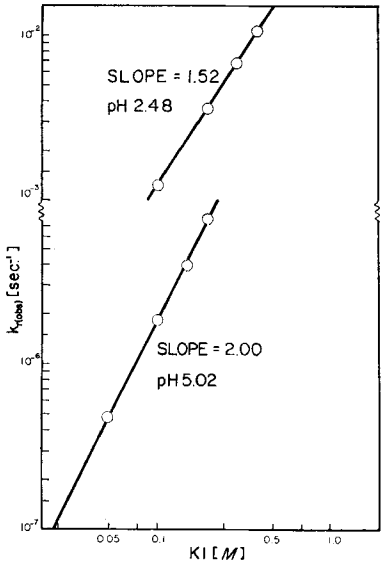

Fig. 4.—Log-log plot of observed first-order rate constant *vs.* potassium iodide for the reduction of dehydromethionine. At pH 5.02: succinate buffer = 0.1 *M*; $C_5H_9NO_2S$ = 0.01 *M*; ionic strength = 0.35 (adjusted with KCl). At pH 2.48: phosphate buffer = 0.01 *M*; $C_5H_9NO_2S$ = 5 × 10^{-5} *M*; ionic strength = 0.41 (adjusted with KCl); temperature = 25.0°.

neutral species requires two, the following rate law can be written:

$$\frac{d[I_2]_T}{dt} = k_{r(obs.)}[De]_T = k_r'[De][H^+][I^-]^2 + k_r''[DeH^+][H^+][I^-] \quad \text{(Eq. 8)}$$

where $[De]_T$, [De], and $[DeH^+]$ represent the concentration of the total, unprotonated, and protonated dehydromethionine, respectively. The constants k_r' and k_r'' are fourth and third-order rate constants, respectively, for these different mechanisms. Since the dissociation constant of the protonated dehydromethionine is

$$Ka = \frac{[De][H^+]}{[DeH^+]} \quad \text{(Eq. 9)}$$

from Eq. 8 the following rate law can be derived:

$$k_{r(obs.)} = \frac{k_r'Ka[H^+][I^-]^2}{[H^+] + Ka} + \frac{k_r''[H^+]^2[I^-]}{[H^+] + Ka} \quad \text{(Eq. 10)}$$

The constant k'_r can be easily determined from the pH profile in Fig. 3, the apparent pseudo first-order rate constant being, above pH 4.5,

$$k_{r(obs.)} \cong k_r'[H^+][I^-]^2 \quad \text{(Eq. 11)}$$

A mean value of k_r', the rate constant for the reverse reaction in essentially neutral system, was calculated on this basis to be 27 [M^{-3} sec.$^{-1}$] at 25°.

From the shape of the pH profile and from Eq. 10, we can estimate the dissociation constant of the protonated dehydromethionine and the rate constant for the reverse reaction in acid solution to be Ka = 3 × 10^{-3} [*M*] and k_r'' = 7 [M^{-2} sec.$^{-1}$].

Although the dissociation constant was not measured directly, the obtained pKa value of 2.52 appears reasonable on another basis. From the structure point of view, a pKa value not too different from that of methionine (pKa = 2.22) appears to be likely because the positive sulfur in dehydromethionine may be expected to increase the dissociation of the carboxyl group as the protonated amino group in methionine does. Furthermore, the pH profile of the hydrolysis of dehydromethionine to methionine sulfoxide (Fig. 10), as will be discussed later, corresponds to the same value based on the assumption that the protonated dehydromethionine hydrolyzes with a different rate than the neutral species.

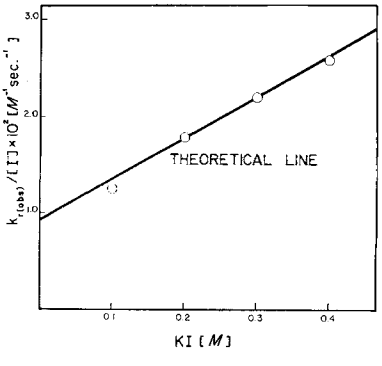

Fig. 5.—According to Eq. 12, observed first-order rate constants obtained at pH 2.48 (see Fig. 4) for the reduction of dehydromethionine divided by the iodide concentration are shown plotted against the iodide concentration. The theoretical curve was calculated from Eq. 12 using the constants showing best fit for pH profile in Fig. 3.

The constants k_r', k_r'', and Ka can also be shown to be internally consistent with the observed rate dependence on the iodide concentration. From Eq. 10 the linear relationship

$$\frac{k_{r(obs.)}}{[I^-]} = \frac{k_r'Ka[H^+][I^-]}{[H^+] + Ka} + \frac{k_r''[H^+]^2}{[H^+] + Ka} \qquad \text{(Eq. 12)}$$

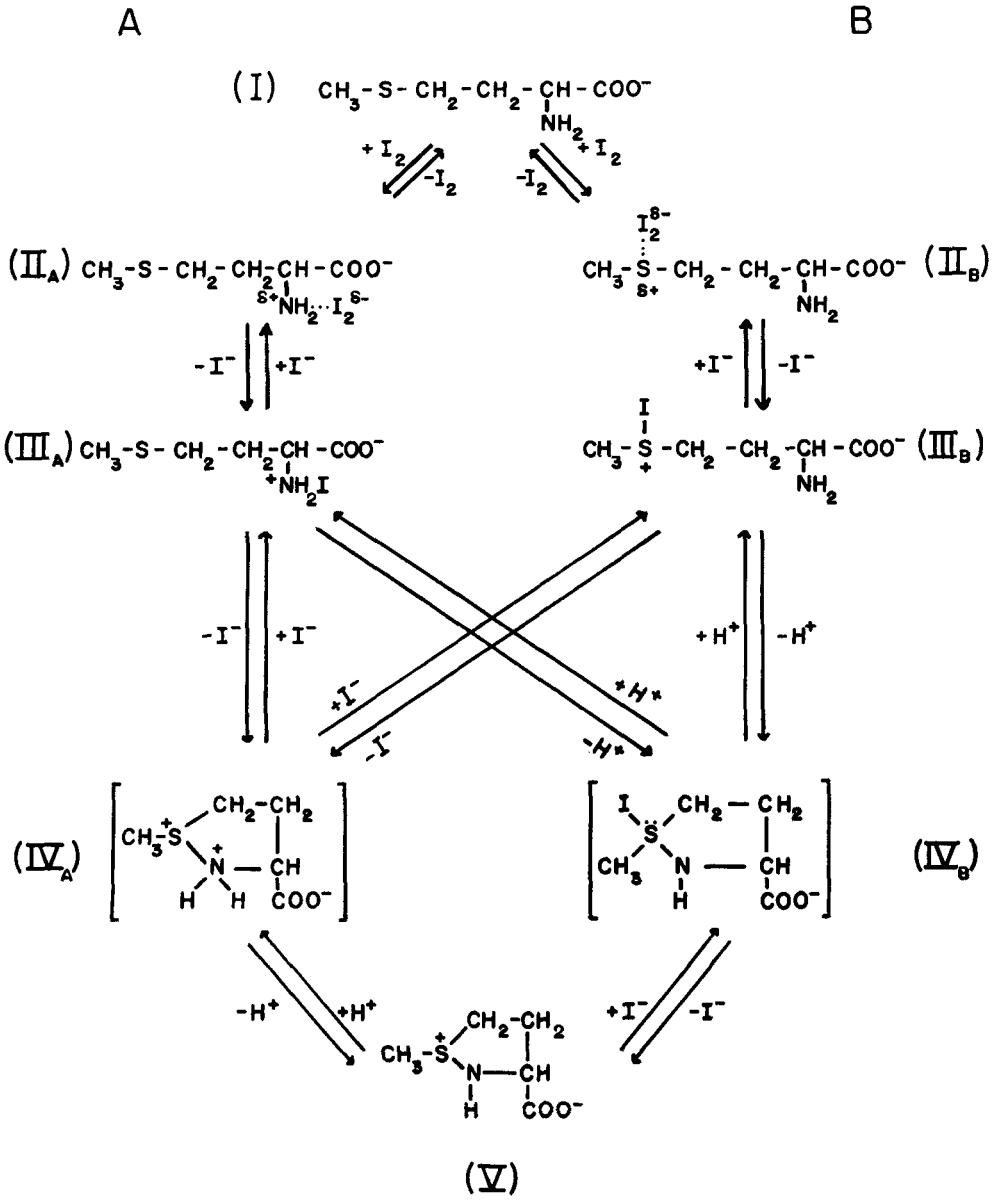
can be derived.

By plotting $k_{r(obs.)}/[I^-]$ against the iodide concentration of a particular system for the reduction of dehydromethionine, the data can be expected to fall on a straight line with a slope of $k_r''Ka[H^+]/([H^+] + Ka)$ and an intercept of $k_r''[H^+]^2/([H^+] + Ka)$. Such a plot is presented in Fig. 5 for data obtained at various iodide concentrations at pH 2.48. The reasonable fit of the theoretical line calculated from Eq. 12 and the constants obtained from Fig. 3 suggest that the proposed mechanism can account for the observed fractional iodide dependence at lower pH.

GENERAL DISCUSSION

Since free iodine has been shown and would be expected to interact with both amines (6) and alkyl sulfides (7), both sites of initial interaction must be considered. Possible reaction schemes based on these routes are diagrammed in Scheme I.

Pathway A considers an attack of iodine on the amino group by which the iodine amine complex



Scheme I

II_A might be formed. Dissociation to III_A seems to be very likely; the further pathway, however, might go either through the species IV_A or IV_B, both of which must be regarded as suitable. Considering the iodination of the amino group to be the rate-determining step, the rate law for the forward reaction would agree with this assumption. Also, the rate law for the reverse reaction is in agreement with pathway A; however, the formation of IV_A in neutral solution and further attack by iodide to form III_A appears to be not very likely. Also, the alternative in the mechanism going from IV_B to III_A cannot be easily accepted because it would require a fast migration of iodine from sulfur to nitrogen for which no support can be presented.

If an iodine attack on sulfur is assumed, as shown in pathway B, the reverse reaction could be more easily explained; the forward reaction, however, would only fit the rate law if additional assumptions were made. Studies with simple aliphatic thioether have revealed (8) that the rate of oxidation by iodine forming sulfoxide is inversely proportional to the square of the iodide concentration. For this reaction, the mechanism in Scheme II is proposed.

$$I_2 + I^- \rightleftharpoons I_3^-$$

$$R{-}S{-}R' + I_2 \rightleftharpoons R{-}\overset{+}{S}(I){-}R' + I^-$$

$$R{-}\overset{+}{S}(I){-}R + OH^- \rightarrow R{-}S(=O){-}R' + H^+ + I^-$$

Scheme II

If in the forward reaction also an iodosulfonium-cation of methionine is formed, the over-all rate, too, should be inversely proportional to the square of the iodide concentration. However, this has not been observed. This contradiction might be removed if one assumes that the dissociation from II_B to III_B is relatively slow or occurs with about the same rate as the cyclization of III_B. The reverse reaction may go through a nucleophilic attack of dehydromethionine by iodide, forming IV_B which on protonation goes under ring opening to the iodosulfonium species III_B. By a second attack of iodide, as the rate law requires, methionine and iodine are formed, the latter is greatly complexed with I^- to form I_3^-. Although pathway V $\rightarrow$ $IV_A \rightarrow III_B$ is also possible, it seems unlikely in neutral solution.

Some support for a mechanism based on attack of iodine on sulfur is evident in the behavior of the forward reaction in the presence of very low iodine, very low methionine, and very low iodide concentration and at pH values not higher than 5.50. The observed second-order rate constants obtained in these studies multiplied by $(1 + K_I [I^-])(1 + [H^+]/Ka_2)$ are shown in Fig. 6 against the reciprocal of the iodide concentration ranging from 3.3×10^{-4} to 1.66×10^{-3} *M* K_I. If Eq. 6 would be the true rate law under these conditions, a rate corrected rate constant should be independent of iodide. The graph, however, shows straight lines with intercepts approximately equal to k_f and with slopes which increased with increasing hydrogen-ion concentration. Although this behavior is not very well understood, it appears likely that at lower pH, where the concentration of Me^- is very low, positive iodosulfonium species is involved in this reaction.

Hydrolysis of Dehydromethionine.—Besides the reduction reaction discussed above, in the presence of iodide and hydrogen ions, dehydromethionine appears to undergo hydrolysis to methionine sulfoxide which is more difficult to reduce than dehydromethionine itself. A critical investigation of the Lavine method must, therefore, also include a kinetic study of this competitive hydrolysis in the absence and in the presence of buffer species.

The rates of hydrolysis in the absence and in the presence of different buffer species have been determined by withdrawing periodic samples from a stock solution of dehydromethionine and titrating the liberated iodine with sodium thiosulfate solution after addition of potassium iodide and hydrochloric acid. Plots of log (ml. 0.01 *N* $Na_2S_2O_3$) *versus* time yielded

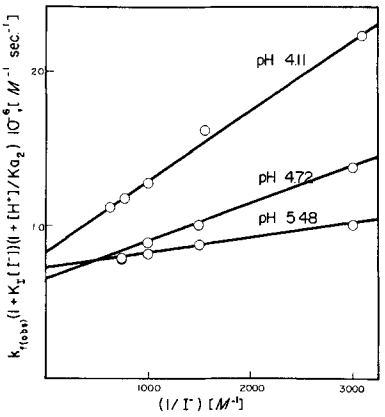


Fig. 6.—Plot showing the change of the dependence of the forward rate on the iodide concentration at different pH values. Initial total iodine = 5×10^{-6} *M*; initial total methionine = 4×10^{-4} *M*; succinate buffer = 0.002 *M*; temperature = 25.0°.

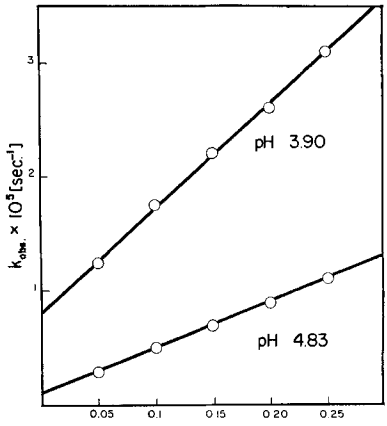

Fig. 7.—Observed first-order rate constants *vs.* total acetate buffer concentration for the hydrolysis of dehydromethionine (measured titrimetrically). Buffer ratio = 0.3 mole CH_3COO^-/0.7 mole CH_3COOH at pH 3.90; 0.7 mole CH_3COO^-/0.3 mole CH_3COOH at pH 4.83. $C_5H_9NO_2S$ = 0.01 *M*; ionic strength = 0.875 (adjusted with KCl); temperature = 25.0°.

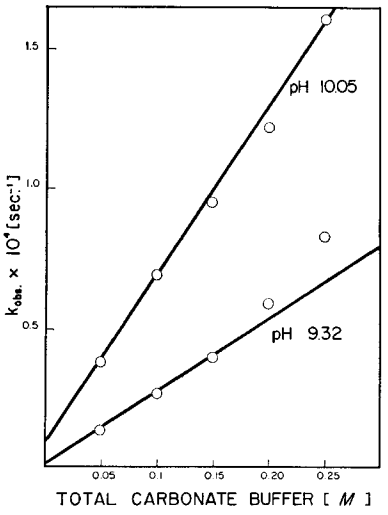

Fig. 8.—Observed first-order rate constants *vs.* total carbonate buffer concentration for the hydrolysis of dehydromethionine (measured titrimetrically). Buffer ratio = 0.3 mole HCO_3^-/0.7 mole $CO_3^=$ at pH 10.05; 0.7 mole HCO_3^-/0.3 mole $CO_3^=$ at pH 9.32. $C_5H_9NO_2S$ = 0.01 *M;* ionic strength = 0.875 (adjusted with KCl); temperature = 2.50°.

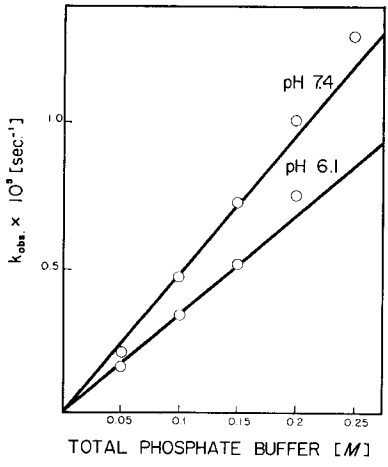

Fig. 9.—Observed first-order rate constants *vs.* total phosphate buffer concentration for the hydrolysis of dehydromethionine (measured titrimetrically). Buffer ratio: 0.15 mole $H_2PO_4^-$/0.85 mole $HPO_4^=$ at pH 7.4; 0.7 mole $H_2PO_4^-$/0.3 mole $HPO_4^=$ at pH 6.1. $C_5H_9NO_2S$ = 0.01 *M;* ionic strength = 0.875 (adjusted with KCl); temperature = 25.0°.

straight lines from which observed pseudo first-order rate constants could be calculated. In strongly acidic solutions, the rate was also measured spectrophotometrically by following the decrease in absorbance at 243 mμ.

Figures 7, 8, and 9 show the influence of the different buffer species on the rate of hydrolysis of dehydromethionine. In these graphs the observed pseudo first-order rate constants obtained in presence of acetate, carbonate, and phosphate buffer are shown plotted against the total buffer concentration. For most plots the experimental points fall essentially on a straight line, the intercepts representing pseudo first-order rate constants at the particular pH in absence of any buffer and the slopes the specific second-order rate constants for the buffer species involved.

$$k_{obs.} = k_{H_2O} + k_T\,[\text{buffer}]_T \quad \text{(Eq. 13)}$$

Since each buffer mixture consisted of an acid and a basic species, the following equation for the slope can be written

$$k_T = k_{base} \times F_{base} + k_{acid} \times F_{acid} \quad \text{(Eq. 14)}$$

where F represents the fraction of the basic or acidic species, *i.e.*, $F_{base} + F_{acid} = 1$. Since for each buffer system two series of experiments with different buffer ratios were carried out from the slopes of these two plots and the particular fractions, the catalytic second-order rate constant for the acidic species and the basic species was calculated. These rate constants are summarized in Table I.

The rate of hydrolysis in absence of any buffer has also been studied, mainly at low and at high pH, the hydrogen-ion concentration was kept constant by repeatedly adding sodium hydroxide solution. The results of these studies and the extrapolated values for zero buffer concentration of Figs. 7, 8, and 9 are presented as the pH profile in Fig. 10 showing that dehydromethionine hydrolyzes easily in presence of hydrogen ions and hydroxide ions and is very stable at neutral pH ($t_{1/2} \approx 600$ days).

As can be seen in Fig. 10, the rate of hydrolysis in strong acid solution is about only a third of the rate which could be expected by extrapolation from the observed values at pH 5. This decrease of the observed rate constants may be due to the slower rate of reaction of the protonated species relative to the free form. On the basis of this assumption, the following rate law for the hydrolysis of dehydromethionine in acidic solution and in the absence of any buffer species can be written:

$$\frac{-d[\text{De}]_T}{dt} = k_{obs.}\,[\text{De}]_T =$$

$$k_{H^+}[\text{De}]\,[H^+] + k'_{H^+}\,[\text{DeH}^+]\,[H^+] \quad \text{(Eq. 15)}$$

Considering Eq. 9, the observed first-order rate constant can be expressed as

$$k_{obs.} = \frac{k_{H^+}\,\text{Ka}\,[H^+] + k'_{H^+}\,[H^+]^2}{[H^+] + \text{Ka}} \quad \text{(Eq. 16)}$$

From Eq. 16 and the experimental data of Fig. 10, the constants were determined to be $k_{H^+} = 6 \times 10^{-2}$ [M^{-1} sec.$^{-1}$], $k'_{H^+} = 1.7 \times 10^{-2}$ [M^{-1} sec.$^{-1}$], and Ka = 3×10^{-3} [*M*] which agrees with the value obtained from Fig. 3. The theoretical curve of

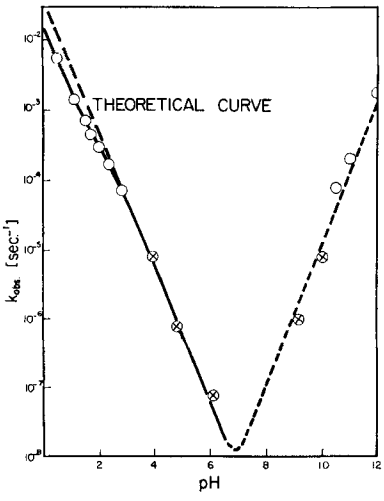

Fig. 10.—Observed first-order rate constants *vs.* pH for the hydrolysis of dehydromethionine (measured titrimetrically and spectrophotometrically). Key: ○, determined directly; ⊗, determined by extrapolation from Figs. 7, 8, and 9. $C_5H_9NO_2S$ = 0.01 *M*; ionic strength = 0.875 (adjusted with KCl); temperature = 25.0°. The theoretical curve was calculated from Eq. 16, derived from the assumption of different rates for unprotonated and protonated dehydromethionine, values of k_{H^+}, k'_{H^+}, and Ka of Eq. 16 were chosen to fit best the experimental points.

Fig. 10 is calculated from Eq. 16 and is in good agreement with the experimental results.

The mechanism of the hydrolysis of dehydromethionine in alkali solution seems to be best rationalized by assuming a nucleophilic attack of hydroxide ion or anionic buffer species on the positive sulfur, followed by ring opening and protonation of the nitrogen. In acidic solution protonation of the imino group probably occurs first, followed by a water attack on sulfur. The relatively high catalytic activity of acetic acid compared to the acetate species might be caused through a nucleophilic attack of the carbonyl oxygen on the sulfur. Protonation of the imino group occurs then through general acid catalysis of the attached carboxyl group.

The influence of iodide ions on the rate of hydrolysis of dehydromethionine as mentioned by Lavine (1) was not observed. It seems to be likely that Lavine was not aware of the catalytic activity of phosphate buffer.

Application of Kinetics Leading to Improvement of Assay Method.—In the original method proposed by Lavine, dehydromethionine stands for 20 min. in contact with 0.2 *M* phosphate buffer at pH 7. It is evident from the data given above on the hydrolysis of dehydromethionine that a significant portion will be observed to form a sulfoxide species which would not undergo reversible reduction back to the amino acid. The extent of loss on the basis of our experiment would be of the order of 1%. Another small error of about 0.2% in the presence of 1 *M* potassium iodide solution and at pH 1 can be calculated from Eqs. 10 and 16 because the reduction and the hydrolysis of dehydromethionine are competitive reactions.

From the relative high value of the specific second-order rate constant $k_f = 6.5 \times 10^5$ $[M^{-1}$ sec.$^{-1}]$ of the forward reaction, it could be expected that at about pH 9 and in presence of low potassium iodide concentration methionine can be directly titrated with iodine. This possibility has already been mentioned by Lavine (1); no result, however, has been presented. The following procedure was tested with the same lot of methionine.

About 150 mg. methionine, previously dried at 60° in vacuum for 2 hr., was accurately weighed and dissolved in 50 ml. of water, with 1 Gm. of sodium borate. After addition of 1 ml. of 1% starch solution, it was titrated with 0.1 *N* iodine until a slightly blue color remained for at least 1 min.

The results are given in Table II for 9 separate analyses and compared with 9 independent determinations of the same sample according to the procedure of N.F. XII.

Both methods have practically the same precision judged by the standard deviation. The differences of about 0.5% between the mean values seems to be partially due to the different ways by which the end point is approached. In the direct iodometric titration a slight excess of iodine is added to produce the starch–iodine complex, while for the back titration of iodine with sodium thiosulfate, a slight excess of the titrant is unavoidable. Therefore, the difference of about 0.5% includes the sum of the titration errors of the two methods. Both methods were also carried out in the presence of glycine (equivalent to 10% of the applied amount of methionine). No higher values were observed.

The value obtained by direct titration can also be checked by continuing with an indirect determination of methionine in the same solution.

The slight excess of iodine is carefully removed by sodium thiosulfate solution, 12 Gm. of potassium iodide and 10 ml. of 25% hydrochloric acid are added, and the liberated iodine is titrated with 0.1 *N* sodium thiosulfate solution. Since in a solution of 1 *M* potassium iodide at low pH the iodide species can easily be oxidized by air, a blank is performed by preparing a solution of 1 Gm. sodium borate, 11 Gm. potassium iodide, and 10 ml. of 25% hydrochloric acid in 70 ml. of water and titrating the liberated iodine after 1 to 2 min. of stirring.

The mean value of the indirect determination and its standard deviation is also given in Table II and shows very good agreement with the direct titration. Since this indirect procedure, however, shows no advantages, the direct iodometric method appears to be sufficient and also superior to the N.F. XII assay, because it can be carried out in much shorter time.

TABLE II.—RESULTS OF A NEW DIRECT AND INDIRECT IODOMETRIC METHOD OF ASSAY OF METHIONINE COMPARED WITH THE DETERMINATION IN "THE NATIONAL FORMULARY," 12TH ED.

Procedure	No. of Determinations	Mean Value, %	S. D., %
Direct	9	100.17	±0.22
Indirect	9	100.00	±0.25
N.F. XII	9	99.68	±0.24

EXPERIMENTAL

Reagents.—Methionine (Eastman-Kodak, white label) was recrystallized from 40% ethanol. All other reagents were analytical grade. Water was purified by distilling tap distilled water from a potassium permanganate solution acidified with sulfuric acid.

The rate of oxidation of methionine with iodine and the rate of reduction of dehydromethionine by iodide forming iodine have been determined spectrophotometrically with a Cary model 11 or 15 by measuring the change in absorbance at 353 mμ, the absorption peak of I_3^-.

For the forward reaction, in general 5 ml. of a methionine solution was added to 45 ml. of a solution of buffer, potassium iodide, and iodine to yield 50 ml. of a solution with concentration as given for each figure. Very fast reactions were measured by injecting 1 ml. of methionine solution through the cover of the cell compartment into 2 ml. of solution containing buffer, iodide, and iodine while the instrument was operating.

For studying the reverse reaction, a stock solution of 0.025 *M* dehydromethionine was prepared by adding an equivalent amount of iodine and sodium hydroxide solution to a methionine solution, the pH was kept between pH 5 and 7. Iodide was removed with silver nitrate, the filtrate was brought to the calculated volume. Pseudo first-order rate constants were obtained as described above in the section for the reverse reaction.

The rate of hydrolysis of dehydromethionine was determined in 0.01 *M* solution of the cyclic species in the presence and in the absence of the buffer species. In both cases 10-ml. samples were withdrawn from the thermostated stock solution, 3 Gm. potassium iodide and 10 ml. 0.5 *N* hydrochloric acid were added, and the liberated iodine was titrated with 0.01 *N* sodium thiosulfate solution. From a plot of log (ml. 0.01 *N* $Na_2S_2O_3$) *versus* time, pseudo first-order rate constants were obtained.

Since dehydromethionine hydrolyzes under acid formation, the rate of hydrolysis in the absence of any buffer was carried out under simultaneous addition of sodium hydroxide solution. For this purpose the reaction solution was kept in a water jacket container closed with a ground-glass plate. Through the holes in the glass plate, electrodes and the tip of a microburet filled with 1 *N* sodium hydroxide solution were immersed into the solution stirred by a magnetic stirrer. Since for most cases a half-life of more than 10 min. was expected, the pH could be easily controlled manually.

In strong acidic solution the rate of hydrolysis was also determined spectrophotometrically by following a decrease in absorbance at 243 mμ.

Coumarins IV

Coumarins of *Pteryxia terebinthina*. Structures of Two New Coumarins, Isopteryxin and Calipteryxin

By B. EICHSTEDT NIELSEN* and T. O. SOINE

The ether extract of the root of *Pteryxia terebinthina* var. *californica* (Coult. and Rose) Mathias, in addition to osthol, anomalin (I), and pteryxin (III), afforded two new coumarins: 3′(*S*),4′(*S*)-3′-angeloyloxy-4′-acetoxy-3′,4′-dihydroseselin (IV) and 3′(*S*),4′(*S*)-3′-angeloyloxy-4′-senecioyloxy-3′,4′-dihydroseselin (V). These coumarins are provisionally named isopteryxin and calipteryxin, respectively.

In keeping with an interest in naturally occurring coumarins (1) and prompted by the recent isolation of anomalin (I) from *Angelica anomala* Lall by Hata *et al.*, and its structure determination as the 3′,4′-diangelate ester of 3′,4′-dihydroxy-3′,4′-dihydroseselin (II), the present paper reports the isolation of I and several related coumarins from *Pteryxia terebinthina* var. *californica* (Coult. and Rose) Mathias.[1] In particu-

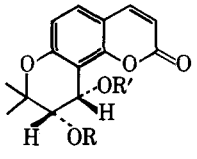
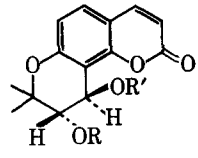
lar, in addition to the isolation of I, pteryxin (III), and osthol, two new coumarins, provisionally named isopteryxin (IV) and calipteryxin (V),[2] have been obtained. Spectral evidence further indicates the probability that a coumarin fraction, thus far unresolved, consists of approximately equal parts of lomatin angelate and senecioate or their isomers.

DISCUSSION

The structure of I, determined prior to the communication of Hata *et al.*, was elucidated by treatment of the isolated coumarin with methanolic potassium hydroxide to yield (+)-*cis*- and (−)-*trans*-methylkhellactones (VI and VII). The acidic hydrolytic component was shown to be only angelic acid by conversion to the *p*-phenylphenacyl ester. The conclusion that I was the 3′,4′-diangeloyloxy derivative of 3′,4′-dihydroseselin was substantiated completely by the nuclear magnetic resonance (NMR) spectrum which, in turn, was in complete accord with that described by Hata *et al.* (2) for I. Similarly, all physical constants were virtually identical, providing a secure basis for assuming the identity of the two coumarins from different sources.

The structure of V was ascertained by alkaline hydrolysis in dioxane to yield the (+)-*cis*- and (−)-*trans*-khellactones (VIII and IX), together with angelic and acetic acids identified by conversion to the *p*-phenylphenacyl ester derivatives. The NMR spectrum showed the 4 and 3 protons, respectively, as the usual pair of doublets at τ 2.38 and τ 3.79 (J = 9.5 c.p.s.) and *ortho* protons in the benzene ring as a pair of doublets at τ 2.62 and τ 3.20 (J = 8.5 c.p.s.). Other signals were noted as doublets (1H each) at τ 3.42 and τ 4.61 (J = 5 c.p.s.), at τ 3.87 (1H, multiplet), at τ 8.55 and τ 8.57 (singlets, 3H each), a multiplet centering at about τ 8.07 (6H), and a singlet at τ 7.90 (3H). The doublets at τ 3.42 and 4.61 are characteristic of the chemical shifts and pattern found for the 4′ and 3′ protons, respectively, in the diesters of *cis*-khellactone (3). The angelate character of one of the ester moieties is evident from the one-proton multiplet centering at τ 3.87 and the six-proton multiplet centering at about τ 8.07, whereas the three-proton singlet at τ 7.90 is characteristic of acetate methyl. The *gem*-dimethyl character of the compound at the 2′-position is evident from the pair of three-proton singlets at τ 8.55 and 8.57. With very minor differences, this spectrum was identical with that of pteryxin (III), the known *cis*-3′-acetoxy-4′-angeloyloxy-3′,4′-dihydroseselin (4). Thus, the weight of evidence indicates that IV is the correct structure. To confirm the placement of the angelate moiety at the 3′-position, advantage was taken of the well-known fact (4,5) that the ester moiety in the benzylic 4′-position is exceedingly labile under fixed base hydrolytic conditions, whereas the ester moiety at the 3′-position is much less reactive. Furthermore, the ester group at the 4′-position undergoes solvolytic *O*-alkyl cleavage and, finally, incorporation of the solvent into the system. Thus, with alcoholic base saponification, the final group in the 4′-position is determined by the alcohol, *i.e.*, methoxy, ethoxy, *etc.* When IV was subjected to ethanolic potassium hydroxide saponification for a short time the workup of the product provided small amounts of *cis*- and *trans*-ethylkhellactones (X and XI) but, more important, also yielded a large quantity of a noncrystalline blue fluorescent compound (XII), apparently identical to the compound obtained by Hata *et al.* (2) in a similar fashion from anomalin (I). The NMR spectrum of this compound showed the usual pattern, integration and splitting constants for the 3,4,5, and 6 protons of the parent compound and showed the usual multiplet pattern and integration expected for the angelate methyls and vinyl proton of a single angelate moiety. The acetate methyl of the parent spectrum was missing but the typical pattern for an ethoxy group was evident with the methyl protons being observed as a triplet at τ 8.67 (3H, J = 7.5 c.p.s.) and the methylene protons as a quartet at τ 5.93 (2H, J = 7.5 c.p.s.). The doublets corresponding to the 3′ and 4′ protons were now found at τ 4.80 and 5.50 (J = 2 c.p.s.) indicating the *trans*-configuration expected on the basis of reasons discussed in an earlier paper (4). These results provide strong evidence for the structure of isopteryxin as 3′-angeloyloxy-4′-acetoxy-3′,4′-dihydroseselin.





I, R = R′ = Angeloyl
II, R = R′ = H
III, R = Acetyl; R′ = Angeloyl
IV, R = Angeloyl; R′ = Acetyl
V, R = Angeloyl; R′ = Senecioyl
VI, R = H; R′ = CH_3
VIII, R = R′ = H
X, R = H; R′ = C_2H_5

VII, R = H; R′ = CH_3
IX, R = R′ = H
XI, R = H; R′ = C_2H_5
XII, R = Angeloyl; R′ = C_2H_5

The structure of V was established by a short hydrolysis of the compound with ethanolic potassium hydroxide which yielded principally XII, unreacted V, and small amounts of X and XI. The acidic hydrolytic components were identified as principally senecioic acid and, in much smaller amount, angelic acid through the *p*-phenylphenacyl esters. The NMR spectrum of V was remarkably similar to that of I with the major difference being the signals from the senecioyl group at τ 8.05 and 7.78 (3H each) and τ 4.37 (1H). In addition, the signals from the angelate moiety integrated for only one-*half* the values found for I. The decision as to the location of the senecioyl group at 4′ was obvious from the isolation of XII, identical to that obtained from IV in the same way. These results provide conclusive

[2] Hata *et al.* (9) have recently reported on a new coumarin, peuformosin, from the root of *Peucedanum formosanum* Hayata which appears to be structurally identical to calipteryxin. Peuformosin, inexplicably, has a somewhat higher melting point (155–156°) than calipteryxin but has a roughly equal {$[\alpha]D^{27}$ + 67.3° ($CHCl_3$)}, although opposite rotation. Since they have chosen to utilize a name indicating its botanical origins we choose to retain the name calipteryxin to identify this enantiomeric form and thus to preserve its botanical origin. If peuformosin, as seems likely, is the mirror image of calipteryxin it is possible to assign the 3′(*R*), 4′(*R*) 3′-angeloyloxy-4′-senecioyloxy-3′,4′-dihydroseselin nomenclature to it.

evidence for the structure of calipteryxin as 3′-angeloyloxy-4′-senecioyloxy-3′,4′-dihydroseselin.

The NMR spectra of I, IV, and V all show the same coupling constant of $J_{3',4'}$ = 5.0 c.p.s. Furthermore, the signals arising from the two methyl groups in the chroman ring differ by only 0.02 p.p.m. As pointed out by Lemmich *et al.* (6) these spectral features are typical of khellactone derivatives possessing the relative *cis*-configuration. From the observation of a $J_{3',4'}$ = 2.0 c.p.s. and of well-separated *gem*-dimethyl signals (Δ = 0.7 p.p.m.) in the NMR spectrum of XII it is, in turn, quite safe to deduce the relative *trans*-configuration for this compound, bearing out the expectations based on chemical grounds.

The absolute configuration of all previously isolated diesters of 3′,4′-dihydroxy-3′,4′-dihydroseselin has been shown to be 3′(*S*),4′(*S*) (4,7). Since the alkaline degradation products from anomalin (I) and isopteryxin (IV) are shown to be mixtures, respectively, of VI and VII and of VIII and IX the configuration 3′(*S*) may be assigned to I and IV. By optical comparison of XII obtained from IV with that obtained from V the configuration 3′(*S*) may be assigned to calipteryxin (V) also. Since I, IV, and V are all of the *cis*-configuration it follows, therefore, that they all possess the configuration 3′(*S*), 4′(*S*).

EXPERIMENTAL

Melting points were determined in capillary tubes in a Thomas-Hoover melting point apparatus checked for accuracy against a set of standard samples. Infrared spectra were determined on a Perkin-Elmer 237B grating infrared spectrophotometer or a Perkin-Elmer spectrophotometer, model 21. Values of [α] were determined on a Perkin-Elmer 141 polarimeter. NMR spectra were determined on a Varian Associates A-60 instrument through the courtesy of Dr. William B. Schwabacher, School of Chemistry, University of Minnesota. Analyses were performed by the Microanalytical Laboratory, School of Chemistry, University of Minnesota, or by A. Bernhardt, Mülheim, Germany.

Material.—Dried roots of *P. terebinthina* var. *californica* (Coult. and Rose) Mathias, collected at an elevation of 7200 ft. on June 26, 1965, in basalt rocks the first mile after leaving Slinkard Creek and ascending toward Monitor Pass, Alpine County, Calif.

Isolation of the Coumarins.—The dried and ground root (500 Gm.) was extracted with diethyl ether. Upon evaporation of the solvent, 88 Gm. of a viscous oil remained. This residue was dissolved in 90% methanol, defatted with petroleum ether, and evaporated. The residue (60 Gm.) was chromatographed on silica gel (J. T. Baker Co., No. 3405, 450 Gm.) activated at 120° and impregnated with 10% of water. Upon elution with benzene, benzene–chloroform, and, subsequently, chloroform–ethyl acetate, the following fractions were collected.

(*A*) A blue-fluorescent, noncrystalline material (71 mg.). Thin-layer chromatography on silica gel (Merck) using different solvent systems gave only one spot with the same R_f value as jatamansin.[3] The NMR spectrum, however, indicated that it was a mixture of two monoesters, possibly lomatin angelate (*i.e.*, jatamansin) and the isomeric senecioate. The fraction has not been investigated further.

(*B*) Osthol, 10.2 Gm., m.p. 84.5–85.0°. This was identified by its infrared and NMR spectra and also by a mixed melting point determination with an authentic sample of osthol.

(*C*) A fraction (1.3 Gm.) which was rechromatographed on silica gel (J. T. Baker Co., No. 3405, 100 Gm.) activated at 120° and impregnated with 3% of water. The eluant was a mixture of methylene chloride–carbon tetrachloride (2:1) to which increasing amounts of ethyl acetate were added. The following substances were eluted: (*a*) 307 mg. of a blue-fluorescent compound (I), recrystallized from ether, m.p. 173.0–174.0°, $[\alpha]_D^{25}$ −48.5° (*c* 0.5, chloroform), $[\alpha]_{546}^{25}$ − 53° (*c* 0.5, chloroform).

Anal.—Calcd. for $C_{24}H_{26}O_7$: C, 67.59; H, 6.15. Found: C, 67.87; H, 6.15.

(*b*) A 314-mg. quantity of a blue-fluorescent compound (V), recrystallized from ether, m.p. 147.5–148.0°, $[\alpha]_D^{25}$ −55° (*c* 0.8, chloroform), $[\alpha]_{546}^{25}$ −62° (*c* 0.8, chloroform).

Anal.—Calcd. for $C_{24}H_{26}O_7$: C, 67.59: H, 6.15. Found: C, 67.55; H, 6.06.

(*D*) Further elution yielded a fraction (5.8 Gm.) which was rechromatographed using the same conditions as mentioned for fraction (*C*). The following substances were obtained: (*a*) 130 mg. of a blue-fluorescent compound, m.p. 86.0–86.5°, $[\alpha]_D^{23}$ +12.5° (*c* 2.0, ethanol, 95%), $[\alpha]_D^{25}$ − 4° (*c* 1.1, chloroform). The infrared spectrum was identical with that of an authentic sample of pteryxin (III).

(*b*) A 3.5-Gm. quantity of a blue-fluorescent compound (IV), recrystallized from ethanol and cyclohexane, m.p. 135.0–135.5°, $[\alpha]_D^{24}$ − 39° (*c* 2.0, ethanol, 95%), $[\alpha]_D^{25}$ −45° (*c* 1.3, chloroform), $[\alpha]_{546}^{25}$ −52° (*c* 1.3, chloroform).

Anal.—Calcd. for $C_{21}H_{22}O_7$: C, 65.27; H, 5.74. Found: C, 65.29; H, 5.82.

(*E*) Elution with ethyl acetate to which increasing amounts of methanol were added yielded a mixture of several blue-fluorescent compounds. This mixture is currently under investigation.

Treatment of I with Methanolic Potassium Hydroxide.—Compound I (175 mg.) was dissolved in 10 ml. of methanol containing 1.5 Gm. of potassium hydroxide and the mixture refluxed for 6 min. Upon cooling, the reaction mixture was acidified with 4 *N* sulfuric acid, water (20 ml.) was added, and after standing for 30 min. adjusted to pH 8 with sodium carbonate and finally extracted with chloroform. The chloroform extract, after drying and evaporation, was chromatographed on silica gel (Merck, 20 Gm.) activated at 120° and impregnated with 5% of water. The eluant was benzene to which increasing amounts of ethyl acetate were added. The following substances were obtained: (*a*) 4 mg. (+)-*cis*-methyl khellactone (VI), recrystallized from petroleum ether, m.p. 126.5–127.0°, $[\alpha]_D^{25}$ + 74° (*c* 0.15, chloroform), $[\alpha]_{546}^{25}$ + 90° (*c* 0.15, chloroform). The infrared spectrum was identical with that of an authentic sample of (+)-*cis*-methyl khellactone. (*b*) A 74-mg. quantity of (−)-*trans*-methyl khellactone (VII), recrystallized from ether–petroleum ether, m.p. 162.5°, $[\alpha]_D^{25}$ − 30° (*c* 1.0, chloroform). The infrared spectrum was identical with that of an authentic sample of (−)-*trans*-methyl khellactone.

The aqueous phase (pH 8) was evaporated, acidified with 4 *N* sulfuric acid, and extracted with ether.

[3] Supplied by Dr. S. C. Bhattacharyya, National Chemical Laboratory, Poona, India.

TABLE I.—OPTICAL ROTATIONS OF COMPOUND XII OBTAINED FROM COMPOUNDS IV AND V

Compd. from	Concn. in $CHCl_3$	$[\alpha]_D^{25}$	$[\alpha]_{578}^{25}$	$[\alpha]_{546}^{25}$	$[\alpha]_{436}^{25}$	$[\alpha]_{364}^{25}$
IV	0.4	−10.2	−9.6	−9.3	+15.4	+69.2
V	0.2	−11.1	−10.0	−10.0	+11.7	+75.9

Upon addition of dicyclohexylethylamine (100 μl.) the dried ether extract was evaporated. The residue was converted to the *p*-phenylphenacyl ester according to the method described by Stodola (8). A chloroform extract, containing a mixture of this ester and unreacted *p*-phenylphenacyl bromide, was evaporated and chromatographed on silica gel (Merck, 10 Gm.), activated at 120°, and impregnated with 10% of water. The eluant was benzene–petroleum ether (2:1) to which increasing amounts of benzene were added. *p*-Phenylphenacyl angelate (92 mg.), m.p. 88.5–89.0°, was obtained. The identity was established by infrared spectroscopy and by mixed melting point determination with an authentic sample.

Treatment of IV with 1 N Potassium Hydroxide.—A solution of IV (500 mg.) in 5 ml. of dioxane and 15 ml. of 1 *N* potassium hydroxide was left at room temperature overnight. The reaction mixture was acidified with 2 *N* sulfuric acid and, after standing for 45 min., was adjusted to pH 8 with sodium carbonate and extracted with chloroform. The dried extract was evaporated and the residue chromatographed on silica gel (J. T. Baker Co., No. 3405, 15 Gm.) activated at 120° and impregnated with 10% of water. The eluant was chloroform to which increasing amounts of ethyl acetate were added. Besides unreacted IV (81 mg.) the following compounds were obtained: (*a*) 60 mg. (+)-*cis*-khellactone (VIII), recrystallized from benzene, m.p. 172.0–173.0°, $[\alpha]_D^{22}$ + 80° (*c* 0.5, chloroform). The identity was established by infrared spectroscopy. (*b*) A 96-mg. quantity of (−)-*trans*-khellactone (IX), recrystallized from benzene–chloroform, m.p. 184.5–186.0°, $[\alpha]_D^{22}$ − 17.5° (*c* 1.1, chloroform). The identity was established by infrared spectroscopy.

The aqueous phase (pH 8) when worked up as described above for compound I yielded *p*-phenylphenacyl angelate, m.p. 87.5–89.0°, and *p*-phenylphenacyl acetate, m.p. 110.5–111.0°.

Treatment of IV with Ethanolic Potassium Hydroxide.—A solution of IV (300 mg.) in 12 ml. of ethanol was mixed with 12 ml. of 1 *N* ethanolic potassium hydroxide, left at room temperature for 45 sec., and acidified with 4 *N* sulfuric acid. Upon standing for 45 min., 30 ml. of water was added and the mixture extracted with chloroform. The dried extract was evaporated and chromatographed on silica gel (Merck, 20 Gm.) activated at 120° and impregnated with 5% of water. The eluant was methylene chloride–carbon tetrachloride (2:1). XII (221 mg.) was obtained. Further elution with methylene chloride–carbon tetrachloride (2:1) to which increasing amounts of ethyl acetate were added yielded small amounts of (+)-*cis*- and (−)-*trans*-ethylkhellactones (X and XI) which were identified by co-chromatography with authentic samples.

Treatment of V with Ethanolic Potassium Hydroxide.—A solution of V (169 mg.) in 8 ml. of ethanol was mixed with 8 ml. of 1 *N* ethanolic potassium hydroxide, left at room temperature for 1 min., acidified with 4 *N* sulfuric acid, and then diluted with 25 ml. of water. Upon standing for 30 min. the mixture was adjusted to pH 8 with sodium carbonate and extracted with chloroform. The extract, after drying and evaporation, was chromatographed as described above for IV. XII (78.5 mg.) was obtained and, as in the previous case, was found to be an uncrystallizable oil. Further elution yielded 60.7 mg. of unreacted V and small amounts of X and XI (identified by co-chromatography with authentic samples). The water phase (pH 8) was worked up as described for I to yield 0.8 mg. of *p*-phenylphenacyl angelate and 26 mg. of *p*-phenylphenacyl senecioate, m.p. 143.5–145.0°. The identity of these esters was established by infrared comparison with authentic samples.

Comparison of Optical Activity of XII from IV and V.—The noncrystalline compound XII obtained from isopteryxin (IV), distilled at 0.1 mm. Hg (160–180°) when compared with the same compound from calipteryxin (V) obtained directly by chromatography gave the values shown in Table I.

Negative Thixotropy in Flocculated Clay Suspensions

By JOSEPH C. SAMYN and WAN YIN JUNG

The flocculated clay system is shown to possess negative thixotropic flow properties. Low and high shear measurements are performed to demonstrate this phenomenon. The variations in floccule sizes and interfloccule contacts are accepted as the cause of this effect. Sediment volume and filtration rate measurements are presented to demonstrate the floccule size-agitation intensity relationship. These reversible changes in apparent viscosity are also shown to occur more readily with low-intensity agitation than with standing. Several commercial suspensions containing this system did not display appreciable negative thixotropy. However, the influence of negative thixotropy in the control of concentrated clay slurries is still considered important.

THIS PAPER reports the negative thixotropic behavior of the flocculated system: clay[1] plus added salts. Flocculated systems displaying negative thixotropy are characterized by a reversible transformation from a more viscous state achieved by high shear to a less viscous state obtained by low shear. The only previous report of negative thixotropy in a pharmaceutical system was that of Chong *et al.* (1) for milk of magnesia.

The differences between negative thixotropy and dilatancy should be emphasized since these two types of flow can be confused. The negative thixotropic systems are necessarily flocculated as reported by Medalia and Hagopian (2). In addition, they are of relatively low concentrations. The flocculated clay systems cited in this report are in the 1–3% range while the milk of magnesia is a 7–8.5% suspension. The dilatant systems are deflocculated and of extremely high solid content, usually 40–50% (3). Chong *et al.* (1) also point out that the negative thixotropic systems are dependent on duration and rate of shear, while the dilatant systems are dependent on rate of shear only.

It will be shown that the negative thixotropic behavior of these clay slurries is observable with either high or low shear viscometers. Selected sediment volume and filtration rate measurements will be presented to further substantiate the flocculation theory for negative thixotropy. A phenomenon analogous to rheopexy, therefore termed negative rheopexy, has also been observed with the clay systems as well as with milk of magnesia. Finally, the practical significance of negative thixotropy will be considered.

EXPERIMENTAL

Apparatus.—The Brookfield viscometer model LVT (Brookfield Engineering Laboratories, Stoughton, Mass.) was used for the single-point viscosity measurements. The spindle, speed, and time of measurement were kept constant for each system and are listed in each table of data. The suggested conversion factors were used to express the apparent viscosities in Brookfield units.

A Hercules Hi-Shear viscometer (Martinson Machine Co., Kalamazoo, Mich.) was used for the multipoint measurements. The unit was modified to permit the use of a single cup-bob combination for all measurements. A variable lever arm was coupled to a Statham 1-oz. GI-1-350 strain gauge (Statham Instruments, Inc., Puerto Rico). An Ellis Bridge amplifier (Ellis Associates, Pelham, N. Y.) model BAM-1, provided the power, and data were read from the scale of this unit. Speed changes were manual and performed in a procedure as standard as possible. Although provision for thermostating was available, it was not employed since its effectiveness was largely unknown and the temperature effect, if any, would probably be small and opposite to the negative thixotropic effect.

The sedimentation and filtration measurements were made in standard laboratory glassware. S & S (Schleicher and Schuell) No. 588 fluted filter papers were used for the filtration according to the procedure of LaMer (4). The time of filtration of the second 10 ml. of filtrate for each sample was measured.

Materials.—The clay, sodium benzoate, and polysorbate 40[2] were used as received from the suppliers. The milk of magnesia U.S.P. (Parke, Davis & Co., Detroit, Mich.) was a commercial sample.

Sample Preparation.—The clay slurries were hydrated overnight at RT in distilled water using an Equipoise shaker (Fisher Scientific Co.). Rotation of samples was accomplished by end-over-end tumbling at 14 r.p.m. for the prescribed times. A model GT21 mixer (Gerald K. Heller Co., Las Vegas, Nev.) at 1500 r.p.m. was used for the high speed mixing.

RESULTS AND DISCUSSION

The viscosity measurements with the high shear viscometer were only performed on rotated samples. Since the actual process of measurement resulted in viscosity increase due to the high shear, it was unnecessary to measure additional sheared samples. The low shear measurements, on the other hand,

were performed on samples prepared by rotation and by high shear since the measurements did not alter the samples in the above manner.

Milk of Magnesia and Dispersed Clays.—The data in Table I on milk of magnesia were obtained with a Brookfield viscometer after low speed rotation and high speed mixing. These data clearly show that the negative thixotropy of this system is measurable with this procedure. The reproducibility of the measurements as well as the reversible nature of the effect can also be noted.

Table II reports the viscosity values for three dispersed clay slurries after low and high shear mixing. The thixotropic effect, rather than the negative phenomena, is to be noted in these data. The high speed mixing gives the reduced viscosity values for these dispersed systems. These data on disperse systems are presented in order that the contrast in behavior between it and the data on the flocculated systems may be completely obvious.

Clay–Salt Systems.—Figure 1 was prepared from data on clay slurries at two concentrations, each at several salt levels. Each sample was rotated overnight, apparent viscosity measured, stirred at 1500 r.p.m. for 5 min., and then remeasured. At the lower salt levels, the usual thixotropic behavior is evident. In this region, the high shear destroys the particle-to-particle contact and results in reduced apparent viscosity. At the higher salt concentrations, the negative thixotropic effect is noticed. In this region, slow rotation of the samples has facilitated the build-up of relatively large compact floccules. This leads to a lower apparent viscosity because of the increase in free fluid between the floccules and a decrease in contacts between these larger floccules. The application of high shear to these systems disperses these floccules and increases interparticle contact and the apparent viscosity.

In many of the samples prepared by rotation, it was noticeable that some coagulation of the clay particles had occurred on the inner surface of the glass bottle or the cap liner. It seemed possible that this material on redispersion with high shear would explain the apparent viscosity rise with high shear. The data in Table III indicate that this was not the case with these samples. Three flocculated systems were studied by three procedures. In the usual procedure the rotation, measurements, and high shear were performed in a single container for each system. In the second procedure, the clay–salt slurry was transferred to a clean container for measurements and high shear treatment after the rotation step. In this instance, any coagulated clumps of clay adhering to glass and cap surfaces were effectively removed from the system. In the third treatment, the glass containers used were Siliclad[3] treated. No adhering clay was noted in these samples. The data in Table III demonstrate that the negative thixotropy reported for these systems is not affected by the amount of material adhering to the glass and cap surfaces. It should be noted, however, that at much higher clay–salt ratios, slow sample rotation has resulted in almost all the clay adhering to the glass and cap surfaces. In such instances, the viscosity measurements would obviously be affected. It is also worth noting that these coagulated clay particles are sometimes observable as a "gummy

ring" in suspensions containing flocculated clay particles.

Table IV illustrates negative thixotropy of a clay–salt system as measured with the high shear viscometer. Curve *1* was obtained beginning at the lowest shear rate, increasing to a maximum, and then at progressively decreasing rates. Curve *2* was repeated in the same manner immediately after the completion of curve *1* on the same sample. The negative thixotropic effect is clearly seen in curve *1* by the increase in shearing stress values at comparable shear rates. Curve *2* indicates little additional change.

Clay–Salt–Surfactant Systems.—The addition of a surfactant to the clay–salt system results in a degree of redispersion. This is seen in the high shear data of Table V for increasing concentrations of polysorbate 40. The two lower concentrations exhibit the negative thixotropy associated with flocculation, while thixotropy is noted in the 0.2% polysorbate sample. Additives such as surfactants or protective colloids tend to reduce the flocculation and explain to some extent why negative thixotropy is not observed in the complete formulations containing these ingredients.

Negative Rheopexy.—The phenomenon of rheopexy is often associated with thixotropy. The term itself derives from the Greek *pectos*, meaning "curdled" or "solidified" (5). It is generally applied to thixotropic systems which set more rapidly by gently rolling or tapping than by standing. It is reasoned that the orientation of particles is facilitated by the gentle motion induced by these treatments.

For the negative thixotropic systems described in this paper, an analogous effect was noted. Here, too, the gentle rolling resulted in a more rapid change of the system than did the standing. However, since the system "thinned" rather than jelled, the term negative rheopexy was used to describe this effect in a manner analogous to the use of the term rheopexy for the thixotropic systems. The data in Fig. 2 illustrate the negative rheopexy of milk of magnesia and a clay–salt system. For the milk of magnesia samples, it was necessary to rotate the standing samples once by hand prior to measurement because of some internal settling. A single rotation of this nature had no effect on the other rotated or stirred samples.

Floccule Size.—Sediment volume and filtration rate measurements on selected systems were performed to further substantiate that the phenomenon of negative thixotropy was related to floccule size. Although only systems in a limited concentration range could be measured by sediment volume and filtration rate techniques, the data gathered support

the theory that the floccule size varies with sample treatment.

The process of slow rotation results in the formation of relatively large, compact floccules. This yields more free fluid in the system and reduces floccule-to-floccule contacts. Consequently, these rotated samples filter and sediment more readily. The sheared samples present the reverse situation. The large floccules are destroyed and smaller flocs with greater floccule-to-floccule contacts are produced. These sheared samples settle and filter more slowly, both characteristics of the smaller effective particle size. The sedimentation data are shown in Table VI. Sediment volume is expressed as per cent of total volume, 1 day after the shear treatment.

First attempts to demonstrate floccule size by the vacuum filtration procedures of LaMer (6) were unsuccessful. The pressure differential appeared to destroy the floccule structure. However, gravity filtration procedures as used earlier by LaMer (4) were quite successful and gave additional supporting evidence for the floccule theory of negative thixotropy. The system, 1% clay and 0.4% sodium benzoate, selected earlier as an example of negative rheopexy (Fig. 2), was studied. Filtration rate measurements were performed on this system after stirring and after rotation for different time intervals. The data are shown in Table VII. The gradual decrease in filtration times and the apparent viscosities of these systems with rotation is interpretable as negative thixotropy.

Table VI.—Sediment Volumes for Clay–Salt Systems

Systems		Sediment Vol., Expressed as % of Total Slurry Vol.—After 24 hr. Standing	
% Clay	% Na Benzoate	Rotated Sample	Mixed Sample
0.5	0.5	60	80
0.8	0.5	80	100
0.9	0.5	80	100
1.0	0.5	90	100

Table VII.—Clay–Salt System Filtration Rate Measurement after Various Sample Treatment

System	Treatment	Time of Filtration, sec.
1% Clay 0.4% Na benzoate	Stirring 5 min.	830
	Rotation, 15 min.	780
	Rotation, 30 min.	690
	Rotation, 1 hr.	520
	Rotation 6 hr.	360
	Rotation overnight	360

Significance of Negative Thixotropy.—The clay–salt systems described are used as part of the formulas of many suspensions. Since the clay is generally flocculated to induce the viscosity increase, the negative thixotropic properties which have been described might be of importance in the complete suspensions.

The coagulation of clay particles to the inner glass and cap surfaces has already been suggested as being similar to the "gummy ring" encountered in some of these systems. Silicone treatment of the container is suggested from these studies.

In the testing of a series of eight commercial suspensions containing the clay–salt systems, only two samples exhibited higher apparent viscosities under high shear than under low shear. In both cases, the magnitude of the effect was small compared to the negative thixotropy observed in the clay–salt systems. Therefore, other than milk of magnesia, negative thixotropy in these complete formulations would not appear to contribute much confusion to apparent viscosity measurements.

In any attempts to control or correlate complete suspension apparent viscosities with the apparent viscosities of the concentrated clay slurries, negative thixotropy would be expected to cause considerable confusion. A control and knowledge of the shear histories of these concentrated clay–salt slurries would be vital to a correct interpretation of these data.

SUMMARY

The flocculated clay system has been shown to possess negative thixotropic properties. Measurements on these systems as well as on milk of magnesia have been made by both single point and high shear viscometers. In an analogous fashion to negative thixotropy, the negative rheopexy of both the flocculated clays and milk of magnesia has been demonstrated. Some information on the floccule nature has been gained by sediment volume and filtration rate measurements. The importance of the negative thixotropic behavior of the flocculated clay systems has been considered.

3-Cyanopyrrolidines

By J. SWIDINSKY, J. KERVENSKI, and B. B. BROWN

A series of 1-alkyl-3-cyanopyrrolidines was prepared by the reaction of 1-alkyl-3-chloropyrrolidines with sodium cyanide in dimethylsulfoxide. One of these compounds, 1-methyl-3-cyanopyrrolidine, was used as a model to study the chemical properties of this type of substance. It was converted into 1-methyl-3-aminomethylpyrrolidine by hydrogenation, hydrolyzed to 1-methyl-3-pyrrolidine carboxylic acid (ethyl ester and *N*-methylamide), reacted with phenyl magnesium bromide to give 1-methyl-3-pyrrolidinyl phenyl ketone, and alkylated to a series of 1-methyl-3-alkyl-3-cyanopyrrolidines with alkyl halides and sodium amide.

CONSIDERABLE interest has been shown in 3-substituted pyrrolidines because of their biological activity. Compounds derived from 1-R-3-pyrrolidinol and 1-R-3-pyrrolidinylmethanol have been found to possess a wide range of physiological activity as antihistaminics (1), local anesthetics (2), cholinergic and parasympathetic depressants (3–5), ataractic agents (4), adrenergic blocking agents (6), muscle relaxants (7, 8), antispasmodics (9), antiallergenics (10, 11), anti-inflammatory agents (12), and central nervous system stimulants (13). 3-Cyanopyrrolidines, because of the reactivity of the CN group, may be the starting point for a large number of 3-pyrrolidine derivatives.

Up to now, no new 3-cyanopyrrolidines have been prepared by direct substitution on the ring. It has now been found that 1-alkyl-3-cyanopyrrolidines can be conveniently prepared from 1-alkyl-3-chloropyrrolidines by reaction with sodium cyanide in dimethylsulfoxide, a method recommended for the conversion of alkyl chlorides into the corresponding nitriles (14). The required 1-alkyl-3-chloropyrrolidines were prepared in 55–90% yield by reaction of the 1-alkyl-3-pyrrolidinols with thionyl chloride in benzene (3, 13, 15).

The chloro compounds were usually obtained as the free bases by addition of strong alkali to the reaction mixture. However, with the 1-benzyl derivative, a good yield of the hydrochloride was obtained directly from the reaction mixture. The bases were purified by vacuum distillation in order not to expose them to extreme temperatures. The lower members could, however, be isolated by distillation at ordinary pressures without much decomposition. The 1-alkyl-3-chloropyrrolidines were colorless liquids which slowly darkened on storage, depositing a solid formed by the self condensation of the chloro group with the tertiary amine. Storage at low temperature minimized this decomposition.

Received June 8, 1966, from the Research Laboratories, S. B. Penick Co., Orange, N. J. 07050.
Accepted for publication September 26, 1966.

DISCUSSION

3-Chloropyrrolidine (V) was obtained as its hydrochloride by hydrogenolysis of 1-benzyl-3-chloropyrrolidine hydrochloride (IV, HCl) in isopropyl alcohol over palladium on charcoal. However, the free base, liberated by treatment with alkali, was found to be less stable than the 1-substituted 3-chloropyrrolidines. In one run, V decomposed suddenly while it was being isolated by distillation at a bath temperature of slightly higher than 100°.

In order to obtain a more reactive halide for use in the alkylation of 1-methyl-3-cyanopyrrolidine (see below), 1-methyl-3-bromopyrrolidine (VI) was prepared in 43% yield by the reaction of a large excess of phosphorus tribromide with 1-methyl-3-pyrrolidinol in benzene (11). Like the chloro derivatives, it could be isolated as the free base by vacuum distillation. Compound VI decomposed rather rapidly on storage at room temperature, forming a crystalline solid in a few hours. At zero or below, this decomposition, presumably a self quaternization, was considerably delayed. However, after several months at −10°, one sample had solidified completely. The corresponding chloro compounds stored at 5° remained liquid and undiscolored.

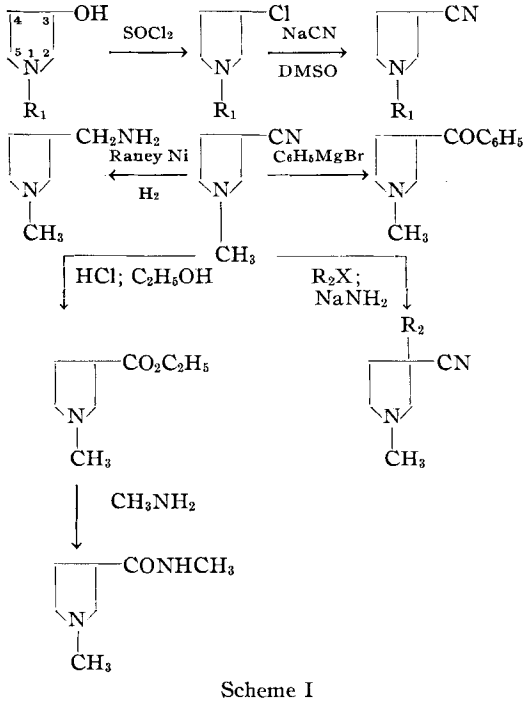
The 1-alkyl-3-chloropyrrolidines were converted to the corresponding 3-cyanopyrrolidines by reaction with sodium cyanide in dimethylsulfoxide (14). The reaction was effected by adding the 3-chloropyrrolidine to a slurry of sodium cyanide in dimethylsulfoxide at 90–100°. The reaction mixture was then heated at 155–170° for 30 min. The yields of the 1-alkyl-3-cyanopyrrolidines varied from 48–71%.

3-Chloropyrrolidine (V) failed to give pure 3-cyanopyrrolidine (XI) when it was treated in the same manner. A substance was obtained which appeared to contain about 72% of XI according to vapor–liquid chromatography analysis. An alternate approach to XI by hydrogenolysis of 1-benzyl-3-cyanopyrrolidine (X) failed.

A preliminary investigation of the chemical properties of these nitriles was made with 1-methyl-3-cyanopyrrolidine (VII) as a model (Scheme I, Table I).

Hydrogenation of VII over Raney nickel in acetic anhydride in the presence of sodium acetate (16) resulted in the formation of 1-methyl-3-acetylaminomethylpyrrolidine from which the free diamine, 1-methyl-3-aminomethylpyrrolidine (XII), was liberated by hydrolysis of the acetyl group (17).

Hydrolysis of VII with concentrated hydrochloric acid gave 1-methyl-3-pyrrolidine carboxylic



Scheme I

acid (18) which was esterified directly to ethyl-1-methyl-3-pyrrolidine carboxylate (XIII) (19). Compound XIII with methylamine gave the *N*-methylamide (XIV). Compound VII and phenyl magnesium bromide gave 1-methyl-3-pyrrolidinyl phenyl ketone (XV). A similar reaction with X gave 1-benzyl-3-pyrrolidinyl phenyl ketone (XVI). The intermediate ketimine magnesium halide of XVI was found to be resistant to the action of boiling concentrated hydrochloric acid. It was converted into the ketone by treatment with sodium hydroxide. The corresponding salt of XV was readily cleaved with ammonium chloride.

Compound VII was readily alkylated with alkyl halides and sodium amide. To effect the alkylation, VII was first added to a slurry of sodium amide in liquid ammonia followed by the alkyl halide. Toluene was then added to the mixture and the ammonia was allowed to evaporate. The toluene was then heated to reflux until the black color of the sodium amide disappeared. The 3-alkylated derivatives were isolated by distillation (20).

EXPERIMENTAL[1]

3-Halopyrrolidines

The 1-alkyl-3-pyrrolidinols used in the preparation of the 1-alkyl-3-halopyrrolidines were prepared according to the method of Franko and Lunsford (3) from 1,4-dichloro-2-butanol (21, 22) and the appropriate monoalkylamine.

[1] All infrared spectra were made with a Perkin-Elmer Infracord spectrophotometer. All melting points are uncorrected. The microanalyses were performed by the Spang Microanalytical Laboratory, Ann Arbor, Mich., and by the S. B. Penick Quality Control Laboratories.

1 - Methyl - 3 - chloropyrrolidine (I).—The method given below for the preparation of I was also used for 1-ethyl and 1-isopropyl-3-chloropyrrolidines (II, III).

To a solution of 50.5 Gm. (0.5 mole) of 1-methyl-3-pyrrolidinol in 500 ml. of dry benzene was added 119 Gm. (1 mole) of thionyl chloride in 100 ml. of benzene at such a rate that the mixture warmed up to 75°. The mixture was refluxed for 1 hr., 300 ml. of benzene distilled off and replaced with 300 ml. of fresh benzene, cooled, and made strongly alkaline with 2 *N* sodium hydroxide solution. The benzene layer was separated, washed once with water, and distilled through a short Vigreaux column to yield 46.3 Gm. (79.5%) of I, b.p. 55–60° at 50 mm. [Lit. value (15) 55–58° at 50 mm.]

1 - Ethyl - 3 - chloropyrrolidine (II).—From 115.2 Gm. (1 mole) of 1-ethyl-3-pyrrolidinol and 180 Gm. (1.5 moles) of thionyl chloride, 105 Gm. (78.8%) of II was obtained; b.p. 157–159° at 760 mm. [Lit. value (13) 155° at 760 mm.]

1 - Isopropyl - 3 - chloropyrrolidine (III) (13).—A yield of 99.5 Gm. (67.4%) of III was obtained from 129.2 Gm. (1 mole) of 1-isopropyl-3-pyrrolidinol and 180 Gm. (1.5 moles) of thionyl chloride; b.p. 93–94° at 47 mm.

Anal.—Calcd. for $C_7H_{14}ClN$: neutralization equivalent, 148. Found: 154.

1 - Benzyl - 3 - chloropyrrolidine (IV) (13).—Similarly, 177.4 Gm. (1 mole) of 1-benzyl-3-pyrrolidinol and 180 Gm. (1.5 moles) of thionyl chloride were reacted in 600 ml. of benzene. However, after the reaction was over, a solid crystallized on

cooling. This substance was filtered and washed free of color with benzene to yield 204.5 Gm. (86.0%) of IV hydrochloride, m.p. 140–142°. [Lit. value (13) 131–132°.]

Anal.—Calcd. for $C_{11}H_{15}Cl_2N$: neutralization equivalent, 232. Found: 236.

To liberate the free base, the hydrochloride was suspended in 1000 ml. of ether and treated with 400 ml. of 1.5 *N* sodium hydroxide. The ether phase was separated, dried over sodium sulfate, and distilled to give 166 Gm. (84.7%) of IV, b.p. 87–89° at 0.4–0.8 mm.

3 - Chloropyrrolidine (V).—A suspension of 38.0 Gm. (0.16 mole) of IV hydrochloride in 150 ml. of isopropyl alcohol was hydrogenated (Parr shaker) at 15–30 p.s.i. and 60–70° over 1.5 Gm. of 15% palladium on charcoal. The theoretical amount of hydrogen was absorbed in 5 hr. After filtration from the catalyst, the solution was concentrated and the product crystallized to yield 19.7 Gm. (83.4%) of crude V hydrochloride, m.p. 106–110°. The product was purified by recrystallization from isopropyl alcohol; yield, 15.4 Gm. (68.1%), m.p. 111–113°.

Anal.—Calcd. for $C_4H_9ClN^+ Cl^-$: Cl^-, 24.96. Found: 25.03.

The free base was liberated by treating a suspension of 15.0 Gm. (0.106 mole) of V hydrochloride in 100 ml. of ether with 20 ml. of 10 *N* sodium hydroxide. Distillation of the ether yielded 8.0 Gm. (72.1%) of V, b.p. 86–88° at 100 mm. 3-Chloropyrrolidine was a colorless liquid which rapidly darkened on storage. In another preparation, the substance suddenly decomposed upon distillation forming a solid black tar. Freshly prepared V was used in attempts to prepare 3-cyanopyrrolidine (XI).

1 - Methyl - 3 - bromopyrrolidine (VI) (11).—To a solution of 8.7 Gm. (0.087 mole) of 1-methyl-3-pyrrolidinol in 100 ml. of dry benzene cooled to below 10°, there was added 28.3 Gm. (0.105 mole) of phosphorus tribromide. The mixture was refluxed for 2 hr., cooled, and treated with 120 ml. of 25% potassium hydroxide. The benzene solution was separated and distilled to give 7.0 Gm. (49.1%) of VI, b.p. 78° at 40 mm. Compound VI was a colorless liquid which soon started to deposit a solid upon standing at room temperature. No attempt was made at analysis. It was used as rapidly as possible for the preparation of 1-methyl-3 - (1 - methyl - 3 - pyrrolidinyl) - 3 - cyanopyrrolidine (XXIII).

3-Cyanopyrrolidines

The following method, illustrated by the preparation of 1-methyl-3-cyanopyrrolidine (VII), was used to prepare all of the 3-cyanopyrrolidines.

1-Methyl-3-cyanopyrrolidine (VII).—To a suspension of 165 Gm. (3.2 moles) of sodium cyanide in 775 ml. of dimethylsulfoxide (dried over calcium hydride) heated to 90–100° was added, with stirring over a 25-min. period, 309 Gm. (2.58 moles) of I. The mixture was heated to 165–170° for 30 min., cooled to 25°, and diluted with 1300 ml. of chloroform. The mixture was poured into 4000 ml. of saturated salt solution. The chloroform phase was separated and the aqueous layer extracted with chloroform. The combined chloroform solution was washed several times with saturated salt to remove residual dimethylsulfoxide and distilled to yield 190 Gm. (67.1%) of VII, b.p. 92–93° at 23 mm. A picrate was prepared in alcohol, m.p. 204–205°.

Anal.—Calcd. for $C_{12}H_{13}N_5O_7$: N, 20.64. Found: 20.61, 20.58.

1 - Ethyl - 3 - cyanopyrrolidine (VIII).—From 26.7 Gm. (0.2 mole) of II and 12.0 Gm. (0.25 mole) of sodium cyanide, 12.0 Gm. (48.5%) of VIII, b.p. 102–104° at 23 mm., was obtained; picrate m.p. 140–141°.

Anal.—Calcd. for $C_{13}H_{15}N_5O_7$: N, 19.82. Found: 20.18.

1 - Isopropyl - 3 - cyanopyrrolidine (IX).—From 81.2 Gm. (0.55 mole) of III and 36.0 Gm. (0.7 mole) of sodium cyanide was obtained 40.0 Gm. (52.6%) of IX, b.p. 102–104° at 10 mm.

Anal.—Calcd. for $C_8H_{14}N_2$: neutralization equivalent, 138. Found: 140. A picrate, m.p. 136–137°, was prepared in alcohol.

Anal.—Calcd. for $C_{14}H_{17}N_5O_7$: N, 19.07. Found: 19.08.

1 - Benzyl - 3 - cyanopyrrolidine (X).—The same procedure was used except the reaction temperature was lowered to 155–160° from 165–170°. Thus, 265.0 Gm. (1.35 moles) of IV and 100.0 Gm. (2.05 moles) of sodium cyanide yielded 179.0 Gm. (71.3%) of X, b.p. 120–124° at 0.5–0.6 mm.

Anal.—Calcd. for $C_{12}H_{14}N_2$: neutralization equivalent, 186. Found: 188.

3-Cyanopyrrolidine (XI).—The procedure for X was used. From 10.6 Gm. (0.1 mole) of V and 6.4 Gm. (0.13 mole) of sodium cyanide, only 1.4 Gm. of a product, b.p. 82–84° at 5 mm., was isolated.

Anal.—Calcd. for $C_5H_8N_2$: neutralization equivalent, 96; C, 62.48; H, 8.38; N, 29.14. Found: neutralization equivalent, 107; C, 59.52; H, 8.20; N, 26.51.

Vapor phase chromatography[2] showed that one component comprised about 72.5% of the above product and three others the remainder. The infrared absorption spectrum of the product showed a distinct CN maximum at 4.48 μ and one for NH at 3.0 μ. It was therefore concluded that XI was the major component of the mixture.

An attempt was made to prepare XI by hydrogenolysis of X hydrochloride. The latter, prepared by neutralizing a solution of X in isopropyl alcohol, was shaken with hydrogen over palladium on charcoal (Parr shaker). More than the theoretical amount of hydrogen was absorbed. Only a tarry product could be isolated. Compound X did not take up hydrogen under the same conditions.

Products from 1-Methyl-3-cyanopyrrolidine

1 - Methyl - 3 - aminomethylpyrrolidine (XII).—A mixture of 11.0 Gm. (0.1 mole) of VII, 120 ml. of acetic anhydride, 12 Gm. of anhydrous sodium acetate, and 3 Gm. of Raney nickel (previously washed and suspended in acetic anhydride) was shaken at 50° at 15–25 p.s.i. of hydrogen (Parr shaker). Approximately 2 moles of hydrogen per mole of VII was absorbed in 1 hr. The reaction

[2] The authors thank Mr. F. A. E. Schilling of these laboratories for performing the analysis on a Perkin-Elmer 154 instrument. A 2-M. 1/4 in. i.d. stainless steel column filled with 20% Silicone SE 52 on Chromosorb W (45/60 mesh) and operated at 150° with 15 p.s.i. of helium at a rate of 33 ml./min. was used to effect the separation.

mixture was filtered from the catalyst and the acetic anhydride was removed by vacuum distillation. The semisolid residue was dissolved in benzene and filtered from the insoluble sodium acetate. A yield of 11.6 Gm. (75%) of what apparently was the acetyl derivative of XII was obtained by distillation of the filtrate, b.p. 104–106° at 0.3 mm. This substance discolored rapidly on standing. To liberate the free diamine, 7.3 Gm. (0.064 moles) of the above product was refluxed in 20 ml. of 7.5 *N* sodium hydroxide until all went into solution. The solution was cooled, neutralized with hydrochloric acid, and evaporated to dryness in vacuum. The residue was treated with excess 50% sodium hydroxide and extracted with ether. The ether extracts were dried over sodium hydroxide pellets and distilled to give 4.5 Gm. (87%) of XII, b.p. 72–76° at 30 mm. A dipicrate was prepared and recrystallized from alcohol, m.p. 206–207°. [Lit. value (17) 208–211°.]

Ethyl - 1 - methyl - 3 - pyrrolidine Carboxylate (XIII) (19).—A mixture of 11.0 Gm. (0.1 mole) of VII and 80 ml. of concentrated hydrochloric acid was refluxed overnight. The resulting orange solution was vacuum stripped to dryness and the residue dissolved in 150 ml. of anhydrous alcohol. The insoluble salt was filtered. Weight, 5.0 Gm. Calcd. for ammonium chloride: 5.2 Gm. The filtrate was saturated with hydrogen chloride and refluxed for 3 hr. The excess hydrogen chloride and alcohol were removed by vacuum distillation. The residue was dissolved in water and extracted with ether. The aqueous solution was made alkaline and extracted 7 times with ether. Distillation of the ether extracts gave 6.2 Gm. (39.3%) of XIII, b.p. 107–109° at 40 mm.

Anal.—Calcd. for $C_8H_{15}NO_2$: neutralization equivalent, 157. Found: 159.

1 - Methyl - 3 - pyrrolidine - N - methylcarboxamide (XIV).—A solution of 3.9 Gm. (0.025 mole) of XIII in 65 ml. of 40% aqueous methylamine was allowed to stand at room temperature for 1 week. The excess methylamine and water were removed and the residue distilled to give 2.4 Gm. of XIV, b.p. 90–94° at 0.2 mm. The liquid distillate soon solidified to give a waxy solid melting at about 35°.

Anal.—Calcd. for $C_7H_{14}N_2O$: N, 19.70. Found: 19.59.

1 - Methyl - 3 - pyrrolidinyl Phenyl Ketone (XV).—To a solution of phenyl magnesium bromide prepared from 62.8 Gm. (0.4 mole) of bromobenzene and 9.7 Gm. (0.4 atoms) of magnesium turnings in 100 ml. of ether, was added 11.0 Gm. (0.1 mole) of VII at such a rate that a gentle reflux was maintained. The reaction mixture was then stirred and refluxed for 5 hr. It was then cooled and treated with 50 ml. of saturated ammonium chloride solution. The ether layer was decanted from the semisolid aqueous phase. The latter was diluted with water to dissolve the solid and extracted with ether. The combined ether solutions were dried over sodium sulfate and distilled to give 7.8 Gm. (41.0%) of XV, b.p. 112–118° at 0.3 mm. A picrate was prepared and recrystallized from benzene, m.p. 146–147°.

Anal.—Calcd. for $C_{18}H_{18}N_3O_8$: N, 13.39. Found: 13.29.

The infrared spectrum of XIV showed a maximum at 5.9 μ corresponding to the C=O group and a doublet at 3.4 and 3.6 μ which characterized the spectra of most of the 1-alkyl-3-substituted pyrrolidines.

1 - Benzyl - 3 - pyrrolidinyl Phenyl Ketone (XVI).—In a manner similar to the procedure for XV, 18.6 Gm. (0.1 mole) of X was reacted with a solution of phenyl magnesium bromide prepared from 18.8 Gm. (0.12 mole) of bromobenzene and 2.7 Gm. (0.12 atoms) of magnesium turnings in 90 ml. of ether. The cold reaction mixture was decomposed with 70 ml. of 8 *N* hydrochloric acid to give, on filtration, 25 Gm. of a crystalline solid. This substance, apparently an acid resistant ketimine magnesium halide, gave an ash on fusion and was recovered unchanged after refluxing overnight with concentrated hydrochloric acid. Suspension in 300 ml. of toluene and agitation at 60° for 30 min. with 160 ml. of 4 *N* sodium hydroxide hydrolyzed it to the ketone. Filtration of the reaction mixture gave some solid magnesium hydroxide. The toluene layer was separated, dried over sodium sulfate, and distilled to yield 19.6 Gm. (74.0%) of XVI, b.p. 179–180° at 0.3 mm.

Anal.—Calcd. for $C_{18}H_{19}NO$: neutralization equivalent, 265. Found: 266.

A hydrochloride, m.p. 120–122°, was prepared by neutralizing a tetrahydrofuran solution of XVI with concentrated hydrochloric acid.

Anal.—Calcd. for $C_{18}H_{20}ClNO$: N, 4.64. Found: 4.25.

The infrared spectrum of XVI showed a maximum at 5.9 μ and a doublet at 3.35 and 3.58 μ.

Alkylation of 1-Methyl-3-cyanopyrrolidine

The following method illustrated in the preparation of XVIII was used for all of the 1-methyl-3-alkyl-3-cyanopyrrolidines.

1,3-Dimethyl-3-cyanopyrrolidine (XVII).—To a suspension of sodium amide prepared from 2.3 Gm. (0.1 atom) of sodium in 150 ml. of liquid ammonia (23) was added 11.0 Gm. (0.1 mole) of VII. The mixture was stirred in refluxing ammonia for several minutes and 17.0 Gm. (0.12 mole) of methyl iodide followed by 150 ml. of dry toluene were added. The ammonia was allowed to evaporate off, the mixture heated to reflux until the black color of the sodium amide disappeared (3–4 hr.), cooled, and mixed with 100 ml. of water. The aqueous layer was separated and extracted with toluene. The combined toluene solution was dried over sodium sulfate and distilled to yield 7.8 Gm. (63.2%) of XVII, b.p. 88–89° at 24 mm. A picrate was prepared in alcohol, m.p. 211–213°.

Anal.—Calcd. for $C_{13}H_{15}N_5O_7$: N, 19.82. Found: 19.89, 19.81.

1 - Methyl - 3 - n - propyl - 3 - cyanopyrrolidine (XVIII).—Compound XVIII, 9.6 Gm. (63.3%), b.p. 112–113° at 23 mm., was obtained in a similar manner from 20.4 Gm. (0.12 mole) of *n*-propyl iodide and the same quantities of sodium amide and VII; picrate, m.p. 163–164°.

Anal.—Calcd. for $C_{15}H_{19}N_5O_7$: N, 18.36. Found: 18.49.

1 - Methyl - 3 -i-propyl - 3 - cyanopyrrolidine (XIX).—Similarly, 7.1 Gm. (46.7%) of XIX, b.p. 76–79° at 5 mm., was obtained from 20.4 Gm. (0.12 mole) of *i*-propyl iodide; picrate, m.p. 221–223°.

Anal.—Calcd. for $C_{15}H_{19}N_5O_7$: N, 18.36. Found: 18.32.

1 - Methyl - 3 - n - butyl - 3 - cyanopyrrolidine (XX).—Similarly, 8.1 Gm. (48.5%) of XX, b.p. 136° at 25 mm., was obtained from 18.4 Gm. (0.1 mole) of *n*-butyl iodide; picrate, m.p. 158–160°.

Anal.—Calcd. for $C_{16}H_{21}N_5O_7$: N, 17.71. Found: 17.78, 17.62.

1 - Methyl - 3 - cyclopentyl - 3 - cyanopyrrolidine (XXI).—Similarly, 17.9 Gm. (0.12 mole) of cyclopentyl bromide yielded 3.3 Gm. (18.7%) of XXI, b.p. 106–108° at 5 mm.; picrate, m.p. 204–206°.

Anal.—Calcd. for $C_{17}H_{21}N_5O_7$: N, 16.78. Found: 17.10, 17.21.

1 - Methyl - 3 - benzyl - 3 - cyanopyrrolidine (XXII).—Similarly, 11.5 Gm. (57.6%) of XXII, b.p. 134–136° at 2 mm., was obtained from 12.7 Gm. (0.1 mole) of benzyl chloride; picrate, m.p. 176–177°.

Anal.—Calcd. for $C_{19}H_{19}N_5O_7$: N, 16.31. Found: 16.12, 16.38.

1 - Methyl - 3 - (1 - methyl - 3 - pyrrolidinyl)-3 - cyanopyrrolidine (XXIII).—Similarly, 19.7 Gm. (0.12 mole) of freshly prepared VI yielded 2.7 Gm. (13.8%) of XXIII, b.p. 120–126° at 8 mm.; dipicrate, m.p. 232–233° dec.

Anal.—Calcd. for $C_{23}H_{25}N_9O_{14}$: N, 19.35. Found: 19.60, 19.52.

1 - Methyl - 3 - (2 - dimethylaminoethyl) - 3-cyanopyrrolidine (XXIV).—Similarly, with double the amount of sodium amide used for the preceding compounds, 28.0 Gm. (0.12 mole) of 2-dimethylaminoethylbromide hydrobromide yielded 2.9 Gm. (16.2%) of XXIV, b.p. 110–112° at 6 mm.; dipicrate, m.p. 148–150° (opaque liquid), clear at 155–160°.

Anal.—Calcd. for $C_{22}H_{25}N_9O_{14}$: N, 19.71. Found: 19.60.

Separation and Quantitative Determination of Adrenaline Using Thin-Layer Chromatography

By N. H. CHOULIS

The separation of adrenaline from noradrenaline and dopamine and its quantitative determination using thin-layer chromatography have been studied. A complete spot separation of the above amines can be achieved by the use of cellulose thin layers and a phenol–water solvent system. For the quantitative determination of the separated adrenaline two methods were used, namely (*a*) a method studying the weight/area relationship of the spots and (*b*) a method employing elution of the spots and measurement of the ultraviolet absorption of the eluents.

PAPER CHROMATOGRAPHIC methods for the separation of catecholamines and related compounds using various solvent systems have been reported (1, 2). These methods require 5–20 hr. for a satisfactory development of the chromatograms, and as a result of the prolonged exposure, oxidation of the catecholamines to the corresponding red aminochromes is usually observed on the paper.

Received April 25, 1966, from the School of Pharmacy, Texas Southern University, Houston 77004.
Accepted for publication October 19, 1966.
Presented to the Drug Standards, Analysis and Control Section, A.PH.A. Academy of Pharmaceutical Sciences, Dallas meeting, April 1966.

Thin-layer chromatographic methods have often been used for the separation of various components of a mixture. The importance of this method and the ease with which it is carried out have been generally recognized since Stahl (3–5) introduced it as an analytical tool.

A complication in the interpretation of chromatograms of catecholamines (on paper or thin-layer chromatography) may result from the presence of multiple spots which are sometimes produced during chromatography of pure substances

1 - Methyl - 3 - n - butyl - 3 - cyanopyrrolidine (XX).—Similarly, 8.1 Gm. (48.5%) of XX, b.p. 136° at 25 mm., was obtained from 18.4 Gm. (0.1 mole) of *n*-butyl iodide; picrate, m.p. 158–160°.

Anal.—Calcd. for $C_{16}H_{21}N_5O_7$: N, 17.71. Found: 17.78, 17.62.

1 - Methyl - 3 - cyclopentyl - 3 - cyanopyrrolidine (XXI).—Similarly, 17.9 Gm. (0.12 mole) of cyclopentyl bromide yielded 3.3 Gm. (18.7%) of XXI, b.p. 106–108° at 5 mm.; picrate, m.p. 204–206°.

Anal.—Calcd. for $C_{17}H_{21}N_5O_7$: N, 16.78. Found: 17.10, 17.21.

1 - Methyl - 3 - benzyl - 3 - cyanopyrrolidine (XXII).—Similarly, 11.5 Gm. (57.6%) of XXII, b.p. 134–136° at 2 mm., was obtained from 12.7 Gm. (0.1 mole) of benzyl chloride; picrate, m.p. 176–177°.

Anal.—Calcd. for $C_{19}H_{19}N_5O_7$: N, 16.31. Found: 16.12, 16.38.

1 - Methyl - 3 - (1 - methyl - 3 - pyrrolidinyl)-3 - cyanopyrrolidine (XXIII).—Similarly, 19.7 Gm. (0.12 mole) of freshly prepared VI yielded 2.7 Gm. (13.8%) of XXIII, b.p. 120–126° at 8 mm.; dipicrate, m.p. 232–233° dec.

Anal.—Calcd. for $C_{23}H_{25}N_9O_{14}$: N, 19.35. Found: 19.60, 19.52.

1 - Methyl - 3 - (2 - dimethylaminoethyl) - 3-cyanopyrrolidine (XXIV).—Similarly, with double the amount of sodium amide used for the preceding compounds, 28.0 Gm. (0.12 mole) of 2-dimethylaminoethylbromide hydrobromide yielded 2.9 Gm. (16.2%) of XXIV, b.p. 110–112° at 6 mm.; dipicrate, m.p. 148–150° (opaque liquid), clear at 155–160°.

Anal.—Calcd. for $C_{22}H_{25}N_9O_{14}$: N, 19.71. Found: 19.60.

Separation and Quantitative Determination of Adrenaline Using Thin-Layer Chromatography

By N. H. CHOULIS

The separation of adrenaline from noradrenaline and dopamine and its quantitative determination using thin-layer chromatography have been studied. A complete spot separation of the above amines can be achieved by the use of cellulose thin layers and a phenol–water solvent system. For the quantitative determination of the separated adrenaline two methods were used, namely (*a*) a method studying the weight/area relationship of the spots and (*b*) a method employing elution of the spots and measurement of the ultraviolet absorption of the eluents.

PAPER CHROMATOGRAPHIC methods for the separation of catecholamines and related compounds using various solvent systems have been reported (1, 2). These methods require 5–20 hr. for a satisfactory development of the chromatograms, and as a result of the prolonged exposure, oxidation of the catecholamines to the corresponding red aminochromes is usually observed on the paper.

Received April 25, 1966, from the School of Pharmacy, Texas Southern University, Houston 77004.

Thin-layer chromatographic methods have often been used for the separation of various components of a mixture. The importance of this method and the ease with which it is carried out have been generally recognized since Stahl (3–5) introduced it as an analytical tool.

A complication in the interpretation of chromatograms of catecholamines (on paper or thin-layer chromatography) may result from the presence of multiple spots which are sometimes produced during chromatography of pure substances

(6–11). Multiple spots are formed when catecholamines are chromatographed in the presence of acids (*i.e.*, dichloro- or trichloroacetic, picric, etc.) and also when pure samples of salts of catecholamines (tartrate, hydrochloride) are chromatographed in *n*-butanol–HCl or *n*-butanol–acetic acid–water solvent systems (2, 12).

Adrenaline and noradrenaline have been previously chromatographed on buffered silica gel plates, using a 70% solution of ethanol as solvent system (13). Waldi (14) has also achieved the separation of adrenaline, noradrenaline, and serotonin and other catecholamines on Silica Gel G plates, but after conversion of the amines to their acetyl derivatives.

For quantitative thin-layer chromatography a number of methods have been used. Seher (15) has suggested that in thin-layer chromatography the weight of the material and the spot are proportional. Purdy and Truter (16) found that quantitation is based on a linear relationship existing between the square root of the area of a component after chromatographing, and the logarithm of the weight of the applied sample; according to them Seher's data as well as that of Stahl (17) and Breuner and Niederwieser (18) fit the relationship for loads of 1–80 mcg. per spot. Pelka and Metcalf (19) examining long-chain tertiary amines, found the method applicable for loads of approximately 200 mcg.

Recently Morrison and Orr (20), in an analysis of selected pharmaceutical mixtures in tablet and capsule forms, by using thin-layer chromatography, obtained quantitative results from the developed chromatograms. A linear relationship between the spot area, in sq. mm., and the weight of the spot was observed.

The method was applicable for concentrations up to 250 mcg. However, this method requires a satisfactory spray reagent, otherwise its use for quantitative work is doubtful.

Ganshirt *et al.* (21) used the thin-layer chromatography for the quantitative assay of a number of bile acids, and Zollner *et al.* (22) found the method applicable for the quantitative estimation of cholesterol esters.

Millett *et al.* (23) described other techniques for quantitative thin-layer chromatography using furoic and hydroxymethylfuroic acids as model compounds. An application of thin-layer chromatography for quantitative assay of tryptamine was suggested by Eble and Brooker (24).

The purpose of the present paper is to provide, by means of thin-layer chromatography, a rapid method of separation and quantitative determination of catecholamines.

EXPERIMENTAL

Materials.—Adrenaline, dopamine, and noradrenaline were used. Adrenaline and noradrenaline were liberated from the hydrochloride and bitartrate monohydrate salts, respectively, by the addition of a dilute ammonium hydroxide solution containing a trace of sodium metabisulfite. The precipitates were filtered off, washed with water, methanol, ether, and dried at low temperature. Thin-layer chromatography, melting point determinations, and infrared spectra analysis demonstrated that each compound had a high degree of purity.

Solvent Systems.—The following solvent systems were used: (*1*) *n*-butanol–acetic acid–water, 4:1:5 v/v (the liquids were shaken together and set aside overnight; the organic layer was separated and used as the running solvent). (*2*) *n*-Amyl alcohol–acetic acid–water, 4:1:5 v/v. (*3*) Methanol–acetone–triethylamine, 50:50:1 v/v. (*4*) Dimethylformamide. (*5*) Phenol–water, 8:2 w/w.

Detection.—The spots were visualized by spraying the plates with a solution of 0.6 Gm. of potassium ferrocyanide and 0.5 Gm. of sodium hydroxide in 100 ml. of water (25).

An ultraviolet lamp was used also to locate the spots in cases where spraying reagents had to be avoided.

Thin-Layer Plates.—All plates used were 20 × 20 cm.

Using MN 300G cellulose powder (Machery, Nagel & Co.) Silica Gel G (Merck), and aluminum oxide G (Merck), plates were prepared according to Stahl (3). The plates were kept in a desiccator using calcium chloride and reactivated at 100° for 5 min. before use.

Methods

Separation of Amines.—Two per cent solutions of the amines were prepared using a 5% acetic acid solution in water. One-tenth microliter quantities were applied 1.5 cm. from the bottom edge of the plates. A distance of 10 cm. from the origin was marked off, and ascending chromatograms were run to this mark (at room temperature).

Quantitative Determination of Adrenaline.—*Weight/Area Relationship.*—A solution of adrenaline was prepared by dissolving 300 mg. of pure compound in 10 ml. of a 2% solution of acetic acid in water, in a 10-ml. volumetric flask. Using a micropipet, quantities of 1 to 5 μl. were applied to the plates 1.5 cm. from the bottom edges. Ascending chromatograms were run (at room temperature).

When the solvent front reached the 10 cm. mark (60–70 min.), the plates were removed and air dried, sprayed, and the spot areas were measured by means of a photovolt Densicord (model 52-C); the graph plotted by the instrument was rendered quantitative by an electronic integrator (Integraph model-49) adapted to the Densicord, and which calculated the spot area which then was expressed in the equivalent square centimeters by the use of a Gelman spot calculator. The area of the spots representing the various concentrations was taken and plotted, using the appropriate relationship.

Elution of the Spots.—A solution of adrenaline was prepared by dissolving 100 mg. of the amine in 3 ml. of a 2% solution of acetic acid in water (master solution). Five different concentrations

of the amine were prepared by diluting quantities of 1 to 5 μl. of the master solution into 10-ml. volumetric flasks and bringing up to the volume using the same solvent. The ultraviolet absorption of each solution was taken at 280 mμ, and from the values obtained, a standard curve was plotted.

Quantities of 1 to 5 μl. of the adrenaline solution (master solution) were applied to thin-layer plates of either silica gel or alumina, and the chromatograms were run in the usual manner.

After drying the plates, the spots were located using an ultraviolet lamp and were marked off. Each spot was then scraped off into small conical flasks. The adrenaline was eluted from the coating material by adding about 7 ml. of the solvent. Each flask was shaken well for about 10 min., centrifuged, and filtered into 10-ml. volumetric flasks. Solvent was added to volume.

No adrenaline residues were found on the filter, testing with the detection reagent (25).

A similar elution process was followed for a blank sample of the coating material alone.

Ultraviolet absorption of each solution was taken at the same wavelength as above (280 mμ), and the values obtained after reducing the absorption due to the blank were recorded next to the standard curve and compared.

To all solvent systems used, small quantities of sodium metabisulfite were added as antioxidant. All chromatograms were carried out in chromatographic chambers enriched in nitrogen atmosphere.

RESULTS AND DISCUSSION

All experiments were performed in duplicate.

The results for the separation of the amines, using alumina, cellulose, or silica gel plates and the various solvent systems, indicate that although there was a considerable movement of the amine spots on alumina plates, when No. *1* and *2* solvent systems were used, the mixture of the three amines could not be separated completely, since the observed R_f values were very close together. A complete separation, however, between dopamine and noradrenaline can be achieved, when the No. *1* solvent system is used.

Similarly on silica gel plates, separation between two amines can be observed, but not complete separation of the three amines.

On cellulose thin layer, solvents No. *1* and *2* showed a partial separation between the amine spots, but when phenol–water (solvent No. *5*) was used, the separation between the three amines was complete (Fig. 1). This indicates that among the layers studied, only that of cellulose, along with the phenol–water solvent system, can give a complete separation when even large quantities of the amines are used.

However, for very small loads (1–30 mcg.) combinations of the above-mentioned solvent systems and alumina, cellulose, or silica gel plates would give complete separation of the amines with the exception of alumina plate and the No. *3* solvent system. Furthermore, in no case was separation between adrenaline and noradrenaline observed when alumina and the No. *4* solvent system or silica gel and the No. *3* or *4* solvent systems were used, but a complete separation of these amines from dopamine always occurred.

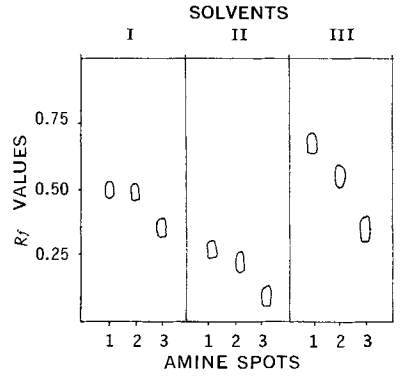

Fig. 1.—Thin-layer chromatography of adrenaline [1], dopamine [2], and noradrenaline [3] on cellulose layers using various solvent systems. Solvents: I, *n*-butanol–acetic acid–water, 4:1:5 v/v; II, *n*-amyl alcohol–acetic acid–water, 4:1:5 v/v; III, phenol–water, 8:2 w/w.

The results obtained for the quantitative estimation of adrenaline by applying the weight/area relationship method when *n*-butanol–acetic acid–water or phenol–water solvent systems were used are shown in Figs. 2 and 3, respectively. In Fig. 4 results obtained from the elution method are depicted.

For the weight/area method, a linear relationship between the spot area and the weight of the compound has been found when silica gel or alumina plates and either solvent systems No. *1* or *5* were used. This relationship shows the dependence of the area of the spot upon the amount of the sample used, and although the size of the spot varied with the thickness of the layers, the temperature of the experiment and the purity of the solvent used, the observed results were reproducible within ±5%. However, it is advisable ro run on the same plate both the standards and the sample.

Although the best separation of adrenaline from the other amines was achieved on cellulose plates,

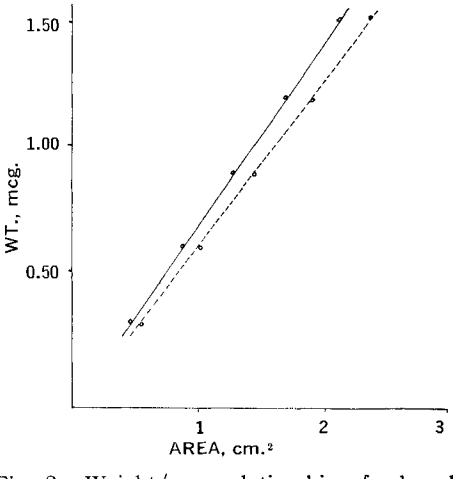

Fig. 2.—Weight/area relationship of adrenaline spots when *n*-butanol–acetic acid–water, 4:1:5 v/v solvent system, was used. Key: - - - - - -, silica gel plates; ——, alumina plates.

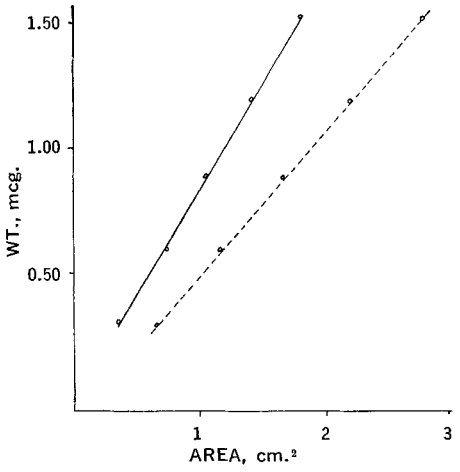

Fig. 3.—Weight/area relationship of adrenaline spots when phenol–water, 8:2 w/w solvent system, was used. Key: - - - - - -, silica gel plates; ——, alumina plates.

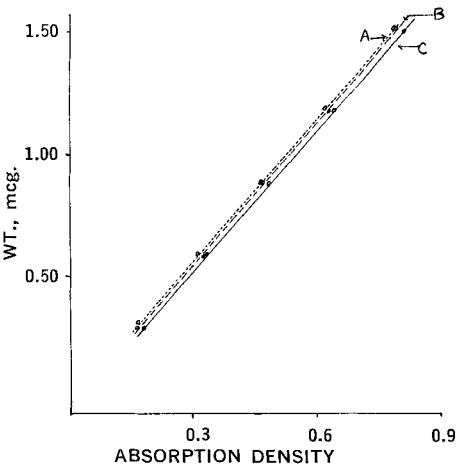

Fig. 4.—Adrenaline recovery after elution of the spots from thin-layer chromatograms of alumina (A) and silica gel (B). The straight line (C) indicates the blank. *n*-Butanol–acetic acid–water, 4:1:5 v/v solvent system, was used.

using the phenol–water solvent system, it was found that for the quantitative estimation of the separated amine, alumina or silica gel plates and the No. *1* solvent system gave the most accurately reproducible results (Fig. 4).

The recovery of the compounds, after the elution of the spots, was 93 and 97%, respectively, for thin layers of alumina or silica gel. The lower recovery on the alumina thin layer can be attributed to the strong adsorption forces by which the substance is held on the alumina (11). A recovery of below 85% was observed when cellulose layers were used. Here the adsorption and partition forces influence the recovery (11).

However, for quantitative determination of adrenaline, the above-mentioned methods may be regarded as simple and accurate, though the second method has been found more reliable, since factors which might have influenced the spot area in the first method are involved only to a certain extent in the elution method.

The use of these methods can also be extended for quantitative determination of other sympathomimetic amines and other compounds.

Polymorphism and Drug Availability II

Dissolution Rate Behavior of the Polymorphic Forms of Sulfathiazole and Methylprednisolone

By W. I. HIGUCHI, P. D. BERNARDO, and S. C. MEHTA

The dissolution rate behavior of the two polymorphic forms of sulfathiazole and methylprednisolone has been studied. A correlation between the rates of reversion of the metastable forms to the stable forms during dissolution and the crystal growth rates of the stable form was found. Data obtained in a number of solvents showed that when the crystal growth rate of the stable phase was slow, there was little tendency for reversion during dissolution. These findings support the idea that the rate-determining step in the solvent mediated reversion of these polymorphs is the crystal growth of the stable phase. The recently presented mixture theory for dissolution rate was extended to explain the dissolution behavior of polymorphic mixtures. Experimental data on the effect of the agitation rate upon the dissolution rates of polymorphic mixtures agreed well with theory. It is proposed that this theory provides the explanation for the enigma of "the loss of sensitivity in distinguishing the difference in dissolution rates of polymorphs at high agitation rates."

FOR THERMODYNAMIC reasons (1) a drug exhibiting crystal polymorphism should possess different thermodynamic activities (or fugacities) depending upon its crystalline modification. Therefore, the drug release rate from any solid dosage form, *in vivo* or *in vitro*, may be strongly dependent upon this factor when the rate process is diffusion controlled. From the practical pharmaceutical standpoint, the existence of polymorphism may lead to good or bad consequences. The successful utilization of a polymorph of significantly greater thermodynamic activity than that of the stable modification may provide, in some instances, therapeutic blood levels for an otherwise inactive drug formulation. On the other hand, when the existence of multiple crystalline modifications goes unrecognized in a particular formulation, this may possibly result in too wide a range of dose-to-dose drug availability for the patient.

The purpose of this paper is to present some of the authors' studies on the dissolution rates of higher energy polymorphs of sulfathiazole and methylprednisolone. The data, when viewed in the light of the authors' crystal growth studies (2), provide a clear picture of what factors could be important in determining the physical kinetic stability of drug polymorphs. Furthermore, these studies appear to explain the mystery of the anomalous effect of agitation on the dissolution rate behavior of polymorphs (3–5).

Accepted for publication September 20, 1966.

This investigation was supported by a grant from The Upjohn Co., Kalamazoo, Mich.

Presented to the Basic Pharmaceutics Section, A.PH.A. Academy of Pharmaceutical Sciences, Dallas meeting, April 1966.

EXPERIMENTAL

General Considerations.—The compounds selected for this study were sulfathiazole and methylprednisolone.[1] These are both known to exhibit dimorphism under usual conditions. The designations I and II will be used for the thermodynamically stable and the unstable forms, respectively.

Various aqueous and organic media were considered for this work. This provided a wide range of solubilities and a variation in the intermolecular interactions at the crystal–solution interface.

It was decided to employ methods involving dissolution from a plane surface. Thus, the techniques as described by Milosovich (6) for fast dissolution rates and by Higuchi *et al.* (7) for slow rates were used in this work. These arrangements with controlled agitation were expected to provide situations and yield results that could be handled conveniently by mathematics.

Preparation of Stable and Metastable Forms.—Sulfathiazole crystal forms are I, which melts at 174°–175°, and II which melts at 200°–201°. The recrystallization of sulfathiazole in warm ethyl alcohol gave form I which was hexagonal plates. Form II was obtained by using the method of Grove and Keenan (8), *i.e.*, by supersaturating a normal propanol solution, filtering, and allowing it to recrystallize over a water bath at approximately 80°. Elongated rods resulted. It was found that form II could also be obtained by recrystallizing from *sec*-butyl alcohol at room temperature. A third method for obtaining form II was also used so that verification of the appropriate form could be made. This was accomplished by melting sulfathiazole on a hot bar and then allowing it to crystallize at approximately 90°.

The form I of methylprednisolone was obtained by recrystallization from acetone, while form II was prepared by recrystallization from *tert*-butyl alcohol as was noted by Shell (9).

[1] The authors thank Dr. L. C. Schroeter, The Upjohn Co., for supplying us with samples of this material.

Characterization of Respective Forms.—Several methods were used in determining the appropriate crystal forms.

The powder method using the nickel-filtered copper radiation of a Siemens Crystalloflex IV counter-tube X-ray diffractometer provided one means of characterization. This was done for both sulfathiazole and methylprednisolone. Note recordings in Figs. 1–3.

For sulfathiazole, melting point determinations were also conducted. The microscope method using a Zeiss microscope equipped with a Kofler hot stage was used and results agreed with those in the literature (8). The characterization of the methylprednisolone could not be accomplished by this method since decomposition occurred.

Infrared spectra were also obtained to help characterize methylprednisolone forms I and II. The model 137, Perkin-Elmer spectrophotometer was used and data agreed with those in the literature (1).

TABLE I.—SOLUBILITIES AND ABSORBANCE MAXIMA

Solvent	Solubility at 30°, Gm./100 Gm.	$\lambda_{max.}$, mμ
Sulfathiazole		
Water	0.114	282
n-Propanol	0.277	291
sec-Butyl alcohol	0.149	291

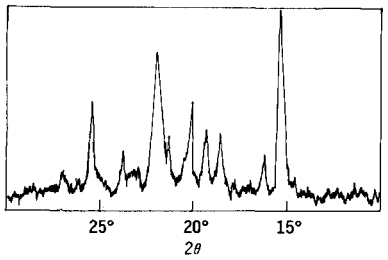

Fig. 1.—X-Ray recording of sulfathiazole form I.

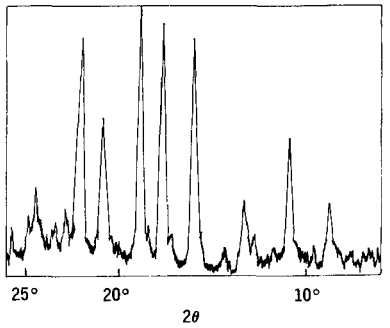

Fig. 2.—X-Ray recording of sulfathiazole form II.

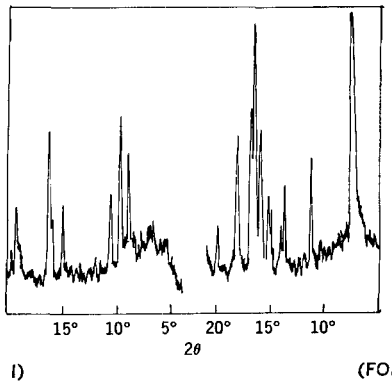

Fig. 3.—X-Ray recordings of methylprednisolone.

Solubility Determinations.—Excess sample was placed in the appropriate solvent and agitated in a water bath at 30.0° ± 0.1°. Samples were taken in duplicate at 12–24-hr. intervals. A preheated 10-ml. glass syringe was used to withdraw the samples which were filtered through a 0.45 μ membrane filter (Millipore HAWP 01300) by means of the syringe-Swinny-adapter assembly. The samples were then weighed and diluted for spectrophotometric assay. Reproducible data were obtained upon equilibration of the sample (Table I).

Apparatus and Procedure.—The apparatus and the procedure used were essentially those described by Milosovich (6). The sample was compressed by placing the powder in the die between the hardened steel block and a $^3/_8$ in. punch and compressing using a Carver press at approximately 2000 lb. pressure. The die had been previously ground to eliminate the tapered shoulder. This, therefore, ensured a constant surface area. The die containing the sample was mounted in the holder and placed into the dissolution solvent at zero time. The amount dissolved as a function of time was measured automatically by a Varian model G-10 recorder attached to a Beckman DU spectrophotometer through which the solution from the dissolution rate beaker was continuously circulated.

For the study of the dissolution rates of methylprednisolone in water, a second apparatus was necessary as the low water solubility of this compound demanded time intervals of 2 to 8 hr. The apparatus used was that described by Higuchi, Mir, and Desai (7). The tablet was made in the same manner as before and then the open end of the die was stoppered with a cork. This was placed in a Plexiglas holder which was mounted on the beaker cover. This was then placed into a 600-ml. water-jacketed beaker containing 200 ml. of water at 37°. A stainless steel stirrer, attached to a Bodine synchronous motor and mounted on the beaker cover, provided the necessary agitation. The speeds utilized were 10, 50, and 150 r.p.m. At time zero the entire unit was introduced into the solvent. Samples were pipeted out at specified times and assayed spectrophotometrically.

RESULTS AND DISCUSSION

Solvent Effects with Sulfathiazole.—Some typical dissolution rate results of the pure forms of sulfathiazole are given in Fig. 4. In all solvents the form I data were always linear as expected over the entire time period of the runs. With the form II experiments the results varied. Only in the two solvents, *n*-propanol and *sec*-butyl alcohol, were the rates for form II constant during the entire run. In many of the solvents initial constant rates were observed, but these decreased after some time and approached those for form I (see, *e.g.*, the II-in-ethanol and the II-in-50% ethanol–hexane curves in Fig. 4). In pure water and in water–ethanol mixtures containing up to 25% (v/v) ethanol, the form II rates and the form I rates could not be distinguished, even for initial rates. Conversion of II to I must be extremely rapid in water.

In all cases where the initial greater form II rates were observed, the ratios of the initial form II rate to that for form I in the same solvent were found to be essentially the same in all solvents. This ratio = 1.70 is the same as that reported by Milosovich for the sulfathiazole polymorphs in ethanol. According to the Noyes-Whitney relation, this ratio should correspond to the ratio of the solubilities of the two forms.

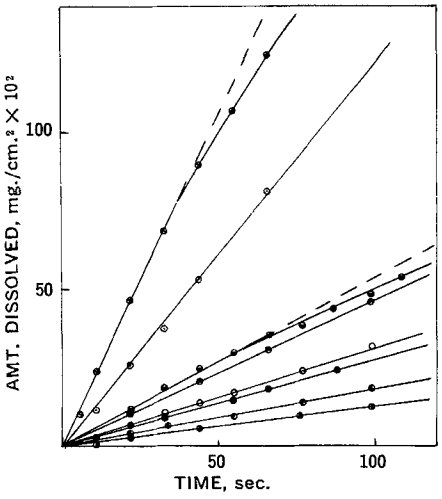

Fig. 4.—Dissolution rate of sulfathiazole (form I and form II) in various solvents. These findings correlate with the authors' studies (2) on the crystal growth behavior of sulfathiazole form I. No measurable crystal growth of form I was found in *n*-propyl alcohol and in *sec*-butyl alcohol up to supersaturation ratios of 2.2 and 5.5, respectively. These supersaturations are far above the maximum supersaturation ratios (~1.7) available during the dissolution of form II in the present experiments. On the other hand, appreciable form I crystal growth rates were observed at supersaturation ratios below or near 1.7 in those solvents that have exhibited reversion in the present studies. Water and ethanol exhibited relatively rapid crystal growth rates at low supersaturations, and in the present studies these same solvents provided the most rapid reversion of II to I. Thus, one finds that reversion appears to occur rapidly in those solvents that allow relatively rapid crystal growth of the stable form and slowly in those solvents that require a relatively high supersaturation for the growth of the stable form.

In Fig. 5 the effect of 0.10% gelatin in 60% ethanol–water on the dissolution behavior of sulfathiazole can be seen. There appeared to be a retardation of the reversion of II to I. As the dissolution rate of I and the initial dissolution rate of II were not affected by the presence of gelatin, one can conclude that solution diffusional processes were not affected, and therefore gelatin must interfere at the crystal intreface. More studies with additives are planned for the future.

Solvent Effects with Methylprednisolone.—Some of the results in various solvents are presented in Figs. 6 and 7. The data given in Fig. 6 were obtained with the automatic recording apparatus. In the time ranges encountered here, the methylprednisolone form II data obtained in decyl alcohol did not show noticeable curvature with time. With 50% water–ethanol as the solvent, appreciable reversion of II to I was observed in less than 1 min. With ethanol as the solvent, the results were not conclusive as the dissolution was extremely rapid and disintegration of the tablet face was observed in some of the runs.

Because of the low solubility of methylprednisolone in water, the data given in Fig. 7 were obtained by the manual sampling procedure. The experiments were carried out at three agitation rates and much longer times were involved. It can be seen that, in water at 37°, reversion of II to I also occurred, although more slowly as reflected in these data.

If the results obtained in ethanol are excluded from consideration, these findings also correlate with the crystal growth data for form I in the same solvents (2). Thus, as was found with the sulfathiazole system, reversion was observed in those solvents (*e.g.*, water, water–ethanol mixtures) in which the crystal growth rates of form I were relatively rapid. In those solvents (*e.g.*, decyl alcohol) where the crystal growth rates of form I were extremely slow even at high supersaturation ratios, reversion was not observed in the experiments.

From these limited studies it appears that polymorphic reversion of those crystalline phases that are generally regarded as kinetically stable in the absence of solvent contact may be frequently controlled by the solvent-mediated crystal growth kinetics of the more stable phase and *not* by the dissolution rate of the less thermodynamically stable polymorph. This is perhaps not surprising if the crystal growth rates are controlled by a cooperative process such as two-dimensional nucleation. In these instances the reverse process, dissolution, likely would not be the reciprocal of growth but instead follow an energetically more comfortable route such as "peeling off" of molecular layers initiated at the corners and edges of the crystals.

Dissolution Rate from a Mixture of Two Polymorphs (Theory).—In order to be able to describe the results of the experiments with mixtures of polymorphs and of the authors' studies on the unusual effects of agitation on dissolution rates of polymorphs, a discussion of a quantitative theory is presented. This theory is an extension of that discussed recently (7) for the dissolution behavior of general polyphase mixtures.

Figure 8 schematically shows the three stages (from left to right) during the dissolution process. It is assumed that the mixture is initially uniform and reversion does not occur during dissolution. As dissolution of the drug begins by diffusion across the effective liquid diffusion layer of thickness h, only form II dissolves initially because C', the solution concentration at the tablet boundary–solution interface, is still greater than, C_s^{I} the solubility of form I. Thus, at time zero, $C' = C_s^{II}$, the solubility of form II. At later times

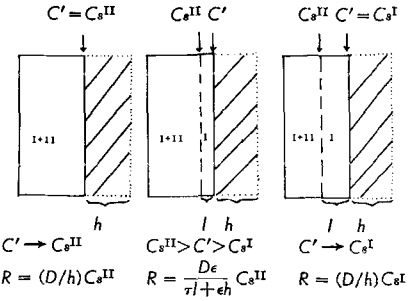

Fig. 8.—Mixture theory model.

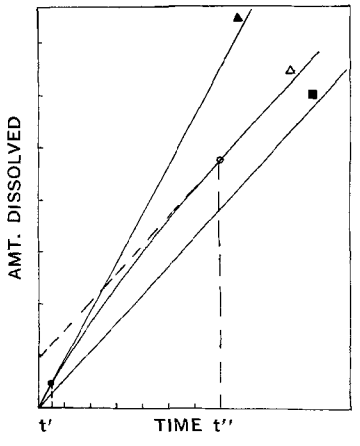

Fig. 9.—Comparison of dissolution rate of the two polymorphs and a mixture according to theory. Key: ▲, II; △, mixture; ■, I.

$C_s^{II} > C' > C_s^{I}$. Finally, in the steady-state, $C' \simeq C_s^{I}$, and both forms I and II dissolve at rates proportional to their percentages in the original mixture.

Mathematically, one may write for the dissolution rate per unit tablet area, R,

$$R = \frac{dw}{dt} = (D/h)C' = \frac{D\epsilon}{\tau l}(C_s^{II} - C') \quad \text{(Eq. 1)}$$

where

C' = concentration at the tablet–solution interface,
C_s^{II} = solubility of the form II,
ϵ = porosity of the form I residue layer,
τ = tortuosity of the form I layer,
h = diffusion layer thickness,
l = layer thickness of the form I layer,
w = amount dissolved per unit area of tablet at time, t,
D = diffusion coefficient.

Solving for C', one obtains

$$C' = \frac{C_s^{II}}{\left(1 + \frac{\tau l}{\epsilon h}\right)} \quad \text{(Eq. 2)}$$

whence

$$R = \frac{D\epsilon}{\tau l + \epsilon h} C_s^{II} \quad \text{(Eq. 3)}$$

R is also related to l and t by

$$R = H_{II}\frac{dl}{dt} \quad \text{(Eq. 4)}$$

where H_{II} is the amount of form II per unit volume in the original mixture.

Both Eqs. 3 and 4 will be examined in the time period up to the time, t'', when form I begins to dissolve. After $t = t''$ when a steady-state is reached, neither Eq. 3 nor Eq. 4 will correctly give the total dissolution rate. Instead one must write

$$R = \frac{D}{h} C_s^{I} \text{ for } t > t'' \quad \text{(Eq. 5)}$$

Therefore, when $0 < t < t''$,

$$H_{II}\left(\frac{dl}{dt}\right) = \frac{D\epsilon}{\tau l + \epsilon h} C_s^{II}$$

Integrating,

$$H_{II}\int_0^l dl(\tau l + \epsilon h) = \int_0^t C_s^{II} D\epsilon \, dt$$

or

TABLE II.—COMPARISON OF DIFFUSION LAYER THICKNESS TO INTERCEPT. SULFATHIAZOLE IN *n*-PROPYL ALCOHOL

Mixture Compn.	Diffusion Layer Thickness h, cm.	Ratio of h	Intercept	Intercept Ratio
50% II	5.62×10^{-3}	1.91	4.3	1.87
	2.94×10^{-3}	1	2.3	1
20% II	5.62×10^{-3}	1.91	1.7	1.85
	2.94×10^{-3}	1	.91	1

$$l^2 + \frac{2\epsilon h l}{\tau} = \frac{2C_s^{II} D\epsilon}{H_{II}\tau} t \qquad \text{(Eq. 6)}$$

If now one considers the situation when $C' \simeq C_s^{II}$ and defining t' as the maximum time up to which the dissolution will be essentially that from pure form II, one obtains from Eq. 6,

$$l = \frac{C_s^{II} D}{H_{II} h} t'$$

since

$$\frac{2\epsilon h l}{\tau} \gg l^2$$

Arbitrarily t' may be defined as the time up to which the dissolution rate is still within 99% of the pure form II rate. In this case

$$t' = \frac{0.01\ \epsilon h^2 H_{II}}{\tau\ C_s^{II}\ D} \qquad \text{(Eq. 7)}$$

The results of these theoretical considerations are graphically illustrated in Fig. 9. Here t' is shown as the point where deviation of the mixture curve from the pure form II curve begins to become important, and t'' is the point at which the rate of dissolution of the mixture becomes equal to the rate for pure form I as given by Eq. 5.

Finally, let us now obtain an equation for the intercept of the extrapolation of the linear portion of the mixture curve on the ordinate. If w″ is the amount dissolved at t'', one has then

$$\int_0^{w''} dw = \int_0^{l''} H_{II} dl \qquad \text{(Eq. 8)}$$

where

$$l'' = \frac{\epsilon h}{\tau}\left(\frac{C_s^{II} - C_s^{I}}{C_s^{I}}\right) \qquad \text{(Eq. 9)}$$

Integration of Eq. 8 gives

$$w'' = \frac{H_{II}\epsilon h}{\tau}\left(\frac{C_s^{II} - C_s^{I}}{C_s^{I}}\right)$$

Therefore, the intercept I will be given by

$$\frac{D}{h} C_s^{I}\, t'' + \mathrm{I} = w'' \qquad \text{(Eq. 10)}$$

where t'' is given by Eqs. 6 and 9. One has then

$$\mathrm{I} = \frac{H_{II}\epsilon h\,(C_s^{II} - C_s^{I})^2}{2\tau\ C_s^{I} C_s^{II}} \qquad \text{(Eq. 11)}$$

for the intercept.

Dissolution Rates from Mixtures, Effect of Agitation.—The effect of the agitation rate upon the dissolution rate, as predicted by the above theory, may be examined through the use of Eq. 11. Let us first note that Eq. 11 may be written

$$\mathrm{I} = Kh \qquad \text{(Eq. 12)}$$

where K is a constant for a given two-phase mixture of constant composition. The values of the diffusion layer thickness, h, at different agitation rates may be determined from the dissolution rate experiments with either of the pure polymorphs employing the Noyes-Whitney relation. If Eq. 12 is correct, the ratio of two h values should be the same as the ratio of corresponding intercepts.

Figures 10 and 11 present the experimental dissolution rate data in *n*-propanol at 30° for two mixtures of the sulfathiazole polymorphs obtained at two agitation rates corresponding to $h = 2.94 \times 10^{-3}$ cm. and $h = 5.62 \times 10^{-3}$ cm.

The intercepts were estimated as shown from the extrapolation of the linear portions of the data. These are given in column 4 of Table II. The ratio of the intercepts given in column 5 may be compared with the corresponding ratio of the h values given in column 3. The agreement between the h ratios and the intercept ratios is very satisfactory supporting the correctness of the theory.

Figure 12 presents the dissolution rate data obtained for the 50–50 mixture of methylprednisolone polymorphs at three agitation rates. Also presented, for reference purposes, are the pure form I

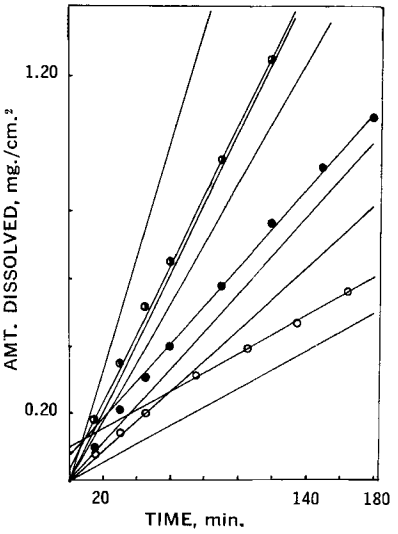

Fig. 12.—Dissolution of 50% I and 50% II mixture of methylprednisolone in water at agitation speeds of 10, 50, 150 r.p.m. Key: ○, mixture at 10 r.p.m.; ●, mixture at 50 r.p.m.; ◑, mixture at 150 r.p.m. Form II lines are those predicted if no reversion occurred.

TABLE III.—50% I AND II METHYLPREDNISOLONE MIXTURE IN WATER AT 37°

Agitation Speed, r.p.m.	Diffusion Layer Thickness h, cm.	Ratio h/h 150	Intercept	Ratio Intercept: Intercept 150
10	9.09×10^{-3}	3.68	.51	3.40
50	4.43×10^{-3}	1.79	.28	1.87
150	2.47×10^{-3}	1.00	.15	1.00

and form II data (taken from Fig. 9). Table III compares the ratio of the h values to the intercept ratios from the mixture data. Again one finds that the agreement of theory and data is excellent.

So far we have only examined the data with theory through the use of Eq. 11. Another look at the data, this time through Eq. 7, is helpful. Equation 7 predicts that the place where the dissolution data begins to deviate from the pure polymorph II line is proportional to the square of h. Therefore, for a given mixture, at low agitation rates, the data should follow the pure form II curve for a much longer time than at high agitation rates. An examination of the data given in Figs. 10–12 shows that the dependence of t' upon h^2 is essentially quantitatively followed in all instances.

The assumption that appreciable concomitant reversion did not occur in the runs with these mixtures should be a good one. Pure sulfathiazole form II in *n*-propanol showed no tendency to revert (Fig. 4). Pure methylprednisolone form II in water did show (Fig. 7) some reversion during dissolution. However, the mixture effect itself with the methylprednisolone 50–50 mixture appeared to be much larger during the times under consideration than the little reversion that did occur with pure form II. Therefore, the agreement of both the sulfathiazole and the methylprednisolone data with theory in the many aspects leaves little doubt that the theory is quantitatively sound.

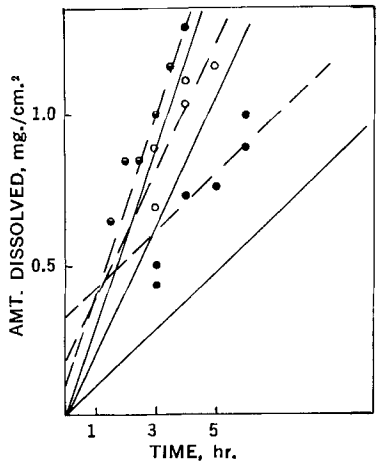

Fig. 13.—Interpretation of the dissolution rate data of Hamlin *et al.* Key: ●, form II at 0 r.p.m.; ○, form II at 6 r.p.m.; ◒, form II at 12 r.p.m.

Discussion of Some Previously Published Studies.—Hamlin, Nelson, Ballard, and Wagner first reported (3) the unusual effect of agitation upon the dissolution rate of a metastable polymorph. The material they investigated was methylprednisolone form II. These investigators found that upon increasing the agitation rate, it became increasingly difficult to distinguish the difference in the dissolution rates of form I and form II. Subsequently, Levy (4) and then Taylor and Wurster (5) observed similar effects with metastable methylprednisolone and prednisolone, respectively.

We propose that the answer to this mystery may be provided by the results of the authors' present studies. The following is the suggested description of the "anomalous" dissolution rate behavior.

First, it is necessary to have the reversion tendency of II to I neither very great (*e.g.*, sulfathiazole II in water at 30°) nor very small (*e.g.*, methylprednisolone in decyl alcohol at 30°) in the time range of interest. Methylprednisolone tablets in water at 37° (Fig. 9) appear to be in this "moderate" tendency category when the dissolution rate experiment is carried out for several hours under usual agitation conditions.

Then when the dissolution rate experiment is started, the initial rate will be dominated by the form II solubility, C_s^{II}. After some time, however, because of the reversion of II to I a layer of I will form if the rate of reversion is fast enough compared to the leaching-out rate of II. If the rate of reversion is not fast enough, the little form I that crystallizes out will probably flake out into the medium.

Assuming that a substantial deposit of I does form, some of the remaining II would leach out into the solution, and some would contribute to the deposit by further reversion. The net effect after a lag time should then be the same as having dissolution from a mixture of the two forms. That this situation is plausible may be seen by comparing the later time data of Fig. 7 with the early time data of Fig. 12.

At this point one may refer to Eq. 7. At high agitation rates h will be small. Therefore, the data in this case will, very quickly, become very like the data for pure form I. On the other hand at very low agitation rates, even though comparable reversion may have occurred, the dissolution rate

TABLE IV.—INTERCEPT AND h RATIOS CALCULATED BY THEORY FOR DATA OF HAMLIN *et al.*

Agitation, r.p.m.	Redrawn Slope of Form I	Slope from Lit.	D/h cm. hr.$^{-1}$	h (cm.)	Ratio $h:h_{12}$	Intercept	Ratio Intercept: Intercept$_{12}$
0	.096	.091 ± .021	.818	.022	3.06	.33	3.00
6	.208	.203 ± .027	1.77	.012	1.67	.18	1.64
12	.294	.276 ± .011	2.50	.0072	1.00	.11	1.00

may follow the expected pure form II behavior for much longer times.

The methylprednisolone form II data of Hamlin *et al.* (3) have been replotted in Fig. 13 and compared with theory (dotted lines) assuming a constant K value (Eq. 12). The corresponding h ratios and the intercept ratios are given in columns 6 and 8 of Table IV.

Because the use of a constant K value is subject to question here, the agreement of the theory with data must be regarded as only qualitatively satisfactory. However, the authors believe that the present arguments are the most satisfactory ones for explaining this phenomenon.

A quantitative model that can account for simultaneous reversion and dissolution is presently being investigated. Results of these studies will be reported at a later date.

Enzyme Inhibitors XVI

Mode of Binding of Some 9-(2-Hydroxyalkyl)-6-(substituted)-purines to Adenosine Deaminase

By HOWARD J. SCHAEFFER and CHARLES F. SCHWENDER

The syntheses of a variety of 6-substituted-9-(2-hydroxybutyl)-, 9-(2-hydroxyheptyl)-, and 9-(2-hydroxyoctyl)purines have been completed. Those compounds with a 6-amino or a 6-methylamino group were inhibitors of adenosine deaminase, the compounds with a 6-amino group being more active than those compounds with a 6-methylamino group. For a series of 9-substituted adenines, the decreasing order of binding was: 9-(2-hydroxypropyl) > 9-(2-hydroxyethyl) ≅ 9-(2-hydroxybutyl) >9-(2-hydroxyheptyl) > 9-(2-hydroxyoctyl). From the data, it is concluded that there is a specific binding site for the terminal methyl group in 9-(2-hydroxypropyl)adenine and that the hydroxyl binding site and the main hydrophobic site of adenosine deaminase cannot be bridged by adenine derivatives which are substituted at the 9-position by straight-chain alkyl group bearing a hydroxyl group on carbon 2.

RECENTLY EVIDENCE was presented that there exists on the enzyme, adenosine deaminase, a nonpolar area which is involved in binding, by means of hydrophobic interactions, the alkyl group of some 9-alkyladenines (1). In addition, evidence was presented that if a hydroxyl group is attached to the alkyl group of a 9-alkyladenine, the hydroxyl group may either increase or decrease the binding of the inhibitor to the enzyme depending on the position of the hydroxyl group on the alkyl chain (1, 2). On the basis of these studies, it was suggested that in the reversible complex between a 9-(hydroxyalkyl)adenine and adenosine deaminase there is only one hydroxyl binding site on adenosine deaminase, and that this site on the enzyme is an area two to three carbon atoms removed from the site on the enzyme which binds the 9-position of the purine nucleus of the inhibitor (2). In order to study further the binding sites of this enzyme, it is apparent that it should be possible to prepare compounds which would occupy the hydrophobic binding region as well as the hydroxyl binding site of adenosine deaminase; such compounds should be bound more tightly to the enzyme. Compounds which may be able to occupy both binding sites on this enzyme are the 9-(2-hydroxyalkyl)-6-substituted purines. The present paper describes the synthesis and enzymatic evaluation of these compounds as inhibitors of adenosine deaminase.

CHEMISTRY

The compounds which were selected for synthesis are the 6-substituted purines which are substituted at the 9-position by either a 2-hydroxybutyl, a 2-hydroxyheptyl, or a 2-hydroxyoctyl group. The general method of synthesis is a modification of the

procedure previously utilized to prepare 9-alkyl-6-chloropurines (3, 4) and is outlined in Scheme I. Condensation of 5-amino-4,6-dichloropyrimidine (I) with the appropriate amino alcohol; *i.e.*, 1-amino-2-butanol (II*a*), 1-amino-2-heptanol (II*b*), or 1-amino-2-octanol (II*c*) gave the corresponding 5-amino-6-chloro-4-(2-hydroxyalkylamino)pyrimidine which on treatment with ethyl orthoformate and hydrochloric or ethanesulfonic acid produced the desired 6-chloro-9-(2-hydroxyalkyl)purine. When 6-chloro-9-(2-hydroxybutyl)- and 6-chloro-9-(2-hydroxyheptyl)purines were allowed to react with ammonia, methylamine, dimethylamine, 1 *N* hydrochloric acid, or thiourea, the desired 6-substituted derivatives were obtained. In the case of 6-chloro-9-(2-hydroxyoctyl)purine, only the 6-amino and the 6-mercapto derivatives (V*c*, IX*c*) were prepared.

Scheme I

EXPERIMENTAL[1]

5 - Amino - 4 - chloro - 6 - (2 - hydroxybutylamino)pyrimidine (IIIa).—A mixture of 1.08 Gm. (6.62 mmoles) of I, 650 mg. (7.29 mmoles) of 1-amino-2-butanol (5), and 739 mg. (7.30 mmoles) of triethylamine in 50 ml. of 1-butanol was heated at reflux temperature for 22 hr. After the reaction mixture was evaporated *in vacuo* to a syrup, the crude product was crystallized and recrystallized from water and gave the crystalline product, 743 mg. (51.6%), m.p. 160°. ν in cm.$^{-1}$ (KBr): 3425 (OH); 3275 (NH); 1670 (NH); 1585 (C=C, C=N). $\lambda_{max.}$ in mμ ($\epsilon \times 10^{-4}$): 0.1 *N* HCl, 305 (1.22); H_2O, 265 (0.830) and 292 (0.848); 0.1 *N* NaOH, 265 (0.839) and 292 (0.882).

Anal.[2]—Calcd. for $C_8H_{13}ClN_4O$: C, 44.34; H, 6.05; N, 25.86. Found: C, 44.40; H, 6.15; N, 26.14.

6-Chloro-9-(2-hydroxybutyl)purine (IVa).—A mixture of 5.66 Gm. (25.1 mmoles) of III*a* and 2.09 ml. (25.1 mmoles) of concentrated hydrochloric acid in 100 ml. of triethyl orthoformate was stirred at room temperature for 2.5 hr. After the reaction mixture was evaporated *in vacuo* to a crude liquid product, crystallization of the syrup from chloroform–hexane and recrystallization yielded 3.09 Gm. (54.3%) of solid product, m.p. 125°. ν in cm.$^{-1}$ (KBr): 3275 (OH); 1590 and 1555 (C=C, C=N). $\lambda_{max.}$ in mμ ($\epsilon \times 10^{-4}$): 0.1 *N* HCl, 267 (0.832); H_2O, 267 (0.816); 0.1 *N* NaOH, 266 (0.860).

Anal.—Calcd. for $C_9H_{11}ClN_4O$: C, 47.68; H, 4.89; N, 24.71. Found: C, 47.88; H, 5.01; N, 24.76.

6-Amino-9-(2-hydroxybutyl)purine (Va).—In a stainless steel bomb a mixture of 305 mg. (1.34 mmoles) of IV*a* in 20 ml. of liquid ammonia was heated at 50° for 21 hr. After the ammonia had evaporated, the residual solid was recrystallized from 5% methanol in chloroform and hexane to give the white solid product; yield, 184 mg. (66.4%), m.p. 184°. ν in cm.$^{-1}$ (KBr): 3350 (OH); 3200 and 1710 (NH); 1630 and 1570 (C=C, C=N). $\lambda_{max.}$ in mμ ($\epsilon \times 10^{-4}$): 0.1 *N* HCl, 259 (1.08); H_2O, 261 (1.21); 0.1 *N* NaOH, 261 (1.17).

Anal.—Calcd. for $C_9H_{13}N_5O$: C, 52.16; H, 6.32; N, 33.80. Found: C, 51.96; H, 6.20; N, 33.53.

6-Methylamino-9-(2-hydroxybutyl)purine (VIa).—A mixture of 472 mg. (2.08 mmoles) of IV*a* and 20 ml. of aqueous methylamine (40%) was heated at 85° in a steel bomb for 68 hr. After the reaction mixture had been evaporated *in vacuo*, the residual material was extracted with hot ethyl acetate. Addition of hexane to the extract yielded the white crystalline product, 221 mg. (50.4%), m.p. 39°. The product was recrystallized from ethyl acetate–hexane and gave the analytical sample; yield, 164 mg. (37.5%), m.p. 39°. ν in cm.$^{-1}$ (KBr): 3350 (OH); 3250 and 1620 (NH); 1580 and 1540, sh (C=C, C=N). $\lambda_{max.}$ in mμ ($\epsilon \times 10^{-4}$): 0.1 *N* HCl–10% EtOH, 262 (1.48); H_2O–10% EtOH, 265 (1.40); 0.1 *N* NaOH–10% EtOH, 265 (1.40).

Anal.—Calcd. for $C_{10}H_{15}N_5O$: C, 54.27; H, 6.83; N, 31.66. Found: C, 54.19; H, 7.10; N, 31.45.

6-Dimethylamino-9-(2-hydroxybutyl)purine Hydrochloride (VIIa).—A mixture of 499 mg. (2.20 mmoles) of IV*a* and 5 ml. of ethanol and 25 ml. of 25% aqueous dimethylamine solution was heated at reflux for 4 hr. After the reaction mixture was evaporated *in vacuo*, the residual liquid was extracted with chloroform. The extract was cooled and hydrogen chloride gas was passed through the solution. The crude hydrochloride salt of the product which precipitated was collected by filtration; yield, 533 mg. (89.6%), m.p. 188–190.5°. Recrystallization of the crude product from isopropyl alcohol gave the pure material; yield, 316 mg. (53.0%), m.p. 189–192°. ν in cm.$^{-1}$ (KBr): 3300 (OH); 2700 (acidic hydrogen); 1650 (NH^+); 1590 and 1540 (C=C, C=N). $\lambda_{max.}$ in mμ ($\epsilon \times 10^{-4}$): 0.1 *N* HCl, 268 (1.63); H_2O, 275 (1.65); 0.1 *N* NaOH, 275 (1.71).

Anal.—Calcd. for $C_{11}H_{18}ClN_5O$: C, 48.60; H, 6.68; Cl, 13.04; N, 25.77. Found: C, 48.88; H, 6.75; Cl, 13.23; N, 25.50.

6-Hydroxy-9-(2-hydroxybutyl)purine Hydrochlo-

[1] The infrared spectra were determined on a Perkin-Elmer model 137 spectrophotometer; the ultraviolet spectra were determined on a Perkin-Elmer model 202 spectrophotometer; the enzyme studies were done on a Gilford instrument model 2000 spectrophotometer. The melting points, unless otherwise noted, were taken in open capillary tubes on a Mel-Temp apparatus and are corrected.

[2] The analyses reported in this paper were performed by Galbraith Microanalytical Laboratories, Knoxville, Tenn.

ride (VIIIa).—A solution of 399 mg. (1.76 mmoles) of IV*a* in 10 ml. of 1 *N* hydrochloric acid and 5 ml. of water was heated at reflux for 30 min. Evaporation of the reaction mixture *in vacuo* gave a syrupy material which was recrystallized from ethanol–ether; yield, 339 mg. (78.7%), m.p. 188.5–193°. ν in cm.$^{-1}$ (KBr): 3450 (OH); 2800–2300 (acidic hydrogen); 1720 (C=O, enol); 1680 (C=N^{+}—H); 1560 and 1540 (C=C, C=N). $\lambda_{max.}$ in mμ ($\epsilon \times 10^{-4}$): 0.1 *N* HCl, 250 (1.11); H_2O, 250 (1.14); 0.1 *N* NaOH, 256 (1.22).

Anal.—Calcd. for $C_9H_{13}ClN_4O_2$: C, 44.17; H, 5.36; Cl, 14.49; N, 22.90. Found: C, 44.17; H, 5.35; Cl, 14.54; N, 23.04.

6-Mercapto-9-(2-hydroxybutyl)purine (IXa).—A mixture of 402 mg. (1.77 mmoles) of IV*a* and 135 mg. (1.77 mmoles) of thiourea in 10 ml. of 1-propanol was heated at reflux for 15 min. Upon cooling the reaction mixture, the crystalline product precipitated and was collected by filtration, 281 mg. (70.8%), m.p. 277–280° Recrystallization of the product from methanol–propanol gave the analytical material, m.p. 276–280°. ν in cm.$^{-1}$ (KBr): 3450 (OH); 2700 (acidic hydrogen); 1590 and 1545 sh (C=C, C=N). $\lambda_{max.}$ in mμ ($\epsilon \times 10^{-4}$): 10% EtOH–0.1 *N* HCl, 326 (1.90); 10% EtOH–H_2O, 323 (2.24); 10% EtOH–0.1 *N* NaOH, 313 (2.12).

Anal.—Calcd. for $C_9H_{12}N_4OS$: C, 48.19; H, 5.39; N, 24.98; S, 14.30. Found: C, 48.33; H, 5.38; N, 25.08; S, 14.29.

5 - Amino - 4 - chloro - 6 - (2 - hydroxyheptylamino)pyrimidine (IIIb).—A mixture of 283 mg. (1.72 mmoles) of I, 249 mg. (1.90 mmoles) of 1-amino-2-heptanol (6), and 253 mg. (2.50 mmoles) of triethylamine in 25 ml. of 1-butanol was refluxed for 17.5 hr. under a nitrogen atmosphere. Evaporation of the reaction mixture *in vacuo* gave a liquid which was crystallized from ethanol–water to give 328 mg. (73.5%), m.p. 120°. Further recrystallization from ethanol–water yielded 267 mg. (59.9%) of the analytical sample, m.p. 121°. ν in cm.$^{-1}$ (KBr): 3350 (OH); 3250 (NH); 1640 (NH); 1575 (C=N). $\lambda_{max.}$ in mμ ($\epsilon \times 10^{-4}$): 0.1 *N* HCl, 305 (1.14); H_2O, 265 (0.821) and 293 (0.877); 0.1 *N* NaOH, 265 (0.809) and 293 (0.842).

Anal.—Calcd. for $C_{11}H_{19}ClN_4O$: C, 51.04; H, 7.36; Cl, 13.74; N, 21.65. Found: C, 51.14; H, 7.50; Cl, 13.91; N, 21.47.

6-Chloro-9-(2-hydroxyheptyl)purine (IVb).—A mixture of 638 mg. (2.46 mmoles) of III*b* and 0.4 ml. of concentrated hydrochloric acid (4.78 mmoles) was stirred at room temperature in 40 ml. of triethyl orthoformate for 9.5 hr. The reaction mixture was evaporated *in vacuo* to a syrupy residue which was extracted with hot hexane. Cooling the extract yielded 342 mg. (51.8%) of pure white solid product, m.p. 96°. Recrystallization of the material from chloroform–hexane yielded the analytical sample, m.p. 96°. ν in cm.$^{-1}$ (KBr): 3325 (OH); 1590 and 1560 (C=C, C=N). $\lambda_{max.}$ in mμ ($\epsilon \times 10^{-4}$): 10% EtOH–0.1 *N* HCl, 266 (0.912); 10% EtOH–H_2O, 266 (0.929); 10% EtOH–0.1 *N* NaOH, 267 (0.956).

Anal.—Calcd. for $C_{12}H_{17}ClN_4O$: C, 53.63; H, 6.38; Cl, 13.19; N, 20.85. Found: C, 53.53; H, 6.30; Cl, 13.48; N, 20.63.

6-Amino-9-(2-hydroxyheptyl)purine (Vb).—A mixture of 402 mg. (1.49 mmoles) of IV*b* in 25 ml. of methanolic ammonia (20%) was heated at 80–84° for 20.5 hr. in a steel bomb. The reaction mixture was evaporated *in vacuo* to a residual solid, which was recrystallized from ethanol–water and gave 190 mg. (51.2%) of pure white crystalline solid, m.p. 190–193°. ν in cm.$^{-1}$ (KBr): 3400 (OH); 3350 and 1710 (NH); 1620 and 1570 (C=C, C=N). $\lambda_{max.}$ in mμ ($\epsilon \times 10^{-4}$): 10% EtOH–0.1 *N* HCl, 260 (1.39); 10% EtOH–H_2O, 261 (1.41); 10% EtOH–0.1 *N* NaOH, 261 (1.39).

Anal.—Calcd. for $C_{12}H_{19}N_5O$: C, 57.81; H, 7.68; N, 28.09. Found: C, 57.78; H, 7.64; N, 27.90.

6 - Methylamino - 9 - (2 - hydroxyheptyl)purine (VIb).—A mixture of 498 mg. (1.85 mmoles) of IV*b* in 5 ml. of ethanol and 20 ml. of 40% aqueous methyl amine solution was heated at reflux for 3 hr. The reaction mixture was evaporated *in vacuo* to a residual glass, which was recrystallized from chloroform–hexane, giving 239 mg. (49.1%) of white crystalline product, m.p. 112–113°. ν in cm.$^{-1}$ (KBr): 3400 (OH); 3175 (NH); 1625 (NH); 1570 and 1530 (C=C, C=N). $\lambda_{max.}$ in mμ ($\epsilon \times 10^{-4}$): 10% EtOH–0.1 *N* HCl, 261 (1.83); 10% EtOH–H_2O, 266 (1.58); 10% EtOH–0.1 *N* NaOH, 265 (1.78).

Anal.—Calcd. for $C_{13}H_{21}N_5O$: C, 59.30; H, 8.04; N, 26.60. Found: C, 59.35; H, 7.88; N, 26.41.

6 - Dimethylamino - 9 - (2 - hydroxyheptyl)purine (VIIb).—In a steel bomb was heated a mixture of 536 mg. (1.94 mmoles) of IV*b* in 5 ml. of methanol and 20 ml. of aqueous dimethylamine (25%) at 86° for 18.5 hr. After the reaction had been evaporated *in vacuo* to a liquid residue, the crude product was extracted from the residue with hot hexane. Cooling of the hexane extract yielded 356 mg. (62.2%) of a glassy material which upon recrystallization from hexane gave the white crystalline solid; yield, 280 mg. (49.0%), m.p. 55–59°. ν in cm.$^{-1}$ (KBr): 3475 (OH); 1610 and 1570 (C=C, C=N). $\lambda_{max.}$ in mμ ($\epsilon \times 10^{-4}$): 5% EtOH–0.1 *N* HCl, 268 (1.57); 5% EtOH–H_2O, 274 (1.66); 5% EtOH–0.1 *N* NaOH 274 (1.66).

Anal.—Calcd. for $C_{14}H_{23}N_5O$: C, 60.61; H, 8.72; N, 25.25. Found: C, 60.90; H, 8.44; N, 25.33.

6-Hydroxy-9-(2-hydroxyheptyl)purine Hydrochloride (VIIIb).—A mixture of 317 mg. (1.18 mmoles) of IV*b*, 7.1 ml. of 1 *N* HCl, and 5 ml. of water was heated at reflux for 30 min. The reaction mixture was evaporated *in vacuo* and gave white solid material. The crude product was recrystallized from ethanol saturated with hydrogen chloride giving the pure product; yield, 185 mg. (54.7%), m.p. 197–201°. ν in cm.$^{-1}$ (KBr): 3475 (OH); 2700–2300 (acidic hydrogen); 1725 (C=O, enol); 1680 (C=N^{+}—H); 1570 and 1540 (C=C, C=N). $\lambda_{max.}$ in mμ ($\epsilon \times 10^{-4}$): 10% EtOH–0.1 *N* HCl, 248 (1.14); 10% EtOH–H_2O, 248 (1.18); 10% EtOH–0.1 *N* NaOH, 253 (1.28).

Anal.—Calcd. for $C_{12}H_{19}ClN_4O_2$: C, 50.22; H, 6.68; Cl, 12.36; N, 19.54. Found: C, 50.46; H, 6.66; Cl, 12.31; N, 19.54.

6-Mercapto-9-(2-hydroxyheptyl)purine (IXb).—A mixture of 468 mg. (1.80 mmoles) of IV*b* and 137 mg. (1.80 mmoles) of thiourea in 10 ml. of 1-propanol was refluxed for 15 min. Upon cooling the reaction mixture, the crystalline material which precipitated was collected by filtration, 325 mg. (67.6%), m.p. 263–267°. The product was purified by recrystallization from ethanol; yield, 280 mg. (58.4%), m.p. 267–271°. ν in cm.$^{-1}$ (KBr): 3375 (OH); 2700

(acidic hydrogen); 1595 and 1560 (C=C, C=N). $\lambda_{max.}$ in mμ (ε × 10^{-4}): 10% EtOH–0.1 *N* HCl, 325 (1.93); 10% EtOH–H_2O, 322 (2.10); 10% EtOH–0.1 *N* NaOH, 313 (1.87).

Anal.—Calcd. for $C_{12}H_{18}N_4OS$: C, 54.10; H, 6.81; N, 21.03; S, 12.04. Found: C, 54.07; H, 6.63; N, 21.08; S, 12.09.

5 - Amino - 4 - chloro - 6 - (2 - hydroxyoctylamino)pyrimidine (IIIc).—A mixture of 482 mg. (2.94 mmoles) of I, 466 mg. (3.21 mmoles) of 1-amino-2-octanol (7), and 404 mg. (4.00 mmoles) of triethylamine in 25 ml. of 1-butanol was heated at reflux temperature for 24.5 hr. The reaction mixture was evaporated *in vacuo* to a liquid residue which after crystallization from methanol–water gave 273 mg. (76.3%), m.p. 111–114°. Further recrystallizations of the solid from ethanol–water gave the analytical product, m.p. 115–116.5°, 109 mg. (30.5%). ν in cm.$^{-1}$ (KBr): 3450 (OH); 3300, 3150, 1660 (NH); 1580 (C=N). $\lambda_{max.}$ in mμ (ε × 10^{-4}): 0.1 *N* HCl, 305 (1.15); H_2O, 265 (0.873) and 293 (0.891); 0.1 *N* NaOH, 265 (0.842) and 293 (0.865).

Anal.—Calcd. for $C_{12}H_{21}ClN_4O$: C, 52.83; H, 7.76; Cl, 13.00; N, 20.54. Found: C, 52.77; H, 7.74; Cl, 13.15; N, 20.64.

6-Chloro-9-(2-hydroxyoctyl)purine (IVc).—A mixture of 2.72 Gm. (9.96 mmoles) of IIIc and 667 mg. (6.01 mmoles) of ethanesulfonic acid in 120 ml. of triethyl orthoformate was stirred at room temperature for 30 min. After the reaction mixture was cooled, 1.62 Gm., m.p. 125°, of solid material was collected by filtration. The filtrate was evaporated *in vacuo* and gave a syrup which was extracted with hot hexane. The hexane extract was cooled and gave 1.18 Gm. of additional solid, m.p. 91°. The crude solid fractions were combined, 2.80 Gm. (99.2%), and recrystallized from chloroform–hexane giving the pure white crystalline product; yield, 1.36 Gm. (48.3%), m.p. 71–73°. ν in cm.$^{-1}$ (KBr): 3350 (OH); 1590 and 1560 (C=C, C=N). $\lambda_{max.}$ in mμ (ε × 10^{-4}): 10% EtOH–0.1 *N* HCl, 262 (0.735); 10% EtOH–H_2O, 263 (0.738); 10% EtOH–0.1 *N* NaOH, 263 (0.747).

Anal.—Calcd. for $C_{13}H_{19}ClN_4O$: C, 55.21; H, 6.77; Cl, 12.54; N, 19.81. Found: C, 55.27; H, 6.91; Cl, 12.82; N, 19.41.

6-Amino-9-(2-hydroxyoctyl)purine (Vc).—A mixture of 281 mg. (0.992 mmoles) of IVc in 20 ml. of methanolic ammonia was heated at 80° for 66 hr. in a steel bomb. The reaction mixture was evaporated to a residual solid which was recrystallized from ethanol–water giving 202 mg. (77.6%), m.p. 186–189°. Further recrystallizations from ethanol–water gave the analytical sample; yield, 148 mg. (56.7%), m.p. 186–189°. ν in cm.$^{-1}$ (KBr): 3300 (OH); 3250 (NH); 1700 (NH); 1610 and 1560 (C=C, C=N). $\lambda_{max.}$ in mμ (ε × 10^{-4}): 10% EtOH–0.1 *N* HCl, 258 (1.18); 10% EtOH–H_2O, 260 (1.26); 10% EtOH–0.1 *N* NaOH, 260 (1.26).

Anal.—Calcd. for $C_{13}H_{21}N_5O$: C, 59.30; H, 8.04; N, 26.60. Found: C, 59.08; H, 8.17; N, 26.29.

6-Mercapto-9-(2-hydroxyoctyl)purine (IXc).—A mixture of 279 mg. (0.985 mmole) of IVc and 83.7 mg. (1.10 mmoles) of thiourea in 15 ml. of 1-propanol was heated at reflux temperature for 15 min. Upon cooling the reaction mixture, a precipitate formed which was collected by filtration, 242 mg. (87.9%), m.p. 263–267°. The crude product was recrystallized from 1-propanol; yield, 98.4 mg. (35.7%), m.p. 264–267°. ν in cm.$^{-1}$ (KBr): 3450 (OH); 2650 (acidic hydrogen); 1600 and 1570 sh, (C=C, C=N). $\lambda_{max.}$ in mμ (ε × 10^{-4}): 10% EtOH–0.1 *N* HCl, 323 (1.78); 10% EtOH–H_2O, 322 (1.64); 10% EtOH–0.1 *N* NaOH, 310 (1.90).

Anal.—Calcd. for $C_{13}H_{20}N_4OS \cdot 1/2C_3H_8O$: C, 56.10; H, 7.80; N, 18.05; S, 10.32. Found: C, 56.00; H, 7.57; N, 17.90; S, 9.93.

The sample was dried at 100° *in vacuo* for 30 hr. and reanalyzed.

Anal.—Calcd. for $C_{13}H_{20}N_4OS$: C, 55.68; H, 7.22; N, 19.98; S, 11.44. Found: C, 55.83; H, 7.20; N, 19.62; S, 11.20.

Reagents and Assay Procedure.—Adenosine and adenosine deaminase (type I, calf intestinal mucosa) were purchased from the Sigma Chemical Co. The assay procedure for reversible inhibitors has previously been described (1, 2, 8) and is a modification of the general procedure described by Kaplan (9). The measurements of the initial rates of the enzymic reactions were performed at 25° in 0.05 *M* phosphate buffer at pH 7.6. The stock solutions of the enzyme, substrate, and inhibitors were prepared in 0.05 *M* phosphate buffer at pH 7.6. Those inhibitors which were only slightly soluble in phosphate buffer were dissolved in phosphate buffer containing 10% dimethylsulfoxide and evaluated as previously described (10). In order to determine the concentration of inhibitor required for 50% inhibition, a plot of V_0/V *versus* I was made where V_0 = initial velocity of the uninhibited enzymic reaction, V = initial velocity of the inhibited reaction at various concentrations of inhibitor, and I = the various inhibitor concentrations (8). Each plot was made with five different concentrations of inhibitor; each point for each plot is an average of at least three assays, and each reported value is an average of at least two different determinations of the concentration of inhibitor required for 50% inhibition of the enzyme. The concentration of adenosine was 0.066 m*M* in all experiments. The ratio of the m*M* concentration of the inhibitor for 50% inhibition to the m*M* concentration of the substrate $[I/S]_{0.5}$; *i.e.*, the inhibition index, was used to compare the inhibitory properties of the various compounds.

RESULTS AND DISCUSSION

As reported earlier, the authors believe that in the formation of a reversible enzyme–inhibitor complex with adenosine deaminase, the enzyme has a polar and a nonpolar region in the area where the 9-substituent of a 6-substituted purine is bound (1, 2). If the polar area (hydroxyl binding region) and the nonpolar area (hydrophobic region) of the enzyme are spatially closely related, it should be possible to synthesize inhibitors which take advantage of both the polar and nonpolar regions of adenosine deaminase. One way in which these two areas on the enzyme may be related to each other is in a "linear" manner; *i.e.*, in which the carbon chain at the 9-position of the purine nucleus is unbranched and has a hydroxyl group at the 2-position of the alkyl chain.

In agreement with previous findings, those 9-substituted compounds with a 6-chloro, a 6-dimethylamino, a 6-hydroxy, or a 6-mercapto group were either noninhibitory or only weakly inhibitory com-

TABLE I.—INHIBITION INDEX AND PARTIAL INHIBITION OF ADENOSINE DEAMINASE BY SOME 9-(HYDROXYALKYL)ADENINES

Compd.[a]	No.	mM Concn. for 50% Inhibition[b]	$[I/S]_{0.5}$[b]

[a] None of these compounds served as substrates of adenosine deaminase. [b] The concentration of adenosine in all experiments was 0.066 m*M*. In no experiment of reversible inhibition did the concentration of inhibitor exceed 0.12 m*M*. In those cases where a higher concentration is shown for 50% inhibition, the value was obtained by extrapolation of a plot of V_0/V *vs. I*. [c] Average deviation. [d] Data taken from *Reference 2*.

pared to the corresponding 6-amino derivative when evaluated against adenosine deaminase (2). However, an examination of Table I reveals some interesting features about the binding of some 9-substituted adenines to adenosine deaminase. Thus, as the 9-substituent of the adenine derivative is increased from a 2-hydroxybutyl group (V*a*) to a 2-hydroxyheptyl group (V*b*) to a 2-hydroxyoctyl group (V*c*), the compounds become progressively weaker as inhibitors. For comparison the $[I/S]_{0.5}$ of 9-(2-hydroxyethyl)adenine (XII) is 1.1, and the $[I/S]_{0.5}$ of 9-(2-hydroxypropyl)adenine (XIII) is 0.25. Similar results were obtained with the 6-methylamino derivatives (VI*a* and VI*b*) whose $[I/S]_{0.5}$ are 2.7 and 5.0, respectively.

From these results the conclusion is that the hydroxyl binding region and the principal hydrophobic binding region on the enzyme cannot be bridged by a straight chain compound with a 2-hydroxy group. However, there appears to be a specific binding region for a methyl group as noted by the increase in binding by XIII compared to XII. This methyl binding region has limited bulk tolerance[3] since the binding was decreased when the chain was lengthened from V*a* to V*b* to V*c*. Studies are continuing in an attempt to prepare 9-substituted adenines which can bind to both the hydroxyl and hydrophobic binding region of adenosine deaminase. Preliminary results with some hydroxylated branched chain compounds of the general structure of 9-(1-hydroxy-2-alkyl)-6-substituted purines indicated that these compounds are binding to both regions and will be the subject of a future paper.

[3] It is also possible that the area on the enzyme beyond the methyl binding region is quite polar and thereby repels the longer chain compounds (V*a*, V*b*, and V*c*).

NMR Spin–Spin Decoupling Studies of Some 5,6-Disubstituted Bicyclo[2.2.2]oct-2-enes

Assignment of Vinylic Protons and Demonstration of Allylic Coupling

By DAVID B. ROLL*, BERNARD J. NIST, and ALAIN C. HUITRIC

Assignment of the NMR signals of the vinylic protons has been accomplished by spin–spin decoupling in endo-5-nitro-exo-6-(*p*-chlorophenyl)-bicyclo[2.2.2]oct-2-ene (I), endo-5-amino-exo-6-(*p*-chlorophenyl)-bicyclo[2.2.2]oct-2-ene hydrobromide (IV), endo-5-cyano-exo-6-(*p*-chlorophenyl)-bicyclo[2.2.2]oct-2-ene (V), endo-5-cyano-endo-6-(*p*-chlorophenyl)-bicyclo[2.2.2]oct-2-ene (VII), all of which show significant differences in the chemical shifts of the two vinylic protons. A long-range coupling of 1.5 c.p.s. is demonstrated between H-1 and H-3 and between H-4 and H-2 in these systems.

In two recent publications (1, 2) the authors have reported partial analyses of the NMR spectra of some 5,6-disubstituted bicyclo[2.2.2]-oct-2-enes. The analyses have now been expanded by spin–spin decoupling through frequency sweep double resonance technique.

DISCUSSION

In the initial analysis of the spectra of compounds I and II (1) it was possible to assign the signals of H-1, H-4, H-5, and H-6, but unambigous differentiation of the signals of H-2 and H-3 was not possible, even though these signals are separated by about 23 c.p.s. in the spectrum of compound I measured in carbon tetrachloride at 60 Mc. In the isomeric compound II, in which the nitro group is exo and the aromatic group endo to the double bond, the difference in the chemical shift of the vinylic protons is much smaller (1). The differences in chemical shifts of H-2 and H-3 are attributed to the long-range shielding effects resulting from the magnetic anisotropy of the aromatic ring (3) and the nitro group (4).

Assignment of the signals of H-2 and H-3 in the spectrum of I has now been accomplished by spin–spin decoupling. Pertinent portions of the spectrum and decoupled spectra of I are given in Fig. 1.

Only that portion of the spectrum including the signals of H-1 through H-6 is given in each case. In spectrum F, prior to decoupling, the signals of the vinylic protons appear essentially as triplets centered at τ 3.46 and 3.85. Components of the triplet at τ 3.46 are further split by about 1.5 c.p.s., and those of the upper field triplet are broadened, indicating the presence of long-range coupling. Irradiation at the resonance of H-1, spectrum E, caused the triplet at τ 3.46 to collapse into a doublet, J_{23} = 8.5 c.p.s., while the triplet at τ 3.85 now appears as a quartet, J_{32} = 8.5 and J_{34} = 6.0 c.p.s. These results establish the signal at τ 3.46 as that of H-2. The sharpening of the signal at τ 3.85 into a well-defined quartet by irradiating at the signal of H-1 shows that H-3 is coupled slightly with the allylic H-1 in spectrum F.

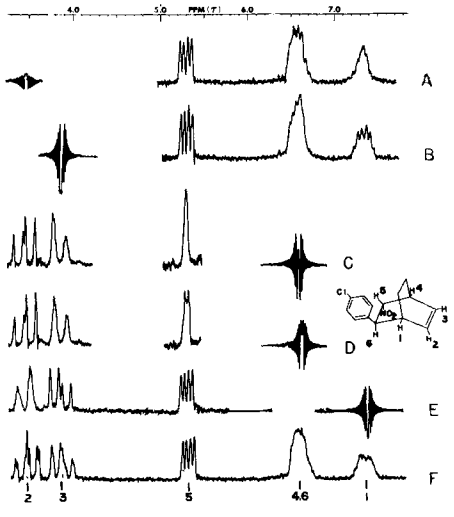

Fig. 1.—Portions of NMR spectrum and decoupled spectra of endo-5-nitro-exo-6-(*p*-chlorophenyl)-bicyclo[2.2.2]oct-2-ene; 60 Mc., about 1 *M* in carbon tetrachloride with TMS internal reference.

[1] As the hydrobromide salt.

Irradiation at the position of overlapping signals of H-4 and H-6 (spectra C and D) caused the triplet at τ 3.85 to collapse into a doublet, $J_{23} = J_{32} =$ 8.5 c.p.s., and simultaneously produced a sharp quartet, $J_{23} = 8.5$ and $J_{21} = 6.5$ c.p.s., for the signal of H-2. This confirms the assignment of H-2 and H-3 and also shows an allylic coupling of 1.5 c.p.s. between H-2 and H-4 in spectrum F. The sharp singlet of H-5 in spectrum C shows that H-5 is simultaneously decoupled from H-4 and H-6, while in spectrum D H-4 is not completely decoupled from H-5.

Additional evidence for long-range allylic coupling between H-1 and H-3 is found in spectrum B. Irradiation at the position of the signal of H-3 produced a much better resolved signal for H-1. Irradiation at H-3 also caused a narrowing of the combined signals of H-4 and H-6 as expected due to decoupling of H-3 from H-4. Spectrum A shows the expected narrowing of the signal of H-1 by irradiation at the signal of H-2.

Compound III was obtained by the reduction of I with iron in acetic acid by the method of Kornblum and co-workers (5). The spectrum of the free amine (not shown) was measured in tetrachloroethylene with TMS as internal reference. The vinylic protons give two triplets, centered at τ 3.57 and 3.89, which are quite analogous in shape to those of the corresponding nitro compound I. The spectrum has a signal at τ 7.10 which integrates to 1 proton, a signal at τ 7.60 which integrates to 2 protons, and a signal at 7.83 which accounts for 1 proton. Signals of the remaining hydrogens, including the amino protons, are overlapping at higher field. The spectrum of the hydrobromide salt of III, determined in D_2O with sodium 3-(trimethylsilyl)-1-propane sulfonate as internal reference, has the following pattern: the vinylic protons give 2 triplets centered at τ 3.03 and 3.39; there are unresolved singlets each integrating to 1 proton, at τ 5.82, 6.66, 6.90, and 7.25. The signals of the remaining ring protons are overlapped over a broad region at higher field and the exchangeable protons gave a signal at τ 4.89. The signal at τ 5.82 has experienced the largest downfield shift upon protonation and is assigned to H-5. Decoupling studies of the spectrum of this amine salt in D_2O made it possible to assign the signals of H-1 through H-6. Irradiation of the signal at τ 6.66 caused the signal of H-5 at τ 5.82 to appear as a poorly resolved doublet with separation of about 4.5 c.p.s., and caused the signal of the vinylic proton at τ 3.39 to collapse to a doublet with separation of about 7.5 c.p.s. These results show that the signal at τ 6.66 is due to H-4 and that the signal at τ 3.39 is that of the vinylic H-3. Irradiation at τ 7.25 caused the triplet at τ 3.03 to collapse to a doublet with separation of about 7.5 c.p.s. and a narrowing of the signal at τ 6.90. Irradiation at τ 6.90 caused a narrowing of the signal at τ 5.82 but did not cause any change in the signal of the vinylic protons. These results show that the signal at τ 7.25, 3.03, and 6.90 are due to H-1, H-2, and H-6, respectively.

The spectra of compounds V, VI, and VII have been published previously (2). The spectra of V and VII show a greater difference in chemical shifts of the vinylic protons than the spectrum of VI. The assignment of the signals of the vinylic protons was not done in the original publication. This has now been done by double resonance for compounds V and VII. A large solvent effect on chemical shift in going from deuterochloroform to pyridine was observed for H-5 of VII, causing the overlapped signals of H-5 and H-6 in chloroform to appear as discrete peaks in pyridine (2), but the pattern of the vinylic protons was almost identical in the two solvents.

Pertinent portions of the spectrum and decoupled spectra of VII measured in pyridine are given in Fig. 2. Spectrum C shows the signals of H-1 through H-6 without decoupling. The assignment of H-5 at τ 6.64 and H-6 at τ 6.82 was accomplished by deuteration at C-5 (2). The vinylic protons give partially overlapped sextets (doublets of triplets with minor splitting of 1.5 c.p.s.) centered at τ 3.48 and 3.67. The signals of the bridgehead protons appear at τ 7.14 and 7.39. Spectrum B shows the effects of irradiating at τ 7.14. The signal of H-5 has collapsed to a doublet, $J_{56} = 10$ c.p.s., showing that the signal at τ 7.14 is due to H-4 and that H-4 is now decoupled from H-5. In addition, the signal at τ 3.67 has collapsed to a broad doublet with separation of about 8.5 c.p.s., and the minor splitting of 1.5 c.p.s., due to allylic long-range coupling has disappeared in the signal at τ 3.48. This permits assignment of the signal at τ 3.67 to H-3 and that at τ 3.48 to H-2. These assignments are confirmed by irradiation of the signal of the other bridgehead proton (H-1) at τ 7.39, spectrum A, which causes no change in the signal of H-5 but causes the signal at τ 3.48 to collapse to a broad doublet with separation of about 8.5 c.p.s. and causes the signal at τ 3.67 to become a triplet with separation of 8.5 c.p.s., $J_{12} \simeq J_{23} = 8.5$ c.p.s.

The decoupled spectra of V are not shown. The original spectrum measured in deuterochloroform without decoupling (2) shows two sextets (essentially triplets with minor splitting of 1.5 c.p.s.) for the vinylic protons centered at τ 3.42 and 3.68; a sharp quartet for H-5 at τ 7.16; a signal accounting for two hydrogens at τ 6.97 which shows the poorly re-

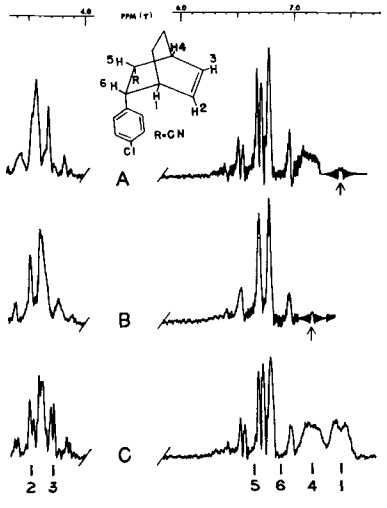

Fig. 2.—Portions of the NMR spectrum and decoupled spectra of endo-5-cyano-endo-6-(*p*-chlorophenyl)-bicyclo[2.2.2]oct-2-ene; 60 Mc. about 1 *M* in pyridine with TMS as internal reference.

solved quartet of H-6 overlapped by the signal of one of the bridgehead protons; and the signal of the other bridgehead proton at τ 7.41. Decoupling was done in deuterochloroform. Irradiation at τ 7.41 did not cause any change in the quartet of H-5 but caused the poorly resolved signal of H-6 to appear as a sharper doublet and also caused the sextet at τ 3.42 to collapse to a doublet with separation of 8.5 c.p.s., with simultaneous change of the sextet at τ 3.68 to a quartet of coupling constants of 8.5 and 6.0 c.p.s. These changes in the pattern of the vinylic protons are analogous to those shown in spectrum E of Fig. 1, compound I. The results allow the assignment of the signal of H-1 at τ 7.41; H-2 at 3.42; H-3 at 3.68; and $J_{23} = J_{32} =$ 8.5 and $J_{21} = J_{34} =$ 6.0 c.p.s. The long-range allylic coupling of 1.5 c.p.s. is again demonstrated. These assignments are confirmed by irradiation in the vicinity of τ 6.97 where the other bridgehead proton (H-4) overlaps with the signal of H-6. This caused a collapse of the signal at τ 3.68 to a doublet with separation of 8.5 c.p.s. and a simultaneous change of the signal at τ 3.42 to a quartet, $J_{23} = 8.5$ and $J_{21} = 6.0$ c.p.s., changes similar to those seen in spectra C and D of Fig. 1.

The spectrum of exo-5-cyano-exo-6-(*p*-chlorophenyl)-bicyclo[2.2.2]oct-2-ene (VIII) was determined in deuterochloroform and in pyridine. The spectra are not shown. In deuterochloroform the signals of H-5 and H-6 overlap to give a single peak at τ 7.02. The signals of the bridgehead protons are centered at about τ 7.11 and 7.40. The signals of the vinylic protons at τ 3.50 and 3.76 have a pattern of complex triplets analogous to those of H-2 and H-3 in spectrum F of Fig. 1. In the spectrum measured in pyridine the signals of the vinylic protons appear at τ 3.62 and 3.89 and there is no significant change in the pattern of the complex triplets. The signals of the bridgehead protons are centered at about τ 7.27 and 7.51. The most significant difference in the spectra from the two solvents is a separation of the signals of H-5 and H-6 in pyridine which appear at τ 6.88 and 7.08 and give a pattern analogous to that of H-5 and H-6 of VII in pyridine, spectrum C, Fig. 2. The signal of one of these two hydrogens is shifted downfield, while the other one experiences very little change in pyridine compared to deuterochloroform. This effect has been observed in other isomers of VIII (2) where the assignment of H-5 and H-6 had been done through deuteration and in each case it was the signal of the hydrogen on the cyano-bearing carbon which experienced the downfield shift. Decoupling was done on VIII in pyridine by irradiation of the positions of the signals of the bridgehead protons. Irradiation at τ 7.51 caused the vinylic signal at τ 3.62 to collapse to a doublet and did not bring any change in the signal at 6.88, while irradiation at τ 7.27 caused a collapse of the signal of the vinylic proton at τ 3.89 to a doublet and caused the quartet at 6.88 to appear as a doublet with separation of 10.5 c.p.s. This shows that the bridgehead proton giving the signal at 7.51 is located between the vinylic proton responsible for the signal at τ 3.62 and the proton responsible for the signal at τ 7.08 while the bridgehead proton giving the signal at τ 7.27 is located between the other vinylic proton, τ 3.89, and the proton giving the signal at τ 6.88. If, as observed in other isomers (2), it is H-5 which experiences the deshielding effect in pyridine then the following chemical shifts would hold: H-1, 7.51; H-2, 3.62; H-3, 3.89; H-4, 7.27; H-5, 6.88; H-6, 7.08.

A summary of chemical shifts is given in Table I.

In all bicyclo[2.2.2]oct-2-enes with a nitro or cyano group at C-5 and a *p*-chlorophenyl group at C-6 in which the signals of the vinylic protons could be differentiated by spin–spin decoupling the signal of H-2 was found to be further downfield. Since the spatial orientation of the functional groups varies in these compounds and since the long-range shielding effects due to the magnetic anisotropy of the aromatic and nitro groups are affected by con-

Synthesis of Tropine-Labeled Atropine I

Micro Methods for the Synthesis of Tropine and for Its Esterification with Tropic Acid

By GILBERT C. SCHMIDT, THOMAS E. ELING*, and JOHN C. DRACH†

Yields for each step in the esterification of tropine and tropic acid have been determined with micro and semimicro quantities of reactants. In a similar way, the Robinson condensation has been studied. Data are compared with the findings of other investigators. In the esterification of micro quantities of tropine and tropic acid, 70–75 per cent of theoretical atropine yields are obtained routinely. Based on any intermediate in the Robinson condensation, micro quantities of reactants routinely produce 67–72 per cent of theoretical tropine yields. Predicted yields of 47–54 per cent atropine from Robinson intermediates were confirmed by synthesis of atropine from each of the Robinson reactants. The procedures are designed for the synthesis of labeled tropine and tropine-labeled atropine from labeled arabinose.

THE ESTABLISHMENT of metabolic pathways in tropine metabolism awaits the development of synthetic methods for selectively labeling the tropine ring. The fate of this heterocycle, free or as a structural component of atropine and related compounds, is essentially unknown because suitably ring-labeled compounds are not available in amounts adequate for animal studies.

Tritium-labeled atropine (1) and randomly-^{14}C-labeled atropine (2) are of limited usefulness because the labeling is not specific. Biosynthetic atropines (3, 4) are suitably labeled, and could be used to determine the metabolic fate of the tropine moiety, but complexities of preparation have limited their availability and prevented their use in animal studies. Fodor *et al.* (5) and Werner *et al.* (6) prepared *N*-methyl-^{14}C-tropine, then esterified it with unlabeled tropic acid to obtain tropine-labeled atropine. Subsequent metabolic studies (7), although not extensive, clearly indicate the need to label tropine and atropine in other positions. During studies of atropine toxicity, this need became very apparent to the authors.

The extreme toxicity of atropine and related compounds is an added complication, because low doses must be used for *in vivo* studies, and minor metabolites are correspondingly difficult to detect. Compounds of reasonably high specific

Predicted yields of 47–54 per cent atropine from Robinson intermediates were confirmed by synthesis of atropine from each of the Robinson reactants. The procedures are designed for the synthesis of labeled tropine and tropine-labeled atropine from labeled arabinose.

THE ESTABLISHMENT of metabolic pathways in tropine metabolism awaits the development of synthetic methods for selectively labeling the tropine ring. The fate of this heterocycle, free or as a structural component of atropine and related compounds, is essentially unknown because suitably ring-labeled compounds are not available in amounts adequate for animal studies.

Tritium-labeled atropine (1) and randomly-^{14}C-labeled atropine (2) are of limited usefulness because the labeling is not specific. Biosynthetic atropines (3, 4) are suitably labeled, and could be used to determine the metabolic fate of the tropine moiety, but complexities of preparation have limited their availability and prevented their use in animal studies. Fodor *et al.* (5) and Werner *et al.* (6) prepared *N*-methyl-^{14}C-tropine, then esterified it with unlabeled tropic acid to obtain tropine-labeled atropine. Subsequent metabolic studies (7), although not extensive, clearly indicate the need to label tropine and atropine in other positions. During studies of atropine toxicity, this need became very apparent to the authors.

The extreme toxicity of atropine and related compounds is an added complication, because low doses must be used for *in vivo* studies, and minor metabolites are correspondingly difficult to detect. Compounds of reasonably high specific

activity are required, the use of unlabeled carriers in synthetic procedures is not practical, and a requirement for microsynthetic methods is imposed. For selective labeling of tropine, versatile microsynthetic methods are not available. Furthermore, micro procedures for the esterification of tropine and tropic acid have been used infrequently, by very few investigators (5, 6, 8), and many details essential for good reproducibility have not been published.

The authors concluded that labeling atropine in the tropine moiety would depend on increased reproducibility of published esterification procedures (5–9) and on adaptation of the Robinson condensation for use with micro quantities of reactants. A semimicro, prototype method evolved from quantitated studies of these two reaction sequences. From similar studies of the prototype, there resulted a reproducible microsynthesis of tropine and atropine. Detailed microsyntheses of atropine and tropine, employing 100–200 mg. of reactants, are reported. Results of both the micro and semimicro methods are compared with observations of other investigators. The feasibility of this approach to tropine and atropine labeling is established. Establishment of these pathways, and the availability of a microsynthesis of succindialdehyde from arabinose (10), provide the first feasible approach to labeling tropine in other than the *N*-methyl position.

EXPERIMENTAL

Preparation of O-Acetyltropic Acid Chloride—The method of Wolffenstein and Mamlock (9) was modified for use with micro quantities of reactants. For the synthesis of *O*-acetyltropic acid, 120 mg. tropic acid and 0.12 ml. acetyl chloride[1] were introduced into a 10-ml. round-bottom flask,[2] the flask was stoppered, and the reaction mixture allowed to stand for 12–15 hr. at room temperature. The resulting mass was heated at 100° for 7 min., and the excess acetyl chloride removed at 50°, *in vacuo*, using a flash evaporator.[3] Crystallization of the oily product, which otherwise required several days, was initiated by seeding with a crystal of pure *O*-acetyltropic acid.[4] When stored for 2–4 hr., in a vacuum desiccator, over calcium chloride, the product crystallized as a solid mass which was immediately converted to the acid chloride. To the *O*-acetyltropic acid, contained in the original reaction vessel and usually weighing 148 mg.,[1] was added 0.66 ml. thionyl chloride. The reaction vessel was fitted immediately with a calcium chloride drying tube and the reaction mixture heated, on an oil bath, at 50°, for 1 hr., during which period the mass liquefied and gas evolved. The drying tube was removed, the flask was fitted with a short-path vacuum distillation apparatus, and the excess thionyl chloride removed, at 70°, *in vacuo*.[5] The last traces of thionyl chloride were removed by the addition and *in vacuo* distillation of six 0.5-ml. portions of anhydrous benzene.[6] The product, a lemon-yellow oil having a strong and disagreeable odor, was reacted immediately with tropine HCl.[7]

Preparation of Tropine HCl—To 100 mg. dry tropine,[8] contained in the 10-ml. flask in which it had been prepared, was added approximately 5 ml. anhydrous ether. Tropine HCl[9] precipitated instantaneously when anhydrous HCl was passed carefully into the ether solution. The flow of gas was interrupted immediately, ether was removed quickly, *in vacuo*, and the crystalline product stored immediately,[10] within the reaction vessel, in a vacuum desiccator, over fresh NaOH pellets, until used for esterification.[11]

Esterification of O-Acetyltropic Acid Chloride and Tropine Hydrochloride—Thoroughly dried tropine HCl, 124 mg., was added to 160 mg. freshly prepared *O*-acetyltropic acid chloride, still contained in the original reaction vessel.[9–11] While stirring frequently, the reaction mixture was heated for 20–25 min., under anhydrous condition, in an oil bath that had been adjusted previously to 100° The resulting *O*-acetyltropine HCl was cooled to room temperature, then treated *in situ*[12] with 0.66 ml. water and maintained at 50° for 24 hr. The reaction mixture was cooled quickly to 0° and the atropine precipitated by careful, dropwise addition of 6–8 drops of saturated, aqueous NaOH. While maintaining the temperature at 0°, the aqueous

[1] In some micro experiments, 395 mg. tropic acid and 0.36 ml. acetyl chloride were used. After recrystallization, 148 mg. *O*-acetyltropic acid was removed, transferred to a thoroughly dried 10-ml. flask, then converted to the acid chloride as described here.

[2] Micro-Ware, Vineland, N. J.

[3] Rinco Instrument Co., Greenville, Ill.

[4] If the reaction mixture is not seeded, crystallization is delayed and atropine is contaminated with an unidentified, low-melting impurity. This difficulty is avoided by rapid crystallization and immediate conversion of the product to the acid chloride.

[5] Anhydrous conditions are essential and a dry ice–acetone trap must be placed between the distillation apparatus and the vacuum source.

[6] Unless all traces of thionyl chloride are removed, yields in the subsequent esterification are prohibitively low. The benzene must be anhydrous and the total time to effect all additions and removals should not exceed 15 min.

[7] The product is extremely sensitive to moisture and must be reacted immediately with tropine HCl. Prior to beginning the synthesis of *O*-acetyltropic acid chloride, tropine was prepared, converted to the HCl, and stored in a vacuum desiccator for 24 hr.

[8] Tropine was prepared within a day or two of use and was stored over NaOH pellets until converted to the HCl. Longer period of storage results in significant decomposition of tropine, which can be purified by vacuum distillation.

[9] Formation of the HCl by dissolving tropine in methanolic HCl and removing the solvent *in vacuo* was satisfactory at the semimicro level but gave inadequate yields at the micro level.

[10] Because tropine HCl is extremely hygroscopic, very rigid precautions to exclude moisture must be observed if a crystalline product is to be obtained.

[11] Tropine HCl and *O*-acetyltropic acid were always esterified in the reaction vessel that contained the acyl halide. Prior to esterification, this vessel was fitted with a standard taper T-tube, the side arm of which carried a calcium chloride tube, and the vertical arm of which contained a stirring rod secured in place with rubber tubing. This arrangement assured exclusion of moisture and allowed for manual stirring during the esterification.

[12] Experience has shown that, under the conditions stated, esterification is complete. During heating, the originally plastic mass liquefies, then becomes extremely viscous when cooled. When treated with water and stirred, it gradually dissolves to form a tan solution. If the esterification mixture is heated longer or more vigorously than stated, a brown to dark brown solution results when the product is treated with water. Under the latter conditions, yields are reduced from 10–30%.

phase was removed by careful decantation, the product washed with three 1-ml. portions of ice water, and the washed product seeded with a crystal of pure atropine.[13]

The crystalline, atropine free base was dried immediately in a vacuum desiccator over $CaCl_2$. When dry, the product was dissolved in 75 ml. anhydrous petroleum ether,[14] the solution was concentrated to approximately 10 ml., and purified atropine precipitated by cooling in the deep-freezer. Petroleum ether was carefully decanted from the crystals and the product dried for 12 hr. in a desiccator over $CaCl_2$ before converting to atropine sulfate. The dried, purified atropine base, usually 70% of theoretical yields, was dissolved in acetone and the calculated amount of 2 *N* H_2SO_4 in acetone was added. Atropine sulfate precipitated immediately. When cooled in a deep-freezer to insure complete precipitation, then washed with cold acetone and dried, the collected crystals represented 95–98% conversion to the sulfate.

Preparation of Acetone Dicarboxylic Acid—Acetone dicarboxylic acid was prepared from citric acid by modification of the general scheme outlined by Adams *et al.* (14).

For microsynthesis, 2.2 ml. fuming H_2SO_4 (20% excess SO_3), contained in a 100-ml. beaker, was cooled to −8° in a salt and ice bath. Using a thermometer as a stirring rod, 1.0 Gm. of citric acid was added, with constant stirring during approximately 15 min., at a rate slow enough to maintain the temperature at −5° or lower throughout the addition. The beaker and contents were removed from the cooling bath and stirred on a magnetic stirrer, at room temperature, for about 1 hr., until the evolution of carbon monoxide ceased. The reaction mixture was cooled again to −8°, and 4 Gm. chipped ice was added, carefully and in small portions, so the temperature never exceeded 0°. After the addition of all the ice, the reaction was cooled again to −8°, the product was collected on a sintered-glass filter, and was used at once.[15]

Preparation of Succindialdehyde—Succindialdehyde was prepared *in situ* by hydrolysis of 2,5-diethoxytetrahydrofuran,[16] by a simplified modification of the procedure of Fakstorp (15). To 2 ml. water and 5 μl. concentrated HCl, contained in a 50-ml. beaker, was added 0.17 ml. diethoxytetrahydrofuran.[17] The mixture was stirred at room temperature for 10 min., then used immediately for the synthesis of tropanone.[18]

Synthesis of Tropanone—After preliminary experiments the following "standard" procedure for the synthesis of micro quantities of tropanone was adopted. When molecular ratios were altered, the weight of methylamine hydrochloride was the reference point because this reactant can be weighed easily. Correspondingly more succindialdehyde was made available by simple proportionate changes during its preparation, and the amount of acetone dicarboxylic acid was altered by the use of a greater proportion of the moist material.

To the solution of succindialdehyde, prepared as described above and representing 1 mmole dialdehyde, was added 1 mmole acetone dicarboxylic acid, freshly prepared and still in the moist state.[19] Saturated aqueous Na_2HPO_4 was added to adjust the pH to 4.5–5.0, the solution was transferred to a 250-ml. side arm conical flask, and the system purged with nitrogen for 10 min. After the addition and dissolution of 1 mmole solid methylamine HCl, the system was quickly evacuated to remove most of the gas phase, then closed and allowed to remain under partial vacuum, at room temperature, for 12 hr. The slight evacuation was then repeated and the reaction mixture allowed to remain at room temperature for an additional 12 hr.

After 24 hr., the system was opened and the solution saturated with K_2CO_3, added in small portions, while stirring constantly and cooling the reaction mixture in a salt–ice bath. The alkaline solution was cooled to −5°, extracted with 100 ml. petroleum ether (boiling range 30–80°),[20] and the organic layer removed and reserved. The cooling, saturation, and extraction of the aqueous phase were repeated 6 times, the reaction vessel and separator were washed with petroleum ether, and the combined extracts dried over anhydrous Na_2SO_4. Portions were transferred to a sublimation flask,[21] solvent was removed *in vacuo* at 40° on the flash evaporator, and the Na_2SO_4 finally washed with anhydrous petroleum ether. After the *in vacuo* removal of this final solvent aliquot, crude oily brown tropanone remained in the sublimation flask. The product, contained in the sublimation flask was dried overnight in a desiccator over NaOH and $CaCl_2$.[22]

After drying, the product was purified by sublimation. A cold finger filled with dry ice and acetone was inserted into the sublimation flask containing the crude product. Tropanone was sublimed at 40°

[13] Atropine free base precipitated as a brownish, very viscous oil that adhered to the sides of the reaction vessel. The aqueous phase and washings were easily removed by careful decantation. The product quickly crystallized when maintained at 0° and seeded with pure atropine.

[14] Boiling range 30–60°.

[15] In semimicro experiments it was found that a very carefully washed product may be stored in a desiccator for 4 or 5 days, but that washing and recrystallization are accompanied by significant losses of product. Losses may be minimized by using ice-cold anhydrous ethyl acetate. If traces of sulfuric acid remain, there is significant decomposition in 2–3 hr. For calculation of yields the product was washed with ice-cold, anhydrous ethyl acetate and dried in a desiccator for 2 days. A yield of 95% and a product melting at 135° were obtained. When recrystallized from ethyl acetate, acetone dicarboxylic acid melted at 138°. To prevent losses during the synthesis of tropine, acetone dicarboxylic acid was neither washed nor recrystallized, but was used immediately in the Robinson condensation.

[16] Beacon Chemical Industries, Inc., Cambridge, Mass.

[17] In semimicro experiments, 1 vol. diethoxytetrahydrofuran, 16 vol. water, and 0.02 vol. concentrated HCl was mixed, then stirred until the translucent mixture became crystal clear

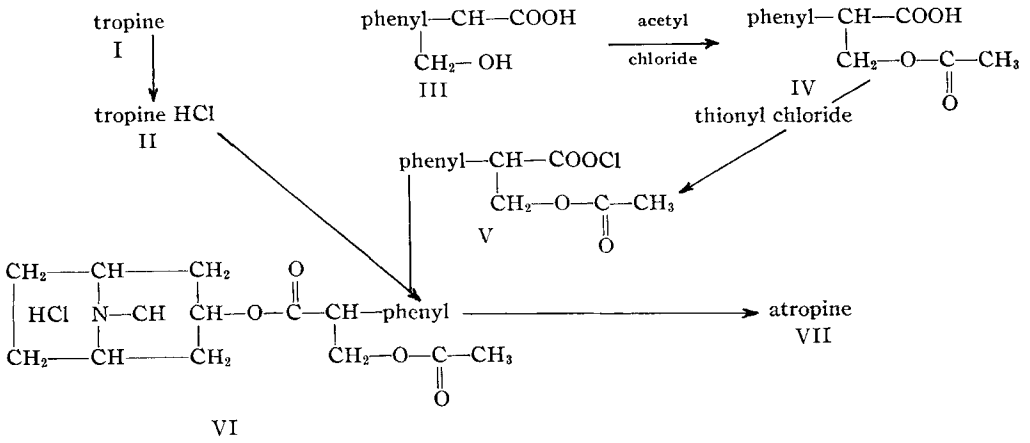
[18] To determine the extent of hydrolysis as a function of time, aliquots were treated with 2,4-dinitrophenylhydrazine, as described by Shriner *et al.* (16). A quantitative yield of the bis-dinitrophenylhydrazone, m.p. 270–275°, without recrystallization, was obtained after 5 min. in micro experiments. At the semimicro level, yields of 95–100% were always obtained when the opaque reaction mixture had become crystal clear.

[19] Twenty per cent of the moist weight of the product resulting from 1 Gm. citric acid corresponds to 1 mmole of acetone dicarboxylic acid.

[20] Allied Chemical Corp. The solvent must have a boiling range of 30–80 or extraction is incomplete and there are appreciable decreases in tropanone yield. Diethyl ether and a continuous extractor were used in semimicro experiments, but difficulties were encountered at the micro level with this solvent. For this reason, petroleum ether and manual extraction were used in micro experiments.

[21] This flask had a 250-ml. capacity and was of the design described by Werner (6).

[22] Care must be exercised in removing the solvent, and the use of a vacuum desiccator is inadvisable, because the low vapor pressure of tropanone results in losses on undue exposure to vacuum.



Scheme I

at 1 × 10^{-4} mm. mercury,[23] for 10 min. The vacuum was disconnected, dry ice and acetone were removed, the cold finger was removed from the flask, and the accumulated tropanone was washed into a 150-ml. beaker using small portions of absolute ethanol. The operation was repeated 2 times, using 10 and 15-min. sublimation periods. The combined ethanol solutions of sublimed tropanone were evaporated to dryness, on the micro flash evaporator, in a previously weighed 25-ml. flask. The product crystallized quickly on cooling, and was dried in a desiccator overnight.[22,24]

Reduction of Tropanone to Tropine—To the tropanone (approximately 100 mg. from 67.5 mg. methylamine HCl), contained in the 25-ml. flask in which it had been dried, was added 5 ml. absolute ethanol, a magnetic stirring bar, and 0.5 ml. of a suspension of Raney nickel in absolute ethanol.[25] The flask was placed in a water bath, attached to a gas buret, and the reaction mixture continuously stirred while flushing the system seven times by alternate admission and expulsion of hydrogen. Finally, the system was filled with hydrogen, closed, and continuously stirred until reduction was complete.[26]

To remove Raney nickel, the ethanol solution was filtered through a sintered-glass filter into a 25-ml. round-bottom flask, the original flask and nickel were washed repeatedly with small portions of absolute ethanol, and most of the solvent removed on the flash evaporator. When the volume of ethanol had been reduced to approximately 10 ml., the solution was transferred to a tared 10-ml. flat-bottom flask, evaporated to dryness, and both flask and contents dried in a vacuum desiccator[27] before conversion to the hydrochloride.

[23] Two stage vacuum pump, Welch Scientific Co., Chicago, Ill.

[24] Tropanone yield was determined from the weight of this product, m.p. 42°.

[25] To prepare Raney nickel, 2.5 Gm. of alloy (Raney Nickel Co., Chattanooga, Tenn.) was heated at 50° for 15 min. with a solution of 3.2 Gm. NaOH in 12.5 ml. water. The product was washed with water, ethanol, and absolute ethanol, then suspended in absolute ethanol. The final suspension represented 35 mg./ml. of Raney nickel.

[26] When reduction was complete, a 1-μl. aliquot gave a negative test when spotted on filter paper and treated with 2,4-dinitrophenylhydrazine solution. It is sometimes necessary to add additional aliquots of Raney nickel to effect complete reduction.

[27] Conversion to the hydrochloride is carried on in this vessel. The product is white, crystalline, m.p. 63–65°, and adequately pure for conversion to the HCl without recrystallization. Picrate darkens at 275° and melts at 295°.

RESULTS AND DISCUSSION

For the synthesis of tropine-labeled atropine, the two key steps are synthesis of labeled tropine and esterification of the labeled heterocycle with unlabeled tropic acid. Good reproducible yields with micro quantities of reactants must be obtainable with each of these steps for the synthesis of tropine-labeled atropine to be feasible.

Microesterifications of tropine and tropic acid have been done by very few investigators (5, 6, 8). All reported procedures are modifications of the Wolffenstein and Mamlock method (9) and involve conversion of tropine (I) to the hydrochloride (II), conversion of tropic acid (III) to *O*-acetyltropic acid chloride (V) *via* the intermediate acetyl compound (IV), esterification of II and V to form *O*-acetylatropine HCl (VI), and mild, selective hydrolysis to the free alkaloid (VII). (Scheme I.)

Although 63–70% yields have been reported for the microesterification of tropine and tropic acid, there have been no detailed studies of the method. Lack of reproducibility was disclosed in semimicro studies and was re-encountered at the micro level. Werner's data (6) indicate a similar difficulty. He obtained 70% yields of tropine-labeled atropine after a single esterification, but isolation of unreacted tropic acid and two esterifications were required to obtain a 63% yield of tropic acid-labeled atropine. Because of these inconsistencies, the authors quantitatively studied each step in the reaction sequence. Results of these studies are compared in Table I with summarized observations of other investigators.

From the studies summarized in Table I, there evolved a reproducible microesterification of tropine and tropic acid. In contrast to others, equimolar quantities of tropine and tropic acid are used, and the method is equally adaptable for labeling atropine in either of these component moieties. The problem of synthesizing tropine-labeled atropine is thereby reduced to that of labeling the heterocycle. The need is for a microsynthesis of tropine that is adaptable for the introduction of appropriately labeled intermediates.

The classical approach to tropine synthesis is the method of Robinson (11), as modified by Schopf and Lehman (12). Succindialdehyde (VIII), methylamine HCl (IX), and acetone dicarboxylic acid (X) are condensed under essentially physiological condi-

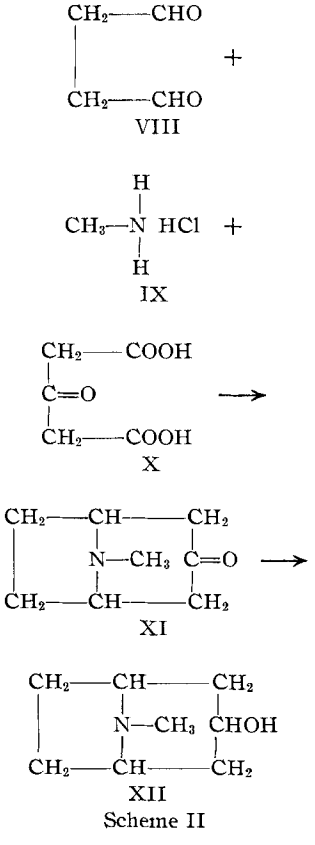
[j] Melting point reported by Fodor is for hyoscyamine. [k] "Merck Index," 7th ed., Merck & Co., Inc., Rahway, N. J., p. 111, reports melting points for the sulfate from 190–194°.



Scheme II

tions to yield tropanone (XI), which then is reduced to tropine (XII). (Scheme II.)

Although the scheme is inherently versatile and therefore potentially suited for radiosynthesis, there have been surprisingly few studies of the reaction (11–13) and no reference to its use at the micro level.[28] In Table II the results of semimicro and microsyntheses, developed during the studies described in this communication, are compared with the findings of other investigators.

To determine the effect of hydrogen-ion concentration and potential losses from decreasing weights of reactants, concentration of all reactants was fixed at 0.20 *M*, while decreasing the weight of methylamine HCl from 33.0 Gm. to 1.69 Gm. at each of four hydrogen-ion levels within the range pH 4.0–pH 10.5. Neither decreasing weights nor varying hydrogen-ion level had significant effects on tropanone yields. The weight of methylamine HCl was then fixed at 1.69 Gm., equimolar concentrations of reactants were used, and concentration was varied from 0.01–0.20 *M*, at each of the four hydrogen-ion levels previously employed. There were no significant differences in tropanone yields, thereby validating arbitrary choices of both concentration and hydrogen-ion level, within the ranges studied. In comparison, Keagle and Hartung (13) reported no significant differences in tropanone yields within the concentration range 0.04–0.16 *M* and the pH range pH 5.0–pH 11.0. Agreement with Keagle and Hartung's findings is apparent.

There is general agreement with Schopf and

[28] Werner's microsynthesis of *N*-methyl-labeled tropine and atropine were published just prior to completion of this investigation.

[a] Hydrogen-ion concentration measured with Corning model 7 pH meter. [b] Yields for micro and semimicro procedures and for Werner's method are as the free base, after purification by sublimation. Other yields are as the picrate. [c] Dipiperonylidene derivative and picrates prepared as described by Keagle and Hartung (13). Melting points reported in this communication were determined with a Fisher-Johns melting point apparatus. For infrared analysis, samples were compared with authentic samples of tropine and tropinone as picrates using a Perkin-Elmer model 221 I.R. spectrophotometer. [d] Semimicro and micro procedures described in this communication.

Lehman (12), but their data indicate a possible interdependence of pH optima and ratios of reactants. When both amine and keto acid were in excess, tropanone yields were appreciably higher at pH 11.0, but when only the amine was in excess, yields were appreciably higher at pH 5.0. Because of the narrow pH range studied, our data do not completely exclude an interdependence. Results obtained in semimicro experiments, with varying ratios of reactants at pH 5.0 and pH 7.0, showed no dependence of tropanone yield on molecular ratios. These findings were confirmed in microsyntheses at pH 5.0, as shown in Table II. All data reported here were obtained when diethoxytetrahydrofuran was used as the source of succindialdehyde, while both Schopf and Lehman and Keagle and Hartung prepared the aldehyde from pyrrole *via* the intermediary succinaldoxime. The furan derivative is a far superior aldehyde source. Based on experience with both pyrrole and diethoxytetrahydrofuran, the authors concluded that Schopf and Lehman's data probably reflect a lack of reproducibility arising from the use of pyrrole.

During adaptation and modification of the prototype procedure, previously described experiments were repeated on a more limited scale. The data, which are not presented here, showed that flexibility of pH was no different when microquantities of reactants were used. An initial pH of 5.0 was chosen arbitrarily because carbon dioxide evolution is readily apparent and is a reliable, visual indication that the condensation is progressing properly. Because carbon dioxide is totally or partially bound, this guide is not available at hydrogen-ion levels near and above neutrality.

Changes in buffer composition were considered for possible effects on tropanone yields. The micro procedure described here was compared in parallel experiments with Werner's method (6). Identical 70% yields of pure tropanone were obtained, thereby confirming Werner's work and indicating that acetate offered no advantage over phosphate. Phosphate was then compared with citrate at different hydrogen-ion levels and different reaction times. Maximum yields of 50% pure tropanone were isolated when citrate buffers were used. The authors

could not confirm the claims of Hungarian workers (17) that the use of citrate buffers results in tropanone yields of 90% or more and a decrease in reaction time to 6 hr. The intent was to isolate pure tropanone in maximum yields, and the variables introduced by their use of the reineckate as a criterion for completeness of condensation was not considered. For our purposes, phosphate and acetate were equally effective and both were superior to citrate. Phosphate was chosen on the basis of more extensive experience with this system.

Further studies with the microsynthetic method, shown in Table II, were limited on the basis of probable conditions in radiosyntheses. Variations of methylamine weight from 67.5–135 mg., concentrations from 0.01–0.04 *M*, and molecular ratios within the probable experimental range had no significant effect on tropanone yields. Similarly, the use of an excess of one or more reactants had no effect. These observations confirm, for the micro modification, the results obtained with the semimicro prototype; reproducibility is good, there is a flexibility in actual quantities and molecular ratios of reactants, and there is no requirement for an excess of any particular intermediate.

The micro condensation was developed as an instrument for tropine labeling and is well suited for this purpose. It is flexible and reproducible. Equimolar ratios, or any desired proportion of reactants, can be used without affecting yields. There is no requirement for added carriers and specific activity of the product is limited only by the specific activities of the intermediates.

CONCLUSIONS

The esterification of tropine and tropic acid has been studied in detail, using both semimicro and microquantities of reactants. Yields for each step in the sequence have been determined and have been compared with the findings of other investigators. From these studies there evolved a micro procedure for esterifying tropine and tropic acid. Equimolar quantities of reactants are employed and the method is equally suited for labeling either of the component moieties of atropine. With proper attention to detail, esterification is unusually reproducible and yields of 70–75% atropine free base are obtained routinely.

In a similar way, the Robinson condensation has been studied. There has evolved a reproducible micro method for condensing equimolar quantities of methylamine HCl, acetone dicarboxylic acid, and succinic dialdehyde. There exists an ideal flexibility of molecular ratios, concentrations of reactants, and hydrogen-ion levels. The method is ideally suited for labeling tropine through any or all intermediates of the Robinson condensation, and yields of 67–72% tropine are obtained routinely.

Based on studies of the esterification and the condensation, yields of 47–54% atropine free base should result from any precursor of the Robinson condensation. This prediction has been confirmed by synthesis of atropine from each of the three compounds. This study, and Werner's work, clearly establish the feasibility of using the Robinson condensation to label tropine. The feasibility of esterifying labeled tropine with unlabeled tropic acid has been established. Results of this study, and a preliminary report describing a prototype synthesis of succindialdehyde from arabinose (10), make available for the first time a synthetic method for labeling the carbon skeleton of the tropine moiety. Details of the synthesis will be published in the second paper of this series.

Microbiological Methods for Quality Control of Membrane Filters

By FRANCES W. BOWMAN, MIRIAM P. CALHOUN, and MACK WHITE

Microbiological methods are presented for quality control of membrane filters of 0.45 and 0.22 μ porosity.

ALTHOUGH MEMBRANE filters have been produced for more than 100 years, they were not widely used in the United States until after World War II. According to a report by Goetz (1), the Germans made dramatic use of them during the war for preventing epidemics that could have been caused by contaminated water supplies. Using membrane filters, they developed a rapid test to determine the safety of public water supplies after bombings.

The technology for producing membrane filters was later brought to the U. S. where, under the sponsorship of the U. S. Department of the Army, extensive research was conducted on their production. This research resulted in practical procedures for commercial production. The filters were produced from cellulose esters in sheets approximately 150 μ thick. The pore sizes were predetermined and controlled in the manufacturing process.

At the present time, 12 distinct pore sizes or classes ranging from 8 μ (class 1) downward in pore size to 10 mμ (class 12) are commercially available. According to the reports by the manufacturers, some of the membranes are composed of pure cellulose acetate, whereas others contain a mixture of cellulose acetate and cellulose nitrate. Due to the demand for these membranes, an Interim Federal Specification (2) was published for the purpose of securing bids for the Defense Supply Agency. This federal specification includes methods for evaluating the quality of each class of membrane.

In the past decade, scientists have found innumerable applications for the membrane filters as an analytical tool. The filters have been widely used in the sampling and measurement of airborne particulates, microbiological analysis of water and foods, clinical diagnosis, sterile filtration, beer manufacturing, and sterility testing.

Holdowsky (3) first suggested the use of bacterial retentive membranes in sterility testing of antibiotics to provide a means of removing the antibiotic from the test medium. Using the membrane filtration technique, Bowman (4) developed procedures for soluble antibiotics, and the Antibiotic Regulations were subsequently amended to include the membrane filtration sterility test. For this test, the Antibiotic Regulations state that the bacterial membrane filter should have a nominal porosity of 0.45 $\pm$ 0.02 μ, a diameter of approximately 47 mm., and a flow rate of 55 to 75 ml. of distilled water passing each sq. cm. of filter area per min., with a differential pressure of 70 cm. of mercury at 25°. Bacterial retentive membranes that fulfill these specifications are available from a number of suppliers. Most manufacturers conduct laboratory quality control tests. In addition to these tests, it is desirable that laboratories conducting sterility tests assess the quality of the membranes to be used. Therefore, a reliable standard method for evaluating the bacterial retentive membranes was sought.

Among the methods currently used for determining pore size are Sauer's pore-size bubble test (5), Erbe's pore-size distribution determination (6), Ritter's mercury intrusion measurement of pore radius (7), and particle passage methods (8). The latter are the most commonly used, and are the basis of the current pore-size rating system. These tests tell whether the filter will retain particles larger than the nominal pore size. For large pores, colored or radioactive particles are used; for microbiological filters, bacteria are used.

The particle passage method provides a practical method for determining the quality of class 7 (0.45-μ) membranes used for sterility testing. Special equipment such as that used for the mercury intrusion and other methods is not needed. Most of the equipment and materials required for this test are found in any laboratory performing membrane filtration sterility tests. For this reason, a passage test using *Serratia marcescens* ATCC 14756 has been developed for accepting the membranes used for the sterility testing of antibiotics under the certification program. The acceptance test employs a general inspection level I, double sampling plan, MIL-STD-105, at a 1% acceptable quality level. For example, if a lot (batch) of 1201 to 3200 membrane filters is to be sampled for tests, 32 filters

Received October 27, 1966, from the Division of Antibiotics and Insulin Certification, Bureau of Science, Food and Drug Administration, U. S. Department of Health, Education and Welfare, Washington, D. C. 20204.
Accepted for publication November 10, 1966.

will be selected randomly from the lot and tested for retention of *S. marcescens*. If none is found defective, the batch is acceptable. If one is defective, a second test is performed on an additional 32 filters. If two or more are found defective in either the first or the first and the second test, the lot is rejected. The double sampling plan allows acceptance of acceptable quality filters with minimum testing of one sample; the second sample allows for the probability occurrence of one defective membrane in a sample of 64 filters having an average quality level of 1% defective.

ACCEPTANCE TEST PROCEDURE FOR CLASS 7 MEMBRANES

Bacterial Culture.—Prepare a suspension of *S. marcescens* ATCC 14756 as follows. Transfer the organism to a Roux bottle containing 300 ml. of U.S.P. peptone–casein agar, incubate at 25° for 24 hr., and harvest the growth with 50 ml. of sterile 0.1% (w/v) peptone diluting fluid and sterile glass beads. Perform a viable cell count on the suspension and determine the dilution that will yield between 50,000 and 100,000 cells/ml.

Apparatus.—Assemble 32 filtration units as shown in Fig. 1. Each unit consists of a 1-L. side-arm Pyrex suction flask (*1*) fitted with a No. 8 rubber stopper which has a hole in the center for the support of a 300-ml. Pyrex filter funnel. The fritted-glass base which supports the membrane is held to the 300-ml. funnel with a spring action aluminum clamp. One end of a 2-in. long piece of vacuum tubing ($^1/_4$-in. bore and $^3/_{16}$-in. wall) is attached to the side-arm of the 1-L. flask. At the other end (*2*) a female adapter, Luer-Lok, is inserted to hold a Swinny hypodermic adapter (*3*) containing a 13-mm. diameter microfiber glass air filter. A male adapter, Luer-Lok (*4*), attached to the Swinny adapter is inserted in additional tubing which is connected to the vacuum source. The top of the side-arm flask and the base of the funnel are covered

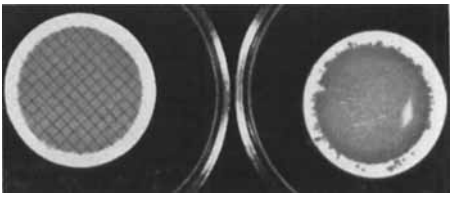

Fig. 2.—Membrane with satisfactory growth of *S. marcescens* (left) and unsatisfactory growth (right) after incubation in acceptance test.

with aluminum foil. The top of the funnel is closed by a rubber stopper pierced with an 18-gauge hypodermic needle attached to a Swinny adapter as described above. After the entire unit is autoclaved for 1 hr. at 121°, a sterile class 7 membrane is aseptically placed on the fritted-glass base of the funnel with flat bladed forceps to avoid damaging the membrane.

Test Procedure.—Lift the stopper of each of the 32 filter funnels prepared as described above and carefully pour in 200 ml. of U.S.P. peptone broth that has been seeded with 1 ml. of the *S. marcescens* suspension appropriately diluted as previously described. Replace the stopper firmly on the funnel and apply negative pressure to start the filtration. When the filtration has been completed, stop the vacuum and allow air to be drawn rapidly into the flask through the air filter inserted in the rubber tubing. With the funnel still attached, remove the rubber stopper from the suction flask and cover the top of the flask containing the filtrate with a presterilized gauze square approximately 11.5 × 11.5 cm. (*5*), saturated with 5% phenol. Remove each membrane aseptically and place it on the surface of peptone–casein agar in a sterile Petri dish (20 × 100 mm.). Incubate the 32 agar Petri dishes containing the membranes and the 32 side-arm flasks (*6*) at 32°. Observe the growth on the membranes after 24 and 48 hr., and examine the filtrates in the flask after 5 days' incubation. No growth of organisms in the filtrates proves complete retention of the organisms by the membranes and indicates their suitability. As shown by the membrane on the left in Fig. 2, growth on the plates should be confluent and contained on that part of the membrane inside the filtering area. Growth of the organisms on the edge of the membrane, as shown on the right in Fig. 2, indicates faulty technique and may produce growth in the filtrate. Side leakage can occur if the membrane is not perfectly sealed in the unit by the clamp. Therefore, extreme care should be taken when assembling the units to avoid leakage.

Evaluation of Results.—If no growth is detected in any of the 32 filtrates after 5 days and the growth of *S. marcescens* on the membranes is confluent, the batch of membranes is acceptable for sterility testing. If two or more filtrates show growth, the batch is rejected. However, if there is growth at the edge of a filter and the related broth exhibits growth, the test is judged invalid, and it is repeated in full. The results of tests judged invalid are not considered a part of the supplier's quality performance record.

If one filtrate shows growth, a repeat test is performed on 32 additional membranes. If no growth

TABLE I.—RESULTS OF ACCEPTANCE TEST ON CLASS 7 MEMBRANES[a]

Mfgr.	Batch	Filtrates—First Test	Filtrates—Second Test	Membranes—First Test	Membranes—Second Test
A	1	0	NA	Satisfac.	NA
	2	0	NA	Satisfac.	NA
	3	0	NA	Satisfac.	NA
B	1	0	NA	Satisfac.	NA
	2	1/32	0	Satisfac.	Satisfac.
	3	0	NA	Satisfac.	NA
C	1	0	NA	Satisfac.	NA
	2	0	NA	Satisfac.	NA
	3	0	NA	Satisfac.	NA

[a] 0, no growth; NA, not applicable; 1/32, one filtrate with growth out of 32 tested; satisfactory, confluent growth confined to the filtering area.

is detected in any of the additional 32 filtrates after 5 days at 32°, the batch of membranes is acceptable for sterility testing. If growth is detected in one or more of the filtrates, the batch is rejected.

Experimental.—In order to evaluate some of the commercially-produced class 7 membrane filters, membranes were obtained from three different manufacturers. An acceptance test, as described previously, was performed on three batches from each manufacturer. The manufacturers were identified as *A*, *B*, and *C* for the evaluation studies. It can be concluded from the results shown in Table I that all membranes tested were acceptable for sterility testing. A retest was necessary in only one out of nine acceptance tests.

DISCUSSION

Although class 7 (0.45-μ) and class 9 (0.22-μ) membranes are both used to sterilize liquids by filtration, the latter are always used with solutions containing sera, plasma, trypsin, or other enzymes where species of *Pseudomonas* of small size are known to occur. The class 7 filter, having larger pores, yields flow rates approximately 3 times those of the class 9 filters, but can only be used for sterile filtration where prior experience indicates that organisms smaller than 0.45 μ are not present in the solution to be filtered. For example, in the production of penicillinase (9) from *Bacillus cereus* ATCC 13061, it was found in this laboratory that the class 7 membrane was not adequate for sterilizing the enzyme. This membrane removed all of the *B. cereus* from the broth in which the enzyme was produced, but on several occasions the broth was also heavily contaminated with a small Gram-negative bacillus which the membrane did not filter out completely. However, in every case the class 9 membrane was able to retain all cells of this organism and yield a sterile penicillinase. The organism was identified as a species of *Pseudomonas* and was later used to develop an acceptance test for 0.22-μ filters. Its ability to pass through a class 7 is dependent on its small size (approximately 0.3 × 1.0 μ). It has been successfully used in the quality control of the class 9 membranes for over 1 year and has been transferred approximately 200 times with no increase in its size. Since it proved to be so useful in testing class 9 membranes, the organism was deposited with the American Type Culture Collection where it was given the accession number ATCC 19146.

The fact that class 7 membranes (0.45 μ) will not retain all microorganisms does not preclude their use in sterility testing. Investigational studies proved that the passage of these small *Pseudomonas* cells occurs only when the population size is relatively high. Therefore, the passage of a few cells is not significant, since the majority of the cells are retained on the membrane and their recovery in the sterility test is assured. For this reason, class 7 membranes, which provide a better flow rate than class 9 membranes, were selected for the antibiotic sterility tests.

As previously mentioned, class 9 membranes are used in this laboratory to sterilize penicillinase for use in testing insoluble penicillins, such as benzathine penicillin G. The sterile enzyme is aseptically added to sterile thioglycollate medium for use in the direct method sterility test. The class 9 membranes purchased for sterile filtration are tested by using the same sampling plan and the same equipment as that used in the acceptance test for class 7, except for changes in the organism and the procedure as described below.

ACCEPTANCE TEST PROCEDURE FOR CLASS 9 MEMBRANES

Maintain *Pseudomonas* sp. ATCC 19146 on U.S.P. peptone–casein agar. Transfer the organism to a conical flask containing 50 ml. of trypticase 2% (w/v) which contains 0.6% sodium citrate, and incubate the flask at 25° until the viable cell count reaches approximately 1,000,000 cells/ml. Filter 50 ml. of the broth suspension through a class 7 membrane into a sterile flask. Transfer the membrane to the surface of a sterile peptone–casein agar in a 20 × 100-mm. Petri dish. Incubate the Petri dish at 32° and observe the growth after 24 and 48 hr. Transfer three 1-ml. aliquots of the filtrate that has passed through the 0.45-μ membrane to each of three tubes containing 10 ml. of thioglycollate or any other suitable liquid nutrient medium. Filter the remaining portion of the filtrate through a class 9 membrane into a second sterile receiving flask. Incubate the flask for 5 days at 32°. Transfer the class 9 membrane to the surface of sterile agar in a Petri dish (20 × 100 mm). After 24–48 hr., the class 7 membrane should show confluent growth and after 48–72 hr., the class 9 membrane should show individual colonies of the test organism. The three tubes of thioglycollate medium should show growth. The filtrate that passed through the class 9 membrane should not show growth after 5 days' incubation at 32°. The evaluation of the results are the same as for the class 7 membranes except that the test organism must pass through the class 7 membrane and be retained by the class 9 membrane in each of the 32 tests performed.

SUMMARY

A microbiological method has been developed for performing an acceptance test for class 7 (0.45-μ) membrane filters, used in sterility testing, and class 9 (0.22-μ) membrane filters, used in sterile filtration. *S. marcescens* is used as the test organism for the

former and *Pseudomonas* sp. for the latter. The sampling plan of MIL-STD-105-D is used for the statistical evaluation of the membranes for acceptance or rejection.

Mannich Bases from 2-Phenylindolizines I

3-Alkyl-1-dialkylaminomethyl Derivatives

By WILLIAM B. HARRELL* and ROBERT F. DOERGE

In a search for new therapeutic agents, a series of Mannich derivatives of 3-methyl-2-phenylindolizine and 3-ethyl-2-phenylindolizine has been prepared. The mechanism by which 2,3-disubstituted indolizines participate in the Mannich reaction has been examined and alternate S_N1 and S_N2 routes have been proposed. 1-Diethylaminomethyl-3-methyl-2-phenylindolizine has been tested and found to have central nervous system depressant activity.

MANY PHYSIOLOGICALLY active compounds have the indole nucleus in their structure. The similarity between the indole and indolizine nuclei has prompted speculation that indolizine analogs of biologically important indoles could conceivably have potent physiological activity (1–3). It is this concept, coupled with the observation that only a few such investigations had been reported in this area, that encouraged the consideration of the indolizine nucleus for the present investigation.

Reports on the biological activity of indolizines are indeed very scarce in the literature. On subcutaneous injection 1-acetyl-3-amino-2-methylindolizine was shown to cause convulsions in frogs, mice, and rabbits (4). β-(1-Indolizinyl)-α-aminopropionic acid, the indolizine analog of the amino acid tryptophane, has been prepared (2) and shown to inhibit indole formation by an indole-accumulating mutant of *Salmonella typhimurium* (5). A series of arylindolizines was synthesized by Venturella for pharmacological testing (3, 6, 7), but to date no report on the activity of these compounds has appeared in the literature.

Having decided upon the indolizine structure, attention was focused on the various possibilities of chemical modification which might logically be expected to produce physiologically active compounds. Among the biologically active indoles, many are aminoalkyl derivatives such as serotonin, bufotenine, psilocin, reserpine, and lysergic acid diethylamide, all of which are known to have pronounced activity on the central nervous system. It was noted that in all of these compounds, the indole nitrogen and the extra-indole nitrogen are separated by four carbon atoms  , a spatial arrangement which might be a contributing factor in determining their activities. It was therefore reasoned that certain aminoalkylindolizines with the same carbon spread between the nitrogens might also possess activity on the central nervous system. After considering several possible chemical modifications, the Mannich reaction was chosen because the resulting dialkylaminomethyl substituent, when introduced at the C-1 position, would give the desired intramolecular spread. A comparison between bufotenine (I) and the Mannich bases (II) obtained by the reaction of 2,3-disubstituted indolizines with formaldehyde and dimethylamine illustrates this similarity.

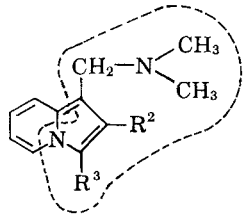
I



II

The purpose of this investigation was to synthesize several 1-substituted Mannich bases derived from selected 2-phenylindolizines to be evaluated for possible activity on the central nervous system. If interesting activity was found, a study of the relationship of chemical structure with activity would be conducted.

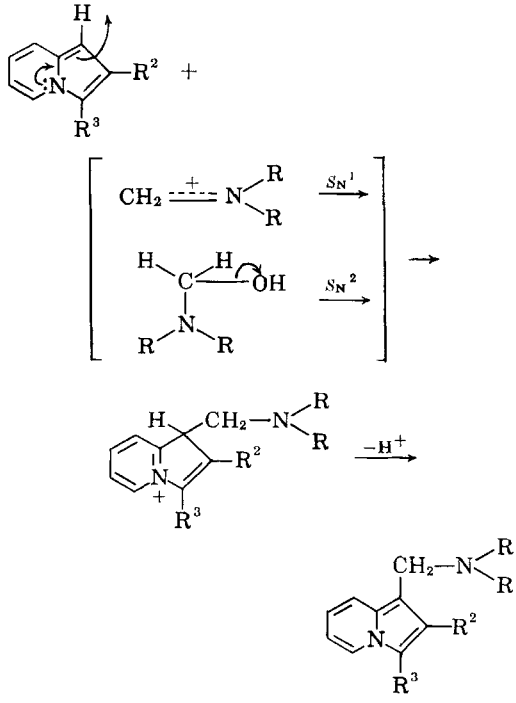
Preliminary pharmacological data were obtained for 1-diethylaminomethyl-3-ethyl-2-phenylindolizine (IV*b*). When injected in mice as a suspension in gum acacia, the compound exerted a depressant action on the central nervous system. The approximate LD_{50} was determined and found to be in the range of 70–100 mg./Kg. These compounds will be investigated more extensively and the results reported elsewhere.

DISCUSSION

The indolizines employed in this investigation were 3-methyl-2-phenylindolizine (III) and 3-ethyl-2-phenylindolizine (IV). These compounds were prepared by the Chichibabin synthesis (8) which involves condensing α-picoline with the appropriate phenacyl bromide and heating the resulting picolinium bromide in aqueous sodium bicarbonate.

There have been only two reports in the literature on the synthesis of Mannich bases from indolizines. Rossiter and Saxton obtained 2,3-dimethyl-1-dimethylaminomethylindolizine as an unstable oil using glacial acetic acid as the solvent (9). Carbon and Brehm (2), employing the same reaction conditions, prepared 3-acetyl-1-dimethylaminomethylindolizine. The present investigators, however, found that the acid conditions employed by these two groups gave undesirable results when applied to 2-phenylindolizines. Before proceeding further, it was considered advisable to examine more closely the mechanics of the Mannich reaction (10) with the hope that a set of reaction conditions could be devised that would be more favorable than those previously described in the literature.

The mechanism by which indolizines participate in the Mannich reaction has not been previously discussed in the literature, although several mechanisms have been proposed for the participation of ketones and other active hydrogen compounds (11–18). While most of the more prominent theories propose that the reaction results from a nucleophilic attack on a species of the type $(R_2N{=}CH_2)^+$ or $R_2N{-}CH_2OH$, the nature of the attacking nucleophile has not been clearly defined. According to Cummings and Shelton (14), two possibilities exist with ketones: attack by a carbanion of the type $R{-}\overset{O}{\overset{\|}{C}}{-}CH_2^-$, enhanced by running the reaction in basic medium, and attack by the enol form $R{-}\overset{:OH}{\overset{|}{C}}{=}CH_2$, which seems to be favored in acid medium. The present authors observed that ionization of indolizines in the presence of base is not likely to occur at the C-1 or C-3 position, the positions which are involved in the Mannich reaction, because of the high electron density at these positions (19, 20). It was also observed that, if such a carbanion should exist, it would be highly unstable due to the lack of resonance-stabilization. Since the enamine nature of indolizines has been observed (21) and because the similarity of enamines to enols is well established, the authors propose that indolizines participate in the Mannich reaction either by an S_N1 or S_N2 mechanism. (Scheme I.)



Scheme I

An important side reaction which can cause interference if conditions are not carefully controlled is the condensation of the indolizine with formaldehyde to form bis(indolizinyl)methanes. As a further means of control, the authors prepared bis(3-ethyl-2-phenyl-1-indolizinyl)methane (VI) and bis(3-methyl-2-phenyl-1-indolizinyl)methane (V) by reacting the corresponding indolizine with formalde-

hyde in the absence of a secondary amine. These are new compounds and the methods of synthesis are reported under *Experimental*. The compounds and their pertinent analytical data are given in Table I.

EXPERIMENTAL

All melting points were taken on a Thomas-Hoover capillary melting point apparatus and are uncorrected. Elemental analyses were provided by Weiler and Strauss Microanalytical Laboratory, Oxford, England. Preliminary pharmacological screening was performed by Dr. Robert Brummett, Department of Pharmacology, University of Oregon Medical School, Portland, Oreg.

Materials.—The preparation of 3 - methyl - 2 - phenylindolizine and 3-ethyl-2-phenylindolizine has been previously reported in the literature (22, 23).

Preparation of Mannich Bases.—The following general procedure was employed in the synthesis of these compounds. The formaldehyde (0.05 mole) and the secondary amine (0.05 mole) were combined and allowed to stand at room temperature for 15 min. The mixture was then added to a solution containing the indolizine (0.01 mole) dissolved in 30

ml. dioxane. The reaction flask was stoppered and allowed to stand at room temperature for 24 hr. In most instances the product crystallized on evaporation of the solvent under a stream of cold air accompanied by vigorous scratching with a glass rod. In cases where no crystallization occurred on evaporation, the residual oil was taken up in a minimum quantity of alcohol or acetone and placed in the freezing compartment of the refrigerator. The product crystallized after remaining in the refrigerator for periods ranging from 5 days to 3 weeks. The preparation of 3-ethyl-2-phenyl-1-pyrrolidinomethylindolizine is described in the following section and is typical of the experimental procedures employed.

3-Ethyl-2-phenyl-1-pyrrolidinomethylindolizine (IVc).—To 30 ml. *p*-dioxane was added 5.34 Gm. pyrrolidine (0.075 mole) and 6 ml. of 37% aqueous formaldehyde (0.075) mole and the resulting solution allowed to stand at room temperature for 15 min. To this mixture 3.3 Gm. 3-ethyl-2-phenylindolizine (0.015 mole) was added, and the flask was swirled until a clear solution was obtained. The reaction mixture was then set aside at room temperature for 24 hr. The clear solution containing the product was poured into an evaporating dish and cold air was blown across the surface to remove the solvent. Crystallization of the product occurred upon scratching the walls of the container with a glass rod during the evaporation process. The product was removed by filtration, recrystallized from ethanol, and yielded 3.5 Gm. (76%), m.p. 78–79°.

Bis(3 - methyl - 2 - phenyl - 1 - indolizinyl)methane (V).—Ten milliliters of 37% aqueous formaldehyde (0.125 mole) and 3 Gm. 3-methyl-2-phenylindolizine (0.015 mole) were dissolved in 30 ml. dioxane and the mixture was allowed to stand at room temperature for 48 hr. Crystallization of the product commenced after the first 24 hr. At the end of the 48-hr. period, 20 ml. of water was added in 5-ml. portions over a 2-hr. interval to complete crystallization. Rapid addition of the water tended to cause precipitation of an oil. The flask was allowed to stand an additional 24 hr. in the refrigerator. The crystalline product was then filtered and washed with 50% ethanol. The yield was 2.7 Gm. (87%), m.p. 162–163° dec. The product was recrystallized from hot acetone–water.

Anal.—Calcd. for $C_{31}H_{26}N_2$: C, 87.29; H, 6.14; N, 6.57. Found: C, 86.84; H, 6.14; N, 6.65.

Bis(3-ethyl-2-phenyl-1-indolizinyl)methane (VI).—Three milliliters of 37% aqueous formaldehyde (0.037 mole) and 1 Gm. 3-ethyl-2-phenylindolizine (0.0045 mole) were dissolved in 10 ml. of glacial acetic acid and the mixture was allowed to stand at room temperature for 48 hr. An equal volume of water was then added and the solution was made slightly basic with ammonium hydroxide. The gritty precipitate was filtered, washed with distilled water, and air dried. The product was dissolved in a minimum amount of hot ethyl acetate and, after cooling, was placed in the freezer compartment of the refrigerator. Crystallization occurred after 2 days in the refrigerator. The yield was 0.71 Gm. (70%), m.p. 106–107°.

Anal.—Calcd. for $C_{33}H_{30}N_2$: C, 87.19; H, 6.65; N, 6.16. Found: C, 87.29; H, 6.70; N, 6.20.

SUMMARY

Twelve new Mannich bases and two new bis-(indolizinyl)methanes derived from two indolizines have been synthesized. One of the compounds, 1 - diethylaminomethyl-3-methyl-2-phenylindolizine, has been tested and found to have CNS depressant activity.

Mechanism of Crystallization of Hydrocortisone by Ultrasonic Irradiation

By STANLEY L. HEM*, DONALD M. SKAUEN, and HAROLD M. BEAL

Reproducible, reduced crystal size distributions resulted from insonating a supersaturated solution, whose background particle count is controlled, at a fixed temperature. The crystallization temperature of the insonated and uninsonated samples was dependent on the number of heterogeneous nuclei present. The ultrasonic energy used in this study was in excess of the amount required to reduce the particle size. Ultrasound acted in the initial phase of crystallization. Ultrasound is believed to act by eroding, shattering, or in some way disrupting nuclei that form in a normal manner.

Ultrasound has been effective in reducing the particle size of a large number of substances. It is surprising to note the many theories which have been suggested to explain the action of ultrasound in producing small, uniform crystals. The simplest suggestion, that the reduction in particle size is due to agitation, has been rejected by several authors (1, 2).

Experimentation on supercooled Wood's metal (3, 4) led to the conclusion that friction between the solid and the melt is responsible for the reduction in grain size. It has been generalized that the increased crystallization rate of metals is due to an increased number of crystallization centers as a result of ultrasonic scattering of the microcrystals forming in the melt (5). Ultrasound may increase the number of crystal nuclei by shattering or eroding the nuclei that occur in a normal manner (6, 7). A number of reports have concluded that ultrasound accelerates the process of spontaneous crystallization and plays an essential role in the formation of nuclei (8). Brown (9) and Mazhul (10, 11) have stated that cavitation bubbles themselves act as nuclei for the crystals to initially form around.

The increased crystallization velocity of supercooled benzophenone was attributed to the localized removal of heat at the phase boundaries (12).

Evaporation from the surface of the cavitation bubble during cavity growth may cause sufficient cooling to initiate nucleation (13).

The large pressures which occur after the collapse of the cavitation cavity may cause a sufficient change in melting point to cause nucleation (14).

The effect of ultrasound was hypothesized to be analogous to an increase in the supersaturation of the solution (15).

Thus, it has been established that ultrasonic treatment during a phase change can improve the product in terms of an increased rate of crystallization and a smaller, more uniform size distribution. At present no clear understanding of the mechanism of ultrasonic crystallization is available.

EXPERIMENTAL

Cohn's (16) investigation of the factors involved in the ultrasonic crystallization of hydrocortisone was chosen as a foundation for this study. The conditions in terms of solvent, degree of supersaturation, and treatment temperature that were reported to yield the smallest particle size were used. Thus, a saturated solution of hydrocortisone in ethanol was prepared at 65°.

The solubility curve for hydrocortisone in ethanol has been reported by Cohn (17). The pertinent values for this study are given in Table I.

Table I.—Solubility of Hydrocortisone in Ethanol

Temp., °C.	Concn., mg./ml.
65	63.1
55	42.3
50	36.2
45	31.5
40	25.4
35	21.5
30	17.7
25	15.4

The solution was filtered while at 65° through either a 0.45-μ membrane filter or a Whatman No. 42 filter paper which was also maintained at 65°. A 10-ml. sample of the saturated solution was transferred by a warm pipet to the treatment vessel and covered. The solution was permitted to cool from 65° to the bath temperature.

The Sonifier, model S-125,[1] provided the ultrasonic energy. It is a high-intensity piezoelectric type source with a frequency of 20 Kc./sec.

The geometry of the treatment vessel and the Sonifier tip was the same as reported by Cohn (16). The Sonifier tip was positioned 2.3 mm. from

the bottom of the 20-ml. beaker. The Sonifier, model S-125, has a fully transistorized power supply; no warm-up time was required as power was available immediately. This enabled treatment times of 5 sec. to be employed. Weissler's (18) method for measuring relative cavitation intensity confirmed that this geometry provided maximum ultrasonic effects.

Weissler's (18) method for measuring relative cavitation intensity was used to calibrate the Sonifier to permit operation at several intensities. The method is based on the sonochemical liberation of chlorine from carbon tetrachloride dissolved in water. *o*-Tolidine was reacted with the liberated chlorine and yielded a yellow color suitable for colorimetry. The absorbance at 436 mμ wavelength is linear with respect to the chlorine concentration. Various ultrasonic intensities were defined by plotting the absorbance against time. The slope of the straight line was used to designate a particular intensity. Calibration curves for the 3 cavitation levels used in this study are given in Fig. 1.

Weissler's (18) method requires measurement in an aqueous system. The addition of small amounts of such chemicals as petroleum ether, ethyl ether, and ethanol completely block the sonochemical decomposition of carbon tetrachloride. It has been suggested that these substances have a protective action on the solution. They have high vapor pressures and are thought to penetrate the cavitation bubble and interfere with the electronic effects associated with cavitation (19). It has also been suggested that the presence of organic liquids reduces the thermal conductivity of the gas-filled bubbles. This may reduce the thermal reactions occurring in the cavity. The possibility exists that the presence of these compounds causes a change in the decomposition products of carbon tetrachloride (20).

The crystallizations in this study were carried out in ethanol. Cavitation depends upon the surface tension, viscosity, density, vapor pressure, cohesive strength, and heat transfer of the liquid (21). At a fixed setting the amount of cavitation in an aqueous solution will differ from the amount in an alcoholic solution. The linear nature of the absorbance *versus* time plot would indicate a fairly simple, direct relationship among these solvent variables. Thus, it can be assumed that the relative cavitation levels in an aqueous solution will be directly related to the relative cavitation levels in an alcoholic solution.

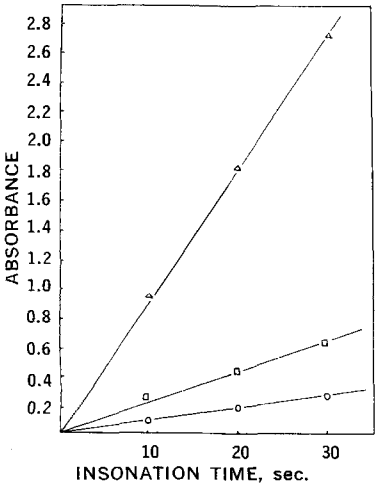

Fig. 1.—Calibration curves for measuring relative cavitation intensity. Key: △, 120 v., setting 8; □, 120 v., setting 2; ○, 100 v., setting 2.

The measurement of cavitation has been one of the major problems in ultrasonic research. There is no other satisfactory method available for measuring cavitation. Previous to Weissler's method it was impossible to accurately calibrate an instrument or monitor its day to day operation. In view of these conditions it was felt that this assumption was justified.

At a line voltage of 120 v. and a power level setting of 8 (maximum for the Sonifier), Weissler's (18) method gave a slope of 0.090. A line voltage of 120 v. and a power level setting of 2 gave a slope of 0.021. A slope of 0.009 was obtained at a line voltage of 100 v. and a power level setting of 2. These calibration curves are shown in Fig. 1.

These intensity levels are in the approximate ratio of 10:2:1. Although the cavitation levels were different in ethanol, it was assumed that these settings would also give ultrasonic intensities in ethanolic solutions in the ratio of 10:2:1.

The collection of a sample of crystals for evaluation was performed by vacuum filtration using a 0.20-μ membrane filter. Only a small sample of crystals was required for size analysis by the Coulter counter.[2] It was possible to obtain the necessary sample by quickly removing the mother liquor from 1 ml. or less of the crystallization suspension.

Particle size distributions were determined using a Coulter counter with a 70-μ aperture tube. It was found that an aqueous electrolyte of 0.9% sodium chloride saturated with hydrocortisone was suitable. The crystal sample was dispersed with 1 drop of 2% methylcellulose 400[3] prior to analysis. Enough sample was added to the counting vessel to give between 10,000 and 20,000 counts per 500 μl.

The particle size distributions were found to follow the log-normal distribution law. The geometric mean, $\overline{M}g$, the most appropriate measure of central tendency for log-normal systems, and the geometric standard deviation, σg, were used to characterize the results of the crystallizations. As these values are based on the measurement of 10,000 to 20,000 individual crystals, they are the best estimates available of the population mean and the population standard deviation for each case (22–24).

Two series of experiments were performed. In the first a saturated solution was prepared at 65°. The solution was filtered through a 0.45-μ membrane filter or Whatman No. 42 filter paper and transferred to the treatment vessel. A series was also performed on the unfiltered supernatant. Preparation of the solution, then filtering a portion through a membrane filter or filter paper was done to vary the number of heterogeneous particles present in the saturated solution. This was confirmed by the Coulter counter data in Table III.

[2] Coulter Electronics, Hialeah, Fla.
[3] Marketed as Methocel 400 by the Dow Chemical Co., Midland, Mich.

The 65° saturated solution was allowed to stand undisturbed for 2 hr., and then 10 ml. of supernatant was transferred by pipet to the treatment vessel. The Sonifier was positioned, and the solution was covered. A number of treatment bath temperatures were used varying from 55 to 30° in 5° intervals. The solution was examined 60 min. after reaching thermal equilibrium. A visual observation for the presence or absence of crystals was performed. This procedure was repeated with the application of ultrasound to the clear solution after thermal equilibrium in the treatment bath had been reached. Ultrasonic energy was applied for 1 min. at relative cavitation levels of 10 and 1. Each solution was visually examined after 1 hr. for the presence of crystals. These results are contained in Table II.

In order to evaluate the number of particles in the saturated solution before treatment, a particle count was run with the Coulter counter. Because the Coulter counter requires a conductive solution it was impossible to perform a background count on the alcoholic solutions. An aqueous 0.9% sodium chloride solution was saturated with hydrocortisone at room temperature. The clear supernatant was either taken as the sample or the solution was filtered through 0.45-μ membrane filter or Whatman No. 42 filter paper. The particle size distribution of each of these solutions was then determined by Coulter counter analysis. They are listed in Table III. The results were taken as approximations of the number of potential heterogeneous nuclei present in the crystallization solution.

Control: $\bar{M}g$ 9.2 μ, σg 2.7

The second experiment examined the effect of ultrasonic intensity on the crystal size distributions. A saturated solution was prepared at 65°, filtered through a 0.45-μ membrane filter, and brought to thermal equilibrium in either a 25 or 35° water bath. Thirty-five degrees was chosen as one treatment temperature because this was the highest temperature at which crystals developed after filtration through a 0.45-μ membrane filter. The solution was clear to the eye at this point. It was then treated with ultrasound at a relative cavitation intensity of either 10, 2, or 1 for 60, 15, or 5 sec. The crystals were collected and their size distributions determined with the Coulter counter. The crystal size distributions are shown in Tables IV and V.

RESULTS AND DISCUSSION

The results of the crystallizations from filtered solutions are given in Table II. Table III lists the Coulter counter analysis of these solutions. The number of particles in the solution prior to treatment represents contamination by foreign material contained in either the hydrocortisone or the ethanol, or originating from the glassware. Undissolved hydrocortisone may also contribute to the total particle count.

It was observed that the crystallization temperature of the untreated samples decreased as the number of particles in the saturated solution was reduced. This behavior is in agreement with the heterogeneous nucleation theory.

Heterogeneous nucleation refers to nucleation which occurs on particles which are present in the solution. Filtration would remove some of these potential nucleation sites and cause a reduction in the temperature at which crystals appear. A similar observation has been reported by Melia and Moffitt (25).

Heterogeneous nucleation can be better understood by comparing it with homogeneous nucleation. In supersaturated solutions there is continual formation and dissolution of molecular clusters of

solute (26). The Becker-Doring theory (26, 27) and the Christiansen-Nielsen theory (27) view this as a series of bimolecular collisions. These clusters may continue to grow by collision or may shrink due to the loss of individual molecules. When the cluster reaches a point where the tendency to dissociate is balanced by the tendency to grow (in order to decrease surface free energy) it is termed a critical nucleus. The size of the critical cluster is unknown but it is thought to be several hundred molecules for most solids (27, 28). The tendency to grow is dominant once a cluster is larger than the critical nucleus. Nucleation followed by crystal growth then proceeds.

The energy barrier to nucleation may be reduced by the catalytic effect of foreign particles in the solution. The presence of these substrates for the critical nucleus permit nucleation to occur more readily (26, 29).

The activation energy of heterogeneous nucleation, $\Delta G_{het.}$, can be related to the activation energy of homogeneous nucleation, $\Delta G_{hom.}$ An equation (26) has been derived for the nucleation of vapor drops on surfaces in terms of the contact angle, θ.

$$\Delta G_{het.} = \frac{\Delta G_{hom.}\,(2 + \cos\theta)(1 - \cos\theta)^2}{4}$$

It is seen from the equation that $\Delta G_{het.}$ will always be smaller than $\Delta G_{hom.}$ If heterogeneous nucleation is possible it will cause crystallization to occur more readily than homogeneous nucleation. In most cases crystallization will be complete before homogeneous mechanisms have begun.

It was observed that ultrasound did not cause crystallization to occur at any temperature above the crystallization temperature of the untreated samples. This temperature was dependent on the number of particles present in the solution prior to insonation. The behavior of the insonated samples is in agreement with the heterogeneous nucleation theory. There is no indication that ultrasound initiates crystallization. It only affected solutions at or below their normal crystallization temperatures.

The particle size distributions obtained at 35° with varying cavitation intensities and treatment times are given in Table IV. The results of similar experiments at 25° are given in Table V. These results were obtained by Coulter counter analysis. This instrument proved very suitable for characterizing particle size distributions. A number of problems were encountered in calibrating the instrument, finding a suitable electrolyte, obtaining complete dispersion of the crystal cake, and developing an adequate technique. However, the advantages in terms of number of particles counted, reproducibility, and speed would recommend this technique for future particle size studies.

The particle size distributions show virtually no difference for treatment times ranging from 5 to 60 sec. Cohn (17) reported that treatment times of 1 to 15 min. showed no effect on particle size. This indicates that ultrasound acts at an early stage in the crystallization process, and that continued insonation has no effect.

Little change was noted in the particle size distribution when varying relative cavitation intensities were used. An excess of energy was available for this application.

Based on this study the following mechanism of ultrasonic crystallization is visualized. A cavitation bubble collapses with great force in the proximity of a nucleus or a growing crystallite. The high pressure generated is sufficient to erode, shatter, or in some way disrupt the small particle or crystallite. This results in the formation of new nuclei. These nuclei may grow into crystals or may be further dispersed by cavitation. The net effect is a great multiplication in the number of nuclei in the supersaturated solution. This results in reduced crystal size and an increased rate of crystallization. Ultrasound does not initiate nuclei but acts on nuclei which normally appear in the solution.

SUMMARY AND CONCLUSIONS

1. Crystal size was reduced by the application of ultrasound to a supersaturated solution of hydrocortisone in ethanol.

2. Reproducible distributions resulted from insonating a supersaturated solution, whose background particle count is controlled, at a fixed temperature.

3. The crystallization temperature of the supersaturated solution was observed to depend on the number of heterogeneous nuclei present.

4. Ultrasound did not initiate crystallization above the crystallization temperature of the untreated supersaturated solution.

5. Ultrasound acts in the initial phase of crystallization. The size distributions obtained after 5-sec. insonation compared favorably with those obtained after 60-sec. insonation.

6. The ultrasonic energy used in this study was in excess of the amount required to reduce the particle size.

7. Ultrasound is believed to act by eroding, shattering, or in some way disrupting nuclei that form in a normal manner. This effect increased the number of crystal nuclei and resulted in reduced particle size.

8. The Coulter counter was adapted for measuring the hydrocortisone crystals. The advantages of this technique in terms of number of particles counted, reproducibility, and speed would recommend it for future particle size studies.

Variability of Uniformity of Weight Test as an Indicator of the Amount of Active Ingredient in Tablets

By J. M. AIRTH, D. F. BRAY, and C. RADECKA

Fifty-four samples, embracing five drugs sold as compressed tablets, were obtained. Individual tablet weights were determined and individual chemical assays were carried out on 10 tablets from each sample. There was little or no relationship between the amount of active ingredient and tablet weight for promazine tablets in which the active ingredient formed a small proportion (15–23 per cent) of tablet weight, but this relationship was high for tolbutamide tablets in which the active ingredient formed a large proportion (73–90 per cent) of tablet weight. This observation suggests that the uniformity of weight test may sometimes be usefully employed instead of individual tablet chemical assays when the proportion of active ingredient in the tablets is high and that the emphasis in developing direct measures of content uniformity should be placed on preparations containing small proportions of active ingredient. The present data do not confirm the observation of Moskalyk *et al.* (1961) that "Greater deviations 'in active ingredient' were found to occur in lighter weight tablets" within preparations.

THE UNIFORMITY of weight test has been included in the "British Pharmacopoeia," the "United States Pharmacopeia," and the "National Formulary" for many years. Its purpose has been to provide an indication of the amount of active ingredient in each tablet. The validity of such a test depends, of course, on the assumption that the amount of active ingredient is directly proportional to the weight of the tablet. While various aspects of the uniformity of weight test have been studied previously (see for example *References 1–3*), general recognition of its inadequacy in certain situations has only recently been recognized. The 17th revision of the U.S.P. and the 12th edition of the N.F. included for the first time a content uniformity test for certain tablets. While determinations of the amount of active ingredient in individual tablets will be necessary for some preparations, there seems little point in taking these more costly observations in cases where the uniformity of weight test gives comparable results. It is the purpose of this paper to present some data which suggest that the uniformity of weight test may be satisfactory for some tablet preparations, but inadequate for others.

Received July 18, 1966, from the Research Laboratories, Food and Drug Directorate, National Health and Welfare Department, Ottawa, Ontario, Canada.

MATERIALS AND METHODS

Samples of five drugs sold in compressed tablet form were procured from Canadian retail outlets in bottles of 100 tablets. A total of 54 samples from 36 different companies were obtained. In general, not more than one sample of each drug was obtained from each company, and in fact 53 of the possible 180 company-compound combinations are represented.

MATERIALS AND METHODS

Samples of five drugs sold in compressed tablet form were procured from Canadian retail outlets in bottles of 100 tablets. A total of 54 samples from 36 different companies were obtained. In general, not more than one sample of each drug was obtained from each company, and in fact 53 of the possible 180 company-compound combinations are represented.

TABLE I.—METHODS OF ASSAY

Drug	Samples, No.	S.D., % Recovery	Analytical Method
Promazine hydrochloride	5	0.37	Milne and Chatten (4)
Isoniazid	7	0.60	Scott (5)
Phenylbutazone	13	0.60	B.P. (6) with refinement to permit assay of 100 mg. of drug
Phenobarbital	7	0.60	Chatten (7) and/o Mattson (8)
Tolbutamide	22	0.32	U.S.P. (9)

Ten tablets were taken from each bottle for chemical assay. Two methods of selecting the tablets for assay were used. In 18 samples, 10 tablets were chosen in an essentially random manner. In the remaining 36 samples, 100 tablets were weighed and the 3 lightest, the 4 medium, and the 3 heaviest were selected for analysis.

The 10 selected tablets from each sample were individually weighed to the nearest 0.1 mg. and individually chemically assayed by the appropriate method indicated in Table I.

A single determination was carried out on each tablet by one of the authors (Radecka). Experience in this laboratory has shown that the assay error is uniformly small for all methods reported here. Values are given in Table I as standard deviations of per cent recovery.

RESULTS AND DISCUSSION

Linear regression techniques were used to study the relationship between amount of active ingredient and tablet weight. The slope (b) of the least squares regression line fitted to the data from each sample was compared with the one which indicated no relationship between active ingredient and tablet weight (β_0), and with the one which assumed the amount of active ingredient to be directly proportional to tablet weight (β_1). The former theoretical line passes through the bivariate mean of the sample data and has slope (β_0) equal zero, while the latter passes through the origin, and has slope $(\beta_1) = \frac{\Sigma xy}{\Sigma x^2}$ which in these data is extremely close to $\bar{y}/\bar{x}$, where y is the amount of active ingredient in a tablet in mg., and x is the tablet weight in mg.

A better estimate of β_1 could be obtained if the tablets had been procured directly from the manufacturer along with data indicating the actual amounts of active ingredient and other materials used. The authors have assumed that such data would give estimates of β_1 which would be essentially similar to those reported here.

It follows, therefore, that any given sample can be placed into one of four categories on the basis of the calculated value of the regression (b) of active ingredient on tablet weight ($P = .05$):

I, not significantly different from either β_0 or β_1.
II, significantly different from β_1, but not β_0.
III, significantly different from both β_1 and β_0.
IV, significantly different from β_0, but not β_1.

Both category I and category II imply the absence of a slope, and hence indicate no useful relationship between active ingredient and tablet weight. In contrast, both categories III and IV indicate the presence of a slope, in the latter case not demonstrably different from β_1, and hence suggest a situation in which the uniformity of weight test may possibly be used as an indicator of content uniformity. A typical example of a sample falling into each category is illustrated in Fig. 1.

Table II gives the number of samples in each category by drug and range of per cent active ingredient. The samples have been divided into a low group and a high group on the basis of per cent active ingredient, with the division occurring at 33%. This classification is an arbitrary one and is simply that suggested by the observed frequencies. Table II suggests that a relationship exists between the proportion of active ingredient and the category of response. Promazine tablets, having the smallest proportion of active ingredient, gave only category I and II responses, suggesting that the uniformity of weight test would be unsatisfactory as an indicator of content uniformity. Tolbutamide tablets, having the highest proportion of active ingredient, gave only category III and IV responses, suggesting that the uniformity of weight test may be usefully employed in such situations.

Since the drugs which gave the extreme responses were also those at the extremes in per cent active ingredient, it is impossible to state whether the observed relationship with category is a property of per cent active ingredient or a property of the drug examined. Only two drugs, phenylbutazone and

High	6	27

phenobarbital, gave sufficiently varied responses and were represented over a sufficiently wide range of per cent active ingredient to give an indication of the effect of per cent active ingredient free from the effect of drug. Table II illustrates that the results of this examination are inconclusive.

The summary given in Table III illustrates the apparent relationship between per cent active ingredient and category. While some caution is needed in interpreting this table due to the partial confounding of drug with per cent active ingredient described in the preceding paragraph, it may be helpful to note that the interaction chi-square is significant at $P = 0.01$.

The data presented here were examined in the light of the observation of Moskalyk *et al.* (1) that, "Greater deviations," in active ingredient, "were found to occur in lighter weight tablets," within preparations. The variance about the line with slope β_1 was computed for the three largest and the three smallest tablets for all 54 samples. The ratio

$$\frac{\text{variance about the line with slope } \beta_1 \text{ of 3 largest tablets}}{\text{variance about the line with slope } \beta_1 \text{ of 3 smallest tablets}}$$

was formed for each sample. Values of the ratio less than 1 support Moskalyk's statement while those greater than 1 do not. In fact, 28 ratios were less than 1, and 26 were greater. This result is not different from the 1:1 ratio which is expected on the basis of no difference between the two variances. At one point in the paper of Moskalyk *et al.* the observation was restricted to "less uniformly mixed brands," these being the ones with large over-all variation about the line having slope β_1. If this hypothesis were true, the ratio would be expected to be small when the variance about the line for all 10 tablets is large, and tend toward 1 when the variance is small. No relationship between variance and ratio is apparent in these data (Fig. 2).

Since the preceding discussion is based on a model assuming that all points lie about the line passing through the origin and since this is not the best fitting line for all 54 samples, the same techniques

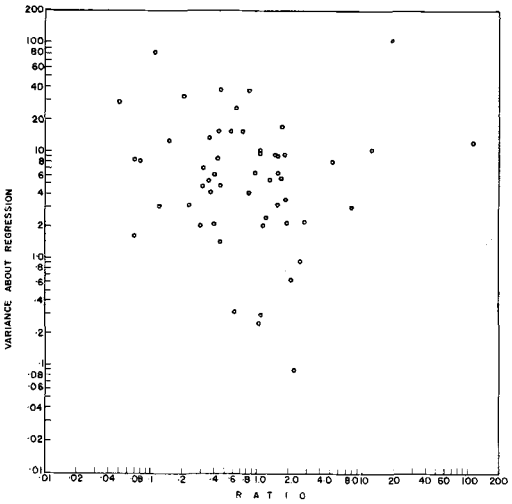

Fig. 2.—Lack of a relationship between variance about regression and ratio:

$$\frac{\text{variance about regression of larger tablets}}{\text{variance about regression of smaller tablets}}$$

were applied to the variation about the least squares line without restriction, *i.e.*, having slope b. A 31:23 ratio of ratios was obtained and the plot was similar to Fig. 2. Not all samples gave exactly similar results, but the conclusions are not different.

The present study fails to confirm the observation of Moskalyk *et al.* that "Greater deviations," in active ingredient," were found to occur in lighter weight tablets." A reason for the apparent contradiction may lie in the fact that no statistical tests were applied to the data bearing on this point in their paper.

Antimalarial Agents IX

3-Alkylquinolones as Potential Repository Drugs

By J. H. BURCKHALTER and DOUGLAS G. MIKOLASEK

As a possible answer to the need for antimalarials with more prolonged activity as well as for drug resistant malaria, several compounds related structurally to endochin (II) have been synthesized. They failed to pass preliminary pharmacological requirements.

ALTHOUGH the 4-aminoquinoline antimalarial agents, chloroquine and amodiaquine, are generally effective suppressive agents in areas of endemic malaria, they must be readministered every few weeks to maintain therapeutic effectiveness (1). An objective of the present study is the synthesis of certain substituted quinolines which might show prolonged antimalarial activity. Should such agents be found, it is hoped that prolonged activity might also contribute effectiveness against the recent serious threat posed by resistant falciparum malaria (2).

DISCUSSION

Compound I (SN-10,275) (3) once gave promise of possessing prolonged activity because 1 to 5% of the drug was still present in the plasma as long as 3 months following the last dose (4). However, photosensitivity manifest by severe itching prohibits administration to humans.

V

Endochin (II) (SN-13,421) has shown prophylactic activity against *Plasmodium cathemerium* in the canary, *P. gallinaceium* in the chick, and *P. lophurae* in the turkey (5). In view of the lipophilic alkyl grouping in position 3 of the quinoline nucleus, it was believed that endochin or its variants might be held in the tissues and gradually released to contribute prolonged antimalarial activity (6). Such structures as III*a* and IV were proposed since they contain structural features of both endochin and I. Particularly, a substituent at the 2 position would not allow the deactivating 2-hydroxylation which occurs upon administration of quinine (7). Since quinoline antimalarials containing a basic side chain at position 4 generally possess greater potency than the parent compound, structure V was desired for comparative biological evaluation with types III and IV.

Compounds of type III were synthesized by the Conrad-Limpach method (8) as outlined in Scheme I.

Ethyl α-cyclopentylacetoacetate (VI) was prepared from bromocyclopentane and ethyl acetoacetate according to the method of Rydon (9). Two methods were employed for the formation of the anilinocrotonates (VII). It was desirable to use conditions that were as mild as possible to avoid any formation of an anilide (IX) which could result at higher temperatures through a Knorr-type condensation (10). In method *A*, a *m*-substituted aniline and ethyl α-cyclopentylacetoacetate (VI)

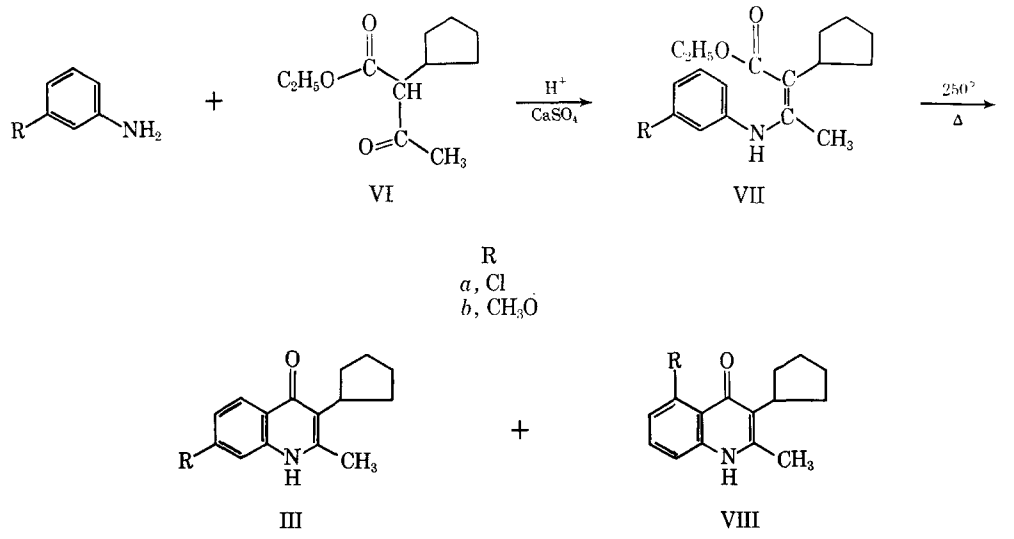
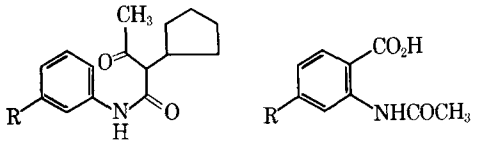


Scheme I



IX X

were heated in ethanol with an excess of anhydrous calcium sulfate and a catalytic amount of the appropriate aniline hydrochloride, according to an early procedure of Hauser and Reynolds (11). Anil formation has been shown to be acid catalyzed (12).

The second method (method *B*) involved the removal of water by azeotropic distillation and gave an increase in yield without apparent adverse reactions (13).

With the exception of ethyl β-(*m*-chloroanilino)-α-cyclopentylcrotonate, the anils were cyclized directly after removal of excess starting materials when it was found that ring closure occurred during attempted distillation. Cyclizations were carried out by addition of the anilinocrotonates (VII) to a refluxing mixture of diphenyl ether and biphenyl, according to the procedure of Hauser and Reynolds (14).

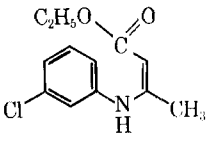
Infrared spectra of the products determined in potassium bromide disks show that the 7-substituted-3-cyclopentyl-2-methyl-4-quinolinols exist in the quinolone (III) form. Absorption peaks appear at 3330 cm.$^{-1}$ characteristic of NH stretching and at 1637 cm.$^{-1}$ characteristic of the lactam carbonyl stretching frequency (15).

A major difficulty with the Conrad-Limpach synthesis, as well as with the Skraup synthesis, is the formation of mixtures of 5- and 7-substituted quinolines when *m*-substituted anilines are used (16). Fortunately, only 3-cyclopentyl-7-methoxy-2-methyl-4-quinolone (III*b*) was isolated when ethyl α - cyclopentyl - β - *m* - methoxyanilinocrotonate (VII*b*) was cyclized. However, in the case of the reaction as applied to *m*-chloroaniline a small amount of solid, m.p. 274–276°, was isolated from the filtrate after removal of 7-chloro-3-cyclopentyl-2-methyl-4-quinolone (III*a*); it is undoubtedly the 5-chloro isomer (VIII). A comparison of its infrared spectrum with that of the 7-chloro isomer (III*a*) showed the two spectra to be very similar except in the region characteristic of aromatic substitution. The spectrum of the lower melting 5-chloro isomer (VIII) contained a broad double peak at 790–810 cm.$^{-1}$ characteristic of three adjacent free hydrogens, while this peak was missing from the spectrum of the 7-chloro isomer (17).

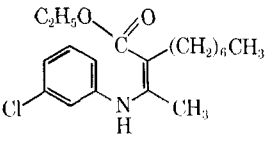
The structures of the 7-substituted quinolones (III*a* and *b*) were proved by oxidation to the appropriate *N*-acetyl-4-substituted anthranilic acids (X*a* and *b*) with alkaline potassium permanganate in the manner of Elderfield and Wright (18). 3-Cyclopentyl-2-methyl-7-methoxy-4-quinolone (III*b*) gave on oxidation *N*-acetyl-4-methoxyanthranilic acid (X*b*), m.p. 197–199°, corresponding to that reported by Friedlander, Bruckner, and Deutsch (19). The melting point of the isomeric *N*-acetyl-6-methoxyanthranilic acid is 176° (19).

Inasmuch as the melting points of the *N*-acetyl derivatives of both 4-chloroanthranilic acid and 6-chloroanthranilic acid are nearly identical (214 and 215°), it was necessary to hydrolyze the amide (X*a*) to the free base. The melting point of the 4-chloroanthranilic acid thus obtained (m.p. 235–238° dec.) corresponded to that reported by Cohn (20). He also reported the melting point of 6-chloroanthranilic acid to be 146–147° dec. (21).

The 7-chloro analog of endochin, 7-chloro-3-heptyl-2-methyl-4-quinolone (IV), was synthesized according to the general procedure of Leonard, Herbrandson, and Van Heynigen (22). The condensation of *m*-chloroaniline and ethyl acetoacetate proceeded smoothly to give ethyl β-*m*-chloro-anilinocrotonate (XI) in 81% yield. XI was alkylated with iodoheptane using sodium hydride in xylene



XI



XII

as the condensing agent. After removal of the solvent and excess starting materials under vacuum, the crude anil (XII) was added directly to a refluxing mixture of diphenyl ether and biphenyl. The yield of 7-chloro-3-heptyl-2-methyl-4-quinolone (IV) was disappointing; only 9% yield based on *m*-anisidine and ethyl acetoacetate was obtained. I.R. suggested a 7-chloro rather than a 5-chloro substituent.

In an attempt to study the effect of a basic side chain upon the antimalarial activity of compounds of the endochin type, it was decided to attach the 4-amino-α-diethylamino-*o*-cresol side chain to 7-chloro - 3 - cyclopentyl - 2 - methyl - 4 - quinolone (III*a*). Treatment of III*a* in methylene chloride with phosphoryl chloride gave 3-cyclopentyl-4,7-dichloro-2-methylquinoline in high yield. This intermediate was condensed with 4-amino-α-diethylamino-*o*-cresol dihydrochloride in the manner of Burckhalter and co-workers (23). 4-(7-Chloro-3-cyclopentyl - 2 - methyl - 4 - quinolylamino) - α-diethylamino-*o*-cresol dihydrochloride (V) was obtained in 54% yield.

PHARMACOLOGICAL RESULTS

Compounds III*a*, III*b*, IV, and V were evaluated as antimalarial agents by Dr. Paul E. Thompson, Research Laboratories, Parke, Davis and Co., Ann Arbor, Mich. III*a* and III*b* were examined for suppressive activity against *P. lophurae* in chicks, according to the method of Thompson (24). Both substances, fed in diet concentrations of 0.05 and 0.2%, were found to be inactive.

IV and V dihydrochloride were tested by Thompson against *P. berghei* in mice by subcutaneous injection. The former in a single subcutaneous dose of 400 mg./Kg. and the latter in twice daily doses of 5 mg./Kg. for 4 days failed to prevent the development of malarial infections. Since quinine is active at 25 mg./Kg., V is less than 5 times as active as quinine.

None of the compounds appear to offer promise as repository agents.

EXPERIMENTAL

Ethyl β - m - Chloroanilino - α - cyclopentylcrotonate (VII*a*).—*Method A.*—A modification of the general procedure of Hauser and Reynolds was used (11). To a mixture of 12.8 Gm. (0.1 mole) of *m*-chloroaniline and 18.2 Gm. (0.1 mole) of ethyl α - cyclopentylacetoacetate (9) in 20 ml. of absolute ethanol, 27 Gm. of anhydrous calcium sulfate and a catalytic amount (12) (0.01 Gm.) of *m*-chloroaniline hydrochloride were added. The mixture was stirred and heated for 4 hr. at 70–80°. The calcium sulfate was removed by filtration and the filtrate was concentrated and distilled under vacuum, giving 15 Gm. (55% yield) of the anilinocrotonate (VII*a*), b.p. 137° (0.2 mm.).

Anal.—Calcd. for $C_{17}H_{22}ClNO_2$: C, 66.33; H, 7.20. Found: C, 66.11; H, 7.29.

Method B.—The improved method of Hauser and Reynolds was employed (13). A mixture of 0.1 mole of *m*-chloroaniline, and 0.1 mole of ethyl α-cyclopentylacetoacetate (9) and 50 ml. of benzene was placed in a flask fitted with a Dean-Stark water separator and condenser. After addition of 0.5 ml. of acetic acid, the mixture was heated to reflux until water no longer separated. After 72 hr., 1.2 ml. of water had collected. The mixture was concentrated and excess *m*-chloroaniline and ester were distilled under vacuum, giving 22 Gm. (72% yield) of crude product. The VII*a* was pure enough to use in the next step.

7 - Chloro - 3 - cyclopentyl - 2 - methyl - 4 - quinolone (III*a*).—A solution of 15 Gm. (0.049 mole of ethyl β - *m* - chloroanilino - α - cyclopentylcrotonate (VII*a*) in 30 ml. of diphenyl ether was added dropwise to 150 ml. of a refluxing mixture of diphenyl ether and biphenyl, according to the procedure of Hauser and Reynolds (14). After the mixture was cooled, the gray solid which separated was collected on a filter, washed with petroleum ether (60–70°), and dried to yield 7 Gm. of crude III*a*, m.p. 334–336°. Recrystallization from dilute alcohol gave 5 Gm. (39% yield) of III*a*, m.p. 362–365° dec. $\nu_{max.}^{KBr}$ in cm.$^{-1}$ 3300 (NH), 1639 (lactam C=O), 780 (2-adj. free H's).

Anal.—Calcd. for $C_{15}H_{16}ClNO$: C, 68.83; H, 6.16. Found: C, 68.79; H, 6.28.

The filtrate from the reaction just described was diluted with 300 ml. of petroleum ether (60–70°) and the solid which separated was collected on a filter. After recrystallization from dilute alcohol, 1.3 Gm. of a white solid (VIII) was obtained, m.p. 276–278° corrected. Infrared: $\nu_{max.}^{KBr}$ in cm.$^{-1}$, 3300 (NH), 1637 (lactam C=O), 788, 812 (3-adj. free H's).

Anal.—Calcd. for $C_{15}H_{16}ClNO$: C, 68.83; H, 6.16. Found: C, 69.03; H, 6.21.

Proof of Structure III*a*: Its Oxidation to N-Acetyl-4-chloroanthranilic Acid (X*a*).—A suspension of 6 Gm. (0.023 mole) of III*a* in 1500 ml. of water made alkaline with 2.5 Gm. of potassium hydroxide was oxidized with 40 Gm. of potassium permanganate according to the procedure of Elderfield and Wright (18). After acidification of the concentrate with concentrated hydrochloric acid, 2 Gm. of *N*-acetyl-4-chloroanthranilic acid (X*a*) was obtained, m.p. 213.5–215.5° corrected. [Lit. (20) m.p. 215°.]

Hydrolysis of the amide (X*a*) in 10% hydrochloric acid, followed by neutralization with sodium bicarbonate, gave 0.2 Gm. of 4-chloroanthranilic acid, m.p. 234.5–237.5° corrected. [Lit. (20) m.p 235°.]

3 - Cyclopentyl - 2 - methyl - 7 - methoxy - 4-quinolone (III*b*).—A mixture of 12.3 Gm. (0.1 mole) of *m*-anisidine and 18.2 Gm. (0.1 mole) of ethyl α-cyclopentylacetoacetate (9) was condensed according to the method of Hauser and Reynolds (11). After distillation under vacuum, 14.5 Gm. (47% yield) of ethyl α-cyclopentyl-β-*m*-methoxyanilinocrotonate (VII*b*) was obtained, b.p. 150° (0.4 mm.), n_D^{27} 1.5252.

A solution of 14 Gm. (0.046 mole) of the foregoing anilinocrotonate (VII*b*) in 30 ml. of diphenyl ether was added dropwise to 250 ml. of a refluxing

mixture of diphenyl ether and biphenyl. The mixture was heated for an additional 30 min., cooled, and the light tan product collected on a filter, washed with petroleum ether (60–70°), and dried giving 5 Gm. (42% yield) of *IIIb*, m.p. 310–312° dec. Recrystallized from 75% ethanol, it melted at 312–313° dec.

Anal.—Calcd. for $C_{16}H_{19}NO_2$: C, 74.68; H, 7.44. Found: C, 74.64; H, 7.49.

Proof of Structure IIIb: Its Oxidation to N-Acetyl-4-methoxyanthranilic Acid (Xb).—A suspension of 6 Gm. (0.023 mole) of 3-cyclopentyl-2-methyl-7-methoxy-4-quinolone (*IIIb*) in 1500 ml. of water containing 2.5 Gm. of potassium hydroxide was oxidized with potassium permanganate according to the procedure of Elderfield and Wright (18). The mixture was filtered free of manganese dioxide, concentrated to one-third of its volume, and acidified with concentrated hydrochloric acid, giving 1.5 Gm. of crude *N*-acetyl-4-methoxyanthranilic acid (*Xb*). Recrystallization first from water and then from methanol gave 1 Gm. of white needles, m.p. 196.5–198.5° corrected. [Lit. (19) m.p. 197–199°.]

Ethyl β - m - Chloroanilinocrotonate (XI).—A mixture of 25.6 Gm. (0.2 mole) of *m*-chloroaniline and 26 Gm. (0.2 mole) of ethyl acetoacetate was condensed according to the general procedure of Hauser and Reynolds (11). Vacuum distillation gave 39 Gm. (81% yield) of XI, b.p. 139–141° (1.2 mm.). [Lit. (12) b.p. 145–148° (1.5 mm.).]

7 - Chloro - 3 - heptyl - 2 - methyl - 4 - quinolone (IV).—A solution of 39 Gm. (0.16 mole) of ethyl β - *m* - chloroanilinocrotonate (11) (XI) in 100 ml. of dry xylene was alkylated with 37 Gm. (0.113 mole) of 1-iodoheptane according to the procedure of Leonard, Herbrandson, and Van Heynigen (22). After filtration, and removal of solvent, the crude oily residue (40 Gm.) was cyclized directly.

To a refluxing solution of 500 ml. of diphenyl ether–biphenyl mixture, 40 Gm. of crude ethyl β - *m* - chloroanilino - α - heptylcrotonate (XII) was added dropwise. After the addition was complete, heating was continued for 20 min. and the mixture chilled. White plates were collected on a filter and washed with petroleum ether (60–70°). Recrystallization from 95% ethanol gave 4.3 Gm. (9% yield) of IV, m.p. 260–262°. $\nu_{max.}^{KBr}$ in cm.$^{-1}$ 3300 (NH), 1637 (lactam C=O), 775 (2 adj. free H's).

Anal.—Calcd. for $C_{17}H_{22}ClNO$: C, 69.97; H, 7.60. Found: C, 69.94; H, 7.44.

3 - Cyclopentyl - 4,7 - dichloro - 2 - methylquinoline.—A mixture of 25 Gm. (0.095 mole) of 7 - chloro - 3 - cyclopentyl - 2 - methyl - 4 - quinolone (*IIIa*) and 75 Gm. (0.5 mole) of phosphoryl chloride was heated on a steam bath for 2 hr. Excess phosphoryl chloride was removed *in vacuo*, and the residue taken up into 200 ml. of methylene chloride. This solution was allowed to flow slowly into a vigorously stirred mixture of ice and water. The two-phase solution was neutralized with concentrated ammonium hydroxide and the resulting mixture extracted with 100 ml. of methylene chloride. The extracts were washed with water and dried over anhydrous potassium carbonate. The dried solution was filtered through a layer of charcoal and diatomaceous earth,[1] and concentrated to dryness. Recrystallization of the residue from methanol gave 26 Gm. (98% yield) of product, m.p. 86–88°.

Anal.—Calcd. for $C_{15}H_{15}Cl_2N$: C, 64.30; H, 5.40. Found: C, 64.06; H, 5.44.

4 - (7 - Chloro - 3 - cyclopentyl - 2 - methyl - 4-quinolylamino) - α - diethylamino - o - cresol (V) Dihydrochloride.—A mixture of 5.2 Gm. (0.019 mole) of 3-cyclopentyl-4,7-dichloro-2-methylquinoline, 4.8 Gm. (0.019 mole) of 4-amino-α-diethylamino-*o*-cresol dihydrochloride (23), and 30 ml. of ethanol was refluxed for 24 hr. on a steam bath. The mixture was cooled, and the solid was collected on a filter giving 2.4 Gm. of orange crystals, m.p. 257–259° corrected. The filtrate was refluxed for an additional 24 hr., cooled, and the product again collected on a filter. After repetition of this procedure a second time, a total of 7.7 Gm. of crude product was obtained. Recrystallization from methanol–acetone gave 5.1 Gm. (54% yield) of V dihydrochloride as orange crystals, m.p. 252–253°. A sample for analysis was recrystallized twice from absolute alcohol, m.p. 252–254° dec.

Anal.—Calcd. for $C_{26}H_{32}ClN_3$ 0.2 HCl: C, 61.12; H, 6.31. Found: C, 60.93; H, 6.39.

Hepatotoxicity of a Series of Organotin Esters

By DAVID J. CALLEY, W. L. GUESS, and J. AUTIAN

Four organotin esters having use or potential use in the formulation of medically used plastics were evaluated for their toxic effects on the liver following oral administration. The liver damage is apparently the cumulative type, requiring several days to manifest damage in the form of elevated SGPT values and prolonged hexobarbital narcosis. The toxic potential was in general solubility related.

CERTAIN ORGANO-METALLIC compounds are currently being used as stabilizers in plastic formulations, curing agents for rubber formulations, antifungal agents, and many other industrial applications. The bulk of the toxicity investigations to date on organotin compounds have been conducted with the alkyl–tin salts of the general formula R—Sn—X, R being an alkyl group, Sn as quadrivalent tin, and X representing a halide, sulfate, or other salt-forming ion. An excellent paper by Barnes and Stoner (1) reviews many of the toxic aspects of these compounds. Relatively little has been published concerning the toxicity of the alkyl–tin esters, R—Sn—O—R, particularly with a view toward delineating the relationship which may exist between varying the number of alkyl groups and the oral toxicities of these compounds. In addition, certain differences have been noted by Barnes and Stoner as to species variations when using the salts of alkyl–tin compounds.

In view of the greater interest being shown in certain of the alkyl–tin esters for various uses in devices for medical and pharmaceutical applications, it was decided that an investigation of the acute oral toxicity of a series of organotin compounds be undertaken. The esters chosen for this study were the acetate esters of the di- and tributyl compounds. In addition the tetrabutyl compound was selected which naturally has no point in the molecule available for esterification. A fourth compound, dibutyltin di-(2-ethylhexoate), was included as a check for the effect of the ester moiety on the resulting toxicity.

EXPERIMENTAL

Materials.—The materials used in this study were: (*a*) tetrabutyltin, lot 42921; (*b*) tributyltin acetate, lot GPI-1281; (*c*) dibutyltin diacetate, lot GP-1108; (*d*) dibutyltin di-(2-ethylhexoate), lot 1246.

Received August 26, 1966, from the Drug-Plastic Research and Toxicology Laboratories, College of Pharmacy, University of Texas, Austin 78756.

Accepted for publication October 25, 1966.

Presented to the Pharmacology and Biochemistry Section, A.PH.A. Academy of Pharmaceutical Sciences, Dallas meeting, April 1966.

This research was supported in part by grant CA-06120 from the National Institutes of Health, U. S. Public Health Service, Bethesda, Md.

The authors thank Carlisle Chemical Works, Reading, Ohio, for supplying the organotin compounds used in this study.

Methods

Oral LD_{50} Determinations.—Since published data were not available, it was necessary to establish LD_{50} values and time of onset of toxicity. These values were determined by a single oral intubation of each organotin, dissolved in sesame oil, into groups of 10 male Swiss-Webster albino mice of uniform weight and age, which had been deprived of food for 24 hr. Dosage levels of organotin were spaced in geometric progression increasing by a factor of two. The volume of each dose was 0.5 ml./20 Gm. body weight. Following intubation, observations for mortality were recorded daily for 1 week.

Liver Function Tests.—Previous reports in the literature have indicated that certain organotins exert an hepatotoxic effect (2), while others indicate toxicity to the bile duct (3). A series of experiments was undertaken to define more clearly the hepatotoxicity of the tin esters. Rabbits were used to obtain direct and indirect evidence of acute toxicity to liver tissue. They were intubated with a single oral dose of each organotin, and the following liver function tests were performed.

(*a*) Serum glutamic-pyruvic transaminase (SGPT), as an index of hepatocellular injury. (*b*) Prothrombin time, to indicate liver damage in the absence of jaundice. (*c*) Alkaline phosphatase, as an early indicator of hepatic obstruction which might lead to jaundice. (*d*) Thymol turbidity, to differentiate cellular from obstructive hepatic disease.

Four groups of rabbits, three rabbits per group, were each administered approximately one-half the LD_{50} dose of each organotin. A fifth group, administered only the sesame oil vehicle, served as controls. Values obtained from each rabbit before organotin dosing also served as controls for determining acute response after dosing. Five-milliliter blood samples were withdrawn from the median ear artery before dosing and again at intervals of 48 and 144 hr. (6 days) after dosing.

Cholestasis in Mice.—Plaa and Becker (4) recently reported a reliable method for the determination of intrahepatic cholestasis. This method employs an intravenous dose of fluorescein dye, which accumulates in the gall bladder and bile duct in the absence of intrahepatic bile stasis. The dye is visualized under ultraviolet light as a brilliant yellow-green color. If cholestasis does occur due to a toxic response or liver damage, fluorescence in the biliary tract should be absent, using all-or-none criteria. This method was used in this study. Groups of 10 mice were orally intubated with 50 mg./Kg. of organotin (except dibutyltin diacetate at 25 mg./Kg.). After an interval of 7 days the fluorescein dye was injected intravenously *via* the

tail vein, 0.1 ml./10 Gm., with a concentration of 20 mg./10 ml. in 0.17 *N* $NaHCO_3$. Fifteen minutes later the animals were sacrificed and examined under ultraviolet light for yellow-green fluorescence.

Determination of Blood Concentration of Tin.—To prove gastrointestinal absorption, hence blood passage through the liver, it was necessary to determine blood levels of tin at various time intervals following oral intubation. Five-milliliter samples of blood were widthdrawn by cardiac puncture from New Zealand albino rabbits prior to a single intubation with one-half the LD_{50} dose of organotin. These blood samples were then assayed for presence of tin according to the method described by Feigl (5). Additional 5-ml. samples were taken at intervals of 1, 3, 5, and 18 hr. following organotin intubation, and similarly analyzed.

Hexobarbital Narcosis.—This study was conducted to determine (*a*) a direct CNS effect after a relatively short time lapse following a single oral dose of organotin and (*b*) the presence of liver damage or change in function after a relatively long period of time following a single oral organotin administration. For part (*a*) sodium hexobarbital, 60 mg./Kg., was administered intraperitoneally 1 hr. after organotin dosing, and in part (*b*) the sodium hexobarbital was administered 7 days after organotin dosing. In both cases one-fourth the LD_{50} dose was given. Sleeping time of dosed mice in parts (*a*) and (*b*) were compared with that of concurrent controls. Sixteen albino male mice per test group were used.

Pathology.—Liver and kidney tissues from animals exposed on an acute and subacute basis to doses of organotins were obtained immediately after sacrifice and preserved in buffered formalin solution. These were subsequently stained with the standard hematoxylin-eosin stain and examined for changes which might be attributed to the organotin compounds.

Response to Acute and Subacute Administration.—In order to broaden the toxicity profile on the compounds under study for effects on the liver, and perhaps to more accurately correlate data, some general observations were made on animals dosed on an acute and subacute basis. Consequently, one group of animals was administered oil solutions in smaller doses, but repeated at intervals over a 1 to 2-week period. A third group of animals was administered saturated aqueous solutions by the intraperitoneal route for acute observations.

RESULTS AND DISCUSSION

LD_{50} Determination.—The oral administration of toxic concentrations of organotin, as oil solutions, resulted in deaths over a long period of time. The earliest deaths began to appear about 8 to 12 hr. after dosing, but continued over a period of days. For purposes of calculation of LD_{50} values, an arbitrary period of 7 days was set for counting deaths due to organotin poisoning. After the 7-day period, any deaths occurring did not enter the calculations, because it was difficult to determine whether death was directly attributable to the compound or whether it occurred through a secondary depressive starvation for food and water. The results of this study are listed in Table I, with confidence limits calculated by the method of Weil (6) and Thompson and Weil (7). It should be noted that the trialkyl ester (tributyltin acetate) had a slightly higher toxicity than the di-ester, though not significantly so. The tetrabutyltin exhibited a very low order of toxicity. Dibutyltin di-(2-ethylhexoate) had an LD_{50} value approximately twice that of the di- and tributyl acetate esters. These data seemed to indicate that the alkyl moiety had less effect in the determination of death than the ester moiety.

Liver Function Tests in Rabbits.—Following a single oral dose (one-half the LD_{50} dose) of the organotin compounds, only the SGPT values showed any significant change from the normal control values. No significant SGPT elevations at the 48-hr. time interval were noted (Fig. 1). At the 144-hr. interval, however, values of all organotin-dosed rabbits showed significant ($P = 0.05$) increases over control values, except with dibutyltin diacetate. The prothrombin time, alkaline phosphatase, and thymol turbidity showed no significant changes from control values at any of the time periods.

SGPT is a highly specific index of hepatocellular injury and is much more sensitive to minimal or moderate damage to the liver than are the other hepatic function tests. The transaminase activity in blood serum parallels the degree of liver cell injury. Elevation of the SGPT indicates that one of the first hepatic responses to organotin poisoning is

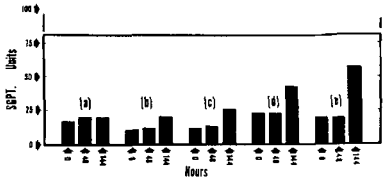

Fig. 1.—Serum glutamic-pyruvic transaminase (SGPT) values in rabbits receiving single oral doses of organotin (average of three rabbits), at 0, 48, and 144-hr. intervals. Key: (a) control rabbits; (b) rabbits receiving dibutyltin diacetate; (c) rabbits receiving dibutyltin di-(2-ethylhexoate); (d) rabbits receiving tributyltin acetate; (e) rabbits receiving tetrabutyltin.

TABLE I.—APPROXIMATE BLOOD LEVELS OF ORGANOTIN 3 hr. AFTER ORAL DOSAGE WITH LD_{50} VALUES

Compd.	Mol. Wt.	Single Oral Dose, mg./Kg.	Elemental Tin in Blood, p.p.m.	Oral LD_{50} Values, mg./Kg. ± S.E.
Dibutyltin diacetate	350.7	110	90	109.7 ± 24.2
Dibutyltin di-(2-ethylhexoate)	518.7	200	130	199.9 ± 43.2
Tributyltin acetate	348.7	300	140	99.1 ± 8.4
Tetrabutyltin	410.7	500	200	6000.0 ± 500.0

from parenchymal cells and involves the activity of one or more enzymes. In the case of the other liver function tests, none proved sensitive enough to detect subtle changes that may have occurred. Lack of any significant change in SGPT values from normal 48 hr. after oral dosing indicated that either the organotin does not reach the site of action in the liver cells in sufficient concentration to produce physiological disturbances of any great consequence within 48 hr., or that the changes produced there are produced slowly so that the accumulated response does not manifest itself until sometime after 48 hr. This also confirms other data indicating a delayed hepatotoxicity from the organotin compounds.

Intrahepatic Cholestasis and Jaundice in Mice.—In the course of the LD_{50} determination, it was noticed that three of the organotin compounds at the higher dose levels (200 mg./Kg.) caused visually evidenced jaundice in mice. Dibutyltin diacetate, tributyltin acetate, and dibutyltin di-(2-ethylhexoate) in large doses produced, in from 5 to 7 days, visually apparent discoloration of the skin, internal organs, and urine. Tetrabutyltin did not cause an apparent jaundiced discoloration in any of the test animals. Confirming evidence of intrahepatic cholestasis by the method of Plaa and Becker (5) is summarized in Table II. This table presents the total number of animals showing cholestasis at various dose levels, all exceeding 50 mg./Kg. These data indicated that all four compounds were at least capable of inducing cholestasis. Since none of the control animals showed cholestasis by the fluorescein dye method, this condition in the other animals must be attributed to the organotin.

Absorption of Organotin into Bloodstream.—Feigl spot tests for tin in the bloodstream of rabbits were negative prior to the oral administration of the four tin compounds. Five-milliliter blood samples taken 1, 3, 5, and 18 hr. after oral intubation of organotins were positive for the presence of tin in all cases. The test color intensity was compared with standards of known concentration. By this comparison it was found that increasing concentrations of tin appeared in the bloodstream, reaching a maximum at 3 hr. after intubation. Positive tests for tin at substantial levels were also obtained through 18 hr., at which time the study was terminated. The blood level of each organotin at the 3-hr. time period was calculated (Table I).

Results of the Feigl spot tests indicated that, with all four compounds, either the organotin itself or a metabolite was capable of being carried into the bloodstream in a reasonably short time in amounts large enough to create a pharmacological or toxicological response. In addition, the presence of relatively high levels of tin persistent in the blood stream after 18 hr. suggested the possibilities that either a large storage depot existed somewhere in the body from which amounts of organotin were steadily being released or that the organotin remained in circulation for a protracted length of time. Concurrent spot tests for tin in the bloodstream of rabbits which had been orally dosed 13 days prior to testing proved negative. This indicated that should a prolonged retention exist, it was depleted within the 13-day period.

TABLE II.—CHOLESTASIS 1 WEEK AFTER ORAL ORGANOTIN ADMINISTRATION

Compd.	Mice, No.	% Showing Cholestasis
Sesame oil controls	17	0.0
Dibutyltin diacetate	33	18.2
Tributyltin acetate	32	6.3
Tetrabutyltin	14	35.7
Dibutyltin di-(2-ethylhexoate)	36	22.2

TABLE III.—EFFECT OF ORGANOTINS ON HEXOBARBITAL NARCOSIS IN MICE

Compd.	Mice, No.	Oral Dose	Sleep Time ± S.E., min.	Significance, P
Control group (sesame oil)	14	0.5 ml./20 Gm.	29.0 ± 14	....
Dibutyltin diacetate	12	30 mg./Kg.	44.5 ± 11.9	0.01
Tributyltin acetate	13	50 mg./Kg.	43.1 ± 8.1	0.01
Dibutyltin di-(2-ethylhexoate)	8	40 mg./Kg.	37.7 ± 11.7	0.05

Hexobarbital Narcosis in Mice.—When sodium hexobarbital (60 mg./Kg.) was administered intraperitoneally 1 hr. after oral dosing with the organotins, there was no significant difference between the sleeping times of the test and the control groups of mice. This indicated that within the limitations of the technique, there was no significant influence on the CNS from these compounds within a 1-hr. time span. On the other hand, groups of mice dosed with sodium hexobarbital (60 mg./Kg.) intraperitoneally 1 week after a single dose of each organotin compound showed significant differences from control sleeping times (Table III). The mice received one-fourth LD_{50} doses. There was a significant prolongation of sleeping times among mice receiving dibutyltin diacetate and tributyltin acetate. This indicates that liver damage from these two compounds did occur to some extent by the end of 1 week. This was confirmed by pathologic manifestations in liver sections. The tetrabutyltin is apparently unstable as evidenced by an increasing toxicity with time. The oral LD_{50} value established on fresh material was approximately 6000 mg./Kg., but it was noted in sleeping-time studies that all mice dosed at one-fourth LD_{50} doses died almost immediately. Rechecking of data and materials indicated that the tetrabutyltin compound had decomposed. Therefore, the sleeping-time data for this compound was discarded. All other data reported in this paper were conducted on the fresh material and are therefore included.

Acute Pharmacological Response.—Response to single large oral doses of organotin dissolved in sesame oil produced no sudden or dramatic responses in mice, even in concentrations 5 to 8 times the LD_{50} value, suggesting slow gastric absorption. After 30 min. to 1 hr., a gradual depressive syndrome was noted, in which activity was decreased, respiration rate, and irritability reduced. Almost complete ptosis was observed after 1 to 2 hr. Death at higher dose levels occurred within 18 hr., but at the LD_{50} levels, death occurred over a period of several days.

Saturated aqueous solutions of each organotin compound were prepared in normal saline and injected, 0.5 ml./20 Gm., intraperitoneally in mice.

Two compounds, dibutyltin diacetate and tributyltin acetate, produced a rapid onset of symptoms, those caused by the former being most severe. Writhing and stretching were observed in both cases within 2 to 4 min. Those injected with dibutyltin diacetate showed severe depression, ataxia, and ptosis with death resulting within 30 to 35 min. due to apparent respiratory paralysis. Gasping with the mouth widely opened was a common response. Cyanosis preceded death. These symptoms were observed in mice receiving the tributyltin acetate, but onset was less rapid and severe, with death occurring between 30 to 60 min. Mice injected with tetrabutyltin showed stretching, but symptoms were very mild by comparison with those caused by the two previously mentioned (no deaths resulted). Solutions of dibutyltin di-(2-ethylhexoate) caused little response except depression, and no deaths occurred with this compound.

Subacute Responses.—Rats dosed repeatedly with one-half the LD_{50} dose at 3 to 5-day intervals generally showed little response either immediately after each dose or at the end of a 1-month time period, with the exception of those receiving dibutyltin diacetate. Slight temporary depression was noted with tributyltin acetate. In the case of the dibutyltin diacetate, diarrhea, ptosis, and general depression was noted, with individuals varying in their response. Onset of diarrhea was observed after the first dose, but the animals did not seem to become depressed to any extent until after receiving four to five doses. In these cases little was observed except depression. Death occurred in two of five rats after the fifth and sixth dose (total dose 250 to 300 mg./Kg.).

Rabbits dosed repeatedly with the same levels of dibutyltin diacetate tended to exhibit diarrhea to a greater extent than rats receiving the same dose. In one rabbit, following six repeated doses with dibutyltin diacetate at weekly intervals, complete paralysis of the hind legs resulted. Dosing was thereupon discontinued and no recovery was seen after 3 weeks. Other rabbits exhibited considerable malaise and some depression, but no paralysis was noted after seven doses.

Pathology.—The tissue sections submitted for pathological examination generally confirmed that the organotin compounds do exert a toxic effect on liver tissue. A significant finding is that liver damage is rather slowly manifested after a single oral dose. No pathology of liver tissue could be observed 3 days after a single dose of organotin, but definite pathology could be observed after 7 days. The primary change in liver tissue of rats and mice appears to be a moderate increase in reticuloendothelial cells and mild hepatocellular damage with cloudy swelling, which could cause retention of bile. (See Fig. 2.)

These data confirm prior indications of liver damage at the 7-day time interval as evidenced by the prolonged sleeping time from hexobarbital, by the elevated SGPT, by bile stasis indicated in the fluorescein test, and by jaundice from high doses in mice. Apparently there was no bile duct pathology during this time period as had been observed for salts of certain organotin compounds (1). This was somewhat surprising in view of the elimination of these compounds by way of the bile into the intestinal tract and finally through the feces.

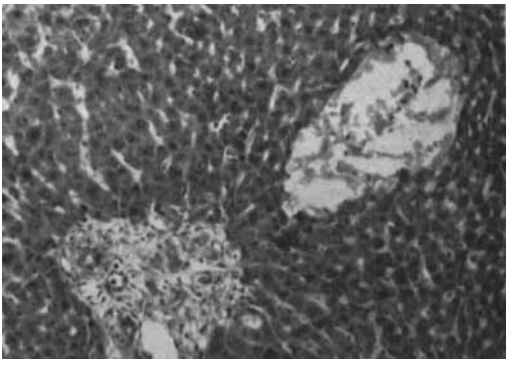

Fig. 2.—Liver of rat receiving dibutyltin diacetate, nine repeated oral doses of 50 mg./Kg., spaced over a 5-week period. The tissue shows cloudy swelling, most noticeable in the centrilobular location, with minimal fatty degeneration. A slight increase in fibrous connective tissue exists, and there are islands of acute necrosis, with minimal infiltration of polymorphonuclear leucocytes throughout the section.

SUMMARY

The results of the experiments on a series of organotin esters indicated that the compounds are absorbed from the gastrointestinal tract following oral administration in an oil solution. After absorption into the bloodstream, there is evidence that the compounds remain in the blood for periods in excess of 18 hr. and then are eliminated *via* the feces. In the passage of these compounds through the liver, there accumulates over a period of several days a uniform and general liver damage. This damage usually takes the form of cloudy swelling, mild hepatocellular involvement, and a moderate increase in reticuloendothelial cells following a single oral dose. There does not appear to be any significant difference between the hepatotoxic effects of the di- and tributyl esters, but the tetrabutyl compound exhibits a reduced toxicity. In view of the delayed effects of these compounds on liver tissue, it is suggested that long-term studies should be conducted on them.

Effects of β-Hydroxyethylhydrazine on Growth and Alkaloid Formation of *Datura stramonium*

By LEO A. SCIUCHETTI and GORDON K. NIELSEN*

The aerial parts of *Datura stramonium* were sprayed with aqueous solutions of β-hydroxyethylhydrazine (BOH) in strengths of 1, 0.01, and 0.0001 per cent. Treatment with 1 per cent of BOH reduced the height 54 per cent and the total dry weight 67 per cent. Malformations which were induced in the plants are described. The formation of flowers was inhibited. The concentration of leaf-tops alkaloid was decreased 45 per cent, while root alkaloid was increased 61 per cent. The total alkaloidal content per plant was only 26 per cent of controls. The habit of the groups treated with 0.01 and 0.0001 per cent of BOH resembled the controls. The concentration of alkaloids of the 0.01 per cent BOH group was decreased 17 per cent in the leaf-tops, but increased 161 per cent in the roots. The total alkaloidal content of the roots was 230 per cent of controls. In the 0.0001 per cent BOH group increases of 11, 103, and 209 per cent were found in the concentration of alkaloid of the leaf-tops, stems, and roots, respectively. The total alkaloidal content of this group was increased 31 per cent per plant, 99 per cent in the stems, and 219 per cent in the roots.

GOWING AND Leeper (1) in 1955 demonstrated that β-hydroxyethylhydrazine (BOH)[1] induced flowering in pineapples. In subsequent work these authors (2) tested 39 hydrazine derivatives for induction or inhibition of flowering and toxicity to the pineapple plant and found that BOH was one of six hydrazine derivatives which forced the pineapple to flower. The first effect of BOH was retardation of stem elongation which then was followed by floral initiation (3, 4). Reed (5) has indicated that BOH forces flowering in pineapple plants, possibly by reducing auxin concentration. This compound also was found to be a potent inhibitor *in vivo* of animal diamine oxidase (5).

B995, known chemically as *N*-dimethylaminosuccinamic acid, can also be considered to be a hydrazine derivative, *viz.*, the 1,1-dimethylhydrazide of succinic acid. Reed (6) has indicated that inhibition of shoot elongation in dwarf and tall peas by B995 was correlated with the inhibition of the oxidation of tryptamine-2-^{14}C to indoleacetaldehyde-2-^{14}C in homogenates prepared from epicotyls of young plants treated with B995. Previous investigations (7, 8) in this laboratory have shown that B995 caused significant reductions in height, growth, and the total alkaloid content of *Datura tatula* and *D. innoxia*. Plant maturity was notably delayed. It was also found that a 2% aqueous spray of B995 caused significant increases in the concentration of stem alkaloids.

B995 has induced interesting effects on the growth of various *Datura* species, and since the chemical structures of this compound and BOH are closely related, it was decided to determine the effects of various concentrations of BOH on the growth and alkaloid synthesis of *D. stramonium* L. Furthermore, BOH has not been reported to have been tested on medicinal plants.

EXPERIMENTAL

Growth of Plants.—*D. stramonium* plants employed in this investigation were germinated from seeds obtained from plants grown in the Oregon State University drug garden in 1961. The germination of the seeds, transplantation of the seedlings into individual 1-gal. metal containers, and soil composition are described in a previous publication (9). The growth studies were performed under greenhouse conditions at temperatures varying from 85° F. at night to 95° F. during the day. A humid condition was maintained in the greenhouse.

Treatment Plan.—A total of 72 five-week-old plants was selected on July 1, 1965 (zero time), for uniformity as to size and height from a pool of 100 plants grown in individual 1-gal. metal containers. The experimental period which started at this time lasted 4 weeks. Three harvests were made—at 0, 2, and 4 weeks. Each harvest consisted of 6 plants from each of the 4 groups, *viz.*, control plants (untreated plants), plants treated with 1% of BOH, those treated with 0.01% of BOH, and plants receiving treatment with 0.0001% of BOH. The first harvest, at zero time, however, consisted of 24 plants which were considered controls since none had been treated. At zero time, the plants were labeled according to treatment and randomized on a greenhouse bench.

The treatment solutions were prepared on a v/v basis from a stock preparation of β-hydroxyethylhydrazine.[2] At zero time, the aerial portions of the plants were sprayed to run-off with an atomizer with the previously designated solutions to assure an approximate equal dosage on a volume-to-unit area relationship. Specially prepared paper shields

prevented the solutions from entering the soil. Treatment according to group was conducted in a separate room to prevent cross-contamination. The plants received four weekly treatments. Height measurements were taken twice weekly, and the plants were observed periodically for any morphological changes.

The dosage regimens employed in this investigation were determined by a preliminary experiment performed 3 months earlier on *D. stramonium* and *D. meteloides*. Groups of 5 plants from each species received biweekly treatments by spraying to run-off for 5 weeks with the following strengths (v/v) of BOH: 1, 0.1, 0.01, 0.001, 0.0001%, and distilled water (controls). The 1% strength of BOH drastically inhibited plant growth and was phytotoxic which was manifested by the appearance of necrotic areas on the leaf blades. In *D. stramonium* the total fresh weight of the plants was only 8.7% of controls, and the average height of the treated plants at the end of the fifth week was only 6.6 cm. *versus* 27.3 cm. for controls. In *D. meteloides* growth was even more drastically inhibited, the total fresh weight being only 1.2% of controls. In this species the average height of the treated group at the end of the fifth week was 5.4 cm. *versus* 29.8 cm. for controls. The plants receiving the 0.1% strength of BOH were shorter than controls, and growth (fresh weight) was decreased 15 and 45% in *D. stramonium* and *D. meteloides*, respectively. The plants treated with 0.01 and 0.001% of BOH closely resembled the controls, whereas a slight increase was noted in height and growth in those receiving the weakest concentration (0.0001%) of BOH. Thus, it was decided to employ weekly treatments instead of biweekly treatments, and to use the previously designated concentrations of the chemical.

Measurements and Harvesting.—Height measurements were taken twice weekly from the soil line to the apex of the highest leaf. At harvest time each plant was immediately washed and cleaned, and the moisture was removed with towels. The plant then was divided into leaf-tops, stem, and root portions. The leaf-tops and stems were cut into small segments, and the fresh weight of each portion was taken immediately. Dry weights were taken after drying 48 hr. in a forced-air drier at 60° C. The plant parts were then ground to a No. 40 powder in a Wiley mill, pooled according to treatment and harvest, and stored in colored glass containers in a desiccator until subsequent analyses were performed.

Alkaloid Analysis.—The dried plant parts, employing pooled samples, were assayed for alkaloid concentration, expressed as scopolamine, according to the Brummett-Sciuchetti method (10). Two extractions were made per group, and each of the extracts was analyzed in duplicate. When duplicate determinations did not agree within a reading of 0.005 absorbance, two further extractions and analyses were made for each group. The total alkaloidal content per plant and per plant organ was obtained by multiplying the dry weight of the plant by the per cent of alkaloids obtained from the alkaloid analyses, and expressing the results in milligrams.

RESULTS

Growth Effects.—Plants treated with 1% of BOH were drastically inhibited in growth. Deformative effects were also noted. The height of this group was only 46% of the controls at the terminal harvest (Fig. 1). The newly formed leaves of this group appeared to be slightly chlorotic, whereas the older leaves were a darker green in color. The young leaves also became curled and wrinkled, and a characteristic yellow splotching was noted among the veins of this group as the leaves matured (Fig. 2). The newly formed leaves were smaller and narrower than similarly formed ones of the controls. Contrasted with this, the older leaves of the group treated with 1% of BOH were thicker than the controls. Numerous necrotic areas varying from 15 to 30 mm. in diameter were noted usually in the upper portion of the blade of these leaves. The width of the blades and petioles of the older leaves

[a] Calculated from dry weight and alkaloid analyses data; per plant = leaf-tops + stems + roots.

of this group was about 60% of the controls. The leaves of this group were extremely brittle. This brittleness was noted after the second treatment with 1% of BOH and became more pronounced with each subsequent treatment. Great care had to be taken in handling these plants since the leaves would break off from the plant simply by brushing against them. This characteristic was not noted in the other groups. The formation of floral buds and flowers did not occur in the 1% BOH group. On the other hand, the number of floral buds and flowers of the two groups receiving the weaker strengths of BOH was similar to the controls. The habit of the plants receiving treatments with 0.01 and 0.0001% of BOH in general resembled the controls.

Statistical analysis[3] of the height data indicated that the height of the plants treated with 1% of BOH was depressed significantly (at the 1% confidence level) as soon as 2 weeks following application of the chemical. The two weaker concentrations of BOH did not significantly alter the height of the plants.

The growth of the plants as indicated by dry weight data was markedly inhibited by treatment with 1% of BOH (Table I). Statistical analysis of the dry weight data indicated that with the lower concentrations (0.0001 and 0.01%) of BOH there was little difference in growth between treated and

[3] The statistical analyses of height and dry weight data were performed by Dr. R. G. Petersen, Oregon State University, Corvallis.

untreated plants. At a concentration of 1% of BOH, plant growth was depressed. This inhibition of growth became more pronounced with time. In considering the individual plant parts, the effect of 1% of BOH on the depression of growth was least pronounced in the roots and most pronounced on plant height. At the terminal harvest, total dry weight, leaf-top dry weight, and stem dry weight were significantly decreased at the 1% confidence level and root weight at the 5% confidence level.

Effect on Alkaloid Patterns.—At the terminal harvest the concentration of alkaloids of the group treated with 1% of BOH was reduced 45% in the leaf-tops, but increased 61% in the roots (Table II). Similar figures for the 0.01% BOH groups were a decrease of 17% and an increase of 161%. The concentration of stem alkaloids was not affected in either group. Significant increases in the concentration of alkaloids were found in the group treated with 0.0001% of BOH, *viz.*, twofold in the stems and threefold in the roots (Table II).

The total alkaloidal content of the plants receiving treatment with 1% of BOH was significantly decreased (Table III). At the terminal harvest, the total alkaloidal content per plant was only 26% of the controls. All of the plant organs indicated a significant reduction. This was due primarily to the inhibition of growth. Decreases of 19% per plant and 28% in the leaf-tops were noted in the total alkaloidal content of the group treated with 0.01% of BOH, while an increase of 130% was found in the roots. Significant increases of 31% in the leaf-tops and of 219% in the roots of the group receiving the 0.0001% treatment were noted.

DISCUSSION AND CONCLUSIONS

Treatment of *D. stramonium* with 1% of BOH definitely inhibited plant growth. Deformative effects were noted in the leaves. These were manifested by a curling and wrinkling of the newly formed leaves and the appearance of a characteristic yellow splotching among the veins of the leaves of the treated plants. The latter indicates a damaged root system which would limit growth. This suggests that the 1% strength of BOH was a growth inhibitor in *D. stramonium* rather than a growth retardant as has been indicated for B995 (3, 7, 8). Although BOH and B995 are closely related chemically, treatment of *Daturas* with approximately the same concentration of each chemical does not produce the same effect. The effects on the plants treated with 1% of BOH more closely resemble those noted when *Daturas* have been treated in this laboratory with maleic hydrazide or its ester. Other unusual effects noted in this group included the appearance of necrotic areas in the upper portion of the older leaves which had a reduction of about 40% in the width of their blades and petioles compared with leaves from untreated plants, an exceptional brittleness of the leaves, and inhibition of floral bud formation. Flowers did not appear in any of the plants of this group, while the formation of floral buds and flowers in the groups receiving 0.01 and 0.0001% of BOH approximated the controls.

The total alkaloidal content of the 1% BOH group was about one-fourth that of the controls at the final harvest. This was due primarily to the inhibition of growth, although the 45% reduction in the concentration of leaf-tops alkaloids was a contributing factor. The 61% increase in root concentration of alkaloids did not offset the latter since the roots represent slightly more than 10% of the total plant weight compared with 50% for the leaf-tops.

The habit of the plants treated with 0.01 and 0.0001% of BOH generally resembled the controls. Noteworthy was the effect that the treatments with the weaker strengths of BOH had on the concentrations of alkaloids in the plant organs. The concentrations of leaf alkaloids in the group treated with 0.01% of BOH was 83% of controls compared with 111% for the 0.0001% BOH group. This concentration was intermediate between the latter and the group treated with 1% of BOH. The concentration of root alkaloids was increased 161% in the 0.01% BOH group and 209% in the 0.0001% BOH group. This suggests that the synthesis and/or accumulation of alkaloids in this organ was significantly increased by the two weaker strengths of BOH. The only treatment which affected the concentration of stem alkaloids was that with 0.0001% of BOH which resulted in a twofold increase. Due to the phenomenal increase in the concentration of alkaloids in the stems and roots of this group, the total alkaloidal content per plant was increased 31%, that of the stems increased 99%, and that of the roots increased 219%. These increases were considered significant. No precise explanation is presently forthcoming as to why BOH in all three of the strengths employed significantly increased the concentration of root alkaloids.

Kinetics of Aggregation of Denatured Proteins I

Methodology Based on the Multichannel Particle Size Analyzer

By NORMAN F. H. HO and WILLIAM I. HIGUCHI

The purpose of this study was to develop a method for studying the kinetics and the mechanisms of aggregation of denatured protein particles. It was found that a procedure based on the RIDL multichannel particle counter and size analyzer system was suitable. The precipitation behavior of urea denatured ovalbumin was studied near its isoelectric point. An evaluation of the data showed that the Smoluchowski theory for rapid aggregation of monodispersed particles and the self-preservation theory satisfactorily accounted for the results.

THE PROPENSITY of proteins to undergo gross physical and chemical changes by denaturation is realized in clinical biochemistry. This characteristic property is the basis for diagnostic procedures involving sedimentation, salt precipitation, and heat coagulation of proteins, such as the erythrocyte sedimentation reaction, the Weltman coagulation band technique, turbidity, and flocculation reactions (1, 2). More recently, medical researchers have developed the use of denatured protein particles complexed with radioisotopes to measure renal, liver, splenic, and pulmonary blood flow (3–5). One preparation, *i.e.*, the particle denatured human serum albumin —^{131}I complex, is used for the rapid diagnosis and location of pulmonary embolism by scintillation scanning on the basis of differential filtration of the tracer particles at the site of embolism (6). The particle size and stability of the suspension are critical problems of this preparation.

While the protein chemists have intensified their investigations on the denatured protein mainly in the direction to unravel the structure of the native protein and to study the kinetics, mechanisms, and energetics of the denaturation process itself, the kinetics of growth and aggregation of denatured protein particles has received little or no attention. Research on the particulate behavior of denatured proteins should contribute to the fundamental understanding of the techniques in clinical laboratory procedures involving sedimentation of denatured proteins and in the interpretation of relevant data. In the field of applied pharmaceutical chemistry, such studies should provide a basic approach to the preparation of protein particles tagged with radioactive substances for the rapid diagnosis of embolism. Through the application of controlled growth and aggregation, one should be able to "tailor-make" a stable denatured protein particle or aggregate of uniform and desired size.

The long range objective of the present research is to study this aspect of denaturation on a quantitative basis. The authors hope to examine the effects of protein species and concentration, the method of denaturation, pH, temperature, mono- and polyvalent electrolytes, solvents, and surface-active agents.

The purpose of this paper is to present a well-defined procedure for carrying out such studies. It involves the use of an electronic resistance counter with a multichannel particle size analyzer to follow changes in particle size distributions with time. For the model system studied here, the urea–pH induced denaturation of ovalbumin (7) was chosen taking advantage of the well-defined properties and the better controlled irreversible denaturation of ovalbumin.

EXPERIMENTAL

Materials and Method of Denaturation.—A single lot of twice crystallized, lyophilized ovalbumin[1] was used throughout the study without further recrystallization and stored in a tight container under refrigeration to maintain stability of the protein. Urea used was reagent grade. Buffer solutions were prepared from reagent grade salts and standardized with the Beckman zeromatic pH meter.

One-half and 1% ovalbumin solutions in 8 *M* urea–phosphate buffer were prepared in the following manner. Ovalbumin was dissolved in a small amount of 0.05 *M* phosphate buffer (pH 6.88 and previously filtered through 0.45 μ Millipore filters) without stirring. To this was added the freshly prepared phosphate buffered urea solution with gentle stirring. The final pH was 7.1. Denaturation of the protein was carried out at constant stirring of 20 r.p.m. with a synchronous motor and in a closed system thermostated at 30°. At the end of 5 days, the denatured protein solution was discarded to avoid the complications of cyanate formation from the alkaline hydrolysis of urea (8).

Procedure for Aggregation[2] Studies.—Samples of the urea-denatured ovalbumin were used for the

[2] Throughout this study "aggregation" means the formation of conglomerates of particles as distinguished from molecular aggregation.

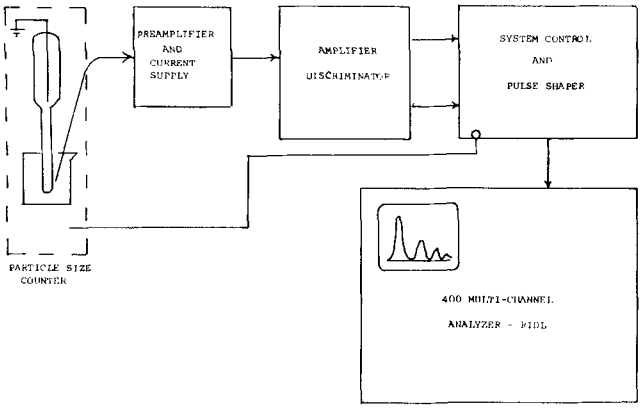

Fig. 1.—Particle counter and size analyzer system.

aggregation experiments after the viscosities of the solutions became constant. The viscosities were followed with an Ostwald viscometer. After denaturation periods of at least 18 hr., the protein solutions were diluted into 0.01 *M* acetate–normal saline buffer solutions, previously adjusted to pH 4.6 or 5.5, so that the final concentration was 1 mcg. denatured protein per ml. Also, normal saline adjusted to pH 8.7 with sodium hydroxide was used as a diluting solution. Initially, the solutions were mixed with gentle stirring and then allowed to stand without disturbance. Dilutions were made for several denaturation periods. The course of the aggregation with time was followed by the single channel Coulter counter, model A, and the RIDL multichannel particle analyzer. Both the 30-μ and 50-μ aperture tubes were used. For the counting runs, a further 1:11 dilution of the master suspension was necessary to minimize coincidence errors. The initial particle concentrations were in the neighborhood of 1×10^7 particles per ml. Since the aggregating system was somewhat sensitive to the method of dilution, a procedure was developed that did not influence the results. A 1-ml. transfer pipet, Kimax -51 No. 37034-A, blow-out type, was used to pipet and deliver an aliquot at the rate of 1 ml./15 sec. The delivery was performed with the tip of the pipet under the surface of the diluting medium and the remaining drops were gently blown out. The samples were then immediately counted.

Particle Counter and Size Analyzer System and Its Standardization.—To follow aggregation, changes in the particle size distribution as a function of time were followed by a new electronic resistance counter system shown schematically in Fig. 1. The system consists of a particle detector apparatus based on the Coulter counter[3] principle and a sophisticated transistorized RIDL 400 channel analyzer,[4] which was originally developed for γ-ray spectrometry. A constant current is supplied to the aperture tube of the detector apparatus. As a particle moves through the aperture, there is an abrupt change in the aperture current. The current signal is amplified and converted to a voltage pulse by the preamplifier. The pulse is then shaped and sent on to the pulse height analyzer where it is classified into one of the 400 channels and counted. Only one pulse can be analyzed at a time, but the analyzer performs this task in the order of milliseconds before accepting another pulse.

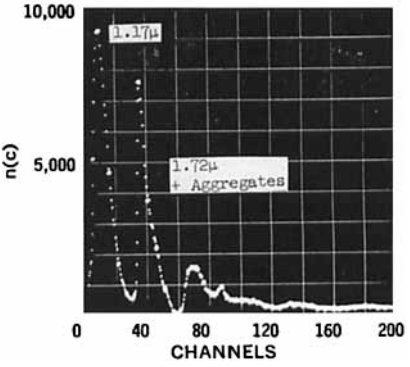

Fig. 2.—Differential distribution data for a mixture of a 1.17 and 1.72-μ diameter latices. Two-hundred channels used. n(c) is the concentration of particles in channel c.

The distribution of particle size densities can be oscillographically displayed or stored in memory. By utilizing only 100 channels at a time, it is possible to simultaneously hold in memory up to four particle size distributions which may be displayed independently or simultaneously on the oscilloscope screen. Corrections for background may also be programmed.

While in most of the present work the data were presented on the oscilloscope screen and photographed with a Polaroid camera, other convenient modes of data retrieval may be used. Numerical readout devices and conventional recorders are easily adapted to the instrument.

Standardization of the multichannel particle analyzer was accomplished with 1.17, 1.72, and 2.051-μ diameter polyvinyltoluene latices[5] suspended in 0.90% sodium chloride solutions. All of the standard latices were washed repeatedly with alcohol and water by centrifugation, and the latter two latices were aggregated to some degree with magnesium sulfate. Microscopic measurements and the Coulter counter, model A, served as a check. Figure 2 shows the differential distribution of a mixture of 1.17-μ and aggregated 1.72-μ diameter

latices. It is the oscillographic spectrum actually displayed by the 400 multichannel analyzer. Here, however, only 200 channels have been used to describe the distribution. The channel number is proportional to particle volume and the x-axis is calibrated with at least two known standards. The total number of particles corresponding to a given channel is represented by a point so that there will be as many points on the smooth distribution curve as there are preselected number of channels. At the 10th channel in Fig. 2, there is essentially a unimodal distribution of the 1.17-μ particles. The sharp singlet peak for the 1.72-μ particles occurs at about the 35th channel, its doublet peak occurs at approximately the 70th channel, and the triplet aggregate at the 105th channel as expected. However, there is in addition an odd small peak at the 90th channel.[6] The somewhat broader distributions of the high order aggregates are probably due to the wider distributions of shapes (configurations).

[6] Tentatively, the authors have assigned both peaks at the 90th and 105th channels to triplet aggregates. Microscopically, the triplet aggregates appear in three general geometrical forms, *viz.*, the triangular, linear, and other angular arrangements. According to rough theoretical calculations on the effect of particle shape factors on the electronic particle detection system and qualitative experimental data on the rearrangement kinetics of the triplet aggregates, there would be approximately a spread of 10 to 20 channels between the more stable triangular triplet aggregate and the other triplet aggregates. This study is being pursued further.

The distribution of the 1.72-μ latices shows about 45% aggregation. When longer sampling times were taken, the statistics for the higher order aggregates improved and even 8-mers were detectable for the 1.72-μ aggregated system at approximately the 285th channel. There is relatively good linearity with this system. Figure 3 shows the same distribution as in Fig. 2 except that the first 100 channels have been expanded by means of the x-axis expansion control. Likewise, the second 100 channels may be expanded for examination of the higher order aggregates.

A quantitative analysis of a mixture of 1.17 and aggregated 1.72-μ latices was carried out with both the multichannel particle analyzer and the Coulter counter, model A, using a 30-μ aperture tube. As shown in Fig. 4, the multichannel analyzer gives directly a differential distribution, while the Coulter counter gives a cumulative distribution. Whereas the differential distribution data were obtained from one 50-μl. sample, the cumulative distribution was obtained with nine 50-μl. samples. The advantages of the multichannel system can be seen from Fig. 4. With the single channel instrument many sample readings must be taken to achieve the same degree of accuracy. For example, if the sixth point in the cumulative plot of Fig. 4 were not taken, it would have been impossible to decide whether the first two peaks were separate or possibly a single broad distribution. Also, the true particle distribution cannot be adequately resolved for rapid flocculating systems without laborious effort.

To compare the data from the multichannel analyzer with that from the Coulter counter, the differential distributions were integrated planimetrically. Therefore,

$$N_v = \int_v^\infty n(v)dv \qquad \text{(Eq. 1)}$$

where N_v is the integral number of particles larger than v, and $n(v)dv$ is the number of particles between the sizes v and $v + dv$. The results are tabulated (Table I) and compared with the Coulter counter data.

As the sophistication of the electronics of the multichannel analyzer allows one to detect rapid changes in particle size distributions, the direct display of the differential distribution and the efficient data recording techniques can be utilized with the aid of Eq. 1 to follow the course of aggregation of an initially monosized particle system as a function of time.

Recently, Samyn (9) reported that when suspension systems are highly polydispersed, the Coulter

120	5.032	1851	1850

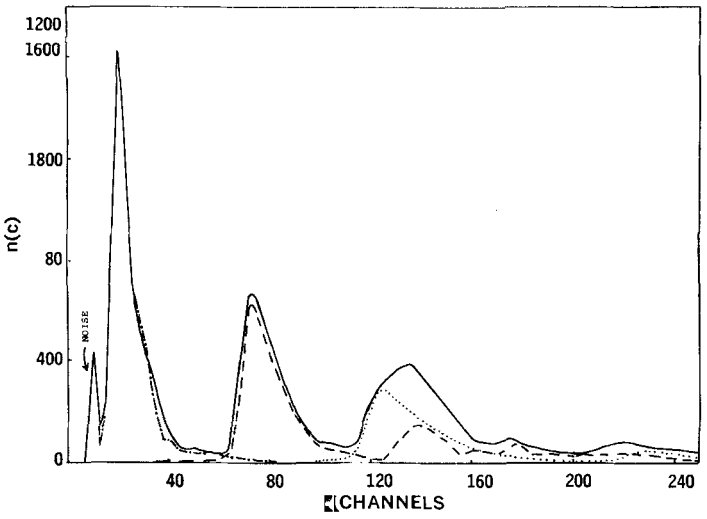

Fig. 5.—Distribution curves accounting for additivity in a polydispersed latex system by the RIDL multichannel analyzer. Key: ———, distributions of mixture of equal parts of 1.17, 1.72, and 2.05 μ; —·—·—, independent distribution of 1.17 μ; — — —, independent distribution of 1.72 μ; ....., independent distribution of 2.05 μ.

counter, model A, may show poor additive results. This prompted the investigation of the reliability of the multichannel analyzer in this aspect, at least in the range of sizes pertinent to our research. Figure 5 shows (broken curves) the independent distributions of 1.17-μ and aggregated 1.72 and 2.05-μ particles. The noise peak at the 10th channel serves as a reference from which the true particle distribution can be differentiated. Upon mixing equal parts of the latex suspensions, the resulting normalized distribution assuming additivity of the separate runs is shown by the smooth curve. It appears therefore that the multichannel analyzer system can give accurate results even when the polydispersity is of the order of thirtyfold in volume.

Because the latex particles are essentially monodisperse, the peak widths given in Figs. 2–5 may be used to estimate the instrument resolution. In the present size range this is found to be about ± 0.1 to 0.2 μ in the diameter. Except in unusual situations, most real suspension systems have broad enough particle size distributions so that the instrument resolution does not constitute a serious limitation.[7]

RESULTS AND DISCUSSION

Process of Denaturation.—The kinetics and mechanisms of denaturation of ovalbumin by urea are discussed in a number of references (7, 10–13). The initial stage is an intramolecular reaction involving the destruction of internal order. This may be interpreted as the unfolding of the helical structures of ovalbumin to a more randomly coiled arrangement accompanied by an increase in viscosity. Usually, this stage is measured by optical rotation. The second stage is characterized by an increase in viscosity of the solution without further change in optical rotation. In contrast to the relatively rapid increase in viscosity in the initial stage, the viscosity increases at a slower rate during this second stage and eventually reaches a plateau. It is believed that association of the denatured protein molecules primarily by exchange reaction with sulfhydryl and disulfide groups is an important factor in this second phase. In general, the concentrations of ovalbumin, urea and electrolytes, pH, and temperature all affect this over-all denaturation process.

With the ovalbumin–urea concentration ratios used in this study, the first stage of denaturation is completed within 3 hr. and the viscosity reached a plateau a few hours thereafter.

Aggregation Experiments.—Typical differential particle distributions at various time intervals, obtained directly from photographs of the oscillographic display of the multichannel analyzer, are shown in Fig. 6 for the aggregation of denatured protein. In this instance the 30-μ aperture tube was used. Since there was a noise contribution in channels 10 to 13, previously pointed out in Fig. 5, only that portion of the distribution from the 15th channel was used for further analysis.

Figure 7 gives the cumulative counts *versus* time curves showing aggregation of denatured ovalbumin at times greater than about 60 min. These results were planimetrically determined from data such as those given in Fig. 6. The pH is in the neighborhood of the isoelectric point for denatured ovalbumin. The two curves correspond to the 0.5% and the 1.0% protein denatured for 24 and 22 hr., respectively. For longer denaturation times the results were essentially the same.

Mass balance was approximately maintained after times greater than the time corresponding to the peak shown in Fig. 7. This was established by graphical integration,

$$M = \int_v^\infty \rho v n(v) dv \qquad \text{(Eq. 2)}$$

where M is the protein mass, ρ is the density, v is the volume of the particle, and $n(v)dv$ is the number of particles between the sizes v and $v + dv$.

The range of sizes observed in these experiments was 0.4 to 1.2-μ radius. The majority of the particles were between 0.4 to 0.8-μ radius. Under the microscope, $\times 970$ in immersion oil, aggregates were found to be nearly spherical in shape and were in the general magnitude of sizes detected by the multichannel analyzer.

[7] A detailed study of this question is underway and will be reported in a later communication.

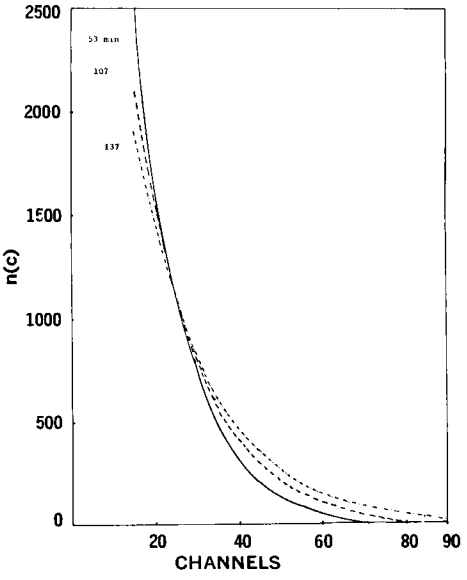

Fig. 6.—Differential distribution data showing aggregation of denatured ovalbumin particles with time in buffered saline, pH = 4.6.

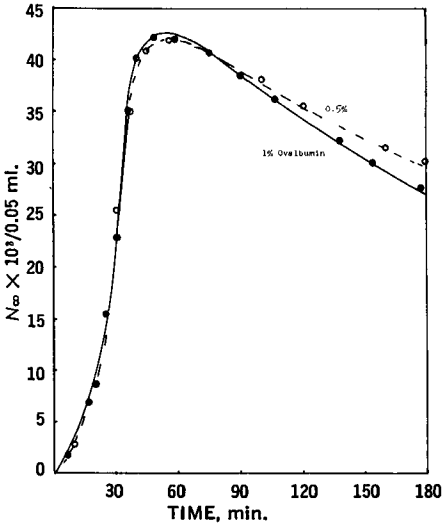

Fig. 7.—Changes in total denatured protein particulate concentration for sizes greater than 0.80-μ diameter as a function of time. Decreasing counts after 60 min. reflect aggregation of particles.

Comparison with Smoluchowski's Theory.—Smoluchowski worked out a basic theory of aggregation of spherical particles of a colloidal suspension (14). When the aggregation is controlled by Brownian diffusion in the absence of a force field, the aggregation of a relatively monodispersed system is given by the kinetic expression for bimolecular collision,

$$\frac{dN_\infty}{dt} = -KN_\infty^2 \qquad \text{(Eq. 3)}$$

Where N_∞ is the number of particles of all sizes, K is the rate constant, and t the time. Upon integration a linear relationship of $1/N_\infty$ *versus* t with slope K is predicted. For this case, the rate constant is:

$$K = \frac{4\pi DR}{W} \qquad \text{(Eq. 4)}$$

where D is the effective diffusion coefficient, R is the distance between centers of the particles, and W is the stability factor. By assuming the Stokes-Einstein relationship for translational diffusion, *i.e.*,

$$D = \frac{kT}{6\pi\mu a} \qquad \text{(Eq. 5)}$$

and the effective collision radius, $R = 2a$, and irreversible collision, $W = 1$, where k is the Boltzmann constant, μ the viscosity of the medium, T the absolute temperature, and a the particle radius, the theoretical maximum rate constant becomes

$$K = \frac{4kT}{3\mu} \qquad \text{(Eq. 6)}$$

At 30° the value of K is 5.6×10^{-12} cm.^{3} sec.$^{-1}$.

By using Eq. 1 the changes of the cumulative number of particles, N_∞, with time were determined by graphical integration with a planimeter of such differential particle distribution data as shown in Fig. 6. In the present experiments N_∞ corresponds to the total number of particles larger than the particle volume of 0.6289×10^{-12} cm.^{3} (15th channel), although the distribution extended to smaller sizes. The Coulter counter, model A, gave this quantity directly by using the appropriate threshold setting. In Fig. 8, the straight line relationship of the Smoluchowski-type plot is found. This is consistent with the theory of aggregation of essentially monodispersed sols. The experimental rate constants obtained with the 30 and 50-μ aperture tubes were not significantly different. The data much beyond 200 min. were believed to be unreliable because of the effects of sedimentation upon the aggregation rate. According to Müller (14), at room temperature, sedimentation may significantly affect the rate constant when the radius of some of the denatured ovalbumin particles are larger than 2 to 3 μ.

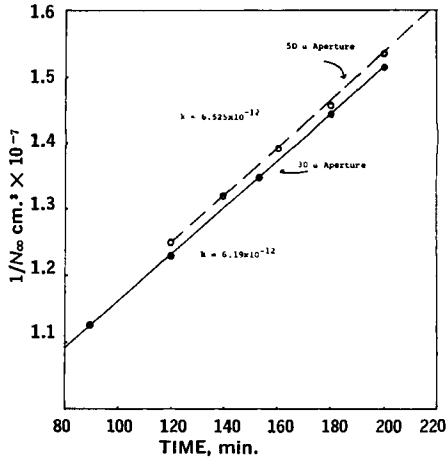

Fig. 8.—Linear plots showing agreement of the aggregation-time data with Smoluchowski theory.

In Table II the summary of some aggregation experiments of urea-denatured ovalbumin is given. The rate constant obtained from the multichannel analyzer and the Coulter counter compared well with each other and also with theory. Once the denatured protein solution reached a constant viscosity level, subsequent rate constants found did not differ from each other. There is a strong dependence of pH on the aggregation. Maximum aggregation was found near the isoelectric point. At pH 5.5 insignificant counts were detected with the 30-μ aperture tube. However, the Tyndall beam showed the presence of many submicron particles in a sol that remained stable for at least 4 weeks. At higher pH values, the Tyndall beam was weaker.

TABLE II.—SUMMARY OF DATA ON AGGREGATION OF UREA-DENATURED OVALBUMIN

Protein Concn., %	pH Buffered Normal Saline	Denaturation Period, hr.	$k \times 10^{-12}$ (cm.^{3}sec.$^{-1}$) Coulter, Model A	RIDL Multichannel

		49	7.1	7.67
	5.5	49	Insignificant counts,	
	8.7	49	but weak Tyndall beam observed.	

Comparison with the Self-Preserving Theory.—Friedlander and Swift (15) showed that certain forms of similarity or self-preserving functions can be applied to the solution of Smoluchowski's fundamental equation for aggregation. The relations depend upon the assumptions that the particle distribution in various sizes is continuous and that a particular form of the size spectrum is invariant with time. Hidy *et al.* (16, 17) have applied the theory to the case of discontinuous particle distributions.

In the theory of Friedlander and Swift the particle distribution is expressed as:

$$n(v, t) = \frac{N_\infty^2}{\phi} \psi_1(\eta) \qquad \text{(Eq. 7)}$$

where $\psi_1(\eta)$ is a dimensionless distribution function, the constant ϕ is the total volume fraction of particles:

$$\phi = \int_0^\infty vn(v)dv \qquad \text{(Eq. 8)}$$

and η is the dimensionless volume distribution:

$$\eta = \frac{vN_\infty}{\phi} \qquad \text{(Eq. 9)}$$

When $\eta = 1$, the average size of the particles with respect to volume is predicted. Furthermore,

$$N_v = N_\infty \int_\eta^\infty \psi_1(\eta)d\eta = N_\infty \psi_2(\eta) \qquad \text{(Eq. 10)}$$

where $\psi_2(\eta)$ is the dimensionless cumulative particle distribution. The terms $n(v)$, N_v, and N_∞, as defined before, are time-dependent; ψ_1 and ψ_2 are time-independent functions and, therefore, do not depend upon the initial size distributions.

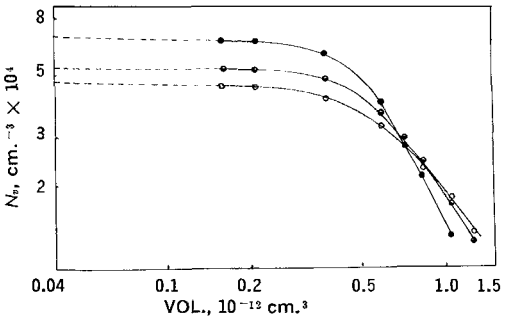

Fig. 9.—Cumulative size distributions for aggregating denatured ovalbumin particles. Key: ●, 53 min.; ◒, 107 min.; ○, 137 min.

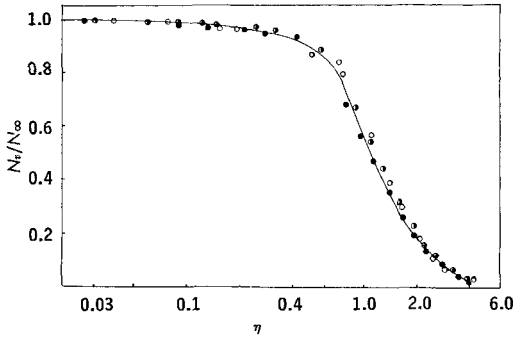

Fig. 10.—Test of self-preservation for aggregating denatured ovalbumin particles. In terms of dimensionless distribution functions, particle distributions taken at different times during the aggregation process fall approximately on a single curve. Data taken from Fig. 9.

The theory was applied to the denatured protein system for the data partially shown in Fig. 6. A log-log plot of N_v *versus* v is shown in Fig. 9 and values of N_∞ were determined by extrapolation of the curve to small values of v. When a Smoluchowski-type plot was made using the extrapolated values, the rate constant was 5.91×10^{-12} cm.^{3} sec.$^{-1}$, which is in good agreement with 6.19×10^{-12} cm.^{3} sec.$^{-1}$ previously found by using that part of the data at larger sizes. The volume fraction was 3.56×10^{-8} cm.^{3} for 0.05-ml. sample of the sol in contrast to the theoretical 3.58×10^{-8} cm.^{3} to indicate that after 53 min. practically all of the insoluble protein came into the detectable range of the RIDL analyzer system. In Fig. 10 the plots of N_v/N_∞ *versus* η at different time intervals shows the tendency of the distribution to preserve its form and gives ψ_2, the time-independent dimensionless cumulative distribution function, as predicted by Eq. 10.

According to Friedlander, if the $1/N_\infty$ *versus* t plot is linear, the rate of aggregation with the self-preserving size distribution can be described by:

$$\frac{dN_\infty}{dt} = \frac{-\alpha A_1 k T N_\infty^2}{3\mu} \qquad \text{(Eq. 11)}$$

where α is the collision efficiency having the same physical meaning as the factor W in Eq. 4, and

$$A_1 = \left[2 + 2 \int_0^\infty \eta^{1/3} d\psi_2 \int_0^\infty \eta^{-1/3} d\psi_2 \right] \quad \text{(Eq. 12)}$$

when $\alpha = 1$ and $A_1 = 4.0$, the rate constant of Eq. 11 reduces to that of Eq. 6 for the homogeneous case. Thus, A_1 is a significant parameter accounting for the effect of heterogeneity on the rate of aggregation. By comparing Eqs. 3 and 11,

$$\alpha = \frac{3K\mu}{A_1 kT} \quad \text{(Eq. 13)}$$

For the protein system, α was approximately 1, and A_1 was 4.148 ± 0.022. Then heterogeneity accounted for about 4% increase in the rate. From Eq. 11 the rate constant found was 5.81×10^{-12} cm.^{3} sec.$^{-1}$. The comparison of methods of determining the rate constant is summarized in Table III.

TABLE III.—COMPARISON OF METHODS OF DETERMINING RATE CONSTANTS OF AGGREGATION

Method of Treatment	Rate Constant, cm.^{3} sec.$^{-1}$
Smoluchowski's theory for monodispersed distribution taking N_∞ from	
(*a*) $\geq v = 0.6289 \times 10^{-12}$ cm.^{3}	6.19×10^{-12}
(*b*) $\geq v = 0.02 \times 10^{-12}$ cm.^{3}	5.91×10^{-12}
Self-preservation theory	5.81×10^{-12}

It should be noted that the approach of self-preservation theory offers a method of determining the aggregation rate constant independent of that approach which assumed a monodispersed system at initial periods of the aggregation process. Since the effective collision between particles was unity and the particle size distribution was essentially monodispersed, the rate constants determined by both methods were in good agreement.

Studies are continuing on the mechanism of the pH influence on the aggregation behavior. Experiments on the effects of electrolytes, temperature, and other additives are also planned.

Some Effects of Chloroquine on Oxidative Processes in Rat Heart

By GLORIA A. ARDUESER* and HAROLD C. HEIM

Chloroquine at a concentration of 5.4×10^{-4} *M* enhanced the oxygen consumption of rat ventricle homogenates respiring in the presence of succinate. This effect was not noted with aged homogenates. Total α-keto acids present after incubation of homogenates with succinate was observed to be diminished when chloroquine was present. The oxidation of malate and β-hydroxybutyrate was inhibited by the addition of chloroquine. Chronic poisoning by this drug did not affect the ability of heart homogenates to utilize β-hydroxybutyrate, but the oxidation of malate was impaired. A purified malic dehydrogenase was not inhibited by chloroquine but, at a concentration of 5.4×10^{-4} *M*, the drug markedly inhibited the oxidation of NADH by a fragmented mitochondrial suspension prepared from rat myocardium.

CHLOROQUINE has been shown to have an unexpectedly wide spectrum of therapeutic uses since its introduction into medicine as an antimalarial. The increased utilization of this drug at fairly high dose levels for extended periods has prompted reconsideration of its potential toxicity.

Visual disturbances, headache, bleaching of hair, electrocardiographic changes, and weight loss have been reported during short-term administration of chloroquine to healthy subjects (1). Electrocardiographic changes, consisting of lowered T wave, ST segment depression, and prolongation of QTc interval have occurred when

$$A_1 = \left[2 + 2 \int_0^\infty \eta^{1/3} d\psi_2 \int_0^\infty \eta^{-1/3} d\psi_2 \right] \quad \text{(Eq. 12)}$$

when $\alpha = 1$ and $A_1 = 4.0$, the rate constant of Eq. 11 reduces to that of Eq. 6 for the homogeneous case. Thus, A_1 is a significant parameter accounting for the effect of heterogeneity on the rate of aggregation. By comparing Eqs. 3 and 11,

$$\alpha = \frac{3K\mu}{A_1 kT} \quad \text{(Eq. 13)}$$

For the protein system, α was approximately 1, and A_1 was 4.148 ± 0.022. Then heterogeneity accounted for about 4% increase in the rate. From Eq. 11 the rate constant found was 5.81×10^{-12} cm.^{3} sec.$^{-1}$. The comparison of methods of determining the rate constant is summarized in Table III.

TABLE III.—COMPARISON OF METHODS OF DETERMINING RATE CONSTANTS OF AGGREGATION

Method of Treatment	Rate Constant, cm.^{3} sec.$^{-1}$
Smoluchowski's theory for monodispersed distribution taking N_∞ from	
(*a*) $\geq v = 0.6289 \times 10^{-12}$ cm.^{3}	6.19×10^{-12}
(*b*) $\geq v = 0.02 \times 10^{-12}$ cm.^{3}	5.91×10^{-12}
Self-preservation theory	5.81×10^{-12}

It should be noted that the approach of self-preservation theory offers a method of determining the aggregation rate constant independent of that approach which assumed a monodispersed system at initial periods of the aggregation process. Since the effective collision between particles was unity and the particle size distribution was essentially monodispersed, the rate constants determined by both methods were in good agreement.

Studies are continuing on the mechanism of the pH influence on the aggregation behavior. Experiments on the effects of electrolytes, temperature, and other additives are also planned.

Some Effects of Chloroquine on Oxidative Processes in Rat Heart

By GLORIA A. ARDUESER* and HAROLD C. HEIM

Chloroquine at a concentration of 5.4×10^{-4} *M* enhanced the oxygen consumption of rat ventricle homogenates respiring in the presence of succinate. This effect was not noted with aged homogenates. Total α-keto acids present after incubation of homogenates with succinate was observed to be diminished when chloroquine was present. The oxidation of malate and β-hydroxybutyrate was inhibited by the addition of chloroquine. Chronic poisoning by this drug did not affect the ability of heart homogenates to utilize β-hydroxybutyrate, but the oxidation of malate was impaired. A purified malic dehydrogenase was not inhibited by chloroquine but, at a concentration of 5.4×10^{-4} *M*, the drug markedly inhibited the oxidation of NADH by a fragmented mitochondrial suspension prepared from rat myocardium.

CHLOROQUINE has been shown to have an unexpectedly wide spectrum of therapeutic uses since its introduction into medicine as an antimalarial. The increased utilization of this drug at fairly high dose levels for extended periods has prompted reconsideration of its potential toxicity.

Visual disturbances, headache, bleaching of hair, electrocardiographic changes, and weight loss have been reported during short-term administration of chloroquine to healthy subjects (1). Electrocardiographic changes, consisting of lowered T wave, ST segment depression, and prolongation of QTc interval have occurred when

the drug was used in the treatment of conditions such as extraintestinal amebiasis (2). Similar changes have been noted during the course of acute, fatal, chloroquine poisoning (3). Muscle weakness and bilateral loss of knee and ankle reflexes have been demonstrated during extended chloroquine therapy in rheumatoid arthritis (4, 5).

Upon examination of several cases of acute chloroquine poisoning in children, a striking similarity to poisoning by quinidine was noted (6). It was suggested that the cardiac arrest which occurred might be due to a direct myocardial action, to anoxia from respiratory depression, or to both.

It has been reported that substantial differences exist in the toxicity of chloroquine for various laboratory animals, the compound being most toxic to the dog and least toxic to the mouse. The rat appeared to be more susceptible to the drug than the mouse. The study further indicated that chloroquine had a distinctly steeper dose-toxic response curve than other 4-aminoquinolines (7). This suggests that the drug has a narrow margin of safety, a factor which may be of great significance in therapeutic applications where high dose levels are necessary.

Long-term, chronic administration of chloroquine to rats indicated slight gross pathological changes (8). However, microscopic examination of tissues revealed a slowly developing necrosis of cardiac and skeletal muscle.

Because some of the cardiac effects of chloroquine might be due to the interference with metabolic processes of the myocardium, it appeared to be of interest to investigate the effect of the drug on some of the respiratory processes of heart homogenates.

METHODS

Conventional manometric techniques were used to study the effect of chloroquine on the oxidation of succinate, malate, and β-hydroxybutyrate by myocardial homogenates prepared from male Sprague-Dawley rats (9).

The animals were stunned by a blow to the head, exsanguinated, and the hearts removed immediately. Each heart was allowed to beat a few seconds in cold 0.1 *M* phosphate buffer, pH 7.35, after which the ventricular tissue was dissected away, cut open, washed in cold buffer, blotted dry on filter paper, and weighed on a torsion balance.

The homogenate was prepared by placing the tissue in a glass homogenizer containing sufficient cold buffer so that 0.5 ml. of homogenate contained 10 mg. of fresh tissue for the succinate studies or 40 mg. for the malate and β-hydroxybutyrate studies. Not more than 15 min. elapsed from the time the animals were sacrificed until the addition of the homogenate to the Warburg flasks. In some experiments the homogenates were aged before use by allowing them to remain in the refrigerator at 5° overnight followed by 5 hr. at room temperature.

The mitochondrial preparations utilized in the study of the effect of chloroquine on the oxidation of reduced nicotinamide adenine dinucleotide[1] were obtained by centrifuging homogenates, prepared in cold 0.25 *M* sucrose, at 700 × g for 12 min. at 2° in a Servall RC-2 refrigerated centrifuge equipped with a SS-34 rotor to remove cell fragments. The supernatant was then centrifuged at 10,000 × g for 12 min. The resulting pellet was dispersed in 0.25 *M* sucrose, and the suspension added to the flasks so that each contained mitochondria representing 100 mg. of ventricle. The suspension was found to oxidize NADH quite rapidly.

In all of the studies utilizing manometric techniques the center well of the Warburg flasks contained 0.2 ml. 10% KOH and a pleated strip of filter paper. All of these experiments employed air as the gas phase. A temperature of 30° was maintained during respiration determinations utilizing malate, β-hydroxybutyrate, and NADH as substrates. The effects of glutamate and chloroquine[2] on the oxidation of succinate were studied at 37°.

The buffer used for control of pH in the Warburg vessels during the succinate studies was 0.1 *M* potassium phosphate, pH 7.35, containing 0.01 *M* disodium ethylenediaminetetraacetate (EDTA) per liter as recommended by several investigators (10, 11). The main compartments of the flasks in which the oxidation of succinate by aged homogenates was studied contained 0.5 ml. of homogenate; 0.3 ml. of 5×10^{-2} *M* chloroquine; 0.3 ml. of 5×10^{-4} *M* cytochrome c; 1.3 ml. of phosphate buffer. Distilled water was used to replace the chloroquine in the control flasks. The sidearm contained 0.4 ml. of 0.1 *M* succinate which was tipped into the main compartment at zero time. In some of the experiments with aged homogenates, 0.2 ml. of 10^{-3} *M* NAD, dissolved in phosphate buffer, replaced 0.2 ml. of the buffer.

When the effect of glutamate and chloroquine on the oxidation of succinate was studied, Warburg vessels with two sidearms were employed. One sidearm of each vessel contained 0.4 ml. of 0.1 *M* succinate and was tipped at zero time. The second sidearm contained 0.3 ml. of either distilled water or 5×10^{-3} *M* of chloroquine or 0.1 *M* glutamate and was tipped after 45 min. The main compartment contained 0.5 ml. of homogenate; 0.3 ml. of 5×10^{-4} *M* cytochrome c; 1.0 ml. of phosphate buffer, and sufficient distilled water to give a final volume of 3.0 ml. In some experiments 0.3 ml. of 0.1 *M* glutamate or 0.3 ml. of 5×10^{-3} *M* chloroquine was placed in the main compartment instead of in the second sidearm.

In the study of the oxidation of malate and β-hydroxybutyrate, the main compartment of each flask contained 0.5 ml. of homogenate; 0.3 ml. of 5×10^{-3} *M* chloroquine or distilled water; 0.1 ml.

[1] Henceforth designated as NADH. The oxidized form will be designated as NAD.

[2] The chloroquine used in this study was graciously supplied by the Winthrop Laboratories, New York, N. Y., as Aralen Diphosphate.

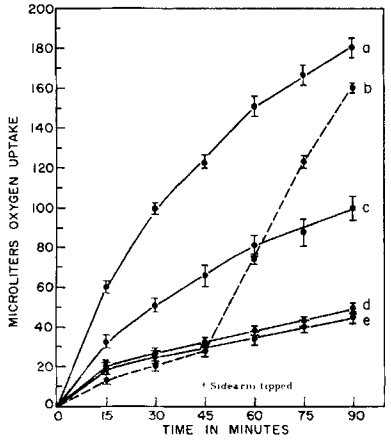

Fig. 1.—The effect of glutamate and chloroquine on succinate in heart homogenates. Key: curve a, glutamate in main compartment; curve b, glutamate tipped from sidearm; curve c, chloroquine in main compartment; curve d, control (no additions); curve e, chloroquine tipped from sidearm.

of 5×10^{-4} *M* cytochrome c; 0.1 ml. of 1.5×10^{-2} *M* $MgCl_2$; 0.1 ml. of 1.5×10^{-2} *M* nicotinamide; 0.1 ml. of 2×10^{-2} *M* adenosine triphosphate; 1.1 ml. of 0.1 *M* potassium phosphate buffer with no EDTA added, pH 7.35; and 0.4 ml. of 0.1 *M* substrate. When malate was employed as the substrate, 0.3 ml. of 1.5×10^{-2} *M* glutamate was included, and the 0.1 ml. of 1.5×10^{-2} *M* malate which was used in the β-hydroxybutyrate studies was excluded from the reaction mixture. Distilled water was added to make the final volume 3 ml.

A reaction mixture similar to that which has been used by other investigators (12) was employed to study the effect of chloroquine on oxidation of NADH by a suspension of swollen and/or fragmented mitochondria. The main compartment of each flask contained 0.75 ml. of a buffer, pH 7.4, consisting of 0.04 *M* potassium phosphate, 0.04 *M* tris (hydroxymethyl) aminomethane, and 0.4 *M* KCl; 0.15 ml. of 0.4 *M* KF; 0.15 ml. of 0.12 *M* $MgCl_2$; 0.5 ml. mitochondrial suspension, and 0.3 ml. 5×10^{-3} *M* chloroquine or distilled water. The sidearm, containing 0.4 ml. of 0.04 *M* NADH, was tipped at zero time. Distilled water was added to make the final volume 3 ml. Readings were taken every 5 min. during a 45-min. period.

The method described by Friedemann (13) was used for the determination of total α-keto acids present in the flasks after a 90-min. incubation of fresh homogenates with succinate as the substrate.

The effect of chloroquine on malic dehydrogenase was determined by following the rate of oxidation of NADH at 340 mμ according to the method of Ochoa (14). In these experiments a purified malic dehydrogenase, obtained from commercial sources,[3] was used, and the reaction was followed for 4 min. at 25° with a Beckman DU spectrophotometer equipped with a Guilford automatic recorder.

The possibility of complex formation occurring between chloroquine and NAD was studied spectrophotometrically using a Beckman DB and recording the spectra between 220 and 400 mμ. In these experiments 0.5 ml. of 5×10^{-5} *M* NAD, 0.5 ml. of 5×10^{-5} *M* chloroquine, 1.0 ml. of H_2O, and 1.0 ml. of 0.1 *M* phosphate buffer (pH 7.35) were incubated for 10 min. at 25° prior to the determination. The reference cell contained the same reagents, except that NAD was replaced by buffer.

In order to study the chronic effects of chloroquine administration on the respiratory processes of the heart, young male rats weighing approximately 100 Gm. were separated into 2 groups of six animals each, further designated as groups A and B. Each rat in group A received daily intraperitoneal injections of 5 mg. of chloroquine phosphate in a volume of 0.5 ml. of distilled water for 7 days and 9 mg. of the drug in the same volume thereafter. Group B received 1.5 ml. of distilled water daily by the same method of administration. On the 14th day the animals were sacrificed, and heart homogenates prepared from each animal. The ability of heart homogenates prepared from animals in group A to utilize malate and β-hydroxybutyrate was compared to that of group B.

RESULTS AND DISCUSSION

Figure 1 shows that chloroquine enhanced the oxygen uptake of freshly prepared homogenates in the presence of added succinate. This effect was previously noted by Datta and Basu (15) with mouse liver homogenates, but not by Hess and Haugaard (16) who used rat heart slices and homog-

enates. The oxidation of succinate proceeds *via* the following pathway: succinate → fumarate → malate $\xrightarrow{NAD}$ oxaloacetate.

It has been reported that oxaloacetate is an inhibitor of succinate oxidation, *in vitro*, (10) and it follows that an accumulation of oxaloacetate in the Warburg vessels might cause a curtailment of oxygen consumption. On the other hand, chloroquine, by preventing the accumulation of oxaloacetate, could conceivably increase oxygen uptake. The data reported in Table I support this concept and show that after 90 min., the α-keto acid content of flasks to which chloroquine was added at the beginning of the experiment was much lower than that of the control flasks. Heim *et al.* (17) have reported that emetine prevents the accumulation of oxaloacetate and augments the oxygen consumption of heart homogenates respiring in the presence of added succinate. Wolff and Ball (10) showed that thyroxine evokes the same effect.

When chloroquine was added to the flasks 45 min. after the beginning of the experiments an enhancement of oxygen uptake was not observed, possibly because sufficient oxaloacetate had accumulated during the 45-min. period to exert an inhibitory effect. Heart tissue is rich in glutamate-oxaloacetate transaminase and, if the lowered oxygen consumption were due to an accumulation of oxaloacetate, the addition of glutamate would be expected to reverse the inhibitory effect of the oxaloacetate. As shown in Fig. 1, when glutamate was added to the flasks, either at the beginning of the experiment or after 45 min. had elapsed, the oxygen consumption was greatly increased. Therefore, it seems probable that glutamate, *via* transamination, removes the oxaloacetate while chloroquine, when added at the beginning of the experiment, appears to prevent the accumulation of the inhibitory compound. This suggests that the drug may inhibit at some point on the pathway between succinate and oxaloacetate.

With aged homogenates it was found that chloroquine evoked an appreciable inhibition of oxygen uptake in the presence of added succinate. When NAD was added at the beginning of the experiments, the oxygen consumption was markedly inhibited and further reduced, but only to a slight extent, by chloroquine. These results are shown in Fig. 2.

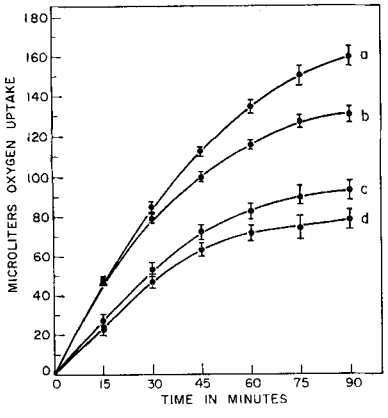

Fig. 3.—Respiration of rat heart homogenates in presence of malate. Key: curve a, control (no drug added); curve b, chloroquine (final concentration 5.4×10^{-4} *M*); curve c, endogenous respiration; curve d, endogenous respiration with added chloroquine.

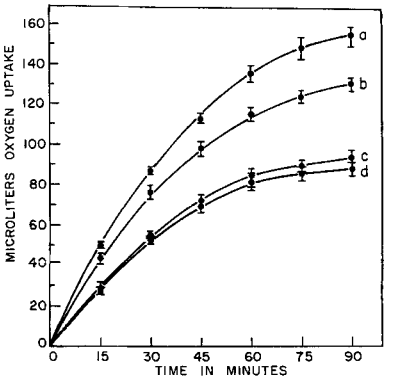

Fig. 5.—Oxidation of malate by heart homogenates from sham-injected and chloroquine-treated rats. Key: curve a, sham-injected animals; curve b, chloroquine-treated animals; curve c, endogenous respiration of chloroquine-treated animals; curve d, endogenous respiration of sham-injected animals.

The oxidation of malate, unlike that of succinate, is an NAD-linked process and contributes substantially to the production of high energy phosphate compounds. Figure 3 shows that chloroquine evokes an inhibitory effect on the oxidation of added malate by homogenates. Datta and Basu (15), utilizing considerably higher concentrations of chloroquine than those employed in this study, demonstrated a rather marked depression of malate oxidation by the drug with mouse liver homogenates.

The oxidation of β-hydroxybutyrate was inhibited by chloroquine, as shown in Fig. 4. It has

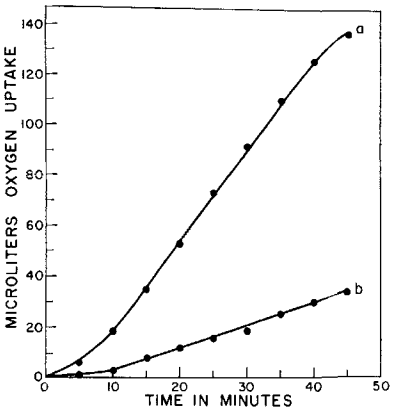

Fig. 6.—Effect of chloroquine on respiration of fragmented mitochondrial suspensions in presence of added NADH. Each point represents determination in duplicate from four animals. Key: curve a, control (no drug added); curve b, chloroquine (final concentration 5.4×10^{-4} *M*).

also been reported by Datta and Basu (15) that certain other NAD-linked reactions are inhibited by chloroquine.

In the animals chronically poisoned by chloroquine a significant loss of weight, similar to that reported by Fitzhugh *et al.* (1), was noted. The ability of heart homogenates, prepared from poisoned animals, to utilize β-hydroxybutyrate was not impaired, but the ability to oxidize malate was somewhat inhibited as illustrated in Fig. 5.

Studies of a preliminary nature were conducted to learn if a complex formation occurs between NAD and chloroquine. No alteration in the absorption spectra could be observed when solutions of the two compounds were mixed. The conclusions which may be drawn from such an observation are limited but present an indication that a complex formation does not occur.

Malic dehydrogenase activity was found to be not significantly affected by chloroquine, in confirmation of the work of Gerlack (18), who observed that the drug elicited no appreciable effect on the activity of either lactic or malic dehydrogenases.

Mushinski *et al.* (19) reported that chloroquine was a potent inhibitor of NADH-cytochrome c reductase in rat skeletal muscle preparations. If this mechanism is operative in heart tissue, it could explain the depression of malate oxidation without a direct effect on malic dehydrogenase. Malate is oxidized in the presence of malic dehydrogenase and NAD to oxaloacetate with the concomitant formation of NADH. NADH is then oxidized to NAD as hydrogen atoms are transferred to flavoproteins, a step which is followed by a series of oxidation–reduction reactions involving the cytochromes. It has been reported that the impermeability to extra-mitochondrial NADH is a characteristic of intact mitochondria (12). The oxidation of added NADH will occur, however, if the mitochondria are exposed to conditions, such as hypotonic media or rigorous isolation procedures, which cause the swelling and/or disruption of mitochondrial membranes. The mitochondrial preparation used in this study displayed a nearly linear oxidation of added NADH over a period of 30 min., and it was found that chloroquine, at a concentration of 5.4×10^{-4} *M*, elicited a marked inhibitory effect on the oxidative process, as shown in Fig. 6. This finding, together with the observed inhibitory effect of the drug on the oxidation of succinate by aged homogenates to which NAD had been added, and the insignificant effect evoked on a purified malic dehydrogenase, suggests that chloroquine may exert effects at or beyond the NAD–NADH step of terminal respiration.

Effect of Ultraviolet Irradiation on Chlorpromazine II

Anaerobic Condition

By CHIAN L. HUANG* and FREEMAN L. SANDS

In this report, ultraviolet light-catalyzed reaction of chlorpromazine under anaerobic condition is presented. It appears that chlorpromazine behaves differently to ultraviolet energy under aerobic and anaerobic conditions. Under the former condition oxidation products prevail, and the sulfoxide and *N*-oxide are formed; however, under the latter condition, the polymerization process predominates and the polymer was found to be the major product. The biological activity of this compound was tested on human volunteers; this study indicated that this compound caused a negligible skin irritation but produced a bluish-purple color resembling that of the skin discoloration observed in patients. Hydrogen chloride liberated in the initial phase of the photochemical reaction may be responsible for the skin rash reported in patients receiving daily maintenance dose of chlorpromazine. Formation of a polymer coupled with melanin may be the cause of the skin discoloration observed in patients under prolonged and high dose of chlorpromazine treatment.

SINCE THE introduction of chlorpromazine in the clinical treatment of psychosis, a number of cases of photosensitivity or photoallergy, namely, abnormal skin reactions (1–16) and ocular changes (8–19), associated with this drug have been reported. Concurrently, these investigators pointed out that skin discoloration occurred on the exposed portions of the body of patients receiving a long-term medication of large doses (300–500 mg. three times a day) of phenothiazines, especially chlorpromazine. The rate of occurrence of the skin discoloration is about 0.1–0.2% of the patients treated with chlorpromazine. The incidences of the ocular changes seem to precede the skin pigmentation in reference to the reports that many patients had ocular changes before skin pigmentation took place (20–22), and the majority of patients with skin changes also had ocular complications (23). It appears that these bizarre phenomena are directly associated with photo energy of short wavelength; however, the nature of these abnormal reactions is not well understood.

It is the purpose of this study to investigate the *in vitro* effect of ultraviolet energy on an aqueous solution of chlorpromazine which might furnish clues toward the nature of the photochemical reactions taking place in patients under chlorpromazine medication.

In a previous communication (24), the effect of ultraviolet (U.V.) irradiation (25–29) on an aqueous solution of chlorpromazine under aerobic conditions was presented; two oxidation products, chlorpromazine sulfoxide and chlorpromazine *N*-oxide, were identified, and the physical properties of 10 other compounds were described. Apparently, oxygen (30) present in the medium played an important role in the formation of oxidation products of chlorpromazine in this photochemical reaction. The site of attack by the oxygen was found to take place first on the S function at position 5 followed by the terminal N.

In this report, the photo-induced reaction products of chlorpromazine in an aqueous solution under anaerobic condition are presented. The chromatographic pattern of the products formed under the anaerobic condition was quite different from that of the aerobic condition. A polymerization reaction was found to be a major process taking place under these conditions, and a polymer and a dimer were isolated from the reaction mixture. Evidently, the cleavage of the chlorine function (31) at position 2 resulted in the formation of a free radical which prompted these reactions. In a preliminary test, an aqueous suspension of the polymer injected intracutaneously to two volunteers exhibited a discoloration resembling that of the photosensitivity observed in patients receiving chlorpromazine medication. The formation of a polymer in the skin might be a cause of photosensitivity reported in patients under a long-term medication of large doses (300–500 mg. three times a day) of chlorpromazine. Promazine and 2-hydroxypromazine were also isolated and identified. Negative tests with ninhydrin and nitroprusside reagents on the reaction products isolated in this experiment indicated that there is no demethylation occurring under these conditions (32).

METHOD[1]

Chlorpromazine hydrochloride (5 Gm.) was dissolved in freshly boiled water (500 ml.) and placed in a glass ampul (10 ml.), which was previously filled with nitrogen gas. The ampul was replenished with nitrogen gas and sealed under nitrogen atmosphere. Fifty ampuls thus prepared were placed in a box with aluminum foil linings on inside walls and subjected to ultraviolet irradiation from a Spectroline B-100 lamp (120 w.) at a distance of 20 cm. At every 24-hr. interval, one ampul was removed from the box and the content examined for the extent of the photochemical effect. It was found that all the starting material was consumed completely within 5 days. The time sequential chromatographic patterns and the ultraviolet absorption spectra of the irradiated media are shown in Fig. 1.

At the end of 5 days, U.V. irradiation was terminated. The ampuls were removed from the box, and the contents emptied into a container filled with nitrogen. It was noted that the colorless solution at the beginning had changed to deep-brown at the termination of the irradiation, and the pH had shifted from 4.5 to 1.9 (33). The results of alkalimetry revealed that approximately 0.8 mole of hydrogen chloride per mole of starting material was liberated in the medium. The solution was adjusted to pH 7 with 10% NaOH solution and the yellowish green precipitate which appeared was collected by centrifugation. The precipitate was washed 3 times with water, and the washings were added to the supernatant liquid.

The supernatant liquid was tested for the presence of dimethylamine according to the procedure described by Yamamoto and Fujisawa (32). Although the product recovered from the reaction vessel (containing dichlorodiphenyldisulfimide reagent) acquired a light brown color at the end of the experiment, it gave the same melting point as that of the starting material, m.p. 211–213°. Therefore, it was concluded that no dimethylamine was present in the irradiated solution of chlorpromazine and no demethylation took place under these conditions.

Thick-Layer Chromatography.—The precipitate collected above was extracted with a large quantity of cold methanol. The methanol extract was condensed to a small volume and subjected to thick-layer chromatography. Approximately, 1.5 ml. of an aliquot specimen was placed linearly in a 0.5-cm. band about 4 cm. from the bottom of a 15 × 48-cm. plate (coated with a 0.5-mm. layer of Silica Gel G and activated at 100° for 1.5 hr.). The chromatogram was developed in a nitrogen atmosphere in a chamber containing a solvent system, ethyl acetate–ethanol–water (8:3:3), for 7 hr. to a height of approximately 31 cm. After the chromatogram was removed from the solvent system, it was dried, examined under a U.V. lamp, and covered with a sheet of plastic wrap (Saran wrap); this left about a 2-cm. strip on one side of the plate uncovered. The exposed strip was sprayed with 50% sulfuric acid to produce color. Twelve fractions with R_f 0–0.78 and the color varying from pink to purple were observed. Using this sprayed strip as a guide, the chromatogram was fractionated, and each fraction was removed from the plate and extracted with the above solvent system. The extract of each fraction was rechromatographed twice for further purification. Only a trace of the starting material was recovered from the medium after 5 days of irradiation.

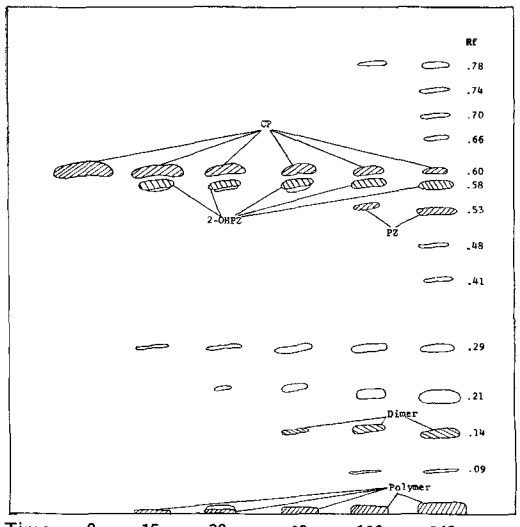

Fig. 1.—Sequential thin-layer chromatographic patterns of ultraviolet light-induced reaction products of chlorpromazine under anaerobic condition. Key: CP, chlorpromazine; 2PZ-OH, 2-hydroxypromazine; PZ, promazine.

Isolation of Promazine.—Fraction *6* was rechromatographed on a thick-layer plate several times for purification. After the final methanol eluate was evaporated to dryness, an oily residue was obtained. The physical properties of this compound—namely, R_f (0.46), color reaction with 50% sulfuric acid (orange), $\lambda_{max.}$ (208, 256, 300 mμ), and I.R. spectrum, were found to be identical with those of a reference promazine. The melting point of the picrate of this compound was found to be 143–144°, and the mixed melting point with an authentic promazine picrate did not show depression (142–144°).

Isolation of 2-Hydroxypromazine.—Fraction *4* was eluted with methanol from a thick-layer plate. The methanol extract was evaporated to dryness and the residue was rechromatographed three times for further purification. The purified fraction had an R_f value of 0.48 and a reddish-purple color reaction with 50% sulfuric acid. The melting point (132–133.5°), U.V. (212, 254 mμ), and I.R. spectra of this compound were found to be identical with those of a reference 2-hydroxypromazine. The color reaction of this compound compared with that of 2-hydroxypromazine (2-PZOH) is shown in Table I.

Isolation of the Dimer.—*Scheme I.*—Fraction *11* (R_f 0.09) was eluted with hot methanol. The methanol eluate was evaporated to dryness and the residue recrystallized from methyl ethyl ketone to a yellow

[1] Melting points were taken on a Fisher-Johns apparatus and are uncorrected. Molecular weights were determined by using a Mechrolab vapor pressure osmometer. Ultraviolet absorption spectra were obtained in a Bausch & Lomb spectronic 505 and infrared absorption spectra were taken in a Perkin-Elmer 237 spectrophotometer.

TABLE I.—COLOR REACTION OF FRACTION 4 AND 2-PZOH

powder. This material had a purple color reaction with 50% sulfuric acid. The melting point of this compound was above 300° (loses color reaction with 50% sulfuric acid at 250°). Ultraviolet absorption peaks were found at 262 and 313 mμ. A quaternary ammonium salt of this compound was prepared by reacting an acetone solution of this compound (1 mole) with methyliodide (1 mole) at room temperature. The mixture was shaken for a few minutes, and ether was added to precipitate the quaternary ammonium salt (m.p. > 300°). The molecular weight of this compound was found to be 816; this is equivalent to the molecular weight of the quaternary ammonium salt of a dimer (31).

Anal.—Calcd. for $(C_{18}H_{21}N_2SI)_2$: mol. wt., 848.7; C, 50.94; H, 4.99; N, 6.61; S, 7.55. Found: C, 50.44; H, 5.13; N, 6.71; S, 7.43; mol. wt., 816.

Isolation of the Polymer.—The greenish-yellow residue left after the methanol extraction above was purified as follows. This material was extracted with chloroform and the chloroform extract was condensed to a small volume and precipitated with *n*-heptane. The yellowish-brown precipitate was filtered and dried. This material was slightly soluble in acetone, ethyl acetate, and ethanol. Both the sodium fusion and Beilstein's flame tests gave a negative reaction for chlorine. It had a bluish-purple color reaction with 50% sulfuric acid, and a green color with 1% ferric chloride reagent. The R_f value on a thin-layer chromatogram was 0–0.01. This compound was found to be extremely resistant to oxidation by hydrogen peroxide. Attempts to degradate this compound with acid or base at elevated temperatures and pressures failed to produce any product. This material is a greenish-brown powder, with m.p. > 300° (loses color reaction with 50% sulfuric acid at 235°). Its picrate has a m.p. 144–145°. The infrared absorption spectrum is shown in Fig. 2. This compound does not rotate polarized light. The proposed structure of this compound is illustrated in Scheme I.

Anal.—Calcd. for $(C_{17}H_{18}N_2S \cdot {}^1/_2H_2O)n$: C, 70.10; H, 6.24; N, 9.63; S, 11.00. Found: C, 70.47; H, 5.90; N, 9.22; S, 10.91; mol. wt., 1990.

A quaternary ammonium salt of the polymer was prepared by refluxing methanol solution of this compound (1 mole) with methyliodide (1 mole) for 15 min. After cooling, ether was added into the mixture to precipitate the quaternary ammonium salt. This compound is a yellowish-brown powder (m.p. 239–245°) with ultraviolet absorption peaks at 220 and 262 mμ.

Anal.—Calcd. for $(C_{18}H_{21}N_2SI)n$: C, 50.95; H, 4.99; N, 6.60; S, 7.56. Found: C, 50.87; H, 5.07; N, 6.36; S, 7.79.

A Preliminary Test on Skin.—Ten milligrams of the polymer was suspended in 10 ml. of normal saline solution, and 0.1 ml. each of the suspension was injected intracutaneously into the inner side of forearms of two volunteers. It produced a bluish-purple stain resembling that of the skin discoloration observed in patients (1–16). The irritating effects of this compound on the injected site was almost negligible. The color of the injected site faded and the skin returned to its normal color within 3 days.

CONCLUSION AND DISCUSSION

Liberation of hydrogen chloride and the subsequent formation of a polymer of chlorpromazine in the tissues has been suggested as a possible cause of the photosensitivity and skin discoloration of patients receiving chlorpromazine medication for a prolonged period.

The hydrogen chloride in the initial phase of photochemical reaction could be responsible for the skin rash (7) observed in patients who were exposed to sunlight. The skin irritability of the patients subsided after they took cover from the sunlight; however, the inflammatory signs remained for hours. It could be due to the residual effects of the hydrogen chloride on the tissues. The chloride function at position 2 of the chlorpromazine molecule seems to be cleaved easily under these conditions; this is evidenced by a shift of the pH toward an acidic side (33) and an increase in the concentration of hydrogen chloride in the irradiated medium after 15 min. Similar findings, namely, cleavage of the $SO_2N(CH_3)_2$ group from thioproperazine to form sulfuric acid has been reported (32).

As the results of the cleavage of the chloride function (31), a carbonium ion is created at position 2. On the other hand, there exists in the chlorpromazine molecule a carbon at position 7 which acquires a relatively high electron density due to the greater *o,p*-directing force of the N at position 10. Thus, it has been speculated that a free radical attack on position 7 triggered by the carbonium ion at position 2 takes place, and a polymer with 2–7 linkage would be formed. Also the formation of a dimer from chlorpromazine with a possible 2–2 linkage has been found in this study (32, 34). Possible roles this compound might have in connection with the ocular and skin changes are currently under investigation.

The polymer isolated from the reaction medium is a greenish-brown powder, insoluble in almost all organic solvents except hot methanol, and resistant to acidic or basic hydrolysis at elevated pressures and temperatures. The intracutaneous injection of this polymer produced a purple color in the injected area of skin resembling that of the photosensitivity observed in patients. Therefore, the polymer formed in tissues as the results of the photo-induced polymerization reaction may be responsible for the skin discoloration.

This photochemical reaction takes place quite rapidly in reference to the observations in two patients (who were receiving 600 mg. three times a day of chlorpromazine medication); 15–30 min. of exposure to a bright sunlight was enough to produce a skin discoloration preceded by a condition

of sunburn. This indicated that photo-induced reaction of chlorpromazine took place at the site of exposure. It appears that chlorpromazine or its metabolites are in a bound state with melanin in tissues, since the drug has been demonstrated to be capable of forming complexes with melanin *in vitro*

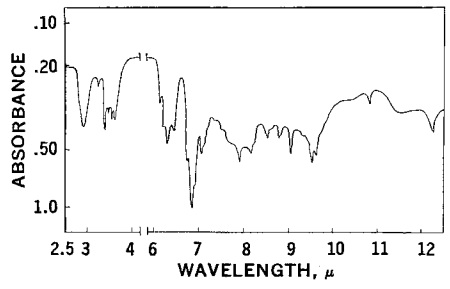

Fig. 2.—Infrared absorption spectrum of the polymer taken on a Perkin-Elmer model 237 spectrophotometer.

(35) and *in vivo* (36–39); however, skin discoloration would not occur without photo energy to trigger the polymerization reaction of chlorpromazine. Since chlorpromazine and its polymer react readily with silver, iron, and other metal ions to produce a color or a precipitate, the reagents currently applied to stain melanin (7) in tissues are expected to react with this drug or its derivatives to produce a melanin-like stain (7, 38).

The skin discoloration produced by the polymer injected intracutaneously to two volunteers faded, and the skin resumed its normal color within 3 days. These findings indicated that the polymer is transported from the site of administration or metabolized. Accordingly, a polymer of the same nature was isolated from a large amount of urine specimens from patients receiving a long-term medication of chlorpromazine (40). This finding suggested that the polymer formed in the skin by a photo-induced reaction is metabolized and excreted in urine. It is speculated that part of the polymer might be deposited or picked up by other organs during the course of transportation; this may be responsible for the appearance of a melanin-like material in the organs not being exposed to sunlight (41). Organs such as hairs and nails which are less affected by the normal process of metabolism would be expected to have a relatively high concentration of the drug. As the results of the accumulation of the drug, the hair might alter its shade because of a possible formation of the polymer, though the rate of formation would be lower than that occurring in the skin. It would be of interest to see further observations on this subject. The polymer of chlorpromazine may be bound to protein or deposited in fat-rich tissues; however, attempts were not made to clarify this matter in this study.

The polymers isolated from the U.V. irradiated medium showed a bluish-purple color reaction with 50% sulfuric acid; however, the reaction is rather sluggish—namely, the color reaction takes 30–60 sec. to develop, and the color density reaches its peak after 2–3 hr. The U.V. absorption peaks were found at 208 and 263 mμ; this indicated a shift toward the longer side of wavelength. There is no evidence of a 310-mμ peak when compared with chlorpromazine (207, 256, and 310 mμ).

The quaternary ammonium salt of this polymer is less soluble in organic solvents than the free base. In the U.V. irradiated medium under the anaerobic condition, 12 fractions (Table II) were detected on a thin-layer chromatogram; however, the sulfoxide could not be demonstrated. As the reaction proceeded and the starting material, chlorpromazine, was consumed, the concentration of the polymer increased in an almost parallel relationship to the irradiation time. The relationship of the appearance of various fractions *versus* irradiation time is illustrated in Fig. 1. The isolated polymer reacted readily with methyliodide to form a quaternary ammonium salt; this indicated the presence of an intact dimethylamino side chain.

Various organic solvents were used in the preparation of chlorpromazine solution for irradiation under anaerobic condition. Chloroform is the only sol-

vent which prevented the formation of the polymer, and other solvents, such as benzene, ethylene dichloride, ethyl acetate, and carbon tetrachloride, failed to suppress the polymerization reaction. The chromatographic pattern of the ethylene dichloride solution of chlorpromazine resembles that of the deoxygenated aqueous solution. A deoxygenated chlorpromazine solution in phosphate buffer solution (pH 7.8), treated with U.V. energy under the same conditions, failed to prevent the polymer formation. It was of interest to observe that ascorbic acid added to the aqueous solution of chlorpromazine prevented the formation of the polymer, whereas sodium bisulfite did not inhibit the polymerization reaction under the same conditions. The aqueous medium containing maleic acid produced only a trace of the polymer. Free radical (24–27) formation elicited by the short wavelength photon is apparently the key step toward the formation of the polymer. However, these free radicals are detectable only in the solvent media, and merely a trace or none of them exists in a solid state.

It appears that the intact chlorpromazine molecules are deposited in the tissues or organs either in the free or bound form (41). When these tissues or organs are exposed to ultraviolet energy, photochemical reactions take place to cleave the chloride function on the chlorpromazine molecules to form hydrogen chloride and, on the other hand, creating free radicals at the site of irradiation. Immediately, a polymerization reaction of these free radicals proceeds to form a polymer which deposits at the site of irradiation along with melanin (7, 38) to cause the skin discoloration. Although hydrogen chloride liberation and the polymer formation are proposed as the main cause of the skin irritation and the abnormal skin discolorations, caution must be taken to differentiate between the photosensitivity of this nature and that of a photo allergy or drug allergy developed in individuals who are sensitive to even a low dose of phenothiazines.

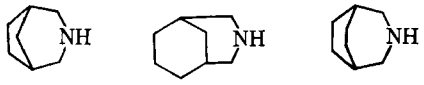
Esters of Aminoalcohols Derived from 3-Azabicyclo[3.2.2]nonane

By PRAMOD P. KARKHANIS* and W. LEWIS NOBLES

A series of esters of the type I and II was prepared utilizing 3-azabicyclo[3.2.2]nonane. The pharmacological testing of one of these esters is reported.

COMPOUNDS having interesting pharmacological activity have been prepared from one or more of the parent amines, 3-azabicyclo[3.2.1]-octane (I), 3-azabicyclo[3.3.1]nonane (II), and 3-azabicyclo[3.2.2]nonane (III) (1).



I II III

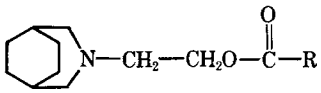
The use of 3-azabicyclo[3.2.2]nonane, extended in other areas of research, was initiated earlier at this institution by Blanton and Nobles (2, 3). These authors investigated the ketonic Mannich bases and their derivatives obtained from 3-azabicyclo[3.2.2]nonane. The ketonic Mannich bases have been shown to exhibit activity against *Staphylococcus aureus, Candida albicans, Trichophyton mentagrophytes,* and *Trichomonas foetus* (4).

Krieger (5) has demonstrated the usefulness of the guanidine derivative of 3-azabicyclo[3.2.2]-nonane as a possible hypotensive agent. Moreover, Martell and Soine (6) have reported that the esters of 3-hydroxy-1-azabicyclo[3.3.1]-nonane and 8-hydroxy-1-azabicyclo[4.3.0]nonane are potent anticholinergic agents.

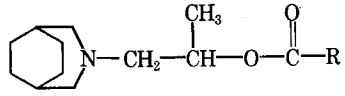
These observations prompted the investigations reported in this paper. The object of the present work was to prepare and examine some of the esters of the amino alcohols obtainable from 3-azabicyclo[3.2.2]nonane and to determine whether they possessed significant pharmacological action.

DISCUSSION

Types of compounds prepared from 3-azabicyclo[3.2.2]nonane are shown as types I and II.

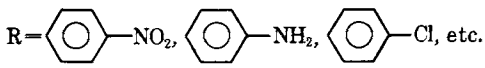


Type I



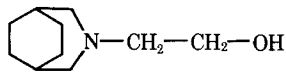
Type II

where



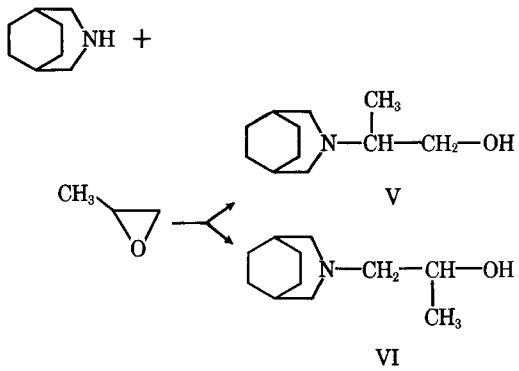
The preparation of 20 new esters of types I and II, starting with 3-azabicyclo[3.2.2]nonane,[1] was accomplished by well-known methods described in the literature.

A modification of the procedure described by Horne and Shriner (7), utilizing ethylene oxide at a lower temperature, was employed to obtain 3-azabicyclo[3.2.2]nonane-3-ethanol (IV) from 3-azabicyclo[3.2.2]nonane (8).



IV

When propylene oxide is treated with 3-azabicyclo[3.2.2]nonane using the same conditions as those used for ethylene oxide, there is a possibility of forming either 2-(3-azabicyclo[3.2.2]nonyl)-3-propanol (V) or 3-(3-azabicyclo[3.2.2]nonyl)-2-propanol (VI) or a mixture of both of these isomers, depending upon the point of ring opening (Scheme I).



Scheme I

When the alcohol was chromatographed on plates coated with Silica Gel G in solvent systems such as ethanol, methanol, chloroform, benzene, and benzene–methanol (40:60), it demonstrated only one sample spot upon visualization with acidic potassium permanganate solution, indicating the formation of only one isomer.

Received April 25, 1966, from the School of Pharmacy, University of Mississippi, University 38677.
Accepted for publication November 3, 1966.
Abstracted in part from a thesis submitted by Pramod P. Karkhanis to the Graduate School, University of Mississippi, University, in partial fulfillment of Master of Science degree requirements.

[a] All the compounds were recrystallized from ethanol–ethylacetate and ether mixture. [b] All the melting points are uncorrected. [c] Elemental analyses were done through the courtesy of Dr. P. N. Craig, Smith Kline & French Laboratories, Philadelphia, Pa.

The NMR data[2] (see under *Experimental*) indicated the formation of 3-(3-azabicyclo[3.2.2]-nonyl)-2-propanol (VI). Contrary to expectations, this alcohol failed to undergo the haloform reaction. Fuson and Bull (9) have indicated that only certain secondary alcohols undergo a haloform reaction.

The alcohol, 3-(3-azabicyclo[3.3.2]nonyl)-2-propanol, on oxidation (10) with chromic acid and sulfuric acid below 20°, gave a compound which reacted with 2,4-dinitrophenylhydrazine to form a 2,4-dinitrophenylhydrazone derivative. The oxidation product did not reduce either Tollen's reagent or Schiff's reagent. The infrared spectrum of the oxidation product showed a strong peak in the region of 1725 to 1705 cm.$^{-1}$. These qualitative tests strongly suggest that the compound thus obtained is a ketone; therefore, the alcohol formed by the reaction of propylene oxide and 3-azabicyclo[3.2.2]-nonane should be 3-(3-azabicyclo[3.2.2]nonyl)-2-propanol.

Two different methods were employed to obtain the esters of 10 aromatic acids. The acid chloride method, as described by Martell and Soine (6), was used for the preparation of the esters of all acids except benzilic and mandelic acids. In general, the reaction proceeded smoothly to yield the expected products. It may be noted, however, that the yields obtained were between 60 and 70%.

A second method, as described in the literature (8), was employed to obtain esters from benzilic and mandelic acids. The yields were consistently in the range of 95–98%.

The esters of *p*-amino and *o*-amino acids were prepared by reducing the nitro groups of *p*-nitro and *o*-nitro benzoates, as described by Wright and Freifelder (11).

Pharmacological Results.—The compound 2-(3-azabicyclo[3.2.2]nonyl)-ethyl benzilate hydrochloride (Table I, compound *4*) was tested for biological activity. This compound was screened for potential pharmacodynamic properties. Intraperitoneal injection of 100 mg./Kg. of the compound in 12 mice resulted in weak central nervous system depression and in weak psychotrophic and anticonvulsant properties in 70% of the mice tested. The activity had its onset within 3 min. with an intraperitoneal injection of 500 mg./Kg., and the duration of the activity was observed to range from 24 to 72 hr.

The side effects of the compound with a dose of 500 mg./Kg. were characterized by marked ataxia, muscle weakness, and dyspnea.

When the same compound was tested for cardiovascular, somatic, and visceral effects in dogs anesthetized by pentobarbital, intravenous injections of

1 and 10 mg./Kg. resulted in slight hypotensive effects, characterized by moderate inhibition of the linguo-mandibular reflex, apparently not related to the hypotensive effect.

EXPERIMENTAL

Compounds of Type I (Table I)

3-Azabicyclo[3.2.2]nonane-3-ethanol.—A solution of 125 Gm. (1.0 mole) of 3-azabicyclo[3.2.2]-nonane in 125 Gm. of methanol was treated over a 1-hr. period with 59.5 Gm. (1.35 mole) of ethylene oxide. The temperature of the reaction was maintained below 47° by keeping the reaction mixture in ice water. The reaction mixture was stirred for 1.75 hr. after the addition of ethylene oxide had been completed. Distillation of the product after removal of the methanol yielded 139 Gm. (82%) of 3-azabicyclo[3.2.2]nonane-3-ethanol, b.p. 94°/1.8 mm.

Anal.—Calcd. for $C_{10}H_{19}NO$: C, 70.96; H, 11.31; N, 8.28. Found: C, 70.93; H, 11.06; N, 8.29.

2-(3-Azabicyclo [3.2.2]nonyl)-ethyl Chloride Hydrochloride.—A solution of 33.8 Gm. (0.2 mole) of 3-azabicyclo[3.2.2]nonane-3-ethanol in 175 ml. of dry benzene was placed in a three-necked flask. The mixture was stirred as 32.1 Gm. (0.27 mole) of thionyl chloride in dry benzene was added dropwise. The reaction was slightly exothermic. After the addition of thionyl chloride had been completed, the mixture was refluxed for 3 hr. and then cooled. The solid product was collected by filtration and was washed with benzene yielding 42.0 Gm. (95%) of 2-(3-azabicyclo[3.2.2]nonyl)-ethyl chloride hydrochloride, m.p. 225° (sublimation).

2-(3-Azabicyclo [3.2.2]nonyl)-ethyl Benzilate Hydrochloride.—A 50-ml. ether suspension of 6.7 Gm. (0.03 mole) of 2-(3-azabicyclo[3.2.2]-nonyl)-ethyl chloride hydrochloride was treated with 1.5 Gm. of sodium hydroxide in 25 ml. of water. The aqueous layer was extracted with two 50-ml. portions of ether and discarded. The ether extracts and ether solution were combined, dried over anhydrous magnesium sulfate, and then poured into 6.6 Gm. (0.02 mole) of benzilic acid in isopropanol. The solvents were distilled at 80°. The reaction then was maintained under total reflux for 3 hr. The solid that recrystallized from the mixture was collected by filtration and recrystallized from isopropanol to yield 8.23 Gm. (98%) of 2-(3-azabicyclo[3.2.2]nonyl)-1-ethyl benzilate hydrochloride, m.p. 198° dec.

Anal.—Calcd. for $C_{18}H_{25}NO_3.HCl$: C, 63.61; H, 7.71; N, 4.12. Found: C, 63.43; H, 7.95; N, 4.27.

2-(3-Azabicyclo [3.2.2]nonyl)-ethyl Benzoate Hydrochloride.—A solution of 3.6 Gm. (0.021 mole) of 3-azabicyclo[3.2.2]nonane-3-ethanol was made in 150 ml. of dry benzene and 3 ml. of triethylamine.

Three grams (0.021 mole) of benzoylchloride in 75 ml. of dry benzene was added dropwise over a period of 30 min. with stirring. The mixture was heated at 70° with stirring for 2.5 hr. The mixture was then cooled, and the triethylamine hydrochloride was removed by filtration. The benzene solution of the free base was washed with four 60-ml. portions of water, dried over anhydrous sodium sulfate, and the solvent was removed *in vacuo*. The residue was dissolved in 75 ml. of dry ether; the hydrochloride was formed by passing anhydrous hydrogen chloride through the solution. The product was recrystallized from ethanol, ethyl acetate, and ether, yielding 4.0 Gm. (61%) of 2-(3-azabicyclo[3.2.2]-nonyl)-1-ethyl benzoate hydrochloride, m.p. 230° dec.

Anal.—Calcd. for $C_{17}H_{23}NO_2 \cdot HCl$: C, 65.91; H, 7.81; N, 4.52. Found: C, 65.71; H, 7.84; N, 4.45.

2-(3-Azabicyclo [3.2.2]nonyl)-ethyl-(p-amino) Benzoate Hydrochloride.—A solution of 2.1 Gm. (0.006 mole) of 2-(3-azabicyclo[3.2.2]nonyl)-ethyl-(*p*-nitro) benzoate hydrochloride in 25 ml. of water was placed in a Parr low-pressure hydrogenator. The solution then was hydrogenated in the presence of 0.2 Gm. of 5% palladium-on-activated charcoal under 5 lb. of pressure of hydrogen. The reduction was complete in 40 min. The solution absorbed 2 lb. of hydrogen. The solution was then filtered from the catalyst and was concentrated under reduced pressure to a syrup. About 15 ml. of absolute ethanol was added to it, and the mass was triturated. The product so obtained was recrystallized from absolute ethanol, yielding 1.7 Gm. (89%) of 2-(3-azabicyclo[3.2.2]nonyl)-1-ethyl-(*p*-amino) benzoate hydrochloride, m.p. 256° dec.

Anal.—Calcd. for $C_{17}H_{24}N_2O_2 \cdot HCl$: C, 62.85; H, 7.76; N, 8.62. Found: C, 62.80; H, 7.89; N, 8.45.

Compounds of Type II (Table II)

3-(3-Azabicyclo[3.2.2]nonyl)-2-propanol.—A solution of 100 Gm. (0.8 mole) of 3-azabicyclo[3.2.2]-nonane in methanol was treated over a 1-hr. period with 48 Gm. (0.83 mole) of propylene oxide. The temperature of the reaction was maintained below 47° by keeping the reaction mixture in ice water. The reaction mixture was stirred for 1.75 hr. after the addition of propylene oxide had been completed. Distillation of the product after removal of the methanol yielded 135 Gm. (93%) of 3-(3-azabicyclo-[3.2.2]nonyl)-3-propanol, b.p. 96°/1.7 mm.

Anal.—Calcd. for $C_{11}H_{21}NO$: C, 72.08; H, 11.55; N, 7.64. Found: C, 72.59; H, 11.69; N, 7.50.

The NMR spectrum in carbon tetrachloride was δ = 1.70 (d, probably CH_3—C, 3H), 1.70 (t, probably ring protons, 10H), 2.23 (d, probably N—CH_2, 2H), 2.65 (m, probably CH_2—N, 4H), 3.28 (s, probably C—OH, 1H), and 3.74 (m, probably —CH—O, 1H), p.p.m.

3-(3-Azabicyclo [3.2.2]nonyl)-propane-2-one.—To 13.7 Gm. (0.075 mole) of 3-(3-azabicyclo[3.2.2]-nonyl)-2-propanol in 35 ml. of acetone was added 7.35 Gm. of concentrated sulfuric acid in a few milliliters of water with cooling and stirring. Then 50 ml. of an aqueous solution containing 10 Gm. of CrO_3 and 16 Gm. of sulfuric acid was added dropwise below 20° by keeping the reaction mixture in an ice bath. The mixture was stirred for 3 hr., and then the solvent was evaporated. The residue was diluted with 250 ml. of water. The crystals formed were removed by filtration, washed several times with water, and recrystallized from water yielding 7.1 Gm. (51%) of 3-(3-azabicyclo[3.2.2]nonyl)-propane-2-one, m.p. 129–131° dec.

Anal.—Calcd. for $C_{11}H_{19}NO$: C, 72.81; H, 10.56; N, 7.72. Found: C, 72.56; H, 10.38; N, 7.61.

Determination of Chlorobutanol in Pharmaceuticals by Gas Chromatography

By K. T. KOSHY*, R. C. CONWELL, and R. N. DUVALL

A gas chromatographic procedure has been developed for the determination of chlorobutanol in a variety of pharmaceutical preparations. Numerous columns were investigated and found useful. Chlorobutanol was separated from its degradation products on all of these columns. Analysis of synthetic mixtures and some commercial preparations containing chlorobutanol indicated that the procedure was applicable to such systems. Peak heights relative to a standard were used to calculate unknown concentrations. If desired, cyclohexanol, camphor, or menthol can be used as the internal standard.

CHLOROBUTANOL U.S.P. is widely used as a preservative and/or an antiseptic and local anesthetic in ophthalmic, otic, nasal, and parenteral preparations. There is considerable interest, therefore, in methods for analyzing these preparations.

Several analytical procedures have been reported for the determination of chlorobutanol. Most of these methods involve the decomposition of chlorobutanol by heating with alkali and subsequent determination of the liberated chloride ion by one of the conventional chloride procedures. The official assay in U.S.P. XVII is based on this principle, utilizing the Volhard method for the determination of the chloride ion. Sinton (1) employed a gravimetric method and Taub and Luckey (2) a turbidimetric procedure. Jensen and Jannke (3) have described a method based on the decomposition of chlorobutanol by a known amount of alkali and determination of the excess alkali. They also reported an assay involving hydrolysis of chlorobutanol to acetone, steam distillation, and iodometric determination of the acetone in the distillate. Vastagh (4) and Ray and Basu (5) distilled chlorobutanol from pharmaceutical formulations and determined chloride ion in the distillate, either argentometrically or iodometrically, following treatment with alkali. All these methods have the inherent disadvantage of not differentiating between free chloride ion present in the formulation or that formed on normal decomposition or alkaline hydrolysis of chlorobutanol. In addition, these procedures are not applicable if other components of the formulation produce halide ions when hydrolyzed with alkali.

Lach *et al.* (6) have described a sensitive amperometric titration for determination of the chloride ion liberated by alkaline hydrolysis of chlorobutanol. For those materials already containing chloride ions from other components in the sample or from normal decomposition of chlorobutanol, they determined the free chloride ion initially and then the total chloride ions after treatment with alkali. The difference represents the chloride contribution by chlorobutanol. This procedure is not directly applicable to samples containing organic compounds which liberate halide ions on treatment with alkali.

Birner (7) has described a procedure for the determination of chlorobutanol by polarography. While this procedure is very sensitive and specific for chlorobutanol, its application to pharmaceutical formulations involves prior separation by steam distillation.

Rehm and Mader (8) reported a procedure based on measurement of the colored ferric hydroxamate complex formed from ferric ion and the reaction product of hydroxylamine and chlorobutanol in alkaline solution. Ketones, aldehydes, esters, imides, acid chlorides, and acid anhydrides interfere since they also form hydroxamates; ferric ion complexing anions such as tartrate, citrate, phosphate, and phthalate also interfere unless a prior distillation step is used (9). Application of the Fujiwara alkali–pyridine reaction for chloroform to the colorimetric determination of chlorobutanol in commercial parenteral dosage forms was recently reported by Chafetz and Mahoney (10). Other polyhalogen compounds interfere as would also chlorobutanol degradation products containing the polyhalo moiety.

From the above discussion it is evident that there is a need for an improved method for the analysis of chlorobutanol preparations. Chlorobutanol is volatile and should lend itself to gas chromatographic analysis, but no such method has been reported in the literature. The purpose of this study was to develop a rapid, specific, gas–liquid chromatographic procedure for the determination of chlorobutanol. Such a method would not be subject to the limitations of the techniques discussed above and would be suitable for evaluating stability samples containing

chlorobutanol, especially those involving new packaging materials. A number of chromatographic columns were investigated in order that chlorobutanol could be effectively separated from the wide variety of drugs and solvents with which it is commonly used.

EXPERIMENTAL

An F and M model 810 dual column gas chromatograph with a dual flame ionization detector and a Minneapolis Honeywell recorder was used.

Anhydrous chlorobutanol U.S.P. (S. B. Penick and Co., New York, N. Y.) was used without further purification as a standard and in the preparation of synthetic mixtures. The material was found to contain 98.4% chlorobutanol when assayed by the official procedure.

A number of chromatographic columns were investigated. Table I lists the different stationary phases and column conditions that were found satisfactory for chlorobutanol separation. Silanized Chromosorb W, 70–80 mesh (Johns-Manville, New York, N. Y.) packed in 0.25-in. aluminum tubing was used as column support. The gas flow rates were: helium, 60 ml./min.; hydrogen, 60 ml./min.; air, 300 ml./min.

Applicability of gas chromatography to the evaluation of stability samples containing chlorobutanol was investigated. A 0.125% solution was hydrolyzed in 1.0 *M* phosphate buffer, pH 7.9 at 70°, aliquots were withdrawn at periodic intervals, and these were analyzed with the polypropylene glycol column listed in Table I.

Synthetic mixtures containing known amounts of chlorobutanol were prepared with three solvents: water, light liquid petrolatum, and propylene glycol. Thiamine mononitrate and methapyrilene hydrochloride were used as active constituents in aqueous solutions, menthol and camphor in the light liquid petrolatum solutions, and benzocaine in the propylene glycol solutions. These solvents are representative of those usually present in formulations containing chlorobutanol. Compositions of these mixtures are shown in Table II. Diisodecyl phthalate was used as the stationary phase in the analysis of these solutions. Concentrations were calculated from peak heights, using a standard chlorobutanol solution chromatographed concurrently with the sample.

The utility of the gas chromatographic procedure for the analysis of commercial chlorobutanol preparations was also investigated. Various samples of unknown age, obtained from retail pharmacies, were analyzed for chlorobutanol content using the diisodecyl phthalate column.

Table I—Columns Found Satisfactory for Chlorobutanol Separation[a]

Stationary Phase	Column Length, ft.	Column Temp.[b]	Retention Time, min.

		1.50	1.54	102.7

RESULTS AND DISCUSSION

The various stationary phases that were found satisfactory for chlorobutanol separation along with column conditions and respective retention times obtained from a 0.5% aqueous solution of chlorobutanol are listed in Table I. Chlorobutanol was separated from its primary degradation products, chloroform and acetone, on all of these columns. The choice of such a variety of columns increases the applicability of the gas chromatographic procedure to the separation of chlorobutanol from the ingredients commonly used with this preservative. A typical chromatogram of a mixture of chlorobutanol, menthol, camphor, and eucalyptus and cinnamon oils obtained on the diisodecyl phthalate column is shown in Fig. 1. The good resolution of such a complex mixture indicates the versatility of this column in separating volatile constituents that are commonly present with chlorobutanol.

Nair and Lach (11) have shown that the degradation of chlorobutanol in buffered aqueous solution is first order with respect to chlorobutanol concentration. Figure 2, based on gas chromatographic analysis of degraded solutions, demonstrates the pseudo first-order kinetics for chlorobutanol decomposition and suggests the usefulness of this technique in stability evaluation of chlorobutanol formulations. The polypropylene glycol column, as described in Table I, was used in this experiment.

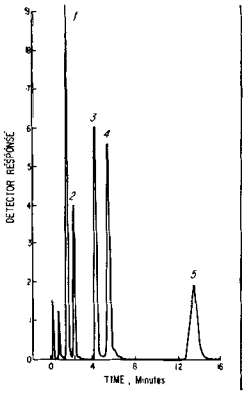

Fig. 1—Chromatogram of a mixture containing chlorobutanol on the diisodecyl phthalate column. Key: 1, eucalyptus oil; 2, chlorobutanol; 3, camphor; 4, menthol; 5, cinnamon oil.

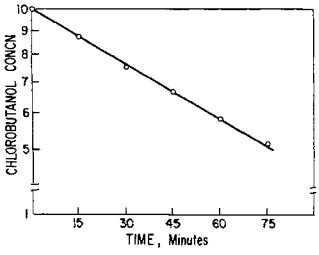

Fig. 2—Plot showing the pseudo first-order degradation of chlorobutanol in buffer pH 7.9 at 70° as determined by gas chromatographic analysis.

Results of the analysis of known mixtures containing chlorobutanol are given in Table II. The diisodecyl phthalate column was used as the stationary phase. The aqueous preparations were injected directly. Reproducibility was poor when the light liquid petrolatum preparations were injected directly but dilution with chloroform prior to injection eliminated this problem and the data presented were obtained in this manner. Tailing of the product solvent peak caused interference in the preparations containing propylene glycol. These were diluted with water and the chlorobutanol extracted with chloroform prior to analysis by comparison with a standard treated in a similar manner. The results indicate quantitative recovery of concentrations ranging from 0.15 to 1.50% in the three solvent systems, and per cent recoveries indicate no significant differences between these solvent systems.

Some commercial preparations containing chlorobutanol were analyzed, and the results are shown in Table III. Depending on the nature of the solvent, these formulations were treated as outlined above. The glycerin-containing product was too viscous to inject directly and was, therefore, analyzed in the same manner as the propylene glycol preparations.

TABLE III—ANALYSIS OF COMMERCIAL PREPARATIONS CONTAINING CHLOROBUTANOL

Prepn.	Solvent	Chlorobutanol, % Label Claim	Chlorobutanol, % Found
A_1	Water	0.15	0.05
A_2	Water	0.15	trace
B	Light liq. pet.	1.0	0.28
C	Water	0.3	0.41
D	Glycerin	3.0	2.98
E	Propylene glycol	0.4	0.39
F	Light liq. pet.	1.0	1.0
G	Water	0.5	0.51

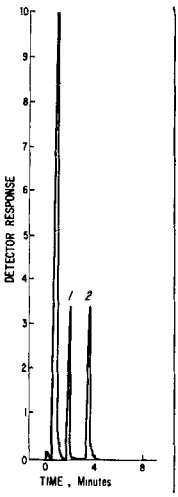

Fig. 3—Chromatogram of a chloroform solution of chlorobutanol and cyclohexanol on the diisodecyl phthalate column. Key: 1, chlorobutanol; 2, cyclohexanol.

Preparation *A* was an ophthalmic preparation packaged in a plastic container. Two different samples were obtained, and it is obvious that the container did not afford sufficient protection against chlorobutanol loss. Preparation *B* was a nasal decongestant packaged in a glass bottle with a rubber dropper assembly. The general appearance of the package indicated that this product was of considerable age, and analysis showed that the chlorobutanol content was considerably below the label claim, probably due to loss through the closure. Product *C*, packaged in a plastic container, was found to contain chlorobutanol in excess of the label claim, presumably the result of the excess needed to maintain the label claim through the product shelf life. Preparations *D* through *G* were found to conform to the label claim.

All chlorobutanol determinations reported in this paper were calculated from peak heights by comparison with a standard chlorobutanol solution. A standard was used for each analysis. The relationship between peak height and concentration was found to be linear in the concentration ranges investigated. However, internal standards are very useful and popular, and it appears that several compounds could be used for this purpose. The potentiality of camphor and menthol as internal standards is evident from Fig. 1, and Fig. 3 illustrates the possibility of using cyclohexanol as an internal standard.

Technique for the Preservation of Tetracycline Fluorescence in Ascites Tumor Cells

By ELIZABETH P. BARBOUR, JAMES R. THOMPSON, and CARL C. RIEDESEL

Fluorescence microscopy has a potential application in cellular pharmacology for the study of intra- and intercellular distribution of pharmacological agents. A method is reported for preparing permanent preparations of tetracycline-retaining ascite tumor cells. A combination of glutaraldehyde fixation followed by glycerol dehydration was found satisfactory.

During an investigation concerning tetracycline retention by ascites tumor cells using fluorescence microscopy, it became essential to make permanent preparations of the cells for more detailed observation. It became apparent immediately that application of traditional histologic techniques would not suffice because tetracycline fluorescence is easily quenched or displaced by otherwise suitable fixatives and dehydrating agents. Numerous agents were screened in an effort to develop a satisfactory method for preserving tetracycline fluorescence. Under the conditions reported in this paper, a combination of glutaraldehyde fixation followed by glycerol dehydration proved to be the most satisfactory technique. Fluorescence microscopy has a potential application in cellular pharmacology for the study of intra- and intercellular distribution of pharmacological agents. For this reason, the technique found useful in preserving tetracycline fluorescence is described.

MATERIALS AND METHODS

All microscopic examinations of the cell preparations were made using a Zeiss GFL fluorescence microscope with a mercury light source (HB200). Excitation filters BG-38 and BG-12 were used along with barrier filters 41 and 53. These filters permit the best observation of tetracycline fluorescence. At the same time they eliminate autofluorescence of the ascites cell which may be seen when wider ranges of the U.V. spectrum are employed. Photomicrographs were taken using a Zeiss Ikon camera attachment and 35-mm. Panatomic X film.

The Ehrlich ascites tumor cells are strain ES obtained from Cailleau (1). They are maintained in Swiss mice by weekly intraperitoneal transfer. All cells used in these investigations were removed from the host 6 to 10 days following passage to assure an optimal growth phase.

All chemicals and reagents employed were of C.P. grade or the equivalent. The following substances were selected for evaluation as fixatives: acetone, diethyl ether and alcohol (1:1), formalin, and glutaraldehyde. A wide range of concentrations of each agent was employed to find the most efficient concentration. The following substances were evaluated as dehydrating agents: acetone, diethyl ether, ethanol, and glycerol. Each of these reagents was similarly tested at a variety of concentrations. A variety of exposure times ranging from 2 to 30 min. in the fixatives and dehydrants was employed.

The general procedure was as follows. Several milliliters of ascites cell suspension were withdrawn from the host animal 15 min. following the intraperitoneal injection of 0.1 mg. of tetracycline. This particular dosage and time lapse were selected to assure adequate fluorescence in the tumor cells. The cell suspension was diluted with an equal volume of Hank's balanced saline, then fixed with one of the fixatives. In the case of control preparations, these were examined and photographed immediately following dilution in Hank's saline solution. Ascites cells which were subjected to fixation were exposed for the appropriate time interval, centrifuged lightly, then washed with several changes of Hank's saline solution. The cells were then either examined under the microscope or further treated by exposure to a dehydrating agent through a series of 3 to 5 min. changes in progressively higher concentrations of the dehydrant. At each step samples of the cells were photographed to determine what changes could be observed in the fluorescence pattern in the cells when compared to control specimens.

As this work progressed, it became obvious that fixation in glutaraldehyde dissolved in Sorensen's phosphate buffer was the most satisfactory fixative. The best preservation of fluorescence was obtained when glutaraldehyde fixation was followed by glycerol dehydration. For this reason, the protocol of the glutaraldehyde–glycerol technique is given in more specific detail: fixation is accomplished by diluting the ascites cell suspension with an equal volume of 4% glutaraldehyde (redistilled) in Sorensen's phosphate buffer, pH 7.4, and allowing the cells to remain in the solution for 5 min. Longer fixation seems to produce no deleterious effect, but offers no real advantage. Following fixation and light centrifugation (100 g) the cells are run through a series of 3 min. changes in progressively higher concentrations of glycerol.

RESULTS

As can be seen from the photomicrographs submitted, this technique does not appear to decrease intensity of fluorescence, or displace the tetracycline within the cell. On the other hand, all other com-

binations of fixatives and dehydrating agents appeared to introduce artifacts, some of these being visible in the photomicrographs.

No photomicrograph is submitted for ascites cells not exposed to tetracycline since at the particular wavelength employed there is no autofluorescence; hence, it is not possible to take a photomicrograph of the cells against the darkfield background. The first five photomicrographs were taken of cells before exposure to dehydrating agents. Figure 1 illustrates the appearance of tetracycline-containing tumor cells freshly removed from the host animal but having been subjected to no treatment other than their removal from the host. They may be considered as control preparations. In such cells the tetracycline seems to be located in the cytoplasmic portion of the cell, with concentration in the perinuclear zone. Figure 2 shows the effect of 4% formalin fixation for 2 min. There is an apparent loss of definition and diffusion of the tetracycline. Higher concentrations of formalin or longer fixation periods further exaggerated these observations. Figure 3 shows the effect of diethyl ether–alcohol fixation for 2 min. The tetracycline complex appears to be precipitated as judged by the altered pattern of fluorescence. The effect of acetone fixation is shown in Fig. 4. There is extensive blebbing with the suggestion that tetracycline has diffused into the karyoplasm. Figure 5 is a photomicrograph of cells fixed with glutaraldehyde. One sees an apparent intensification of the fluorescence. This was a consistent finding in all glutaraldehyde preparations.

The remaining photomicrographs demonstrate the effects of several dehydrating agents. Figure 6 illustrates the result of acetone dehydration following glutaraldehyde fixation. Even when the total dehydrating time is kept to 4 min. there appears to be a reduced fluorescence. The use of ethanol dehydration following glutaraldehyde fixation (Fig. 7) seems to reduce sharpness of detail of the preparation although there is no loss of fluorescence. Areas of bright fluorescence in some of the intercellular spaces suggests a possible leakage of fluorescent substance from the cells. The final photomicrograph (Fig. 8) shows the result of glutaraldehyde fixation followed by glycerol dehydration in accordance with the protocol described in this report. There is no loss of cellular detail, nor any apparent loss or distortion of fluoresence.

Hydrolysis of Methylparaben

By N. N. RAVAL and E. L. PARROTT

The hydrolysis of methylparaben in aqueous solution at 70, 80, and 85° in pH range from 6 to 8 has been studied.

SINCE their introduction into the United States in the 1930's, the parabens have been widely used as preservatives in foods, drugs, and cosmetics (1–5). The lack of toxicity and the broad spectrum of preservative activity of methylparaben have been reported (6–8). The correlation of preservative activity with the binding of methylparaben to other substances has led to more effective and intelligent product formulation (9–11).

Methylparaben is stable in air. Aqueous solutions of methylparaben buffered at pH 3 and 6 showed no decomposition when heated for 2 hr. at 100° or for 30 min. at 120° (12). As the removal of the ester portion by hydrolysis yields *p*-hydroxybenzoic acid, which possesses insignificant preservative activity, this investigation was undertaken to study the extent of hydrolysis of methylparaben in a pH range utilized in pharmaceuticals.

EXPERIMENTAL

A 0.1-Gm. quantity of methylparaben[1] was accurately weighed into a 100-ml. volumetric flask and dissolved in a sufficient amount of buffer to bring to a volume of 100 ml. of solution. The solution was filled and sealed into 10-ml. ampuls. The ampuls were placed in appropriate constant-temperature baths, and after thermal equilibrium was attained, an ampul was removed and, by means of iced water, was cooled to 25°. This solution was analyzed for zero-time concentration of methylparaben.

Five milliliters of the solution was withdrawn, adjusted to pH 7, and sufficient distilled water was added to bring the volume to 100 ml. A 10-ml. aliquot was extracted with four 10-ml. portions of anhydrous ether. The ether was evaporated and the residue was dissolved in 100 ml. of distilled water. The absorbance of the solution was measured at 255 mμ using a Beckman DU spectrophotometer. By means of a standard absorption curve, the concentration of methylparaben was determined. Ampuls were removed at definite intervals of time and analyzed by this procedure, which is essentially that of Aalto *et al.* (1).

All chemicals were reagent grade. McIlvaine's buffer was used for pH 6 and 7; Palitzsch's buffer was used for pH 8 and 9 (13). All buffer solutions were adjusted at and the pH determined at the temperature of hydrolysis by means of Beckman Zeromatic pH meter.

RESULTS AND DISCUSSION

The rate of hydrolysis of methylparaben was followed at pH 6, 8, and 9 at 70, 80, and 85°. A plot of the logarithm of concentration against time produced a straight line. The observed velocity constant k can be evaluated by multiplying the slope of the line by 2.303. The half-life or time required

[1] The methylparaben used was Methyl Parasept, Heyden Newport Chemical Corp.

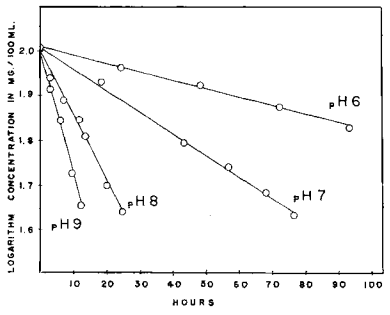

Fig. 1—Pseudo first-order hydrolysis of methylparaben at 85°.

for half of a given amount of methylparaben to decompose can be evaluated by dividing 0.693 by the velocity constant (14). Figure 1 is typical of the results obtained. The experimentally determined velocity constants and half-life periods are given in Table I.

As the hydrolysis appears to follow a first-order relationship, the energy of activation E_a was calculated using the logarithmic form of the Arrhenius equation between the limits of absolute temperature T_2 and T_1 (15).

$$\log \frac{k_2}{k_1} = \frac{E_a}{2.303\,R}\left(\frac{T_2 - T_1}{T_2 T_1}\right)$$

The apparent energy of activation is approximately 24 Kcal./mole. The value for the velocity constant for the reaction was calculated at 25 and 121°. The calculated velocity constants and half-life periods at 25° are listed in Table II.

As autoclaving may be required of certain pharmaceutical solutions, the per cent decomposition of a methylparaben solution in an autoclave was experimentally determined. After autoclaving for 30 min. at pH 6 and 9, there remained 94.5 and 58.0% of the initial concentration, respectively. Using $k_{121°} = 0.105$ hr.$^{-1}$ at pH 6 as calculated from the Arrhenius equation, the predicted decomposition was 5.13%; the experimental decomposition was 5.5%. Likewise, at pH 9 the predicted loss was 48.36%; the experimental decomposition was 42.0%.

Possible Ethanol-Induced Tolerance in Rats

By THEODORE H. EICKHOLT, LEO J. SCHILLACI*, and S. ALAN SEARCY*

A tilting-plane technique was employed to determine the effects of alcohol on performance of rats with specific attention to development of possible tolerance. Significant differences were obtained only on the first day of treatment with possible tolerance developing in only 1 day. No significant learning effects could be shown over the 3-week period.

A VARIETY of tests have been employed for determining performance in humans and animals while under alcohol administration (1–6). The many variables in response to pretreatment, age, sex, strain, and stress confounds the study of tolerance to alcohol using these tests (7–16). Behavioral tolerance has been investigated (17) and was reported in monkeys following once daily administration, 2 Gm./Kg. i.v., for only 4 consecutive

A tilting-plane technique was employed to determine the effects of alcohol on performance of rats with specific attention to development of possible tolerance. Significant differences were obtained only on the first day of treatment with possible tolerance developing in only 1 day. No significant learning effects could be shown over the 3-week period.

A VARIETY of tests have been employed for determining performance in humans and animals while under alcohol administration (1–6). The many variables in response to pretreatment, age, sex, strain, and stress confounds the study of tolerance to alcohol using these tests (7–16). Behavioral tolerance has been investigated (17) and was reported in monkeys following once daily administration, 2 Gm./Kg. i.v., for only 4 consecutive

days (18). Metabolic tolerance has been indicated by a lower blood alcohol level as early as the third day in self-maintained intoxicated rats receiving increased alcoholic intakes (19), and it has been postulated that metabolic tolerance may serve as a limiting factor in alcohol consumption (20). The rate of metabolism of ethanol in humans has been shown to be increased after a 3 to 14-day period of induced intoxication (21). The same has been shown in rats along with fine structural changes in the liver (22, 23).

It was the purpose of this study to demonstrate the effect of alcohol in rats through the use of a tilting-plane technique with specific attention to the development of any degree of tolerance observed over a 2-week administration period.

EXPERIMENTAL

The technique, the tilting-plane technique, proposed by Arvola, Sammalisto, and Wallgren appeared most satisfactory for quantitating equilibrium and motor coordination (24). The test is suitable for differentiating certain degrees of alcohol intoxication. The rat is placed on a board, the board is tipped up, and the angle at which the animal slides is determined. The surface of the plane is rough and the rat clings with its claws to the surface. A deeply intoxicated rat cannot cling to the plane and slides down the plane at a lower angle than an unintoxicated rat. The method has been used and found satisfactory by others (24–27).

Twenty Wistar male rats, 200 Gm. average, were used. Ten served as a control group and 10 were used in the test group.

The first week without any drug administration both groups were put on the tilting-plane and 10 readings of each animal on each of 4 consecutive days were made for control, learning, pretreatment averages. The second and third weeks, the test animals received 2 Gm./Kg. body weight of a 10% solution of ethanol i.p. This dose, 2 Gm./Kg., was chosen as that maximally tolerated and in best agreement with that used in the literature. At this dosage, the animals at first appeared nearly unconscious, but activity after 60 min. was satisfactory for testing on the tilting-plane.

The controls were injected with an equivalent volume of normal saline thus subjecting them to the same handling (stress) as the test group.

Both groups were again placed on the tilting-plane and 10 readings of each animal, on each of 4 consecutive days, for the second and third weeks were made. Readings were taken 60 min. after injections. The room temperature was maintained at 24°.

The tilting-plane was made from rough pine wood with the dimensions being 23.5 × 44 cm. All animals were placed on the plane and raised through an angle of 90° in 5 sec. and the angle at which the animals slid was recorded.

The averages of all readings were determined and the t test of significance performed.

RESULTS AND DISCUSSION

After the first week of alcohol injections, approximately 50% of the rats appeared to enjoy the injection, they were much easier to handle, and would remain quiet during the injection. The same was not true for the saline injected rats. From the averages of the readings taken, the comparisons with t tests and standard deviations were calculated and are shown in Tables I, II, and III.

In the tables, the animals are referred to as control and test groups. A further delineation as to treatment periods within groups is indicated by "Control Learn, Control Test" and "Test Learn, Test Test." The first day control learn indicates the first day the control group was placed on the tilting-plane during the first week learning period. Likewise, the first day test learn indicates the first day the test group was placed on the tilting-plane during the first week learning period.

The first day control test indicates the first day the control group, receiving comparable volume saline injections, was placed on the tilting-plane during the first week of the test period, actually the second week in the test program. Likewise, the first day test test indicates the first day the test group receiving alcohol injections was placed on the tilting-plane during the first week of the test period, again, actually the second week in the test program.

Furthermore, the sixth day control test would indicate the sixth day the control group, receiving the saline injections, was placed on the tilting-plane during the second week of the test period, actually the third week in the test program. Likewise, the sixth day test test indicates the sixth day the test group receiving alcohol injections was placed on the tilting-plane during the second week of the test period, again actually the third week in the test program.

These results show that in the test animals there was a significant difference between the first day trial on the tilting-plane and the first day of test (t = 5.79), and also the fourth day of trial and the first day of test (t = 3.41). Likewise, the first and fourth day control learn animals showed a significant difference from the first day test test animals (t = 4.03 and t = 5.22, respectively). The first day control test animals were not significantly different from the first day test test animals at P 0.05 but were at P 0.1 (t = 2.09), a t value greater than 2.101 being required at P 0.05.

However, in a comparison of the second day of trial on the plane and the second day of test, in all cases of comparison, there were no statistically significant differences. The animals were apparently not as intoxicated the very next day after receiving the same dosage of alcohol. Therefore, it would appear possible to induce alcohol tolerance in 1 day as determined by this method. Behavioral tolerance has been reported to occur in monkeys in 4 days and a metabolic tolerance has been reported in rats in 3 days (18, 19).

Alcohol metabolism may have been altered very rapidly in this study, although Wistar rats have been shown to select less alcohol than G-4 rats when given free choice (9). What this would imply regarding the respective strains' metabolism is questionable. The animals used in this study were males, and males also have been shown to drink more alcohol than females, another possible factor influencing tolerance (11). Operant performance has also been shown to vary between alcohol-preferring and nonpreferring animals (12).

Statistical evaluation of control animals showed no significant difference in these animals over the

whole 3-week period. Apparently with this method, learning played no significant part in this study. It has been reported, however, that alcohol-treated rats appear to learn more slowly (2).

All of the animals' weights were followed; however, no significant differences were determined between the control and test animals.

SUMMARY AND CONCLUSIONS

Male Wistar rats were subjected to a tilting-plane technique to determine the effects of alcohol on their performance. Subjected first to a 1-week learning period, this was followed by a 2-week test period. Control rats received normal saline and test rats received 2 Gm./Kg. of alcohol. All animals were placed upon the tilting-plane and the angle at which they would slide off was recorded. Significant differences were obtained between first day control learn *versus* first day test test, first day control test *versus* first day test test, first day test learn *versus* first day test test, fourth day test learn *versus* first day test test, and fourth day control learn *versus* first day test test. As measured by this method, tolerance would seem to appear after only 1 day. No significant learning effect could be shown by this method in the control animals over the entire 3-week period.

Micelle Size and Stability of Aqueous Amphotericin B (Polyene) Systems

By JOEL KIRSCHBAUM and SAMUEL G. KAHN

Concentrations of components were varied in aqueous amphotericin B systems containing cetyl dimethyl benzyl ammonium chloride, dimethylsulfoxide, amphotericin B, and water. Using the analytical ultracentrifuge and correcting for density and viscosity, the systems containing the smallest micelles were found by determination of sedimentation coefficients. This procedure proved valuable in subsequent formulations, containing amphotericin B for veterinary purposes.

AMPHOTERICIN B is a polyene antifungal antibiotic which has a molecular weight of approximately 960. It is relatively insoluble in water and other common solvents, but exceedingly soluble in dimethylsulfoxide (DMSO) (1). The preparation of an aqueous suspension, colloid, or solution of amphotericin B for use as a medicament would be very desirable. This study was undertaken to investigate how changes in concentration of each component in an aqueous DMSO–amphotericin B–cetyl dimethyl benzyl ammonium chloride system will affect the micelle size and stability of amphotericin in such a system.

EXPERIMENTAL

Solutions were prepared by dissolving the appropriate amounts of amphotericin B and cetyl dimethyl benzyl ammonium chloride in DMSO and diluting with deionized water to the desired concentration. The concentrations of amphotericin B (900 mcg./mg.) were varied from 12.5 to 400 mcg./ml. The alkyl quaternary ammonium salt, cetyl dimethyl benzyl ammonium chloride[1] was used in concentrations from 12.5 to 200 mcg./ml. DMSO (pharmaceutical grade) was varied in concentration from 0.25% to 8% of solution.

Sedimentation coefficients (S) were measured using 20-mm. centerpiece, 4° cells, and centrifuged at speeds of 12,590; 29,500; or 50,740 r.p.m. in the An-E rotor, the temperature being maintained at 20°C. The Schlieren phaseplate angles were from 50° to 65°. Images were recorded on Kodak metallographic plates and tenfold magnifications were traced using a Nikon shadowgraph. The areas under the Schlieren peaks or peak areas, were measured with a planimeter. These areas are proportional to the concentration of sedimenting substances.

Viscosities were measured at 20° C. employing capillary and Zimm viscometers (2). Densities were measured at 20° C. using a 10-ml. pycnometer. For molecular weight calculations, the partial specific volume of amphotericin B was determined in a 1-ml. pycnometer and found to be 0.64 ± 0.02.

Micelle weights were calculated using the Archibald approach to sedimentation equilibrium method (3). Concentration gradients were measured in 12 mm. interference cells at speeds of either 8,766 or 42,040 r.p.m. and evaluated using Engelberg's modification (4). Total concentration was measured with a synthetic boundary centerpiece in an interference cell. The Schlieren phaseplate angle was 75°. Concentration gradients at the meniscus and cell bottom were evaluated from enlarged images as previously described for the determination of S values.

RESULTS AND DISCUSSION

Table I presents data of peak areas and S values, corrected for viscosity and density. When the level of amphotericin B was maintained at 100 mcg./ml. and the concentrations of cetyl dimethyl benzyl ammonium chloride and DMSO varied, S values and peak areas were at a minimum when DMSO levels equalled 1% to 2% and cetyl dimethyl benzyl ammonium chloride concentrations were 25 to 100 mcg./ml. Interestingly, the S values for amphotericin B at these component concentrations did not change after 24 hr., thus indicating that at these concentrations cetyl dimethyl benzyl ammonium chloride and DMSO stabilized amphotericin B against increased micelle growth and precipitation. Increasing cetyl dimethyl benzyl ammonium chloride and/or decreasing DMSO concentrations increased the S values and permitted precipitation of the preparation. Very high concentrations of cetyl dimethyl benzyl ammonium chloride (200 mcg./ml.) and DMSO (8%) promoted large increases in S values and peak areas, indicating increased micelle size.

When DMSO was kept at 1% concentration and the levels of both cetyl dimethyl benzyl ammonium chloride and amphotericin B varied from 12.5 to 400 mcg., the S coefficients were minimum in the region where amphotericin B concentration was 100 mcg./ml. and the cetyl dimethyl benzyl ammonium chloride level was approximately 100 mcg./ml. (Table II). Similar results were obtained when amphotericin B and DMSO levels were varied and cetyl dimethyl benzyl ammonium chloride concentration was kept at a constant 100 mcg./ml. Preparations of greatest stability (lowest S value) were observed when the amphotericin level was 100 mcg./ml., the cetyl dimethyl benzyl ammonium chloride level was 50 to 100 mcg./ml., and the DMSO concentration equaled 1% to 2%. Micelle weight determinations gave parallel results and correlated positively with S values. In an aqueous amphotericin B system (amphotericin B, 100 mcg./ml.; cetyl dimethyl benzyl ammonium chloride, 50 mcg./ml.; DMSO, 1%), the minimal micelle weight of an amphotericin micelle was calculated to be 400,000 daltons. The micelle weight increased into the millions when the concentration of any component of the system was increased or decreased.

The molar ratio between cetyl dimethyl benzyl ammonium chloride (mol. wt. 395), amphotericin B (mol. wt. 960), and DMSO (mol. wt. 78) at minimal S value concentrations (or micelle size) is approximately 1:1:1000.

These results show that in formulating an aqueous system for a water-insoluble substance the concentrations of the substance and other components of the system are critical in determining the physical characteristics of a molecular species. The results suggest that physical chemical analysis, with an analytical ultracentrifuge, as used in these studies, can help select the more stable aqueous system for a relatively water-insoluble substance. This method proved practical when a stable water-miscible amphotericin B formulation was prepared as medication in the drinking water of poultry (5). Using this procedure, other water-insoluble substances, such as the polyene antifungal antibiotic nystatin, can be formulated into water-miscible systems.

Isolation and Identification of Three Alkaloids from the Bark of *Zanthoxylum elephantiasis*

By ALBERT T. AWAD, JACK L. BEAL, SUNIL K. TALAPATRA*, and MICHAEL P. CAVA†

The bark of *Zanthoxylum elephantiasis* (*Rutaceae*) was found to contain three major alkaloids which were identified as 6-canthinone, 5-methoxy-6-canthinone, and laurifoline.

THE GENUS *Zanthoxylum* (*Rutaceae*) contains some 200 species dispersed over the world, many of which have been studied because of their alkaloid content. Price (1) in an excellent review of the distribution of alkaloids in the *Rutaceae* alludes to the nomenclature confusion between the two genera *Zanthoxylum* and *Fagara* when he points out that a number of *Fagara* species are alternatively named as *Zanthoxylum* and vice versa. Indeed, the particular *Zanthoxylum* species which forms the subject of the present investigation was at one time placed in the genus *Fagara* (2). Fosberg (3) recently clarified the situation regarding the relationship of *Fagara* and *Zanthoxylum* in such a way that today less confusion exists.

Zanthoxylum elephantiasis Macf. (*Z. aromaticum* DC., *Fagara elephantiasis* Kr. and Urb.) is indigenous to the Caribbean region having been found

Isolation and Identification of Three Alkaloids from the Bark of *Zanthoxylum elephantiasis*

By ALBERT T. AWAD, JACK L. BEAL, SUNIL K. TALAPATRA*, and MICHAEL P. CAVA†

The bark of *Zanthoxylum elephantiasis* (*Rutaceae*) was found to contain three major alkaloids which were identified as 6-canthinone, 5-methoxy-6-canthinone, and laurifoline.

THE GENUS *Zanthoxylum* (*Rutaceae*) contains some 200 species dispersed over the world, many of which have been studied because of their alkaloid content. Price (1) in an excellent review of the distribution of alkaloids in the *Rutaceae* alludes to the nomenclature confusion between the two genera *Zanthoxylum* and *Fagara* when he points out that a number of *Fagara* species are alternatively named as *Zanthoxylum* and vice versa. Indeed, the particular *Zanthoxylum* species which forms the subject of the present investigation was at one time placed in the genus *Fagara* (2). Fosberg (3) recently clarified the situation regarding the relationship of *Fagara* and *Zanthoxylum* in such a way that today less confusion exists.

Zanthoxylum elephantiasis Macf. (*Z. aromaticum* DC., *Fagara elephantiasis* Kr. and Urb.) is indigenous to the Caribbean region having been found

in Costa Rica, Mexico, Cuba, Hispaniola, and in Jamaica, where it is known popularly as "yellow sanders." It is a tree of moderate size, 15–40 ft. in height, which is conspicuous in having corky conical spiny knobs on the bark around the base of the trunk (2). This report concerns the isolation and identification of three alkaloids from the bark of *Z. elephantiasis*.

EXPERIMENTAL[1]

The bark used in this investigation was collected during the summer of 1962 at the foot of Long Mountain in Jamaica.[2] The coarsely ground bark (1.3 Kg.) was extracted in a modified Soxhlet with ethanol until a negative test was obtained with Valser's test solution. The ethanolic extract was concentrated *in vacuo* to a thick syrupy consistency and extracted 3 times with 750-ml. portions of 2% tartaric acid solution, leaving 35 Gm. of insoluble residue. The combined acid extracts were concentrated *in vacuo* to about 1 L. and then filtered. The filtrate was made alkaline (about pH 9.0) with ammonium hydroxide solution and then extracted with chloroform in a liquid–liquid continuous extractor. The alkaline aqueous solution containing quaternary salts was treated with ammonium reineckate solution according to the method described by Hogg *et al.* (4) to give 35 Gm. of crude alkaloid reineckate.

Isolation of Alkaloids from Tertiary Bases.—The chloroform extract containing the tertiary alkaloids was extracted with 50-ml. portions of 2% sodium hydroxide solution. The combined alkaline extracts were a deep yellowish-brown color and gave a negative test for alkaloids. The chloroform solution was washed with distilled water, dried over anhydrous sodium sulfate, and reduced to dryness *in vacuo* to give 4.8 Gm. of residue. The residue was digested in 150 ml. of 5% hydrochloric acid solution. The resulting solution was filtered and then made alkaline with ammonium hydroxide solution (pH 9.0) and extracted with ether in a small continuous liquid–liquid extractor. Partial evaporation of the ether at room temperature caused the separation of a white amorphous encrustation on the sides of the flask. The ether solution was decanted and the encrusted material was washed with acetone and then crystallized from methanol to give 280 mg. of long needles (5-methoxy-6-canthinone). The decanted ether solution was evaporated to give a viscous dark brown liquid, which after dissolving in boiling acetone, afforded an additional 120 mg. of 5-methoxy-6-canthinone.

The remaining acetone solution was evaporated to dryness and the residue was dissolved in chloroform which was then extracted with 0.1 *N* hydrochloric acid. The aqueous acid extract was concentrated and left at room temperature for 1 day when 150 mg. of an alkaloid hydrochloride separated. The hydrochloride was dissolved in distilled water and the solution was then made alkaline with ammonium hydroxide and extracted with ether. The ether extract was evaporated to dryness to give 105 mg. of amorphous residue. This residue was chromatographed on 5 Gm. of Woelm neutral alumina (grade III) using benzene as the eluant to obtain 90 mg. of crystals, m.p. 150–152°. Rechromatography as above followed by crystallization from methanol gave colorless needles, m.p. 159–160° (6-canthinone).

Treatment of Tartaric Acid Insoluble Residue.—The 35 Gm. of tartaric acid insoluble residue was digested with 5% hydrochloric acid solution. Work up of this acid solution in the same manner as the tartaric acid soluble fraction yielded an additional 80 mg. of 5-methoxy-6-canthinone and 220 mg. of 6-canthinone. A third alkaloid was demonstrated to be present in a small amount by paper and thin-layer chromatography. However, its isolation has been postponed until more plant material can be collected and processed.

Identification of 5-Methoxy-6-canthinone (I).—5-Methoxy-6-canthinone was crystallized from methanol as pale yellow needles, m.p. 237–238° dec. Positive identification of the alkaloid was made by comparison with an authentic sample[3] (mixed melting point determination, infrared, and ultraviolet spectra). In addition, the hydrochloride, the picrate, and the methiodide were prepared as derivatives and were found to have melting points corresponding to those reported in the literature (5).

Identification of 6-Canthinone (II).—6-Canthinone was crystallized from methanol as colorless needles which quickly became yellow on exposure to air (probably loss of solvent of crystallization), m.p. 159–160°. Positive identification of the alkaloid was made by comparison with an authentic sample[4] (mixed melting point determination, infrared, and ultraviolet spectra). In addition, the hydrochloride, the picrate, and the methiodide were prepared as derivatives and were found to have melting points corresponding to those in the literature (6).

Isolation of Laurifoline Chloride.—The 35-Gm. sample of alkaloid reineckate was divided into two portions. A 15-Gm. sample was converted to chloride by the method described by Hogg *et al.* (4), while a 20-Gm. sample was converted to chloride by utilizing an ion-exchange resin described as follows. The 20-Gm. sample was dissolved in a mixture of 600 ml. of acetone and water (1:1). The solution was filtered and then added dropwise to a suspension of 400 Gm. of ion-exchange resin[5] IRA 400 (chloride form) in 800 ml. of acetone and water (1:1) and the mixture was then mechanically stirred for 24 hr. At this time the mixture was filtered, giving a light, straw-colored filtrate which when evaporated to dryness *in vacuo*, gave 7.5 Gm. of residue. Extraction of the residue with methanol left 3.8 Gm. of methanol insoluble, nonalkaloidal material. Thin-layer chromatography of the methanolic solution of crude quaternary chlorides using Silica Gel G as the adsorbent and acetonitrile–methanol–ammonium hydroxide solution (equal parts) as the

[1] All melting points were determined using a Thomas-Hoover Uni-Melt capillary melting point apparatus. The infrared spectra were taken in KBr using a Perkin-Elmer model 237 infrared spectrophotometer. The ultraviolet spectra were determined using a Perkin-Elmer model 4000 Spectracord. Alkaloid tests employed were Valser's and Dragendorff's test solutions.

[2] The material was collected under the supervision of Michael P. Cava and was verified botanically by Dr. Dennis Adams, Department of Botany, University of the West Indies. A fresh bark sample has a local anesthetic effect on the lips and tongue when chewed; this effect is almost entirely lost in the dried bark (Cava, M. P., personal observations).

[3] The authors are grateful to Dr. J. R. Price, Division of Industrial Chemistry, C.S.I.R.O., Melbourne, Australia, for the authentic sample of 5-methoxy-6-canthinone.

[4] The authors are grateful to Dr. E. Ritchie, Department of Organic Chemistry, The University of Sydney, Sydney, New South Wales, Australia, for the authentic sample of 6-canthinone.

[5] Marketed as Amberlite by Rohm & Haas, Philadelphia, Pa.

solvent revealed three Dragendorff positive spots, R_f 0.22, 0.42, and 0.66.

In an attempt to separate the quaternary chlorides the methanolic solution was adsorbed on Woelm acid alumina, grade I, and chromatographed on a column (2.5 cm. × 38 cm.) containing 100 Gm. of the same type of alumina. The column was eluted successfully with benzene, benzene–chloroform (1:1), chloroform, chloroform containing 5% methanol, chloroform containing 10% methanol, and chloroform containing 15% methanol. Only nonalkaloidal material was removed until the chloroform–methanol solvent was introduced. The chloroform–methanol mixtures (2100 ml.) eluted the alkaloid components as a mixture.

The combined eluates containing alkaloid material when concentrated to a syrupy consistency and left for 3 days at room temperature deposited crystals which were recovered by filtration and washed with chloroform containing 1% methanol, yielding 130 mg. of crystalline quaternary chloride. The filtrate was evaporated to dryness and then dissolved in absolute ethanol, to yield an additional 60 mg. of the same crystalline material.

The 15-Gm. sample of alkaloid reineckate that was worked up according to the method of Hogg *et al.* (4) gave 6.6 Gm. of crude quaternary chloride.

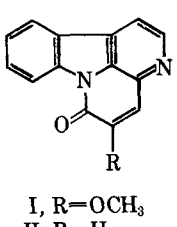
Identification of Laurifoline Chloride.—The above isolated quaternary chloride crystallized from ethanol as colorless prisms, m.p. 253° dec. $[\alpha]_D^{25}$ + 14° (c, 6.22 in methanol); $\lambda_{max.}^{methanol}$ 228 mμ (log ε 4.61), 282 (4.17), 308 (4.26). A strong bathochromic shift at the higher wavelength maxima was observed in an alkaline solution: $\lambda_{max.}^{methanol}$ 335 mμ (log ε 4.28).

Anal.—Calcd. for $C_{20}H_{24}NO_4Cl$: C, 63.56; H, 6.46; Cl, 9.40; N, 3.71; N—CH_3, 8.10; OCH_3, 16.52. Found: C, 63.56; H, 6.46; Cl, 9.26; N, 3.66; N—CH_3, 8.12; OCH_3, 16.06.

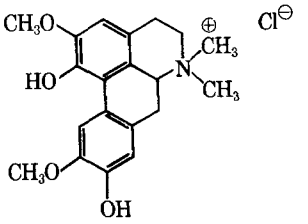
The compound was identified as laurifoline chloride (III) on the basis of infrared and ultraviolet spectral comparison with an authentic sample.[6] In addition, the picrate was prepared and found to have the same melting point (220°) as that reported in the literature (7).

DISCUSSION

The occurrence of alkaloids of the canthinone type in plants was first reported in 1952 when Haynes, Nelson, and Price described the isolation of 6-canthinone (6), 5-methoxy-6-canthinone (5), and 4-methylthio-6-canthinone (8) from *Pentaceras australis* Hook (*Rutaceae*). In a subsequent study of three Australian *Zanthoxylum* species, Cannon, Hughes, Ritchie, and Taylor reported the isolation of 6-canthinone from *Z. suberosum* C. T. White (9). The isolation of canthinones from the bark of *Z. elephantiasis* marks the second report of the occurrence of this type of alkaloid in a species of *Zanthoxylum*.



I, R=OCH_3
II, R=H



III

There have been recent reports of the isolation of canthinone alkaloids from plants belonging to a family other than the *Rutaceae*. In 1961, 4,5-dimethoxy-6-canthinone (10) was isolated from *Picrasma ailanthoides* (*Simaroubaceae*); in 1965, 4-methoxy-6-canthinone (11) was isolated from *Charpentiera obovata* Gand. (*Amaranthaceae*).

The quaternary aporphine alkaloid, laurifoline, was isolated for the first time from *Cocculus laurifolius* (*Menispermaceae*) by Tomita and Kusuda (7). The presence of aporphine alkaloids in the genus *Zanthoxylum* is not uncommon, but the isolation of laurifoline from *Z. elephantiasis* represents only the third report of the occurrence of laurifoline in a *Zanthoxylum* species. Tomita and Ishii (12) reported, in 1958, the isolation of laurifoline from the bark of *Z. ailanthoides*. The only other reported (13) isolation of laurifoline from any plant is from the bark of *Fagara pterota* L. (*Z. pterota* H.B.K.).

[6] The authors thank Dr. M. Tomita, Pharmaceutical Institute, Medical Faculty, University of Kyoto, Japan, and Dr. V. Deulofeu, Department of Organic Chemistry, Faculty of Sciences, Buenos Aires, Argentina, for authentic samples of laurifoline chloride.

Evaluation of Antacid Activity for Metal Complexes of Tris(hydroxymethyl)aminomethane (THAM)

By NANCY CHEN and GABRIEL G. NAHAS

An ideal antacid should buffer in the physiological pH range of 3 to 5, and should have a high neutralizing capacity per unit weight. Also, its initial effect should be rapid and the ideal pH range should be maintained for a relatively prolonged period. The organic aluminum and bismuth salts of a weak organic base, tris(hydroxymethyl)aminomethane (THAM) were prepared and their relative buffer capacities were compared. THAM-gluconatodihydroxo-aluminate was found to be an effective soluble buffer antacid compound.

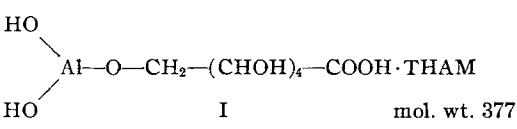
THE EXACT evaluation of antacids for *in vivo* titration is extremely difficult because of the many biological parameters involved. Therefore, *in vitro* methods must be used and these do not take into account individual physiological variations (*e.g.*, variations in composition of gastric juice, rate of secretion, rate of discharge from the stomach, etc.). However, such *in vitro* studies also present methodological difficulties. Hefferren *et al.* (1) compared the results obtained with different procedures and found that there were variations characteristic of a particular antacid and also of the method. Regardless of the procedure used, these *in vitro* studies indicate that an ideal antacid should buffer in the physiological pH range of 3 to 5, and should have a high neutralizing capacity per unit weight. Also, the initial effect should be rapid and the ideal pH range should be maintained for a relatively prolonged period.

The weak organic base, tris(hydroxymethyl)-aminomethane (THAM), is an unsatisfactory antacid because it fails to meet these criteria. Therefore, organic aluminum and bismuth salts of THAM (pH 7.0) were prepared and their relative buffering capacities were compared potentiometrically.

METHODS

Chemical and Physical Properties of Complexes and their Preparations (2).—The complexes with THAM were prepared from the aluminum and bismuth salts of several α-hydroxy-carboxylic acids (citric, gluconic, salicylic, *p*-aminosalicylic acids). Equivalent amounts of THAM were added to a suspension of the salt or to a solution obtained by heating the suspension to 70–80°. The complex was isolated by concentrating this aqueous solution to dryness *in vacuo*. Preparation of these compounds was performed in cooperation with Charra (2) as follows.

Aluminum–Gluconic Acid–THAM (1:1:1).—Gluconic acid (43.6 Gm. of 45% solution, 0.1 mole) is diluted in 200 ml. of water. In this solution, THAM (12.1 Gm., 0.1 mole) is dissolved, and the solution of aluminum isopropylate (20.4 Gm., 0.1 mole) in 100 ml. of isopropanol is added. Only a slight cloudiness appears. The mixture is stirred for 2 hr. at room temperature. It is then filtered and concentrated *in vacuo*. The solid residue is dried to constant weight in a vacuum desiccator. The analysis of the obtained product corresponds to formula I.

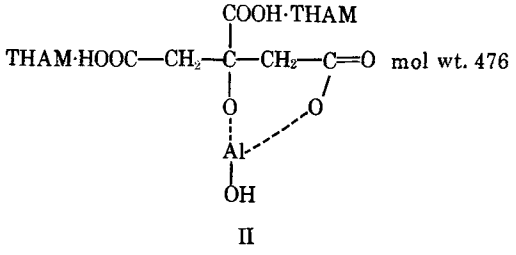


I mol. wt. 377

The pH of a 5% solution of this complex is 7.2.

Aluminum–Citric Acid–THAM (1:1:2).—Potassium alum [$Al_2(SO_4)_3 \cdot K_2SO_4 \cdot 24\ H_2O$, 47.45 Gm., 0.05 mole] is dissolved in 350 ml. of lukewarm water. The solution is alkalized with ammonia. The precipitate of aluminum hydroxide is dried, filtered, and washed until there are no more $SO_4^=$ ions in the filtrate.

The aluminum hydroxide is suspended in 100 ml. of water. Hydrated citric acid (10.5 Gm., 0.05 mole) dissolved in 50 ml. of water is added and the mixture stirred for 1 hr. at room temperature. THAM (12.1 Gm., 0.1 mole) dissolved in 50 ml. of water is then added and the mixture heated for 1 hr. in a water-bath at 50°. The dissolution of aluminum hydroxide is now virtually complete. The solution obtained is filtered and concentrated *in vacuo* while stirring with a magnetic stirrer and heating in an oil bath at 80° at the maximum. The residue is made into paste with 50 ml. of absolute ethanol. It is dried and washed with 25 ml. of ethanol. The residue is then dried to constant weight in a vacuum desiccator. Analytical results of the product show that it corresponds to formula II.



II mol wt. 476

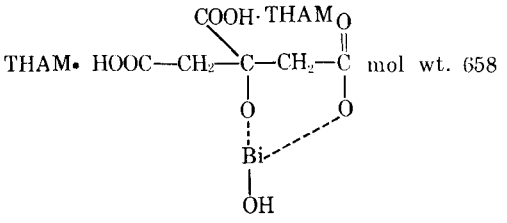
The pH of a 5% solution of this complex is 7.8.

Bismuth–Citric Acid–THAM (1:1:2).—Bismuth citrate (19.9 Gm., 0.05 mole) is suspended in 50 ml. of water. THAM (12.1 Gm., 0.1 mole) dissolved in 30 ml. of water is added. The mixture is heated for 1 hr. at 50°, while stirring, in order to obtain a complete dissolution. It is concentrated *in vacuo* while stirring magnetically. The white crystalline residue is dried to constant weight in a vacuum desiccator. The analysis of the product corresponds to formula III.

Received June 29, 1966, from the Department of Anesthesiology, College of Physicians and Surgeons, Columbia University, New York, N. Y. 10032.

Accepted for publication October 6, 1966.

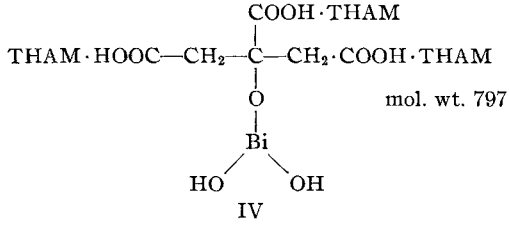
This work was supported in part by grant GM-09069-04 from the National Institutes of Health, U. S. Public Health Service, Bethesda, Md., and Army contract DA-49-193MD-2265.



III

The pH of a 5% solution of this complex is 6.70.

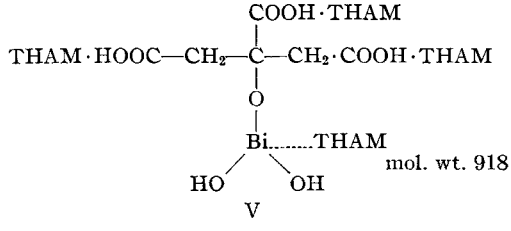
Bismuth–Citric Acid–THAM Complex (1:1:3).—The product is prepared according to the above described method, 0.15 mole of THAM being used. The analysis of the product corresponds to formula IV.



IV

The pH of a 5% solution of this complex is 7.55.

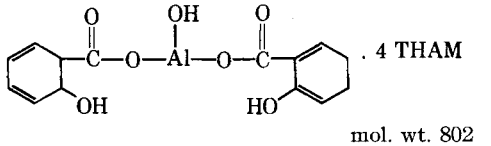
Bismuth–Citric Acid–THAM (1:1:4).—The product prepared by the method described above corresponds to formula V.



V

The pH of a 5% solution of this complex is 7.85.

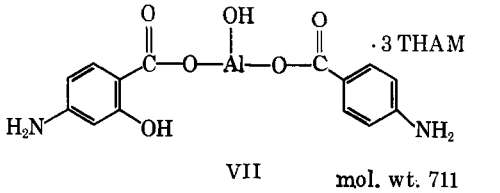
Aluminum–Salicylic Acid–THAM (1:2:4).—The product corresponds to formula VI.



VI

The pH of a 5% solution of this complex is 7.80.

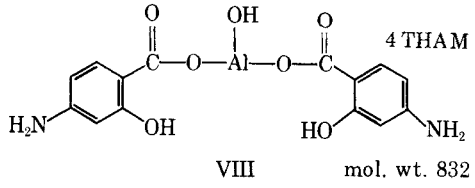
Aluminum–PAS Acid–THAM (1:2:3).—The analysis of the product corresponds to formula VII.



VII

The pH of a 5% solution of this complex is 7.4.

Aluminum–PAS Acid–THAM (1:2:4).—The analysis of the product corresponds to formula VIII.



VIII

The pH of a 5% solution of this complex is 7.5.

Antacid Activity Test.—The method of Gore, Martin, and Taylor (3) was used to determine antacid activity. An arbitrarily selected amount of the complex (calculated exactly to be 20% in excess of the neutralization value) (Table I) was added to 200 ml. of 0.015 *N* hydrochloric acid and the mixture was titrated in a double-walled vessel at 37 ± 0.1°. The pH was measured with a Knick model 35 pH meter and Beckman glass electrodes. Beckman standard buffer solutions at pH 4.00 and 7.00 were used to calibrate the meter. The pH was recorded for 30 min. To simulate the continuous gastric secretion of HCl, hydrochloric acid was then added to the mixture by means of a buret at the rate of 6 meq./hr. until an end point of pH 3.0 was reached.

RESULTS AND DISCUSSION

The relative buffering capacities of the various substances are given in Table II and illustrated in Figs. 1 and 2. A quantity (0.15%) of pepsin, peptone, and sodium chloride can be added to the hydrochloric acid as suggested by Brindle (4), Clemow and Lowry (5), and Grossmith (6). However, the use of such a "mock" gastric juice has little effect and comparable results are obtained with hydrochloric acid alone. In addition, there is some disagreement on the degree of acidity that would be most representative of *in vivo* conditions. However, most investigators recommend a pH of 3.0 to 5.0 and agree that carrying neutralization far beyond this range is undesirable.

TABLE I.—COMPOSITION OF COMPLEXES USED

Complexes	Unit Dose, Gm.
Aluminum–gluconic acid–THAM (1:1:1)	2.3
Aluminum–PAS acid–THAM (1:2:3)	2.5
Aluminum–PAS acid–THAM (1:2:4)	2.8
Aluminum–salicylic acid–THAM (1:2:4)	2.9
Bismuth–citric acid–THAM (1:1:4)	2.0
Bismuth–citric acid–THAM (1:1:3)	1.4
Aluminum–citric acid–THAM (1:1:2)	1.7
Bismuth–citric acid–THAM (1:1:2)	2.2

TABLE II.—BUFFERING CAPACITY

Complexes	0.1 *N* HCl ml. Added
Aluminum–gluconic acid–THAM (1:1:1)	117
Aluminum–PAS acid–THAM (1:2:3)	130
Aluminum–PAS acid–THAM (1:2:4)	140
Aluminum–salicylic acid–THAM (1:2:4)	140
Bismuth–citric acid–THAM (1:1:4)	60
Bismuth–citric acid–THAM (1:1:3)	38
Aluminum–citric acid–THAM (1:1:2)	31
Bismuth–citric acid–THAM (1:1:2)	27

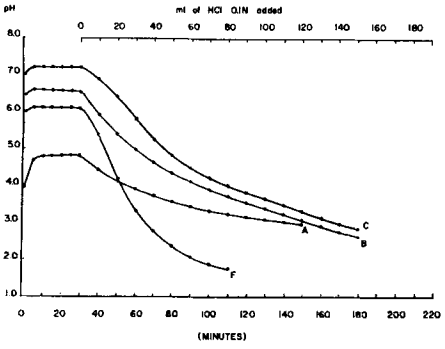


Fig. 1.—Acid consuming activity of four metal complexes of THAM. Key: A, aluminum–gluconic acid–THAM (1:1:1); B, aluminum–PAS acid–THAM (1:2:3); C, aluminum–PAS acid–THAM (1:2:4); F, bismuth–citric acid–THAM (1:1:3).

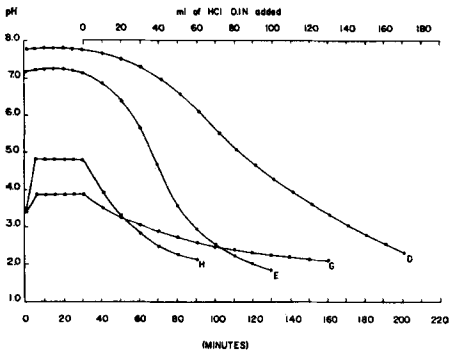

Fig. 2.—Acid consuming activity of four metal complexes of THAM. Key: D, aluminum–salicylic acid–THAM (1:2:4); E, bismuth–citric acid–THAM (1:1:4); G, aluminum–citric acid–THAM (1:1:2); H, bismuth–citric acid–THAM (1:1:2).

In the case of tris(hydroxymethyl)aminomethane–gluconatodihydroxo–aluminate (Al–gluconic acid–THAM, 1:1:1) the pH rose almost instantly to a value of 4.0 and after 5 min., reached a maximum pH of 5.0. The pH remained at about 5.0 for the next 30 min., during which time no additional acid was introduced. This suggests that *in vivo* an overdose of antacid would not increase the pH above 5.0. Moreover, when more acid was reintroduced, the pH did not fall below 3 until after approximately 12 meq. of HCl had been added also indicating that THAM–gluconatodihydroxoaluminate would be an effective soluble buffer antacid compound.

The complex of Bi–citric acid–THAM (1:1:1) had a smaller neutralizing capacity than Al–gluconic acid–THAM within the pH range 3 to 5 and the remaining antacids only have limited buffering capacities.

Catharanthus Alkaloids X. Isolation of Lanceine and Vinosidine from *Catharanthus lanceus* Roots

By RALPH N. BLOMSTER*, NORMAN R. FARNSWORTH, and DONALD J. ABRAHAM

In a continuing search for new biologically active entities in *Catharanthus lanceus*, additional work on the root (A) fraction has led to the isolation of two alkaloids. One of these, lanceine, was previously isolated from this plant by other workers. Vinosidine, however, although previously reported in a related species, is reported from this species for the first time.

EARLIER STUDIES on *Catharanthus lanceus*, as a part of a continued search for new and active antineoplastic principles from the various alkaloid fractions, and in an effort to elucidate, as completely as possible, the alkaloid composition of this plant, have resulted in the isolation of 12 crystalline alkaloids (1–4). Three of these, cathalanceine, pericyclivine, and periformyline proved to be new entities, with periformyline representing a new alkaloid of novel structure. Of the remaining nine, ajmalicine, yohimbine, and tetrahydroalstonine have been reported previously from *C. lanceus* roots by other workers (5–7). The additional six alkaloids have also been reported from the related *C. roseus* (8–12). Of these (leurosine, perivine, vindoline, pericalline, perimivine, and lochnerinine) leurosine is of major interest because of its high order of activity against the P-1534 leukemia, and because it was isolated initially from a *C. lanceus* crude alkaloid fraction that was devoid of activity against the P-1534 leukemia in DBA/2 mice (1).

This is a report on the isolation of two additional alkaloids, lanceine, previously reported from this plant by other investigators (6), and vinosidine, reported previously only from *C. roseus* (13).

Catharanthus Alkaloids X. Isolation of Lanceine and Vinosidine from *Catharanthus lanceus* Roots

By RALPH N. BLOMSTER*, NORMAN R. FARNSWORTH, and DONALD J. ABRAHAM

In a continuing search for new biologically active entities in *Catharanthus lanceus*, additional work on the root (A) fraction has led to the isolation of two alkaloids. One of these, lanceine, was previously isolated from this plant by other workers. Vinosidine, however, although previously reported in a related species, is reported from this species for the first time.

EARLIER STUDIES on *Catharanthus lanceus*, as a part of a continued search for new and active antineoplastic principles from the various alkaloid fractions, and in an effort to elucidate, as completely as possible, the alkaloid composition of this plant, have resulted in the isolation of 12 crystalline alkaloids (1–4). Three of these, cathalanceine, pericyclivine, and periformyline proved to be new entities, with periformyline representing a new alkaloid of novel structure. Of the remaining nine, ajmalicine, yohimbine, and tetrahydroalstonine have been reported previously from *C. lanceus* roots by other workers (5–7). The additional six alkaloids have also been reported from the related *C. roseus* (8–12). Of these (leurosine, perivine, vindoline, pericalline, perimivine, and lochnerinine) leurosine is of major interest because of its high order of activity against the P-1534 leukemia, and because it was isolated initially from a *C. lanceus* crude alkaloid fraction that was devoid of activity against the P-1534 leukemia in DBA/2 mice (1).

This is a report on the isolation of two additional alkaloids, lanceine, previously reported from this plant by other investigators (6), and vinosidine, reported previously only from *C. roseus* (13).

[a] All fractions gave positive tests for alkaloids except fractions 1–2.

EXPERIMENTAL[1]

Chromatographic Separation of C. lanceus Root (A) Fraction.—Two-hundred and forty-five grams of root (A) alkaloid fraction (1) was dissolved in benzene and this solution concentrated *in vacuo* to yield 29.05 Gm. of ajmalicine. Further concentration yielded 6.30 Gm. of benzene-insoluble, non-alkaloid precipitate. The remaining benzene-soluble material was placed at the top of an 8 × 86-cm. glass chromatographic column containing a benzene slurry of 4.0 Kg. of alumina (Alcoa F-20) partially deactivated with 144 ml. of 10% (v/v) acetic acid (1). Elution was accomplished initially with benzene, and then with eluting solvents having an increased polarity to yield 348 one-liter fractions. Each fraction was reduced to dryness, *in vacuo*, the residue dissolved in 20 ml. of the eluting solvent, and monitored by thin-layer chromatography on Silica Gel G plates using an ethyl acetate–absolute ethanol (3:1) eluent and the ceric ammonium sulfate spray reagent (CAS) (14, 15). Shifts in the alkaloid composition of the eluate, as determined by thin-layer chromatographic patterns, as well as differences in chromogenesis of the resolved alkaloids following treatment with the CAS reagent, were the criteria for determining the limits of each fraction (Table I).

Isolation of Lanceine.—Benzene eluate fractions 24–33 from the column chromatographic separation were taken to dryness, *in vacuo*, to yield 20.40 Gm. of residue, from which was obtained 3.60 Gm. of a crystalline material on direct crystallization from benzene. The R_f values of this material as well as its chromogenic reaction to the CAS detecting reagent on Silica Gel G thin-layer chromatography in three solvent systems (16) were identical with a reference sample of lanceine.[2] The melting point and infrared absorption spectrum of this material were identical with those found in the literature for lanceine (17). However, on alumina G thin-layer chromatography, using benzene–ethanol (98:2) as the eluent, the crystalline material proved to be a multicomponent mixture.

Nine grams of the crude alkaloid fraction 24–33 remaining after the removal of the crystals formed from benzene (*vide supra*), was dissolved in benzene and subjected to a gradient pH separation according to the method of Svoboda (18) in an attempt to separate lanceine. The initial pH of the acidic alkaloid solution was 3.3 and it was increased in 0.5 pH increments by the addition of NH_4OH until a final pH of 8.8 was reached. Each fraction was dried with anhydrous sodium sulfate, filtered, and reduced to about 10 ml. *in vacuo*, followed by thin-layer chromatography and treatment of the developed chromatograms with CAS reagent which served to point out those pH fractions to be combined prior to crystallization attempts. The fractions were combined to give two groups corresponding to pH 3.3–4.3 and 4.8–8.8. Fraction pH 3.3–4.3 yielded 0.110 Gm. of crystalline material on direct crystallization from ethanol. Again this material appeared to be identical with lanceine as regards melting point and infrared absorption spectrum, but on alumina G thin-layer chromatography, it proved to be a multicomponent mixture.

Repeated crystallization of the impure materials with several solvents failed to resolve the mixture, as did column chromatography on alumina (Woelm, neutral, activity grade II), utilizing benzene as the initial eluting agent and followed by solvents of increasing polarity. The mixture was finally resolved by repeated preparative thin-layer chromatography, utilizing 1 mm. thick alumina G plates, developed with anhydrous ether in a repetitive manner. In each case the solvent front was allowed to travel 170 mm., the plate air-dried, and rechromatographed. This was repeated 3 times. The area corresponding to lanceine, as determined by chromogenesis with the CAS reagent (16), was removed from the plate, eluted with methanol, filtered, evaporated to dryness *in vacuo*, and the residue was dissolved in a small amount of methanol and placed on the surface of a second

[1] Melting points are uncorrected and were determined using a Thomas-Hoover capillary melting point apparatus. Infrared absorption spectra were determined in a Beckman infrared spectrophotometer model IR-8.

[2] The authors express their appreciation to Dr. Jean LeMen for a sample of crude lanceine which was suitable for thin-layer chromatographic comparison only.

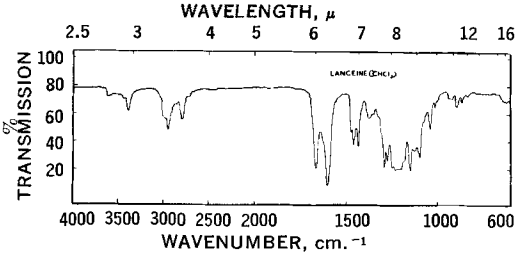

Fig. 1.—Infrared spectrum of isolated lanceine.

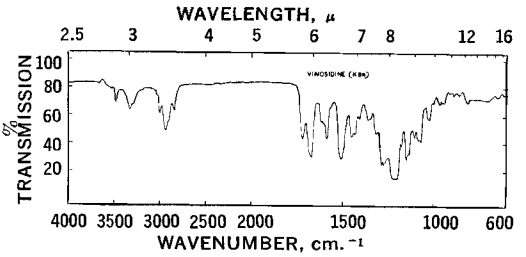

Fig. 2.—Infrared spectrum of isolated vinosidine.

preparative alumina G thin-layer plate. This plate was treated in the same manner as the first plate, and the material obtained on elution of the matrix was crystallized from cyclohexane at room temperature. This yielded 0.013 Gm. of crystalline lanceine, m.p. 143–145°, from each 0.100 Gm. of impure material utilized. The infrared absorption spectrum (Fig. 1) of the isolated lanceine was identical with that found in the literature (17). The R_f values for the isolated lanceine and a reference sample of this alkaloid, as well as chromogenic reactions to the CAS detecting agent after Silica Gel G thin-layer chromatography in three different solvent systems (16), and on alumina G thin-layer chromatography were also identical.

Isolation of Vinosidine.—Treatment of the dried benzene–chloroform (1:1) fractions 79–104 with methanol yielded crystals, which on recrystallization from methanol afforded 0.090 Gm. of vinosidine, m.p. 251–253° dec. The infrared absorption spectrum (Fig. 2) of isolated vinosidine and that of a reference sample[3] were identical, as were their R_f values and chromogenic response to the CAS reagent after thin-layer chromatography in three different solvent systems (16).

SUMMARY

The isolation of two alkaloids is reported. One, lanceine, was previously isolated from *C. lanceus* roots by other workers. Vinosidine was previously isolated from the related species *C. roseus*, but is reported herein for the first time from *C. lanceus*.

[3] A reference sample of vinosidine was supplied through the generosity of Dr. Gordon H. Svoboda.

Steric Aspects of Adrenergic Drugs IV. Antagonism of Norepinephrine Effects by Ephedrine Isomers on the Isolated Rabbit Ileum

By P. N. PATIL, J. B. LAPIDUS, S. MOLINARI*, and A. TYE

The inhibition of the pendular movements of the isolated rabbit ileum, due to norepinephrine, was not antagonized in the presence of 10^{-5} *M* D(−)-ephedrine, L(+)-ephedrine, L(+)-pseudoephedrine, or D(−)-pseudoephedrine. However, a 10^{-3} *M* concentration of these isomers did antagonize the norepinephrine effects. The stereospecificity in such antagonism is not marked.

In the past a number of investigators have reported that in certain tissues such as rabbit ileum and cat uterus, epinephrine-induced relaxation can be blocked by ephedrine (1–4). This observation was recently confirmed by Van Rossum and Mujic (5). Furthermore, they have suggested that certain "indirectly" acting sympathomimetic amines do not of themselves cause inhibition of the rabbit jejunum, but antagonize the effects of "directly" acting sympathomimetic amines. These reports formed the basis for the present investigation, which was aimed at obtaining information regarding stereospecificity in such antagonistic effects.

EXPERIMENTAL

Twenty-four hour starved rabbits of either sex were sacrificed by a sharp blow on the head. The ileum was isolated and a small piece (about 2 cm.) was suspended in a 25-ml. jacketed tissue chamber which contained Tyrode's solution at 37°. A mixture of oxygen (95%) and carbon dioxide (5%) was continuously bubbled through the Tyrode's solution. The composition of the Tyrode's solution was as follows: NaCl, 8.0 Gm.; KCl, 0.2 Gm.; $CaCl_2$ ($2H_2O$), 0.26 Gm.; $MgCl_2$ ($6H_2O$), 0.188 Gm.; $NaHCO_3$, 1.0 Gm.; NaH_2PO_4, 0.05 Gm.; dextrose anhydrous, 1.0 Gm.; double distilled water to make 1000 ml. Pendular movements of ileum were recorded on a smoked drum *via* a light lever (magnification 1:20, tension approximately 500 mg.). The tissue was washed 3 or 4 times before cumulative dose-response curves were obtained. This method is described in detail by Van Rossum and Mujic (5). For each procedure six to nine pieces of ileum were obtained from three to four different animals. Only one dose response curve was obtained from each piece of ileum. The maximum height of the pendular movements was taken as 100% and inhibition expressed as the per cent of the initial activity. Ephedrine isomers were left in contact with the tissue for 2 min. before cumulative dose-response curves of norepinephrine were determined.

A stock solution of norepinephrine[1] was prepared in a solution containing 0.05% sodium metabisulfite. Ephedrine isomers were obtained by a method described previously (6).

RESULTS AND DISCUSSION

Norepinephrine produces a rapid inhibition of the pendular movements. The inhibition is complete in 10^{-6} *M* norepinephrine. The negative log molar concentration of norepinephrine for producing 50% inhibition is 6.9. This value is lower than that for jejunum which is 7.8 (5). Ephedrine isomers in concentrations of 10^{-5} *M* did not produce any intrinsic effects, nor did they exhibit any antagonism toward norepinephrine effects (Fig. 1 and Table I).

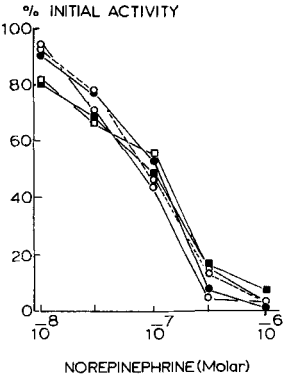

Fig. 1.—Cumulative dose-response curves of norepinephrine on rabbit ileum in the presence of 10^{-5} *M* D(−) - ephedrine (O- - -O); L(+)-ephedrine (O——O); L(+)-pseudoephedrine (□——□); D-(−) - pseudoephedrine (■——■). Norepinephrine control (●——●). Standard errors of the mean were 5 to 7% and showed a marked overlap.

In higher concentration (10^{-3} *M*), ephedrine showed variable intrinsic effects. D(−)-Ephedrine produced 34% (S.E. ± 4.2) inhibition; L(+)-ephedrine and D(−)-pseudoephedrine produced stimulant effects of 10% (S.E. ± 1) and 29% (S.E. ± 2), respectively, while L(+)-pseudoephedrine did not produce any observable effects.

The inhibitory effects of norepinephrine were antagonized by ephedrine isomers (Fig. 2). The dose-response curves were shifted to the right, *i.e.*, in the presence of ephedrine isomers a higher concentration of norepinephrine was required to

produce the same response. It appears that L(+)-pseudoephedrine is < antagonist than D(−)-pseudoephedrine which is ≤ L(+)-ephedrine. The interpretation of the antagonist potency of D(−)-ephedrine is complicated by its intrinsic inhibitory effects. Present results are compatible with the view that sympathomimetic amines may compete for "direct" sites, but the possibility of noncompetitive antagonism must be borne in mind. (Table II.)

3-Thenyl Nitrogen Mustards

By W. LEWIS NOBLES and CHARLES M. DARLING

As potential anticancer agents, three new 3-thenyl nitrogen mustards have been prepared from the corresponding diethanolamine derivatives. The NMR data for these compounds are reported.

IN A SERIES of antihistaminic compounds, Clapp and co-workers (1) have suggested that the inclusion of a halogen atom on the thiophene ring improves the therapeutic ratio. This suggestion has not been exploited in thiophene nitrogen mustards. Indeed, besides dimethyl derivatives (2), no nuclear substituted thiophene nitrogen mustards have been reported.

Campaigne's comparative data (3) suggest that in testing thiophene analogs, there is a high probability that the 3-isomer will be at least as active as the 2-isomer, if not more active. Of the six thiophene nitrogen mustards previously reported (2, 4, 5), four are thenyl derivatives (2, 5) and, of these, only two are 3-thenyl isomers (2).

In this investigation, three 3-thenyl nitrogen mustard derivatives have been prepared as potential anticancer agents. These are denoted by structure I in which R = H, 2-bromo, and 2,5-dichloro.

Received October 3, 1966, from the Department of Pharmaceutical Chemistry, School of Pharmacy, University of Mississippi, University 38677.
Accepted for publication October 14, 1966.

present work, the reaction mixture was allowed to reflux during the addition of thionyl chloride, and higher yields of the nitrogen mustard function were obtained consistently. The compounds along with pertinent data are listed in Table I.

EXPERIMENTAL[1]

3-Thenyl Diethanolamines.—The 3-thenyl bromides were prepared by known methods (6, 7) and were used as the crude lachrymatory oils. Each crude 3-thenyl bromide compound was refluxed with a 2 *M* ratio of diethanolamine in chloroform for 16 to 18 hr. After cooling the solution to room temperature, the mixture was poured over ice and the chloroform layer separated. The chloroform was removed with a flash evaporator. The residue of compound II was recrystallized from diethyl ether as the free base. The hydrochloride salt of compound I was prepared by saturating an ethereal solution of I with anhydrous hydrogen chloride and recrystallizing from acetone. The hydrochloride salt of compound III was prepared by the addition of concentrated hydrochloric acid to a solution of III in acetone; the salt was then recrystallized from absolute ethanol.

The NMR spectrum of I in deuterated pyridine was δ = 3.61 (t, probably C—CH_2—O, 4H), 4.33 (t, probably N—CH_2—C, 4H), 4.84 (s, thienyl—CH_2—N, 2H), 7.87 (s, O—H, disappeared in D_2O exchange), and 7.60 (m, undetermined) p.p.m.

[1] All melting points were taken on a Thomas-Hoover Uni-Melt melting point apparatus and are corrected. The NMR spectra were taken using a Varian model A60-A instrument and were measured at 60 Mc. The chemical shifts are reported as δ-values (p.p.m.) from tetramethylsilane (internal standard). The multiplicity is shown by s = singlet, d = doublet, t = triplet, and m = incompletely resolved multiplet. Coupling constants, *J*, are reported in c.p.s. Assignments are shown in parentheses.

The NMR spectrum of II in deuterated acetone was δ = 2.66 (t, probably C.CH_2—O, 4H), 3.57 (t, probably N—CH_2—C, 4H), 3.68 (s, thienyl—CH_2—N, 2H), 3.15 (s, O—H, 2H), 7.05 (d, probably 5-H of ring, 1H), and 7.39 (d, probably 4-H of ring, 1H) p.p.m. (Each J_{4-5} = 5.7 c.p.s. ± 0.2 c.p.s.)

The NMR spectrum of III in deuterated pyridine was δ = 3.48 (t, probably C—CH_2—O, 4H), 4.25 (t, probably N—CH_2—C, 4H), 4.48 (s, thienyl—CH_2—N, 2H), 7.80 (s, 4-H of ring, 1H), and 8.11 (s, O—H, disappeared on D_2 exchange) p.p.m.

2,2′-Dichlorodiethyl-3-thenylamines.—The general procedure for the preparation of the nitrogen mustard function is reported below. The free base of the appropriate diethanolamine derivative was dissolved in chloroform and a large excess (about 5 *M* ratio) of redistilled thionyl chloride was slowly added without cooling. Reflux began spontaneously and was continued for 5 to 7 hr. The reaction mixture was cooled to room temperature, and the chloroform and excess thionyl chloride were removed with a flash evaporator. In each instance, the residue was recrystallized from acetone using charcoal.

The NMR spectrum of IV in deuterated chloroform was δ = 3.52 (t, probably C—CH_2—Cl, 4H), 4.01 (t, probably N—CH_2—C, 4H), 4.50 (s, thienyl—CH_2—N, 2H), 7.36 (d, probably 4,5-H of ring, 2H) (J = 2.2 c.p.s.), and 7.72 (t, probably 2-H of ring, 1H) (J = 2.2 c.p.s.) p.p.m. (all J's ± 0.3 c.p.s.).

The NMR spectrum of V in deuterated chloroform was δ = 3.62 (t, C—CH_2—Cl, 4H), 4.15 (t, N—CH_2—C, 4H), 4.49 (s, thienyl—CH_2—N, 2H), 7.46 (d, probably 5-H of ring, 1H), and 7.78 (d,

probably 4-H of ring, 1H) p.p.m. (each J_{4-5} = 5.7 c.p.s. ± 0.2 c.p.s.).

The NMR spectrum of VI in deuterated chloroform was δ = 3.58 (t, probably C—CH_2—Cl, 4H), 4.08 (t, probably N—CH_2—C, 4H), 4.38 (s, thienyl—CH_2—N, 2H), and 7.54 (s, 4-H of ring, 1H) p.p.m.

Pemoline and Magnesium Hydroxide *Versus* Pemoline: Enhancement of Learning and Memory of a Conditioned Avoidance Response in Rats

By N. PLOTNIKOFF and P. MEEKMA, JR.

Pemoline and magnesium hydroxide was found to be several times more potent than pemoline in enhancing the acquisition and retention of a conditioned avoidance response in rats.

NUMEROUS STUDIES in Europe indicated that the performance of fatigued humans was enhanced by pemoline under various test conditions (1–3). In previous studies Plotnikoff (4–7) reported that pemoline and magnesium hydroxide (PMH)[1] enhanced the acquisition and retention of a conditioned avoidance response in rats. The present study is a comparative study of PMH and pemoline on the same avoidance response.

EXPERIMENTAL

Methods—The test chamber as well as rates of acquisition and retention used for all conditioning studies were described earlier (4–7). The test equipment consisted of a wood chamber (11 × 12 in.) with a grid flooring. An escape platform was placed 11 in. above the grid floor outside of the test chamber. Male Sprague-Dawley rats (170 to 220 Gm.) were used. Only "slow learners" were used for all drug studies. Suspensions of the test drugs were prepared in 0.3% tragacanth. Acquisition trials consisted of the following 30-sec. sequence: 15 sec. inside the chamber without shock or buzzer, 10 sec. with buzzer, and finally 5 sec. of shock with buzzer. Retention trials consisted of a 30-sec. sequence without buzzer or shock stimulation. Criterion of learning was considered obtained when the mean jump-out time was 15 sec. or less for any given trial and succeeding trials.

Results—The principal difference observed between pemoline and PMH on the jump-out test was one of potency. As the data in Tables I and II illustrate, PMH is more potent in the enhancement of acquisition and retention of the jump-out response. In several studies, significant enhancement was observed with 0.3% tragacanth suspensions of PMH at doses of 1.25, 2.5, and 5.0 mg./Kg. p.o. In contrast, pemoline (0.3% tragacanth suspension) only showed significant enhancement at doses of 10 and 20 mg./Kg. p.o. Lower doses of pemoline (2.5 and 5.0 mg./Kg. p.o.) did not enhance acquisition or retention.

The approximate potency differences on acquisition between the two compounds is at least eightfold. Rats treated with PMH reached criterion of learning by the 9th trial at a dose of 1.25 mg./Kg., whereas pemoline-treated rats reached criterion of learning by the 4th trial at a dose of 10 mg./Kg.

The potency differences between the two compounds on retention were also approximately eightfold (1.25 mg./Kg. *versus* 10.0 mg./Kg.). Significant retention of the jump-out response was observed at a dose of 1.25 mg./Kg. in PMH-treated animals, whereas pemoline-treated animals only showed significant retention at a dose of 10 mg./Kg.

Control studies carried out with $Mg(OH)_2$ indicated there were no significant effects on acquisition or retention.

DISCUSSION

The present study has demonstrated that PMH is a more potent agent in enhancing acquisition and retention than pemoline. A similar difference between pemoline and PMH has been reported by Lange *et al.* (8) on anticonvulsant activity. The principal difference reported was the rate of absorption as determined by onset of anticonvulsant activity. PMH at a dose of 100 mg./Kg. exerted significant activity 15–30 min. after oral administration, whereas pemoline at the same dose exhibited activity only at 60 min. However, both PMH and pemoline have the same LD_{50} values in mice (oral LD_{50} 500 mg./Kg.). The effects of the two compounds are both similar resulting in overt stimulant effects at doses of 5–400 mg./Kg. and paradoxical depression (ataxia followed by coma) at toxic doses (500–1000 mg./Kg.). No convulsions were observed at toxic doses.

In the present study, PMH was demonstrated to be a more potent agent than pemoline in enhancing acquisition and, even more striking, retention of the jump response. Thus, it is possible that magnesium hydroxide component may be enhancing absorption. Clinically (9) PMH has been reported to have a faster onset of action and to have greater potency as an arousal agent than pemoline.

Antiradiation Compounds VIII. Reaction of Thiols with Cyanogen Bromide

By WILLIAM O. FOYE, ALICIA M. HEBB, and JAMES MICKLES

The reaction of a thiol with cyanogen bromide provides a specific synthesis of disulfides without further oxidation. The reaction is apparently general, and was successful for MEA, MEG, and aliphatic, aromatic, and amino thiols. Oxidation of MEA with 3 per cent hydrogen peroxide also gave the disulfide, but similar oxidation of MEG gave the thiolsulfinate, distinguishable from the disulfide by infrared absorption in the 1100 cm.$^{-1}$ region.

THE REACTION of dithiols with cyanogen chloride has been found to result in the formation of cyclic imino dithioester hydrochlorides (1). With the assumption that 2-mercaptoethylamine hydrochloride (MEA) might react with cyanogen bromide in analogous fashion, either an imino dithioester hydrohalide or iminothiazolidine would be obtained, and provide possibly an active antiradiation agent. The former may be expected to liberate MEA *in vivo*, and in the latter case, some thiazolidines are known to be radioprotective (2). A stable, white, granular product was obtained from the proposed reaction (2 moles of MEA hydrochloride with 1 mole of cyanogen bromide) which did not reduce iodine and gave a positive test for the disulfide linkage with Grote's reagent (3). The melting point (221–222°) was somewhat higher than those recorded for the disulfide of MEA hydrochloride (203°, 210°, 212°, 216°) (4), however, and the carbon-hydrogen analysis was somewhat low for this compound.

A pure sample of the disulfide of MEA hydrochloride was accordingly required for comparison. By iodine oxidation of MEA hydrochloride, a product was obtained for which the melting point (217°) agreed with that reported by Schoberl (5). By use of alkaline peroxide (3%), a product was obtained which melted at 222–224° and gave the correct analytical data for the disulfide. The ultraviolet, infrared,[1] and Raman[2] spectra of the disulfide and the product of cyanogen bromide oxidation proved to be identical. (See Fig. 1 for infrared spectrum.) The Raman spectra showed strong absorption at 515 and 650 cm.$^{-1}$, expected for S-S and C-S stretching (6). It was suspected that the low C-H assay values might be due to the presence of bromide ion, but a correct analysis for chlorine was obtained, and no bromide ion was detected by the chlorine water–carbon tetrachloride test. In addition, a dibenzoyl derivative was obtained that was identical in yield and properties to that prepared from the disulfide.

The reaction of cyanogen bromide with other thiols was observed, and in each case the disulfide was formed. With 2-mercaptoethylguanidine (MEG), a compound corresponding to the disulfide (7) was obtained from cyanogen bromide oxidation, and a compound whose analytical data and infrared absorption spectra indicated the thiolsulfinate was obtained from oxidation by 3% hydrogen peroxide at 40°. A strong peak at 1115 cm.$^{-1}$ (Fig. 2), absent in the disulfide (Fig. 3), provided spectral evidence for the thiolsulfinate (8). This region of the spectrum (Fig. 2) was identical when observed in either Nujol or KBr.

Other thiols subjected to cyanogen bromide oxidation included cysteine, homocysteine, 2-diethylaminoethanethiol hydrochloride,[3] 1-amino-2-propanethiol hydrochloride,[4] thiophenol, heptanethiol, dodecanethiol, *o*- and *p*-aminobenzenethiol hydrochloride, and *o*-, *p*-, and α-toluenethiol. The formation of a disulfide in each case was shown by melting point (except for two cases, the disulfides are known), elemental analysis, and infrared absorption spectra (two or three peaks at 1050–1250 cm.$^{-1}$ which were fairly strong in the case of the aromatic and aminoalkyl disulfides). These peaks are apparently due to CH_2 or aryl CH wag of CH_2 or CH adjacent to sulfur (6). Bredereck *et al.* (8) have shown two peaks near 1100 cm.$^{-1}$ for an aryl disulfide.

Antiradiation testing of MEA disulfide dihydrochloride at the Walter Reed Army Institute of Research, through the courtesy of Drs. D. P. Jacobus and T. R. Sweeney, showed the compound to possess good protective properties in mice *versus* 825 r., a finding which is in agreement with previous reports (9).

EXPERIMENTAL

Analyses for carbon, hydrogen, and nitrogen were done by Weiler and Strauss, Oxford, England, or by Carol K. Fitz, Needham, Mass. Sulfur and chloride analyses were done by Parr bomb peroxide fusion. Melting points were taken on a Mel-Temp apparatus and are corrected. Infrared absorption spectra were obtained with a Perkin-Elmer model 137B spectrometer.

2-Aminoethyl Disulfide Dihydrochloride.—*By Cyanogen Bromide Oxidation.*—Cyanogen bromide (3.63 Gm., 0.034 mole) (Eastman Organic Chemicals) was added to a solution of 2-aminoethanethiol hydrochloride (7.78 Gm., 0.068 mole) (Aldrich Chemical Co.) in 20 ml. of absolute ethanol. A precipitate formed immediately, with liberation of heat, and was filtered, washed with ethanol, and air dried. A second crop was obtained by addition of ether to the filtrate. After recrystallization from 95% ethanol, a yield of 3.0 Gm. (78%) was obtained; m.p. 221–222°. [Lit. m.p. 216° (5)] λ_{max}. 245 mμ.

Anal.—Calcd. for $C_4H_{14}Cl_2N_2S_2$: C, 21.33; H, 6.27; Cl, 31.49; N, 12.43. Found: C, 19.87; H, 5.93; Cl, 31.30; N, 12.25.

Benzoylation in pyridine with exactly 2 moles of benzoyl chloride for 4 days at 25° gave a 71% yield of the dibenzoyl derivative, m.p. 132–133°. [Lit. m.p. 132° (10).]

By Alkaline Peroxide Oxidation.—A solution of 5.7 Gm. (0.5 mole) of 2-aminoethanethiol hydrochloride in 10 ml. of water was neutralized with a solution of 2.1 Gm. (0.05 mole) of lithium hydroxide in 20 ml. of water. The solution was cooled in an ice bath, and 3% hydrogen peroxide solution was added dropwise with stirring until the reaction solution gave a negative test for thiol with nitroprusside solution. The resulting solution was acidified with hydrochloric acid (1:1) solution to a pH of 2, concentrated to one-half its volume, and cooled. A semisolid resulted which was triturated in a mortar with 97.5% ethanol, washed with absolute ethanol, and dried *in vacuo*, giving 3.4 Gm. (60%) of crystalline product, m.p. 222–224°.

Anal.—Calcd. for $C_4H_{14}Cl_2N_2S_2$: C, 21.33; H, 6.27; Cl, 31.49; N, 12.43; S, 28.48. Found: C, 21.56; H, 6.32; Cl, 31.99; N, 12.21; S, 28.41.

The dibenzoyl derivative was prepared as above in 72% yield, m.p. 134–135°.

2-Guanidinoethyl Disulfide Dihydrobromide.—*S*-(2-Aminoethyl) isothiuronium bromide hydrobromide (11.2 Gm., 0.04 mole) (Matheson, Coleman and Bell) was dissolved in 30 ml. of water and 6 ml. of concentrated ammonium hydroxide and treated with cyanogen bromide (2.12 Gm., 0.02 mole) with stirring. After 2 hr., the orange solution was refrigerated, and a cream colored solid was isolated and recrystallized from ethanol. The yield was 1.8 Gm. (23%), m.p. 195–196°. [Lit. m.p. 195–197° (7).]

Anal.—Calcd. for $C_6H_{18}Br_2N_6S_2$: C, 18.1; H, 4.5; N, 21.1; S, 16.1. Found: C, 17.6; H, 4.5; N, 20.5; S, 16.0.

2-Guanidinoethyl 2-Guanidinoethanethiolsulfinate Dihydrobromide.—*S*-(2-Aminoethyl)isothiuronium bromide hydrobromide (14.0 Gm., 0.05 mole) was dissolved in 12.5 ml. of concentrated ammonium hydroxide, and 100 ml. of 3% hydrogen peroxide was added in 4 portions with stirring over a 2-hr. period. The solution was kept at 40° during the addition. It solidified on cooling, and the solid was triturated with absolute ethanol and recrystallized from ethanol. The yield was 3.5 Gm. (33%) of white crystalline solid, m.p. 175–176°.

Anal.—Calcd. for $C_6H_{18}Br_2N_6OS_2$: C, 17.4; H, 4.4; N, 20.3; S, 15.5. Found: C, 17.2; H, 4.2; N, 20.1; S, 15.4.

Other Thiols.—2-Diethylaminoethyl disulfide was obtained as the dihydrobromide, m.p. 233–235°, apparently by using an excess of cyanogen bromide.

Anal.—Calcd. for $C_{12}H_{30}Br_2N_2S_2$: C, 33.80; H, 7.11; N, 6.57; S, 15.05. Found: C, 34.81; H, 7.12; N, 6.53; S, 15.55.

o-Aminophenyl disulfide was obtained as the dihydrochloride, m.p. 225–227°, not previously reported.

Anal.—Calcd. for $C_{12}H_{14}Cl_2N_2S_2$: C, 44.89; H, 4.36; N, 8.72; S, 19.96. Found: C, 44.75; H, 4.71; N, 8.34; S, 19.40.

Paper Chromatography Study of *In Vitro* and *In Vivo* Hydrolysis of Heroin in Blood

By GEORGE R. NAKAMURA* and TYUNOSIN UKITA†

A study was conducted using paper chromatography to elucidate the pathway of heroin hydrolysis in human blood *in vitro* and in dog's blood *in vivo*. Results indicated that heroin deacetylated rapidly to monoacetylmorphine which remained relatively stable in blood and left the bloodstream as such. Only a trace amount of morphine was detected *in vitro* and *in vivo*. Both compounds became undetectable after 30 min. in the *in vivo* experiment.

THIS LABORATORY has yet to report a positive finding of morphine or morphine derivatives in whole blood specimens. The problem seems to be in the limited sensitivity of the methods (1, 2) used or/and in the timing of blood collection. While the urine remains a preferred body fluid specimen for narcotic analysis since it acts as a reservoir of metabolic waste, the examination of blood specimens may yield information as to the origin of morphine eliminated in the urine.

For forensic consideration, it seems more convincing to inform the court that the subject had taken heroin, especially when he has had heroin in his possession. A finding of monoacetylmorphine in blood would strongly imply that heroin was taken.

Therefore, some experiments were performed to determine the nature of heroin hydrolysis in human blood and the length of time heroin and its hydrolysis products remain in the blood circulation, *in vivo*.

PROCEDURE

Preparations of diacetylmorphine, 6-monoacetylmorphine, and 3-monoacetylmorphine were the same as those described in a previous paper (3).

Ten milligrams of diacetylmorphine hydrochloride were dissolved in 20 ml. of fresh human serum in a 50-ml. conical flask and to this mixture was added 1 mg. of oxytetracycline HCl to suppress bacterial growth. The flask was fixed in a water bath at 37.5°. At various time intervals, a 1-ml. aliquot was removed and introduced into a small separator containing 0.5 ml. of saturated $NaHCO_3$. The alkaline mixture was immediately shaken with 20 ml. of 9:1 chloroform–ethanol mixture. Then, the extract was filtered through a pledget of cotton into a small beaker. The clear extract was evaporated to near dryness and the entire residue was applied onto a Whatman No. 1 chromatography paper. The chromatographic procedure was the same as that described by Genest and Farmilo (4) and was used as a standard method in this study.

To determine if nonenzymic hydrolysis, *i.e.*, autohydrolysis of heroin and 6-monoacetylmorphine could occur in human blood, serum was this time heated to 60° for 1 hr. and the substrate diacetylmorphine was introduced into the deactivated serum. The resulting mixture was incubated at 37°, extracted, and chromatographed under standard conditions. For further confirmation of possible autohydrolysis of heroin, the substrate was introduced into $^1/_{15}$ *M* phosphate buffer, pH 7.3, and the same standard procedure was followed for the hydrolysis study.

Three dogs, each weighing about 20 lb., were selected for the *in vivo* study of heroin hydrolysis. Each received an intramuscular injection of 80 mg. of pure diacetylmorphine hydrochloride. Twenty milliliters of blood was collected from the jugular vein at 10-min. intervals as shown in Fig. 3. The specimens were treated with heparin and chilled in an ice water bath. Plasma was separated from these specimens using a refrigerated centrifuge, adjusted to pH 8.0 with saturated $NaHCO_3$, and then shaken with 9:1 chloroform–ethanol mixture.

RESULTS AND DISCUSSION

The chromatogram in Fig. 1 showed that the *in vitro* hydrolysis of heroin in human serum proceeded rapidly and it disappeared within 1 hr. Furthermore, the hydrolysis proceeded by pathway of 6-monoacetylmorphine. 3-Monoacetylmorphine was not a product of hydrolysis indicating the more rapid cleavage of the phenolic acetyl group. The amount of morphine liberated at the end of 7 hr. was comparatively small. 6-Monoacetylmorphine was still present in the serum in a large proportion after 7 hr. of incubation, indicating its stability and its possible role as an important mediator for the pharmacological activity of heroin (5). Also this stability in blood offered a possibility for its forensic detection in human blood.

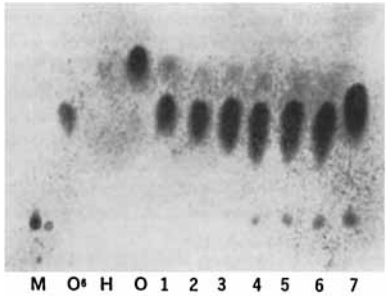

Fig. 1.—*In vitro* hydrolysis of heroin in human serum at 37.5°. Aliquots from reaction mixture examined at 1-hr. intervals. Key: M, morphine; 0^6, 6-monoacetylmorphine; and H, heroin.

† Faculty of Pharmaceutical Sciences, University of Tokyo, Tokyo, Japan.

Control experiments using enzyme-deactivated human serum (Fig. 2) indicated that a rapid hydrolysis of the phenol acetyl group occurred without enzymic catalysis. The same chromatographic pattern was obtained by using phosphate buffer instead of deactivated serum. This observation further indicated that heroin could be degraded mostly to 6-monoacetylmorphine in the human body by autohydrolysis. Autohydrolysis seems to hold true for further degradation of 6-monoacetylmorphine to morphine since the amount of morphine liberated from both the heat-treated and untreated serum was approximately the same. Ellis (6) demonstrated by a manometric method of analysis that human blood was devoid of 6-monoacetylmorphine esterase activity. However, in the authors' study, the rate of morphine liberation was slightly faster in nontreated serum, therefore, the possible occurrence of enzyme catalysis could not be entirely precluded.

Cochin *et al.* (7) has shown that the plasma level of morphine in dogs after a subcutaneous injection attained a peak level at 45 min. The authors' paper chromatographic study of heroin metabolism in dogs showed that 6-monoacetylmorphine was the principal breakdown product of heroin in blood and that it persisted on the chromatogram for a 30-min. period. The chromatogram in Fig. 3 showed strong spots for 6-monoacetylmorphine and weaker spots for morphine for a 30-min. period, indicating again the relatively stable monoacetylmorphine in blood even under *in vivo* conditions. Only a faint spot for morphine could be detected after 30 min. suggesting that most of the degraded products of heroin had left the blood stream by that time. 6-Monoacetylmorphine and morphine were characterized by ultraviolet absorption spectra examination and color tests described by the authors previously (3).

SUMMARY

In vitro and *in vivo* study of heroin in blood revealed that monoacetylmorphine was the principal product and it was relatively stable *in vitro* for at least 7 hr. in blood at 37°. The study further indicated that heroin entered the blood stream and was rapidly deacetylated to monoacetylmorphine, leaving the circulation virtually in this form. The detection of monoacetylmorphine was, therefore, indicated for forensic purpose. However, the study showed that blood must be collected within a 30-min. period after administration.

Morphine was detected on the chromatogram upon *in vitro* and *in vivo* hydrolysis at a much lower level.

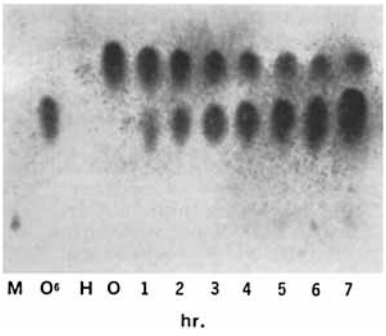

Fig. 2.—*In vitro* hydrolysis of heroin in enzyme-deactivated serum at 37.5°. Same key and conditions as those in Fig. 1.

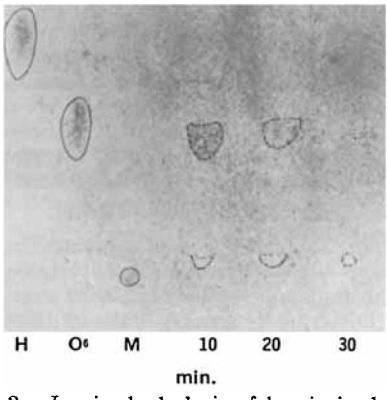

Fig. 3.—*In vivo* hydrolysis of heroin in dog, administered intramuscularly 80 mg. of diacetylmorphine hydrochloride; 20 ml. of blood collected at 10-min. intervals and examined for metabolites. Key same as in Fig. 1.

Effect of Certain Drugs on Perfused Human Placenta VII. Serotonin *Versus* Angiotensin-II

By RONALD F. GAUTIERI and RALPH T. MANCINI*

Serotonin produced vasoconstriction in perfused human placental vessels primarily *via* stimulation of α-adrenergic receptors and secondarily *via* direct stimulation of the vascular smooth muscle, whereas angiotensin-II produced vasoconstriction primarily *via* direct stimulation of the vascular smooth muscle and secondarily *via* stimulation of α-adrenergic receptors. In this system, serotonin was shown to cause a wider variation in its pressor action than angiotensin-II.

PREVIOUS INVESTIGATIONS in this laboratory have shown that serotonin is the most powerful vasoconstrictor of human placental vessels (1–6) and that part of this action is due to α-adrenergic cell stimulation (4). Recently, in testing other known pressor agents in this preparation, it was observed that angiotensin-II produced vasoconstriction which frequently was comparable in degree to that produced by serotonin. Therefore, the purpose of the present investigation was to compare the vasoconstrictor activity of angiotensin-II and serotonin as well as to discern whether angiotensin-II, like serotonin, caused part of its vasoconstricting action *via* stimulation of α-adrenergic receptors.

MATERIALS AND METHODS

Full term human placentas, obtained from the hospital 15–20 min. after normal delivery, were used throughout this investigation. Each was transported to the laboratory in a glass container filled with 1 L. of Tyrode's solution maintained at 38°.

The apparatus employed and the procedures involved in the preparation and perfusion of the placentas, in recording and maintaining the perfusion pressure, and in measuring the inflow and outflow volumes of the perfusate have been described in previous investigations (3, 4). As in previous papers, umbilical cords of placentas measuring more than 5.5 cm. in length were designated as long cords; those under 5.5 cm. as short cords. In 56 successful placental preparations, the duration of each experiment was approximately 1 hr.

The dosage of the agonist serotonin chosen to obtain the desired pressor response was always 50 mcg., because this dosage was formerly shown to yield consistent results (3, 4). The same dosage was used for the agonist angiotensin-II in order to be able to compare its vasoconstricting properties with those of serotonin.

Astrom and Samelius (7) have reported that 1–3 mg. of phentolamine abolished the pressor response of serotonin. However, this laboratory has shown that 3 mg. of phentolamine only partially blocked the vasoconstricting action of serotonin (4). Subsequently, a dosage of 3 and 6 mg. of the antagonist, phentolamine, was utilized after each agonist not only to confirm our previous results with serotonin and observe the effects of the lower dosage of phentolamine upon the activity of angiotensin-II, but also to observe whether doubling the dosage could affect more profoundly the pressor action of either of the agonists.

The experimental regimen was divided into three parts which were: (*a*) obtaining a control response with either agonist, (*b*) administering one of the phentolamine doses, when the agonist's initial pressor action subsided, and (*c*) administering two additional doses of either agonist approximately 3 and 15 min. after the antagonist.

The following drugs were injected into the arterial side of the perfusion: 5-hydroxytryptamine creatinine sulfate (serotonin), 0.01%; angiotensin-II,[1] 0.04%; and phentolamine methanesulfonate,[2] 0.2%.

RESULTS AND DISCUSSION

The following results, which are summarized in Tables I and II, were obtained on full-term placental vasculature perfused at the pressure range of 50–90 mm. Hg which corresponded to inflow rates of 30–60 ml. of perfusion fluid (Tyrode's solution modified by the addition of 0.525% polyvinylpyrrolidone[3]) per minute.

In a total of 42 placental preparations, regardless of the cord length, phentolamine always inhibited the normal pressor action of serotonin, with the 6-mg. dose producing the greatest degree of serotonin antagonism (Table I, Figs. 1 and 2). Angiotensin-II produced increases in perfusion pressure that, based on the mean responses in short cord placental preparations, were not significantly different from those caused by serotonin (Tables I and II). Phentolamine always reduced the vasoconstriction produced by angiotensin-II, though the 6-mg. dose was not more effective in producing antagonism than the 3 mg. dose (Table II, Fig. 3). In addition, within 15 min. after the phentolamine treatment, serotonin and angiotensin-II again produced their normal responses (Figs. 1–3). Also, it can be observed from Tables I and II, that, of the two pressor agents utilized, serotonin caused the widest variation in its pressor action.

Angiotensin-II has been shown to constrict innervated blood vessels (aorta and carotid arteries of pigs) *via* the release of norepinephrine from its stores at sympathetic nerve endings (8). Also, angiotensin-II has been shown to constrict guinea pig intestine both indirectly by stimulating ganglion

cells causing the release of acetylcholine and directly by an action on the intestinal smooth muscle (9). Recently, Vogin and Buckley (10), using a β-adrenergic receptor blocking agent to potentiate the activity of angiotensin-II, noted α receptor cell stimulation as another mechanism whereby angiotensin-II produced vasoconstriction. The present

investigation has confirmed the action of angiotensin-II on α adrenergic receptors in a noninnervated organ (11) by a different procedure—namely, the partial blockade of angiotensin-II's vasoconstrictor action by the use of the α-adrenergic receptor blocking agent, phentolamine.

Because phentolamine can diminish markedly the pressor action of serotonin, it follows that serotonin must produce most of its vasoconstriction, in these vessels, *via* stimulation of α receptors, with the remainder being due to direct stimulation of the vascular smooth muscle. On the other hand, angiotensin-II, whose vasoconstriction can be antagonized only partially by phentolamine, must produce most of its vasoconstriction, in these vessels, by a direct action on the vascular smooth muscle, with the remainder being due to stimulation of α receptors.

Effects of Temperature on Convulsive Liability of Pentylenetetrazol, Strychnine Sulfate, and Thebaine Hydrochloride

By JACK A. HALL*, ROBERT B. NELSON, and ALBERT I. EDLIN

The CD_{50}'s of pentylenetetrazol, strychnine, and thebaine were determined by intraperitoneal injection into white mice after 1-hr. exposure to ambient temperatures of 6, 16, 22, 24, 30, and 35°. Rectal temperatures were also measured. The data are interpreted on the basis of the pharmacology of the compounds used and the observed effects of temperature on the actions of these compounds.

THE INFLUENCE of body temperature and environmental temperature on the potency of central nervous system (CNS) stimulants has been studied by several investigators (1–5). The amount of information available on the effect of temperature on drug action is considerable; however, due to the variations in experimental design the correlation between the work of different researchers is not so clear cut as would be desirable. Indeed, there are more than a few cases of apparent contradiction. To cite but a few: Chen *et al.* (1) reported that the convulsive dose 50 (CD_{50}) of strychnine sulfate in mice was unaltered by changes in environmental temperature from 20 to 40°. Bogdanovic (2) found the toxicity of strychnine to be decreased in rats which had been cooled to 16–18° by the Giaja method. Bogdanovic also reported that the toxicity of pentylenetetrazol (PTZ) was unaltered by hypothermia. Bogdanovic suggests that the different responses to drugs produced by hypothermia may be related to the different levels of the CNS at which the drugs act. This would explain in part his observation that pentylenetetrazol, which acts at numerous levels of the neural axis, is unaltered by a decrease in body temperature.

However, Swinyard and Toman (3) found the susceptibility to convulsions induced by pentylenetetrazol to be increased by lowering the body temperature (*cf. References 4, 5*). This does not necessarily mean that Bogdanovic is wrong in his contention that the temperature-potency relationship is influenced by the level(s) of the CNS at which drugs act. Should his contention be true, it would be expected that two agents which act in a similar manner such as strychnine and thebaine (7) would produce similar responses upon a change in environmental temperature. Furthermore, both compounds should differ from pentylenetetrazol. This study tests such an hypothesis.

Fuhrman and Fuhrman (6) in their excellent review on the effects of temperature on the action of drugs attribute the importance of environmental temperature mainly to the changes it invokes in body temperature. Assuming this to be true, it should be possible to determine the minimum change in body temperature which will result in a significant variation in response to a given drug. If this minimum change were consistent over a wide range of body temperatures, a predictability would exist that would simplify considerably the interpretation of any data which might be gathered over a wide environmental temperature range. This study was undertaken to see if such a predictability exists.

EXPERIMENTAL

Pentylenetetrazol, thebaine hydrochloride, and strychnine sulfate were dissolved separately in distilled water and injected intraperitoneally into male mice of the Swiss albino strain weighing between 14 and 37 Gm. The mice were exposed to environmental temperatures of 6, 16, 22, 24, 30, and 35° for 1 hr. prior to injection of the compounds. Fifty mice/compound/temperature were used to determine the convulsive dose 50 (CD_{50}). Ten additional mice/environmental temperature were employed in determining the mean rectal temperature. All data were evaluated by the statistical method of Litchfield and Wilcoxon (8).

RESULTS AND DISCUSSION

This experiment was designed to study the relationship between temperature (environmental and rectal) and convulsive liability of PTZ, strychnine sulfate, and thebaine hydrochloride. The relatively short time of exposure (1 hr.) was used to minimize the adaptation of the animals to the stresses of the environmental temperatures employed in this study. The results are shown in Table I. Across temperature comparisons are presented in Table II.

Pentylenetetrazol.—Table I shows that the CD_{50} of PTZ rose progressively with the temperature. As can be seen in Table II, the CD_{50} of PTZ was not significantly different at environmental temperatures of 16 through 30°. All other combinations of environmental temperatures compared revealed significant differences in the CD_{50}'s.

Table II shows that the minimum change in rectal temperature which was accompanied by a significant alteration of the CD_{50} of PTZ was 1°. However, an increase in ambient temperature from 6 to 16° raised the rectal temperature 1.7° but did not alter significantly the CD_{50}. In all cases where rectal temperatures differed by 1.8° or more there were significant changes in the CD_{50} of PTZ.

The data for the PTZ portion of this experiment are not in accord with those of Bogdanovic (2) and Braun and Lusky (5), but do agree with those of Swinyard and Toman (3).

Strychnine.—The CD_{50} of strychnine sulfate differed significantly only between the extremes of the ambient temperatures studied and was significantly larger at 35° than at 6°. As expected, the greatest change in rectal temperature (4.2°) occurred between these two environmental temperatures (Table II).

In the case of strychnine the results of the present experiment are at variance with the work of Chen *et al.* (1), who found the CD_{50} and LD_{50} of strych-

30–35	1.0	+	0	+

[a] 0, Indicates no statistically significant alteration of the CD_{50}. [b] +, Indicates a statistically significant alteration of the CD_{50}.

nine to be unaltered by changes in temperature from 20 to 40°. This disagreement may be due in part to the use of a smaller temperature range on the part of Chen *et al.*

Thebaine.—The CD_{50} of thebaine hydrochloride was significantly larger at 30° than at all other environmental temperatures studied. Any change in ambient temperature from this point resulted in a decrease in the CD_{50} of the compound. A change in rectal temperature of 1.7° which occurred between environmental temperatures of 6° and 16° was not accompanied by a significant change in the CD_{50}. On the other hand, a significant difference in the CD_{50} did exist between ambient temperatures of 16 and 22°, although rectal temperature differed by only 0.1° between these two points (Table II). The maximum change in the CD_{50} was obtained between ambient temperatures of 22 and 30° with the CD_{50} being significantly greater at the latter temperature. No references were found concerning the effect of temperature on the CD_{50} of thebaine.

Strychnine and thebaine did not respond to temperature changes in a qualitatively similar manner, although both are reported to act at the same level of the CNS (7). This does not agree with Bogdanovic, who contends that CNS stimulants respond to changes in temperature in accordance with their levels of activity (2).

SUMMARY AND CONCLUSIONS

A study was conducted in order to determine the effects of environmental and body temperatures on the CD_{50} of pentylenetetrazol (PTZ), strychnine sulfate, and thebaine hydrochloride in mice. No correlation was found between the levels of action of the compounds in the CNS and the influence of temperature on their CD_{50}'s. Furthermore, no predictability was found to exist with regard to the minimum change in body temperature which resulted in a significant change in the CD_{50} of any of the compounds studied. The CD_{50}'s of pentylenetetrazol and strychnine sulfate increased as the temperature rose. Thebaine on the other hand had a maximum CD_{50} at an environmental temperature of 30°. The CD_{50} dropped sharply at temperatures both above and below this point.

In conclusion, changes in body temperature produced by varying the ambient temperature are of fundamental importance. However, no predictability exists with regard to the minimum change in body temperature which will result in a significant alteration in the CD_{50} of the compounds studied in this experiment. Finally, little can be said from this experiment about the nature of the influence of temperature on the action of these compounds.

Effect of Reserpine and Chlorpromazine on Some Cold Stress-Induced Biochemical Alterations

By P. C. DANDIYA, R. R. VARMA, R. K. SOGANI, and K. P. KHUTETA

The effects of reserpine and chlorpromazine on cold stress-induced changes in adrenal ascorbic acid of rats and blood glucose, serum cholesterol, and serum sodium levels of rabbits were studied. While pretreatment with chlorpromazine minimized many of these stress-induced alterations, reserpine pretreatment aggravated them. Reserpine was found to be effective in preventing the stress-induced reduction of serum cholesterol level. Pretreatment with chlorpromazine minimized the adrenal ascorbic acid depletion due to cold stress. It also significantly prevented rise in blood sugar and fall in serum sodium produced by cold stress.

STRESS stimulates the hypothalamo-adrenal axis and produces a number of functional and biochemical alterations. It is a well known fact that most types of stresses have associated psychic components, and a number of stress-induced changes are mediated through the hypothalamus. Tranquilizers, by calming the mind, could possibly reduce the psychic component of stress and thus minimize the stress-induced alterations. A survey of the past literature shows that only few sporadic studies have been made so far to study the effect of tranquilizers on stress-induced biochemical changes (1–4). Though a considerable amount of work has been done to study the changes in the adrenal ascorbic acid and blood glucose levels during stress, difference of opinion exists regarding the effectiveness of tranquilizers to counteract these changes (1–3, 5, 6), and the present study is aimed at clarifying the divergent views expressed by different workers in this regard. No previous attempt has been made to study the influence of tranquilizers on stress-induced changes in the circulating ions and cholesterol, and therefore, this virgin field of exploration was selected with the hope that with such lucid exposition of the beginning stages of altered metabolism, an insight into the diverse disturbances caused by stress could be attained which will hasten the development of appropriate therapeutic agents for the prevention or amelioration of some of the stress-induced abnormalities.

MATERIAL AND METHODS

Albino rats (125 to 175 Gm.) and rabbits (1.25 to 1.75 Kg.) were subjected to cold stress by keeping them at an environmental temperature of 2° ± 1° for 1 hr. In order to keep the animals in identical conditions the day before the experiment (12 hr. before experimentation) they were isolated, during which period no food was given. The effects of drugs and stress were determined on rat adrenal ascorbic acid and rabbit blood glucose, serum cholesterol, and sodium. The levels were studied in normal controls, after stress, after tranquilizers, and after producing stress in animals pretreated with tranquilizers. Reserpine and chlorpromazine were administered in doses of 1 mg./Kg. intraperitoneally in rats. In rabbits these drugs were administered intramuscularly in a dose of 0.3 mg./Kg. and 3 mg./Kg., respectively. The animals were subjected to stress 45 min. after chlorpromazine and 4 hr. after reserpine pretreatments. The rats were decapitated and the rabbit's blood was collected immediately after stress or after an equivalent interval following the drug administration in those animals not subjected to stress, for the biochemical studies.

Adrenal ascorbic acid was extracted in 4% trichloroacetic acid and estimated by the method of Roe and Kuether (7). Blood glucose was estimated by Somogyi-Nelson's method (8, 9), serum cholesterol by Bloor's method, as given in the handbook of "Lumetron Photoelectric Colorimeter," model 400-A, p. 536, and serum sodium by using a flame photometer (10).

RESULTS

The findings are summarized in Fig. 1, which shows control levels and alterations in various biochemical parameters after drug, after stress, and after drug plus stress.

The depletion of adrenal ascorbic acid after stress was increased in reserpine-pretreated animals and decreased in chlorpromazine-pretreated animals. While reserpine produced a significant depletion in the control adrenal ascorbic acid level, the change due to chlorpromazine treatment was insignificant. Significant hyperglycemia was seen after cold stress and also after reserpine and chlorpromazine treatment. Stress-induced hyperglycemia was less in chlorpromazine and exaggerated in reserpine-pretreated animals. Stress produced a fall in serum cholesterol level. Reserpine pretreatment reduced this fall, but pretreatment with chlorpromazine was ineffective in this respect. Neither drug altered the prestress control cholesterol level. A moderate reduction in serum sodium level occurred after stress. Pretreatment with reserpine aggravated this stress-induced alteration while pretreatment with chlorpromazine minimized it. The prestress control sodium level was unaltered after reserpine or chlorpromazine.

DISCUSSION

Acute cold stress produces a fall in adrenal ascorbic acid, serum cholesterol, and serum sodium levels and a rise in blood glucose level. Most actions of reserpine are stress-like and a number of stress-induced alterations are aggravated by its pretreatment. Stress-like effects of reserpine have been reported by others (11–13). It may be a nonspecific action or an action mediated *via* hypothalamus as proposed by Maickel *et al.* (12). Most effects of chlorpromazine pretreatment on stress are just opposite to those seen after reserpine.

Accepted for publication October 12, 1966.

This investigation was supported by the Indian Council of Medical Research.

Chlorpromazine and reserpine were supplied, respectively, by May and Baker Ltd., Dagenham, England, and Ciba Pharmaceutical Products Ltd., Bombay, India.

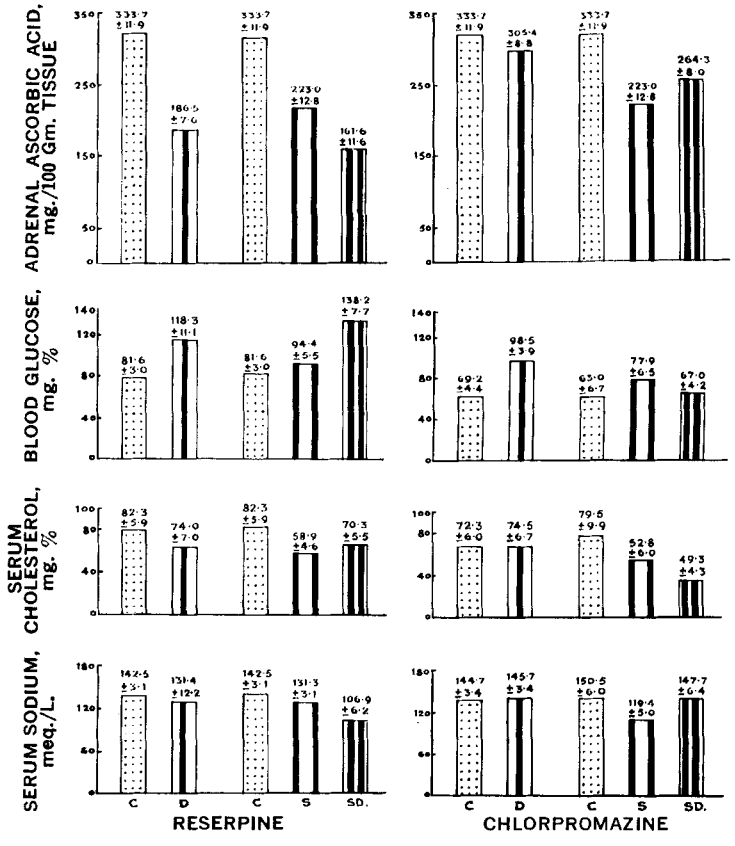

Fig. 1.—Effect of reserpine and chlorpromazine on cold stress-induced biochemical alterations. Key: C, control; D, drug alone; S, stress alone; SD, stress after drug pretreatment. The number of animals used for the adrenal ascorbic acid estimation was 36 (control), 15 (cold stress alone), and 8 each in other groups; while in the case of all other experiments the number of animals was 8 in each group. In some of these experiments control of animals was taken more than once. For easy comprehension, the control values have been shown along with corresponding observation. The figures denote mean values ± standard error in each group.

These opposing actions of reserpine and chlorpromazine point to their different mechanisms of action. There could be some relationship of this difference to their different actions on ergotropic and trophotropic systems of Hess (14), as reported by Brodie *et al.* (15). Work on these lines is in progress.

Tissue Levels of Chloroamphetamines in Rats and Mice

By RAY W. FULLER and C. W. HINES

During the first 4 hr. after i.p. injection of equimolar amounts of the two drugs, more 4-chloroamphetamine than amphetamine was present in the brain and other tissues of rats and mice. The higher levels resulted from a slower disappearance of 4-chloroamphetamine. Other amphetamines substituted with chlorine in the *para* position disappeared more slowly from rat brain than did amphetamine. This may be due to blocking of a major metabolic pathway for amphetamine—*para* hydroxylation—by the *para* substitution, since amphetamines with chlorine substituted in other positions disappeared from tissues at rates comparable to that for amphetamine.

PLETSCHER *et al.* (1) first reported that the levels of 4-chloro-*N*-methylamphetamine were higher than those of amphetamine in the brains of rats given equimolar doses of the two compounds. This has led to the study of the effect of different chloro substitutions on the tissue distribution and disappearance rate of amphetamine. The results of this study, which have been presented in a preliminary form,[1] are reported in detail in this paper.

EXPERIMENTAL

The animals used were male albino rats from the Harlan strain, body weight approximately 150 Gm., or Cox standard albino mice, body weight approximately 16 Gm. Dextroamphetamine sulfate[2] was obtained from Smith Kline & French Laboratories. *l*-Amphetamine sulfate was from the Ott Chemical Co. The chloroamphetamines were synthesized as the hydrochlorides in the Lilly Research Laboratories. In all experiments, the compounds were injected intraperitoneally in aqueous solution at a dose of 0.1 mmole/Kg. (18–24 mg./Kg.). Four rats or six mice per group were used except as otherwise noted. Animals were decapitated at the time intervals indicated. The organs were quickly removed, frozen on dry ice, and stored at −15° prior to analysis. Drug levels were determined by the methyl orange assay as used by Dubnick *et al.* (2). Hydroxylated amphetamines that might be formed metabolically are not measured by this assay. An internal standard curve for each drug and each tissue was used to calculate drug levels. This standard curve was determined from control animal tissues to which drug had been added *in vitro*. Tissue blanks were low. Typical blank values were, in mμmoles/Gm.: heart and spleen, 0; blood, 1; brain, 2; liver, 6; kidney, 18.

RESULTS AND DISCUSSION

The levels of dextroamphetamine and of *dl*-4-chloroamphetamine in the brain of rats and mice after i.p. injection are shown in Fig. 1. In both species, the 4-chloro compound disappeared much more slowly than the unsubstituted amphetamine. 4-Chloroamphetamine and 4-chloro-*N*-methylamphetamine lower serotonin in the brain of rats but not in mice (1, 3). This species difference is not due to differences in concentrations of the compounds in the brain, since the levels and disappearance rates of 4-chloroamphetamine were almost identical in rats and mice. The species difference thus rests on some basis other than tissue levels of the drugs. On the other hand, drug levels may explain why 4-chloroamphetamines lower serotonin in rat brain while amphetamine does not. The former compounds persist in the brain for longer times than does amphetamine.

Disappearance rates (from rat brain) for other substituted amphetamines were calculated from plots of the type shown in Fig. 1. The results are shown in Table I. All of the compounds with a chloro substituent in the 4 position disappeared much more slowly (9–11%/hr.) from brain than did those with no chloro substitution in this position (49–73%/hr.). There seemed to be no steric effect in either group of compounds. Since amphetamine is *para* hydroxylated in rats (4–6) and mice,[3] the slower disappearance rate of the 4-substituted compounds may be closely related to the fact that this metabolic pathway has been blocked.

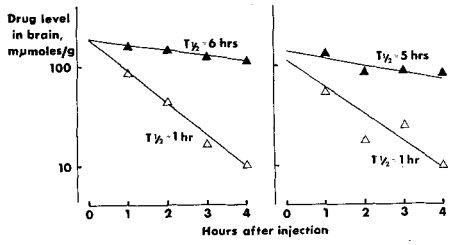

Fig. 1.—Brain levels of dextroamphetamine and *dl*-4-chloroamphetamine in rats (left) and mice (right). Key: ▲, *dl*-4-chloroamphetamine; Δ, dextroamphetamine.

To determine if binding of the drugs in the brain played a role in their rate of disappearance, the drug concentrations were measured in the supernatant and precipitated fractions after centrifugation of brain homogenates from treated rats. The centrifugation was carried out in a Spinco model L ultracentrifuge at a force of 105,000 × g. Drug levels were then determined in both supernatant and precipitated fractions. Results are shown in Fig. 2. The supernatant fraction was taken to represent "free" drug and the precipitated fraction "bound" drug. Unsubstituted amphetamine was found primarily in the soluble fraction, whereas all chlorinated amphetamines were bound to a greater degree. The association of chloroamphetamines with the

[2] Marketed as Dexedrine sulfate by Smith Kline & French Laboratories, Philadelphia, Pa.

[3] After injection of ^{3}H-amphetamine into mice, the authors have isolated from the urine of the mice an ether-soluble substance that was identified by paper chromatography as *p*-hydroxyamphetamine. It was not established whether this represented a major or minor metabolite.

TABLE I.—RATE OF DISAPPEARANCE OF SUBSTITUTED AMPHETAMINES FROM RAT BRAIN

Substitution	Isomer	Disappearance Rate, %/hr.
None	*d*	53
	l	49
2-Chloro-*N*-methyl	*dl*	73
2,6-Dichloro	*dl*	58
3-Chloro	*dl*	53
4-Chloro	*dl*	9
4-Chloro-*N*-methyl	*dl*	11
3,4-Dichloro	*d*	11
3,4-Dichloro	*l*	11

particulate fraction may reflect their greater lipid solubility. The degree of binding may influence the length of time that the drugs remain in the brain. Kuntzman and Tsai (7) found that the chloro derivative of norcyclizine had a longer *in vivo* half-life than did cyclizine, perhaps because of more extensive binding to plasma proteins. However, Fig. 1 and Fig. 2 show that 2,6-dichloroamphetamine had a high bound/free ratio and still disappeared rapidly. This would suggest that drug binding is not the major factor that determines disappearance rate in this case, consistent with the idea that blockade of metabolism accounts for the slower disappearance of chloroamphetamines.

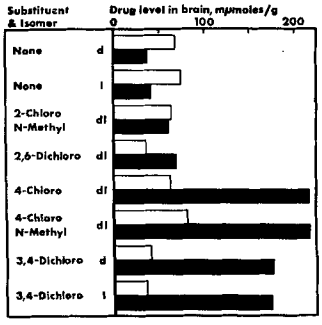

Fig. 2.—Occurrence of substituted amphetamines in free and bound forms in rat brain. Brains were analyzed 1 hr. after administration of the drugs. Key: open bar, free; closed bar, bound.

The levels of amphetamine and of 4-chloroamphetamine in other tissues of the rat, measured at 1 and 4 hr. after injection, are shown in Fig. 3. The relative distribution between the various tissues was similar for the two compounds. Large amounts of the compounds were present in the lung and kidney. (Drug levels in the lung and epididymal fat pads were not determined at 1 hr.) An important difference between the drugs existed in the blood levels. In

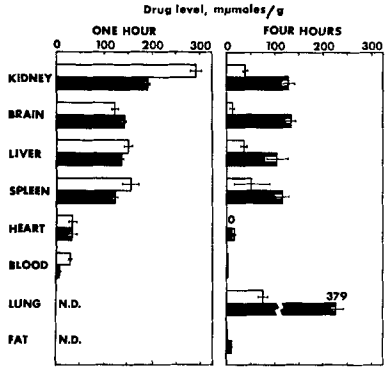

Fig. 3.— Tissue levels of dextroamphetamine and *dl*-4-chloroamphetamine in the rat. Amphetamine levels are represented by open bars, 4-chloroamphetamine by closed bars. Standard errors of the means of determinations in 5 rats per group are shown.

addition to the 60-min. time shown in Fig. 3, blood levels were determined at 15, 30, and 45 min. Levels of amphetamine in blood at these times ranged from 4 to 10 times as high as the levels of 4-chloroamphetamine. Tissue/plasma ratios were therefore much higher for 4-chloroamphetamine than for amphetamine, suggesting that the over-all tissue uptake and binding of the chloroamphetamine was greater. This is also revealed by the fact that at 4 hr., when blood levels of both drugs had dropped to the limits of detection, tissue concentrations of 4-chloroamphetamine were still amost as high as at 1 hr. In all of the tissues, the levels of 4-chloroamphetamine at 4 hr. were substantially higher than those of amphetamine, indicating that a slower disappearance rate of the chloroamphetamine occurs in other tissues as well as in the brain. Tissue distribution of the drugs in mice was very similar to that shown in Fig. 3 for the rat.

The data presented show that substitution of chlorine in the *para* position of amphetamine markedly slows the disappearance rate of the drug from tissues. It is suggested that an important reason may be the blocking of one of the metabolic pathways—namely, *para* hydroxylation—by which amphetamine is normally transformed prior to excretion from the body.

Absorption of Ethanol by the Common Guppy (*Lebistes reticulatus*)

By NATHAN A. HALL and WILLIAM L. HAYTON*

The uptake of ethanol by guppies (*Lebistes reticulatus*) from solutions of varying concentrations has been observed at 25°. Results of the observations were compared with those obtained with goldfish (*Carassius auratus*) at 20° and 25°. Both time of death and time of overturn were used as criteria of pharmacological effect. Plots of the reciprocal time of effect against ethanol concentration failed to intersect the origin in all cases, except for goldfish at 20° where time of death was observed. The experimental demonstration of a threshold concentration for each fish implies that the actual plot should be a sigmoid curve. The results are discussed in relation to the theory of Levy and Gucinski. Guppies appear to be suitable for drug absorption studies.

A THEORY describing the uptake of drugs and toxic chemicals by fish from their aqueous environment has been developed by Levy and Gucinski (1). They have tested the theory with goldfish and have shown it to be useful in the study of factors influencing biological membrane permeation by passive diffusion of drugs (2–4). This investigation represents an attempt to apply the theoretical concepts of Levy to another experimental fish, the common guppy.

The guppy has been used extensively in water pollution studies (5), is easily kept under laboratory conditions, and is sensitive to many toxic substances. Since the usual adult is small (200–500 mg.), it was thought that this fish might be suited for the study of drugs available in limited quantities or for drugs which give poorly predictable responses with other fish.

EXPERIMENTAL

Fish—Common guppies (*Lebistes reticulatus*) were obtained from a local supplier of tropical fish in lots of 100 fish. They were kept in an aerated aquarium filled with tap water and fitted with a submersion filter and a thermostatically controlled heater set at 25°. Regulation of the relative size for use in experiments was accomplished by allowing the fish to escape from polystyrene cups punctured by holes of known size. Only those fish able to pass through 5-mm. holes but unable to pass through 3-mm. holes were used.

Goldfish (*Carassius auratus*) were purchased at a local pet shop.

Method—A single adult guppy was transferred by net from the aquarium to a 100-ml. beaker containing 30 ml. of the drug solution, and a stopwatch was started. Beaker sizes and solution volumes for goldfish were those of Levy and Gucinski (1). The fish was observed for drug effect and the time recorded. Prior to use all drug solutions were equilibrated in a constant-temperature water bath at 25°, and the beaker containing the drug solution was placed inside a 600-ml. beaker suspended in a 25° constant-temperature water bath. The temperature of the test medium was thus maintained at 24 to 25°. A similar procedure was used for studies at 20° with a refrigerated constant-temperature bath.

At each drug concentration several fish were run. None of the solutions were re-used, thus each fish was exposed to fresh solution. Results were expressed as the average time for a group of fish to show an effect, and the standard deviations of means were routinely calculated. Ethanol solutions were prepared by pipeting the calculated quantity of absolute ethanol into a volumetric flask and bringing to volume with distilled water.

Absorption of Ethanol

To gain experience in the use of fish and to test the reproducibility of the previously reported method, a series of experiments with graded concentrations of ethanol were conducted with goldfish at two different temperatures, 25° and 20°. Results were plotted as the reciprocal time of death *versus* percentage by volume of ethanol. Table I lists the regression equations obtained for the plotted lines and those of Levy and Gucinski for comparison. Six fish were used to determine each point at 25° and four at 20°.

The variation among lots of fish was expected and has been previously reported. The higher temperature was observed to increase the slope of the plotted line and to cause a larger negative intercept than previously reported.

A series of experiments was then conducted in a similar manner with guppies. Since these fish have a natural tropical habitat and preliminary experiments showed them sensitive to low temperatures, absorption at only 25° was determined. Six fish were run for each point and at least 5 points were plotted for each run. The regression equations for the plotted experimental data are listed in Table II. The data indicated a greater sensitivity or rate of absorption for guppies than for goldfish, and a lot to lot variation was evident. All plots showed negative intercepts.

Criteria of Drug Effect—Considerable difficulty was encountered in determining the end point of death with guppies because of their size. Although a magnifying lens was helpful in observing the cessation of mouth and gill movements, optical difficulties were complicated by the beakers housing the fish. Investigators in river pollution studies have utilized the loss of balance equilibrium or "overturn" as an indication of toxic effect (6), especially where the death end point is uncertain. Accordingly, observations were made using the overturn time as the criterion of drug effect. Figure 1 is a representative plot of the experimental data for goldfish and guppies with both overturn and death end points at 25°, and Table III lists regression equations for the plotted lines with overturn as the end point.

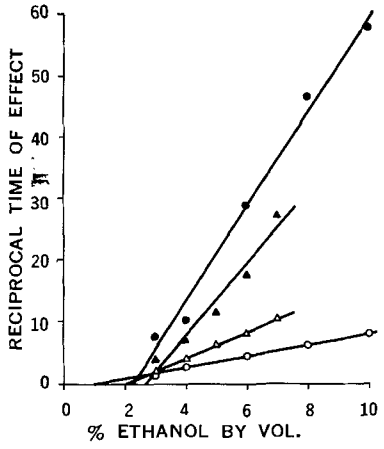

Fig. 1—A plot of reciprocal time of effect as a function of ethanol concentration at 25° for goldfish and guppies. Key: ○, goldfish, death end point; ●, goldfish, overturn end point; △, guppies, death end point; ▲, guppies, overturn end point.

DISCUSSION

The theory developed by Levy and Gucinski (1) to describe the goldfish as an experimental animal in drug absorption states $1/T_L = (K/L)\ C$, in which T_L is time of death, L the lethal dose, K the apparent absorption rate constant, and C the concentration of the drug in the medium, offers a number of attractions including the avoidance of involved chemical assays and tedious lethal dose determinations. It seems, however, that the theoretical model may possess certain limitations in application due to the simplifying assumptions upon which it is based, as pointed out by Levy and Gucinski.

Levy states that a number of assumptions are necessary for the model to be applicable. These include: (*a*) absorptiono ccurs only by passive diffusion; (*b*) the concentration gradient is essentially constant during the experiment; (*c*) the membrane permeability characteristics are unchanging under the experimental conditions; (*d*) drug elimination, including biotransformation, is negligible during the experiment; and (*e*) the pharmacologic end point occurs without significant delay after the lethal dose of the drug has been absorbed. He recommends using the experimental data themselves to indicate if the requirements are met. A plot of the reciprocal death time *versus* concentration should be linear and intersect the origin (2).

Initial experiments with goldfish showed that our experimental techniques would yield results conforming to the theory for ethanol with death as the observed pharmacological effect. (See Table I.) The lower slope of our plot as compared to those of Levy and Gucinski at 20° was ascribed to variations among lots of goldfish. The increase in temperature to 25° increased the slope of the plot and resulted in a negative intercept; the increase in slope would be expected from both more rapid diffusion and greater lethality of the ethanol for the fish at the higher temperature.

When guppies were used as the experimental fish, there was observed a three to fourfold greater slope than with goldfish, but most notable was the consistent negative intercept of the plotted line. Initially, this intercept was thought to be due to the lesser precision of experimental points where death occurred under 10 min.; therefore, a run was designed to obtain a plot where all points were derived from data in which death times were greater than 10 min. (Table II, lot VII G). The negative intercept appeared to be consistent.

The plots of the experimental data for both goldfish and guppies when overturn time was used as the criterion of drug action (Table III) showed a greater slope and greater negative intercept than when death was used. The increased slope was expected, for all fish lost their sense of balance before expiring. The greater slope for goldfish at 25° (lot I F) than for guppies (lots II G, IV G, VII G) was somewhat surprising since guppies seemed more

sensitive to ethanol lethality than goldfish (Tables I, II, and Fig. 1). Goldfish, however, are considerably deeper (measuring from ventral to dorsal surface) than are guppies; thus, their sense of balance is evidently more sensitive to slight CNS depression.

The repeated negative intercepts for plots of all the guppy experiments, for the goldfish experiment at 25°, and for the goldfish experiments where overturn time was observed seem to indicate that the theory fails to describe the experimental observations. Although plots of the data are apparently linear, they do not intersect the origin. Consideration of the assumptions upon which the theory is based may indicate that the failure of guppies to produce plots in agreement with the theory might be due to unknown characteristics of the fish. However, it does not appear reasonable that with guppies factors such as biotransformation, delay of pharmacological effect, and changing membrane permeability would be greatly different from goldfish when the plots exhibit similar linearity. Furthermore, it is difficult to ascribe deviation of the goldfish data for overturn times to factors much different from those functioning where time of death is observed.

One consistency is apparent. Whenever the slope of the plot increases, the negative intercept increases. This observation demonstrates that the kinetic model does not apply under conditions where one or more of the simplifying assumptions is not fulfilled. In 1917 Powers (7) concluded, after extensive experiments with goldfish and various toxicants, that the survival time is inversely related to the concentration only over a limited concentration range. In both low and high concentrations considerable deviation from linearity is evident and the true curve has a sigmoid form. Extrapolation of the linear portion of the curve to zero on either axis will tend to obscure the real behavior of the fish. A plot which intersects the origin cannot show a threshold concentration—that concentration which causes no observable effect. Most toxic substances studied in fish exhibit a threshold concentration (8).

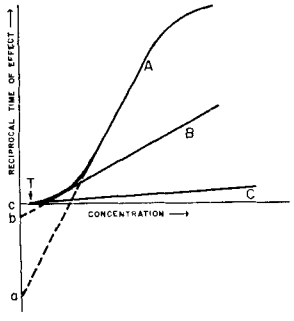

Fig. 2—A hypothetical plot of reciprocal time of effect versus *concentration of drug. Curves* A, B, *and* C *have a common threshold concentration* T. *Extrapolation of the linear portion of each curve intersect the ordinate at* a, b, *and* c.

Both goldfish and guppies have been kept in this laboratory for over 24 hr. in appreciable ethanol concentrations without loss of balance or death. For guppies the threshold at 25° lies between 0.25 and 0.50% and for goldfish between 1.0 and 2.0%. Therefore, the true plot of reciprocal time of effect *versus* concentration should intersect the concentration axis at some point other than the origin; the curves should assume a sigmoid form. If the hypothetical situations depicted in Fig. 2 are considered, the three illustrated cases parallel the results obtained in this study. Extrapolation of the linear part of curve A will give a large negative intercept, a. Curve B will give a smaller negative intercept, b, and curve C will give a negligible intercept, c. The regression equation obtained for goldfish with the time-of-death end point (Table I, 20°) corresponds to hypothetical curve C; equations for goldfish and guppies with the time-of-death end point at 25° (Table I, 25°, Table II) are similar to hypothetical curve B; and equations for goldfish and guppies with the overturn time end point (Table III) resemble curve A.

Since threshold concentrations can be demonstrated experimentally, a deviation from linearity for all plots is implied. The theory in its original form was not designed for low concentrations of ethanol, and the observed deviations from linearity therefore are to be expected. Similar behavior might be expected for other chemicals. The experimental system upon which the theory was based was stated to be useful "due to the relatively large volumes of aqueous medium and high drug concentrations" (1), however, a later publication stated that plots of the data "should be linear and intersect the origin" as a test of the validity of the mathematical model for a particular set of experimental conditions (2). From the foregoing considerations it seems unwise to assign theoretical or physiological significance to the intercept values.

This investigation points up some of the limitations of the original theory which can be encountered, some of which would be expected from the simplifying assumptions. Levy and co-workers have utilized the kinetic model with agents other than ethanol and have found goldfish absorption to correlate well with other biological data (1–3). Italian investigators, working with three different drugs, have also verified the usefulness of the model by making direct comparisons between goldfish absorption and oral absorption in rats (9).

The theory of Levy and Gucinski (1) appears to be applicable to guppies as well as goldfish, provided that the selected drug concentrations are well above the threshold levels.

Potential Antiradiation Drugs: α-Alkyloximinonitriles

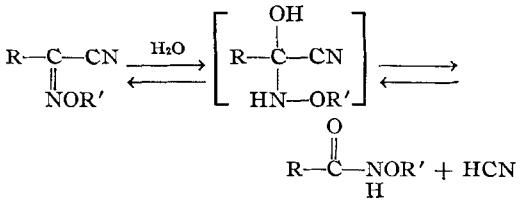
By DOMINICK A. COVIELLO

Of three α-alkyloximinonitriles tested for radiation protection, two were very toxic and inactive, while one with low toxicity gave slight protection.

MANY classes of compounds including nitriles have shown varying degrees of protection against radiation damage in mammals. It has been suggested that conceivably the nitriles act by the slow sustained-release of HCN which is protective (1). If the theory has merit, it was postulated that α-alkyloximinonitriles, reacting with water in the cellular milieu, could yield an intermediate which would decompose to yield HCN and an *O*-alkylhydroxamic acid according to Scheme I.

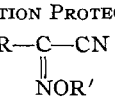
It is interesting to note (Table I) that 1-benzyloximinobutanecarbonitrile gives slight protection, and has an LD_{50} of about 1000 mg./Kg. while the other two, 1-benzyloximinopropanecarbonitrile and 1-benzyloximinoheptanecarbonitrile, give no protection with LD_{50}'s of less than 50 mg./Kg.

Some of the nitriles were previously reported (2). The new compounds were characterized by the characteristic nitrile absorption in the infrared (3) and by alkaline hydrolysis back to the starting acids. They are shown in Table II.



Scheme I

TABLE I.—α-ALKYLOXIMINONITRILES TESTED FOR RADIATION PROTECTION



Compd. R	Compd. R′	LD_{50}, mg./Kg.	Test Dose, mg./Kg.	Test Evaluation

New Compounds:

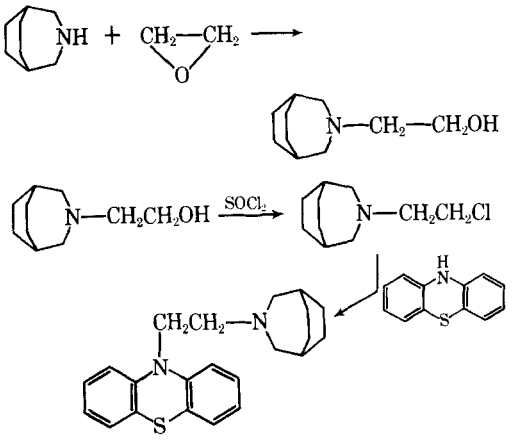
3-[2-(2-Chloro-10-phenothiazinyl)ethyl]-3-azabicyclo[3.2.2]nonane

By WILLIAM T. KING, CHARLOTTE H. BRUENING, and W. LEWIS NOBLES

The synthesis of 3-[2-(2-chloro-10-phenothiazinyl)ethyl] - 3 - azabicyclo[3.2.2]nonane is reported; the pharmacological evaluation of this agent, an analog of promethazine, has not yet been reported.

PREVIOUSLY, Anderson and his associates (1) reported the synthesis of 3 [3-(2-chloro-10-phenothiazinyl)propyl] - 9 - methyl - 3,9 - diazabicyclo - [3.3.1]nonane dihydrochloride in the course of preparing synthetic relatives of various 2-substituted phenothiazines and their 10-aminoalkyl derivatives. Almost simultaneously, the authors were experimenting with the use of an analogous heterocyclic amine, 3-azabicyclo[3.2.2]nonane, as a possible intermediate in the synthesis of potential medicinals (2–5). Thus, the present report is to indicate the extension of these studies to the preparation of the 3-azabicyclo[3.2.2]nonane analog of existing phenothiazines which are of significant value as tranquilizers.

This new compound was prepared by means of the outline shown in Scheme I.



Scheme I

The results of the pharmacological testing of this compound will be reported elsewhere.

EXPERIMENTAL

3-Azabicyclo[3.2.2]nonane-3-ethanol.—To 37.5 Gm. (0.3 mole) of 3-azabicyclo[3.2.2]nonane dissolved in 50 ml. of methanol was added 17.8 Gm. (0.4 mole) of ethylene oxide over a 1-hr. period. The temperature of the reaction mixture was maintained below 47° by keeping the mixture in ice water. The reaction mixture was stirred for 1 hr. and 45 min. after the completion of the addition; the methanol was then removed under reduced pressure. Distillation of the product then yielded 32.3 Gm. (60%) of 3-azabicyclo[3.2.2]nonane-3-ethanol, b.p. 94° (1.8 mm.).

Anal.—Calcd. for $C_{10}H_{19}NO$: C, 70.96; H, 11.31; N, 8.28. Found: C, 70.93; H, 11.06; N, 8.29.

2-(3-Azabicyclo[3.2.2]nonyl)ethyl Chloride Hydrochloride.—A solution of 32.3 Gm. (0.19 mole) of 3-azabicyclo[3.2.2]nonane-3-ethanol in 175 ml. of benzene was placed in a dry, three-necked flask. The solution was stirred while 29.7 Gm. (0.25 mole) of thionyl chloride in dry benzene was added dropwise. The reaction was slightly exothermic. After the addition of the thionyl chloride, the mixture was refluxed for 3 hr. and then cooled. The solid product was collected by filtration and washed with benzene to yield 35.6 Gm. (54%) of the desired product, m.p. 225° (sublimation).

Anal.—Calcd. for $C_{10}H_{18}ClN.HCl$: C, 53.50; H, 8.54; N, 6.24. Found: C, 53.42; H, 8.64; N, 6.18.

3-[2-(2-Chloro-10-phenothiazinyl)ethyl]-3-azabicyclo[3.2.2]nonane.—The hydrochloride salt, indicated above, was converted to the free base by the addition of a saturated solution of sodium carbonate until the solution was slightly basic to litmus. This basic solution was extracted with three 200-ml. portions of ether. The ether layer was dried over anhydrous sodium carbonate for 24 hr. and the free base obtained by distillation after the evaporation of the ether. To 4 Gm. (0.1 mole) of sodamide, dissolved in diethyleneglycol dimethyl ether in an atmosphere of nitrogen, was added 20.3 Gm. (0.11 mole) of 2-(3-azabicyclo[3.2.2]nonyl)ethyl chloride; then 25 Gm. (0.9 mole) of 2-chlorophenothiazine (dissolved in 125 ml. of diethyleneglycol dimethyl ether) was added. After the reaction mixture was stirred and heated for 2 hr. at 135°, it was cooled to room temperature. Filtration produced a muddy semisolid mass which liquefied on exposure to air. Small quantities of this material were dissolved in butanol and precipitated with anhydrous ether. Recrystallization from butanol–hexane yielded a white powder, m.p. 205–206°.

Anal.—Calcd. for $C_{22}H_{25}ClN_2S$: C, 62.69; H, 6.22; N, 6.25. Found: C, 62.29; H, 6.50; N, 6.47.

Received August 15, 1966, from the Department of Pharmaceutical Chemistry, School of Pharmacy, University of Mississippi, University 38677.

Accepted for publication October 27, 1966.

Abstracted in part from an exhibit prepared by William T. King as an entry in the Mississippi Science Fair, Spring 1964.

Rapid Method of Obtaining the Clear Aqueous Filtrate of an Oil/Water Emulsion

Sir:

In most reports on experiments requiring the assay of one or both phases of an emulsion, the technique used to separate these phases involves centrifugation. Very often this technique is useless without the aid of a high-speed (or ultra-) centrifuge. Due to the nature of centrifugation, it is almost impossible to perform any short-term kinetic studies dealing with the partitioning of a drug from one phase of an emulsion to the other.

The authors have found in these laboratories that most o/w emulsions can be filtered, yielding a clear filtrate of the aqueous phase. The technique makes use of a vacuum pump, membrane filter assembly, and membrane filters, such as those manufactured by the Millipore Filter Corp., Bedford, Mass. The pore size required varies according to the droplet size of the internal phase and the interfacial tension between the drop and the external phase. For emulsions of very small particle size ($< 1\ \mu$), it was found that passing the emulsion through a .22-μ filter, and then passing the filtrate through a 100-mμ filter was adequate in most cases. It is difficult to filter large quantities, due to clogging (we assume) of the pores of the filter. This is overcome by changing the filter. Prefilters were tested, but proved ineffective.

In the filtering of preparations containing high amounts of surface-active agents, foaming occurs, but can be controlled by judicious use of the vacuum. Pressure filtration was not attempted. Emulsions (o/w) prepared from nonionic, anionic, and cationic emulsifiers were all capable of being filtered. When the per cent of internal phase was about 8–10%, clogging occurred faster than with more dilute emulsions.

The equation of Young and Laplace (1), $\Delta P = 2\gamma/r$, where ΔP is the pressure difference, inside and out of the drop, γ is the interfacial tension, and r is the radius of the droplet, can be used to determine the filtering requirements. If ΔP of the emulsion is greater than 1×10^6 dynes cm.$^{-2}$, and if the pore of the filter has a significantly smaller diameter than that of the droplet, the droplet will not be appreciably distorted, and can be filtered from the external phase.

This method is currently being employed in studying the rate of transport of a drug from the aqueous phase to an emulsified oil phase. The oil content is about 2%, with the droplet size being approximately 1.5 μ in diameter. The emulsion is sampled initially at 60-sec. intervals, and the disappearance of the drug from the aqueous phase is measured.

It was also determined that the oil phase, if external, can be obtained with the internal phase (water) being left on the filter.

This filtration method was also tested as a means of rapidly determining partition coefficients. Reese *et al.* (2) reported in 1964 a nonemulsion method for determining partition coefficients. They reported the True Partition Coefficient of benzoic acid in cyclohexane as being 1.18; the Apparent Partition Coefficient (their method) was 1.05, with 6 hr. required to be within 1% of equilibrium. Repeating their work, using an emulsion prepared by ultrasonification for 20 min., gave an Apparent Partition Coefficient of 1.27.

This method of filtering emulsions carries with it the limitations of membrane filters, *i.e.*, sorption and/or leaching of the filter materials. This may be minimized by use of the fluorinated hydrocarbon filters. It also permits assay of only the external phase, with the implicit assumption that what is not in the external phase is in the internal.

REVIEWS

Pharmaceutical Chemistry. Vol. 1: Theory and Application. Edited by L. G. CHATTEN. Marcel Dekker, Inc., 95 Madison Avenue, New York, N. Y. 10016, 1966. xii + 504 pp. Price $14.50.

This text is a contributive volume with 13 chapters by 13 different authors. The purpose of the volume, according to the preface, is "to provide a broad basis on which the senior undergraduate and graduate student can build." The editor writes that "Although it is anticipated that the student has a fundamental knowledge of chemistry, each of the chapters deals with some basic principles which will serve as a review." If the advanced student is to use this book and it is assumed that he has studied quantitative analysis and organic chemistry, in the reviewer's opinion, the text has not met these objectives.

A detailed examination of the book supports this contention. The introductory chapter introduces the concept of quality control and sampling; in addition, the subjects of mass and volume determination and laboratory techniques which are usually treated in a first course in analysis are reviewed. Although the calculation of titration curve points and titration of mixtures is treated very well, some twenty pages are used to review equilibria topics which should be familiar to students at this level (or at least they can review on their own). The chapter dealing with precipitation, complex formation, and oxidation-reduction methods is an extensive consideration of the very numerous analyses of this type with some theoretical comment. Similarly, the chapter on acidimetry and alkalimetry deals with rudimentary analytical topics, *e.g.*, methods of expressing solution concentrations, and then treats many different acid-base analyses. This type of material would be better presented in a reference rather than a textbook. Nonaqueous titrimetry is presented at too practical a level without use of topics such as glacial acetic acid equilibria. The chapter on complexometry is good, but rigorous calculations involving complex equilibria are not adequately developed. Although the chapter on alkaloidal assay is interesting, it fails, *e.g.*, to use structures and calculations to point out acid-base behavior and to employ the concept of partition coefficients to explain solvent distribution behavior. However, the use of tables to summarize the many analytical methods is excellent. The miscellaneous methods chapter is very good in its treatment of topics such as the Karl Fischer titration, gas analysis, and nitrosation. Likewise, the section on ion-exchange separations is very well done. Enough theory is presented to permit the student to make simple calculations describing column behavior. Column, thin-layer, and paper chromatography are treated well in a single chapter but certain organizational lapses are disturbing, *viz.*, partition column chromatography and two-dimensional thin-layer chromatography are introduced in sections discussing detection methods. The experiments at the end of this chapter are good. The last two chapters deal with the analysis of (*a*) fixed oils, fats and waxes, and (*b*) volatile oils. It is assumed that since the substances are complex mixtures whose analysis necessitates the use of many methods, they are used as examples. Both chapters are disappointing in that they are listings of physical and chemical procedures with some explanatory comment. The chemical methods are not adequately explained with equations and the calculations are represented by formulas which do not invite reasoning. The section on functional group analysis is not done well.

The following observations may be made in summary. The treatment in several of the chapters is too elementary. No use or mention is made of statistics, nor is enough use made of organic reaction mechanisms. Instrumental topics are introduced with little or no background (thereby requiring another book and additional expense). Not all chapters have problems and questions. If this text is to be used by advanced students, in spite of several good chapters, some good experiments, and an admirable use of literature references, it falls short.

Sulfur Dioxide. Applications in Foods, Beverages and Pharmaceuticals. By LOUIS C. SCHROETER. Pergamon Press, Inc. 44-01 21st St., Long Island City, N. Y. 11101, 1966. xiv + 342 pp. 14 × 22 cm. Price $11.

"Sulfur Dioxide" is an excellent monograph containing both the applications of this commercially important compound in pharmaceuticals, foods, and beverages and theoretical reference material useful to medicinal, inorganic, analytical, and pharmaceutical chemists.

The first chapter contains a complete review of the preparation and properties of sulfur dioxide. The properties of this compound are described in a sophisticated physicochemical manner and are well referenced. An outstanding characteristic of the book is the number of references (over 1100) that are cited.

The second chapter, dealing with the oxidation of sulfur dioxide, is particularly good. Sulfite oxidation in aqueous systems is discussed in detail from a kinetic-mechanistic standpoint reflecting the author's expertness in this area. Many of the key references are to the published work of Dr. Schroeter.

Chapter three contains the inorganic reactions, complexes and clathrates of sulfurous acid species. The reactions are limited to those typical of aqueous sulfurous acid systems. The complexes and clathrates are considered in a quantitative manner.

Chapter four, dealing with the organic reactions of sulfites is another particularly complete and good

REVIEWS

Pharmaceutical Chemistry. Vol. 1: Theory and Application. Edited by L. G. CHATTEN. Marcel Dekker, Inc., 95 Madison Avenue, New York, N. Y. 10016, 1966. xii + 504 pp. Price $14.50.

This text is a contributive volume with 13 chapters by 13 different authors. The purpose of the volume, according to the preface, is "to provide a broad basis on which the senior undergraduate and graduate student can build." The editor writes that "Although it is anticipated that the student has a fundamental knowledge of chemistry, each of the chapters deals with some basic principles which will serve as a review." If the advanced student is to use this book and it is assumed that he has studied quantitative analysis and organic chemistry, in the reviewer's opinion, the text has not met these objectives.

A detailed examination of the book supports this contention. The introductory chapter introduces the concept of quality control and sampling; in addition, the subjects of mass and volume determination and laboratory techniques which are usually treated in a first course in analysis are reviewed. Although the calculation of titration curve points and titration of mixtures is treated very well, some twenty pages are used to review equilibria topics which should be familiar to students at this level (or at least they can review on their own). The chapter dealing with precipitation, complex formation, and oxidation-reduction methods is an extensive consideration of the very numerous analyses of this type with some theoretical comment. Similarly, the chapter on acidimetry and alkalimetry deals with rudimentary analytical topics, *e.g.*, methods of expressing solution concentrations, and then treats many different acid-base analyses. This type of material would be better presented in a reference rather than a textbook. Nonaqueous titrimetry is presented at too practical a level without use of topics such as glacial acetic acid equilibria. The chapter on complexometry is good, but rigorous calculations involving complex equilibria are not adequately developed. Although the chapter on alkaloidal assay is interesting, it fails, *e.g.*, to use structures and calculations to point out acid-base behavior and to employ the concept of partition coefficients to explain solvent distribution behavior. However, the use of tables to summarize the many analytical methods is excellent. The miscellaneous methods chapter is very good in its treatment of topics such as the Karl Fischer titration, gas analysis, and nitrosation. Likewise, the section on ion-exchange separations is very well done. Enough theory is presented to permit the student to make simple calculations describing column behavior. Column, thin-layer, and paper chromatography are treated well in a single chapter but certain organizational lapses are disturbing, *viz.*, partition column chromatography and two-dimensional thin-layer chromatography are introduced in sections discussing detection methods. The experiments at the end of this chapter are good. The last two chapters deal with the analysis of (*a*) fixed oils, fats and waxes, and (*b*) volatile oils. It is assumed that since the substances are complex mixtures whose analysis necessitates the use of many methods, they are used as examples. Both chapters are disappointing in that they are listings of physical and chemical procedures with some explanatory comment. The chemical methods are not adequately explained with equations and the calculations are represented by formulas which do not invite reasoning. The section on functional group analysis is not done well.

The following observations may be made in summary. The treatment in several of the chapters is too elementary. No use or mention is made of statistics, nor is enough use made of organic reaction mechanisms. Instrumental topics are introduced with little or no background (thereby requiring another book and additional expense). Not all chapters have problems and questions. If this text is to be used by advanced students, in spite of several good chapters, some good experiments, and an admirable use of literature references, it falls short.

Sulfur Dioxide. Applications in Foods, Beverages and Pharmaceuticals. By LOUIS C. SCHROETER. Pergamon Press, Inc. 44-01 21st St., Long Island City, N. Y. 11101, 1966. xiv + 342 pp. 14 × 22 cm. Price $11.

"Sulfur Dioxide" is an excellent monograph containing both the applications of this commercially important compound in pharmaceuticals, foods, and beverages and theoretical reference material useful to medicinal, inorganic, analytical, and pharmaceutical chemists.

The first chapter contains a complete review of the preparation and properties of sulfur dioxide. The properties of this compound are described in a sophisticated physicochemical manner and are well referenced. An outstanding characteristic of the book is the number of references (over 1100) that are cited.

The second chapter, dealing with the oxidation of sulfur dioxide, is particularly good. Sulfite oxidation in aqueous systems is discussed in detail from a kinetic-mechanistic standpoint reflecting the author's expertness in this area. Many of the key references are to the published work of Dr. Schroeter.

Chapter three contains the inorganic reactions, complexes and clathrates of sulfurous acid species. The reactions are limited to those typical of aqueous sulfurous acid systems. The complexes and clathrates are considered in a quantitative manner.

Chapter four, dealing with the organic reactions of sulfites is another particularly complete and good

chapter. Of the many reactions covered, the discussions on the reactivity of sulfite with aromatic nitro compounds and with benzyl alcohols are especially thorough.

In the fifth chapter, standard quantitative and qualitative methods of detection for sulfurous acid salts are presented together with the special methods needed for sulfite estimation in foods and beverages.

In the next chapter, the food and beverage applications are discussed. The importance of understanding the chemical reactivity of sulfurous acid salts with sugars, proteins, vitamins, and the like is effectively stressed, and the use of sulfurous acid in specific food preservation is extensively covered.

"Pharmaceutical Applications" comprises chapter seven. There are essentially three major topics in this chapter: (*a*) practical aspects, (*b*) theoretical considerations, and (*c*) an extensive listing of specific applications to various drugs.

The monograph ends with a chapter on the toxicity of sulfur dioxide. Plant, human, and animal toxicity is reported.

As T. Higuchi states in the foreword, this simple compound touches us all—from the preparation of dried apricots to free radical chemistry. Under one cover, Dr. Schroeter has provided us with a reference covering all aspects of sulfur dioxide—from utility to chemical reactivity.

Clinical Pharmacy: A Text for Dispensing Pharmacy. By GLENN L. JENKINS, GLEN J. SPERANDIO, and CLIFTON J. LATIOLAIS. McGraw-Hill Book Co., 330 West 42nd St., New York, N.Y., 1966. viii + 379 pp. 15 × 22.5 cm. Price $11.95.

In their preface, the authors state that their text is to be a departure from the conventional text of compounding and dispensing. The use of the term "clinical" in the title implies the intent of the authors to create a text for a course in dispensing pharmacy given immediately before graduation. It indicates a modern text which will help prepare the student to practice his profession not only as a capable pharmacist today, but also as an informed pharmacist tomorrow.

It is the opinion of this reviewer, however, that "Clinical Pharmacy" falls far short of its worthy goal. Indeed, instead of being a text for advanced students, it more appropriately belongs to that textbook class suitable for the beginning pharmacy student.

In addition to the topics normally covered in a dispensing text of pharmacy, it is heartening to note the chapters on allergenic extracts, investigational drugs, clinical research, the pharmacy as a drug information center, and pharmacy service in small hospitals and nursing homes. A chapter on the ethical and moral aspects of the profession and the relationship between a pharmacist and his patron, should have been added to complete the text. While the material covered in these chapters is necessary, more emphasis could have been placed on the relationship of the community pharmacist with the activities described.

The balance of the text is a shallow treatment of the subjects normally discussed in other dispensing texts. The depth to which a senior student ought to be taken in these subjects is never achieved.

As an example, the chapter on controlled release dosage forms never gets into the problem of evaluating these products from the published literature, and the difficulties which have been encountered with these products in terms of proper release rates and clinical effectiveness. The student must be made aware of these factors if he is going to adequately advise physicians and patrons in this area.

The chapter on calculated solutions is unduly elementary for a senior student. The material in this chapter properly belongs in the arithmetic course given in the first years of the pharmacy curriculum. Similarly, in the chapter on radioactive pharmaceuticals, senior students don't need to be told that an atom is composed of a nucleus of protons and neutrons surrounded by orbiting electrons. Certainly the reader should be informed of the activities of pharmacists in handling radioactive pharmaceuticals, the necessary equipment, and how the agents are used. Problems of storage and assay are also important, as are the mathematics of radioactive decay.

Although the authors attempt to excuse the lack of references, such an omission is a serious drawback in any text. The purpose of references is not only to aid in the instruction of the student, but also to credit the investigator whose works are used in the text.

Pharmaceutical education is in dire need of a text in dispensing pharmacy which clearly demonstrates the application of basic disciplines to community and hospital practice. Many of these disciplines are being adequately taught, but their application is not. This text does not fulfill the expectations embodied in its title.

Methods of Vitamin Assay. 3rd ed. Edited by The Association of Vitamin Chemists, Inc., Methods Committee. John Wiley & Sons, Inc., 605 Third Ave., New York, N. Y. 10016, 1966. xvii + 424 pp. 15.5 × 23.5 cm. Price $14.00.

Probably the technology of vitamin assay has grown too complex in the last 15 years to get it all into a single book. Thus, the Third Edition of "Methods of Vitamin Assay" tries to cover so much ground in food and feed applications that it is not likely to be very useful as a laboratory manual to analysts in the pharmaceutical field. The style and quality of the work varies from one chapter to another because of the multiple authorship. The chapters on sampling and biological assays are good, although not particularly slanted to pharmaceutical analysts. The one on vitamin D is excellent.

My confidence was shaken somewhat by the repetition in the vitamin A chapter of statements from the Second Edition that are no longer applicable today. The authors seem unaware that changes have been made in the U.S.P. Reference Standard, monograph, and assay method since 1951. The only serious defect in the chapter though is that the calculation for the ultraviolet absorption method

My confidence was shaken somewhat by the repetition in the vitamin A chapter of statements from the Second Edition that are no longer applicable today. The authors seem unaware that changes have been made in the U.S.P. Reference Standard, monograph, and assay method since 1951. The only serious defect in the chapter though is that the calculation for the ultraviolet absorption method

will give results about 6% higher than the one adopted by the U.S.P. in 1958. While this could be an isolated oversight, it casts doubt on the thoroughness of the preparation of the Third Edition and on the authenticity that the book might be assumed to have—particularly for pharmaceutical analysts.

The chapter on vitamin E fails to mention any official method, and the one given for pharmaceuticals differs from those in the N.F. and U.S.P. The chapter concerns itself mostly with food and feed applications. Even so, it covers so many methods in so many applications that it is lacking in detail.

The chapters on the other vitamins are about equally divided as to whether they take cognizance of an official method.

This edition could be of value to pharmaceutical analysts as a guide to the many modifications that are possible for specific problems. However, it should be supported by reference to official methods, where they are applicable, and to the orginal literature, where more complete detail is usually given.

Chemical Principles in Calculations of Ionic Equilibria. By EMIL J. MARGOLIS. The Macmillan Co., 866 Third Ave., New York, N. Y. 10022, 1966. xi + 482 pp. 15.5 × 24 cm. Price $7.95 clothbound; $3.95 paperbound.

Although teachers of physical pharmacy and pharmaceutical analysis can assume that their students have been exposed to the principles and calculations of ionic equilibria, review and expansion of the subject matter are usually desirable and necessary. This book can be recommended for that purpose as either a source of self study assignments or for class room use.

The first chapter reviews in a classical fashion simple mathematical operations. Chapter 2 defines components and units of concentration. Each of the remaining six chapters is divided into three sections: a discussion of theoretical principles; a collection of appropriate interpretative problema with solutions; an extensive collection of supples mentary problems. Chapter 3 deals with protolytic equilibria and complex-ion formation. Included are treatments of the hydrolysis of salts, buffers, ionization of polyprotic acids, titration curves, and indicator selection. Brønsted-Lowry concepts are used in the discussion of hydrolysis and ionization. Approximate equations, used for the calculation of species distribution and concentration are derived. Although exact equations are not presented, limitations of the approximate equations are discussed. Here, as with the remaining chapters, interpretative exercises are presented to cover a wide range of situations. Step-wise solutions of the problems are given with extensive helpful commentary on both the chemical and mathematical aspects of the situation. Solid–liquid precipitations and solubilizations are the topics of chapter 4. Emphasis here is placed on the application of K_{sp} principles to inorganic qualitative analysis. Of particular interest is the treatment of simultaneously occurring equilibria as for example the solubilization of weak acids, bases, and ampholytes by pH adjustment or complex formation. Liquid–liquid partitioning behavior and extraction are briefly reviewed in chapter 5. Chapter 6 covers, in an elementary manner, activities, activity coefficients, ionic strength, and the Debye-Hückel equation. The interpretative problems provide useful and illuminating practical illustrations of activity considerations. Principles and applications of electrochemistry are reviewed in chapters 7 and 8. Voltaic and electrolytic cells are discussed and illustrated, standard electrodes are defined and explained. A descriptive elementary treatment of free energy, enthalpy, and entropy is presented as a prelude to the introduction of the Nernst equation. Potential diagrams, redox titrations, and redox indicators are also covered.

In general, the book covers principles and calculations at a level somewhat higher than the usual general chemistry treatment. The author's long experience as a teacher in the area is reflected by his anticipating and emphasizing aspects of ionic equilibria which are usually poorly understood by the average student.

Applied Infrared Spectroscopy. Edited by DAVID N. KENDALL. Reinhold Publishing Corp., New York, N. Y. 10022, 1966. xv + 560 pp. 15.5 × 23.5 cm. Price $23.

The 18 chapters of this volume provide a survey of the state of the art of infrared spectroscopy. Applications are described in eight of the chapters. These include descriptions of the use of infrared spectrometry by organic chemists at the bench and for studies on polymers, inorganics, the structure of coal, and essential oils and related products. Expositions on the use of infrared in the industrial laboratory, in pharmaceutical research and development, and in government regulatory agencies are provided. Techniques are covered in the remaining chapters, which include an introduction to infrared theory, practical hints on technique, a description of instrumentation, general and microsample handling techniques, microtechniques using miniaturized diamond optics, a scheme for qualitative interpretation of spectra, and chapters on attenuated total reflectance and the use of computers in spectroscopy.

Since the book is the product of a collaboration among 21 authors and co-authors, it is not unexpected that the chapters are uneven in quality and that there is considerable overlap in material covered. Detailed descriptions of the use of Beer's law in quantitative analysis are given in chapter 2, "Survey of Practical Information," chapter 6, "Infrared on the Chemist's Bench," and chapter 8, "Application of Infrared Spectroscopy to Polymers." Similarly, a description of the literature and spectra collections available is provided in three of the chapters. The aelative lack of cross-referencing among the chapters is wasteful of space; however, there is a didactic advantage in having each chapter complete in itself.

Chapters on "Infrared in the Regulatory Agencies" by Carol and Hayden of FDA and "Pharmaceutical Applications of Infrared Spectroscopy" by Johnson, Rinehart, and Graham are of most immediate interest to pharmaceutical scientists, but notable also are the fascinating chapter on "The Use of Computers in Spectroscopy" by Savitzky and

will give results about 6% higher than the one adopted by the U.S.P. in 1958. This edition could be of value to pharmaceutical analysts as a guide to the many modifications that are possible for specific problems. However, it should be supported by reference to official methods, where they are applicable, and to the orginal literature, where more complete detail is usually given.

Chemical Principles in Calculations of Ionic Equilibria. By EMIL J. MARGOLIS. The Macmillan Co., 866 Third Ave., New York, N. Y. 10022, 1966. xi + 482 pp. 15.5 × 24 cm. Price $7.95 clothbound; $3.95 paperbound.

Although teachers of physical pharmacy and pharmaceutical analysis can assume that their students have been exposed to the principles and calculations of ionic equilibria, review and expansion of the subject matter are usually desirable and necessary. This book can be recommended for that purpose as either a source of self study assignments or for class room use.

The first chapter reviews in a classical fashion simple mathematical operations. Chapter 2 defines components and units of concentration. Each of the remaining six chapters is divided into three sections: a discussion of theoretical principles; a collection of appropriate interpretative problema with solutions; an extensive collection of supples mentary problems. Chapter 3 deals with protolytic equilibria and complex-ion formation. Included are treatments of the hydrolysis of salts, buffers, ionization of polyprotic acids, titration curves, and indicator selection. Brønsted-Lowry concepts are used in the discussion of hydrolysis and ionization. Approximate equations, used for the calculation of species distribution and concentration are derived. Although exact equations are not presented, limitations of the approximate equations are discussed. Here, as with the remaining chapters, interpretative exercises are presented to cover a wide range of situations. Step-wise solutions of the problems are given with extensive helpful commentary on both the chemical and mathematical aspects of the situation. Solid–liquid precipitations and solubilizations are the topics of chapter 4. Emphasis here is placed on the application of K_{sp} principles to inorganic qualitative analysis. Of particular interest is the treatment of simultaneously occurring equilibria as for example the solubilization of weak acids, bases, and ampholytes by pH adjustment or complex formation. Liquid–liquid partitioning behavior and extraction are briefly reviewed in chapter 5. Chapter 6 covers, in an elementary manner, activities, activity coefficients, ionic strength, and the Debye-Hückel equation. The interpretative problems provide useful and illuminating practical illustrations of activity considerations. Principles and applications of electrochemistry are reviewed in chapters 7 and 8. Voltaic and electrolytic cells are discussed and illustrated, standard electrodes are defined and explained. A descriptive elementary treatment of free energy, enthalpy, and entropy is presented as a prelude to the introduction of the Nernst equation. Potential diagrams, redox titrations, and redox indicators are also covered.

In general, the book covers principles and calculations at a level somewhat higher than the usual general chemistry treatment. The author's long experience as a teacher in the area is reflected by his anticipating and emphasizing aspects of ionic equilibria which are usually poorly understood by the average student.

Applied Infrared Spectroscopy. Edited by DAVID N. KENDALL. Reinhold Publishing Corp., New York, N. Y. 10022, 1966. xv + 560 pp. 15.5 × 23.5 cm. Price $23.

The 18 chapters of this volume provide a survey of the state of the art of infrared spectroscopy. Applications are described in eight of the chapters. These include descriptions of the use of infrared spectrometry by organic chemists at the bench and for studies on polymers, inorganics, the structure of coal, and essential oils and related products. Expositions on the use of infrared in the industrial laboratory, in pharmaceutical research and development, and in government regulatory agencies are provided. Techniques are covered in the remaining chapters, which include an introduction to infrared theory, practical hints on technique, a description of instrumentation, general and microsample handling techniques, microtechniques using miniaturized diamond optics, a scheme for qualitative interpretation of spectra, and chapters on attenuated total reflectance and the use of computers in spectroscopy.

Since the book is the product of a collaboration among 21 authors and co-authors, it is not unexpected that the chapters are uneven in quality and that there is considerable overlap in material covered. Detailed descriptions of the use of Beer's law in quantitative analysis are given in chapter 2, "Survey of Practical Information," chapter 6, "Infrared on the Chemist's Bench," and chapter 8, "Application of Infrared Spectroscopy to Polymers." Similarly, a description of the literature and spectra collections available is provided in three of the chapters. The aelative lack of cross-referencing among the chapters is wasteful of space; however, there is a didactic advantage in having each chapter complete in itself.

Chapters on "Infrared in the Regulatory Agencies" by Carol and Hayden of FDA and "Pharmaceutical Applications of Infrared Spectroscopy" by Johnson, Rinehart, and Graham are of most immediate interest to pharmaceutical scientists, but notable also are the fascinating chapter on "The Use of Computers in Spectroscopy" by Savitzky and

the several chapters on the "common-sense" aspects of infrared by the editor. This book is not over-all a practical manual on infrared spectroscopy nor is it an effective introductory textbook; it is instead a valuable collection of authoritative information on the practice and use of infrared spectroscopy for the non-specialist in infrared. The book is recommended as an addition to the collection of volumes on infrared spectra which should be available in the laboratory.

Food Chemicals Codex. First Edition. Prepared by the Committee on Specifications of the Food Chemicals Codex of the Food Protection Committee. National Academy of Sciences-National Research Council. National Academy of Sciences-National Research Council, 2101 Constitution Ave., N. W., Washington, D. C. 20418, 1966. xv + 846 pp. 15.5 × 23 cm. Price $25.

The "Food Chemicals Codex" promises to develop an importance comparable to the "U. S. Pharmacopeia" and the "National Formulary" as a compendium of chemical identity and specifications.

As an activity of the Food Protection Committee, the First Edition was prepared under the direction of Dr. Justin L. Powers, assisted by various expert committees. Originally published as a series of loose-leaf parts, the present first edition appears in bound form. It is the result of approximately five years of organization and development.

The "Food Chemicals Codex" is designed to provide standards for food grade chemicals, and its status in this respect is established by an endorsement appearing in each book indicating that the Food and Drug Administration will regard the specifications in the "Food Chemicals Codex" as defining an "appropriate food grade" within the meaning of the Food Additives Amendment and regulations. The "Food Chemicals Codex" will, therefore, in the future serve the food industry and its various activities in the same way that the "U. S. Pharmacopeia" and the "National Formulary" have served the drug and pharmaceutical industries.

The first edition consists of over 800 pages of text embracing 518 food chemicals. As would be expected, the makeup is analogous to that of its comparable compendia for drugs. Following the specific monographs there is a section of general tests and apparatus which the quality control chemist will find extremely useful. The policy of the "Food Chemicals Codex" is that other analytical methods with equal or greater accuracy may be used, but that only the assays and tests described therein are authoritative.

The first edition recognizes that in order to keep pace with the use of chemicals in food continuing revision will be necessary. The Governing Board of the National Academy of Sciences has approved a plan for sponsoring the Codex through its next revision, scheduled for publication in 1971. During the interim there will be revision supplements whenever necessary.

The "Food Chemicals Codex" should be available to every chemist who has responsibility for the manufacture, distribution, and quality control of chemicals which fall under the general category of food additive chemicals. It will serve as a valuable reference and text in schools and libraries.

British National Formulary 1966. Published jointly by the British Medical Association and the Pharmaceutical Society of Great Britain. The Pharmaceutical Press, 17 Bloomsbury Square, London W.C.1, England, 1966. 356 pp. 11 × 17.5 cm. Price $1.75.

The "British National Formulary" now is published in only one edition which combines the essential features of the former Standard and Alternative editions in order to retain the information required by both prescribers and pharmacists. Monographs which formerly followed the Notes for Prescribers are replaced with a listing of preparations and page references to the Classified Formulary section of the book.

Monographs in the Classified Formulary, the second half of the book, now have only English titles; synonyms and subheadings have been eliminated. Group headings also are in English. For example, the heading "Unguenta" has been changed to "Ointments," "Ear drops" replaces "Auristillae."

The "Infants Section" has been completely eliminated since so many preparations for children are those prescribed for adults but with a modified dosage schedule.

More conversion to the metric system is in evidence. Many minim dose preparations have been reformulated to a 5-ml. unit dose. Those preparations still using the Imperial system are now being converted for the complete adoption of the metric system which will be in 1968.

The Condensed Chemical Dictionary. 7th ed. Edited by ARTHUR and ELIZABETH ROSE. Reinhold Publishing Corp., 430 Park Ave., New York, N. Y. 10022, 1966. xxi + 1044 pp. 17 × 24.5 cm. Price $17.50.

This is a newly up-dated version of this valuable reference and is vastly expanded over the previous (6th) edition. A great deal of information about a great variety of items has been so condensed to make a book both easily handled and extremely useful. This is an alphabetical listing of chemicals, drugs, materials, trademark names, and terminology with description or definition. A typical chemical entry provides a brief description of the compound, its properties, derivation, uses, grades available, containers, warnings, and shipping regulations. Items which are described in the "National Formulary," "United States Pharmacopeia," or "Food Chemicals Codex" are identified. Trademark names are listed with chemical identification, grades available, uses, manufacturer's name and address, and shipping instructions.

Diffusional Models Useful in Biopharmaceutics

Drug Release Rate Processes

By WILLIAM I. HIGUCHI

THE EVOLUTION of a given body of knowledge from a catalog of apparently unrelated facts to an exact science at the molecular level generally follows a path in which somewhere along the way the consideration of quantifiable *physical* models becomes necessary. Such models, when they enter upon the scene, play many roles in the course of the development of the area of knowledge. Initially they serve to provide the primitive quantitative interrelationships among the variables that considered intuition alone had been unable to do. From these, suitable *in vitro, in situ,* or *in vivo* experiments are designed. With refinement of the models and with continued experimentation, knowledge is efficiently built up to a rather sophisticated level.

This review is intended to cover some of those stiuations in biopharmaceutics where physical models involving drug transport have materially helped or are helping in answering complex questions. Some situations are also discussed where such methods have not yet been applied but are indicated. Attention is given only to those problems in which physical models have been applied in contrast to those where empirical or arbitrary mathematical kinetic models have been employed.

DISSOLUTION RATES OF SOLIDS

General Considerations—Wurster and Taylor (1) have already presented a comprehensive review of this subject. Wagner (2), in an earlier review article, also discussed this subject and related it to biological availability. The readers are referred to both of these excellent reviews which serve to provide more than adequate background for the present discussion.

From the standpoint of rate mechanisms involving pure substances there are basically three processes that have been accessible to the physical model treatment. These have been employed alone or in combinations in setting up the models for describing dissolution rate mechanisms. Figure 1 schematically illustrates those cases when each of these alone is rate determining.

Case *A* represents the diffusion layer showing a crystal or a polycrystalline solid dissolving into pure solvent. This model in its earliest

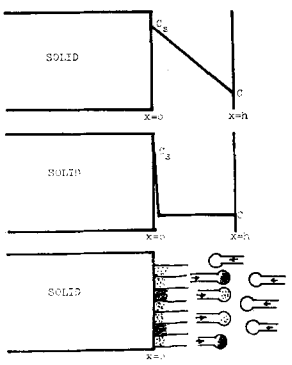

Fig. 1—Illustration of the situations for the three mechanisms of dissolution rate behavior of solids. Concentration profiles are shown for cases A *and* B, *and packet transport is depicted for case* C. *Case* A, *diffusion layer model (top); case* B, *interfacial barrier model (middle); case* C, *Danckwerts' model (bottom).*

Received from the College of Pharmacy, University of Michigan, Ann Arbor, MI 48104

form was probably first discussed by Nernst (3). Here it is assumed that there is a liquid layer ("film") of thickness, h, in which there is a negligible velocity component in the x-direction (perpendicular to the surface). At $x > h$, it is assumed that rapid mixing is present. Therefore, no gradients of concentration may exist in this region. At $x = 0$ (the solid–liquid interface) it is assumed that solid–solution equilibrium exists. Then the rate of solute movement and therefore the dissolution rate is determined entirely by Brownian motion diffusion of the molecules in the liquid "film" ($x = 0$ to $x = h$).

Case B illustrates the interfacial barrier model where, because of a high activation free energy for the interfacial transport step, diffusion across the interface is much slower than diffusion across the "film" or transport by eddy packets to be discussed below. As a result, crystal–solution equilibrium at $x = 0$ may not be assumed, and this consideration must be included in the model.

Finally, we have case C representing the Danckwerts' model (4), where one imagines macroscopic packets of solvent reaching the solid–liquid interface by eddy diffusion in some random fashion. During its residence at the interface the packet is able to absorb solute according to the usual laws of diffusion. These surface elements are continuously replaced by new packets of solvent. This surface renewal process may then be related to the solute transport rate.

Rate Laws Predicted by the Different Mechanisms—Let us consider the situation where a one component, one phase, solid of macroscopic ($\gtrsim 1$ mm.) dimensions and of low to moderate ($\simeq 5\%$) solubility dissolves without disintegration and without chemical reaction into a solvent under mild to high agitation conditions. Then the dissolution rate per unit area, G, according to the diffusion layer model for this case will be

$$G = \frac{D}{h}(C_s - C) \qquad \text{(Eq. 1)}$$

where D is the solute molecule diffusion coefficient, C_s is the solubility, C is the solute concentration, and h as defined in Fig. 1 is the effective diffusion layer ("film") thickness.

The Danckwerts' model for this case gives

$$G = S^{1/2}D^{1/2}(C_s - C) \qquad \text{(Eq. 2)}$$

where S is the mean rate of production of fresh surface.

When an interfacial barrier is important, it is much more difficult to derive a relationship for G in physically significant terms. First of all, the true (or microscopic) surface area rather than the geometric external area (of a tablet) should be considered. Furthermore, the different faces of a crystal should have different interfacial barriers. However, one often writes for this case,

$$G = k_i(C_s - C) \qquad \text{(Eq. 3)}$$

where k_i is the effective interfacial transport rate constant. The first-order dependence on $(C_s - C)$ implies that the process is a unimolecular one. This is reasonable as one would expect that the step movement rate on a crystal surface would be usually unimolecular. However, perhaps at large undersaturations cooperative molecular effects may become important. More experimental studies are needed before the $(C_s - C)$ part of Eq. 3 can be regarded as the usually expected form in a surface controlled situation. For the present we shall take Eq. 3 as the best at the moment to represent this case.

When the interfacial barrier concept is combined with the diffusion layer case we have a double-barrier model

$$G = \frac{D(C_s - C)}{h\left[1 + \frac{D}{hk_i}\right]} \qquad \text{(Eq. 4)}$$

which reduces to Eqs. 1 or 3, respectively, in the limits, $k_i \gg D/h$ and $k_i \ll D/h$.

When the interfacial barrier idea is combined with Danckwerts' surface renewal mechanism we have

$$G = \frac{S^{1/2}D^{1/2}(C_s - C)}{\left[1 + \frac{S^{1/2}D^{1/2}}{k_i}\right]} \qquad \text{(Eq. 5)}$$

which reduces to Eqs. 2 or 3 in the limits.

The diffusion layer and the Danckwerts theories may also be combined (5, 6). Surface elements of a finite length, L, in the x-direction must be taken. This combination leads to expressions which reduce to Eqs. 1 and 2, respectively, in the limits, $L \to 0$ and $L \to \infty$.

Experimental Approach to an Examination of the Theories for One Component—One Phase Case—The reviewer believes[1] that there has been relatively convincing experimental work showing which theory is applicable and under what conditions. Part of this stems from the fact that the researchers frequently have been more interested in establishing other aspects than in differentiating the three basic models described above.

[1] Readers are referred to Wurster and Taylor's discussion (1). (See also *References 7* and *8*.)

The classical Noyes-Whitney law (9), which states that

$$G = \text{constant } x(C_s - C) \qquad \text{(Eq. 6)}$$

really, by itself, reveals very little mechanistically when a single substance dissolves in a pure solvent under constant hydrodynamic conditions. This is because all theories predict the same first-order dependence upon $\Delta C = C_s - C$.

When the dissolution behavior of many substances in the same solvent is compared under the same hydrodynamic conditions, it may be possible to separate those which follow Eqs. 1 or 2 from those following Eqs. 3, 4, or 5. If, furthermore, compounds with a sufficiently wide range of D values are included in the study while maintaining everything else but C_s constant, one should be able to distinguish data conforming to Eq. 1 from those following Eq. 2 or the diffusion layer–Danckwerts combination theory (6). The reviewer is not aware of work on this latter aspect that has led to unambiguous results. The work of Desai *et al.* (10), to be discussed later, probably provides a more promising approach to this problem.

Finally by varying the rate of agitation one should be able to distinguish between those following Eq. 3 from those following Eqs. 4 or 5, provided that sufficient data are available with other substances obeying Eqs. 1 or 2 under the same hydrodynamic conditions. Data obeying Eqs. 4 and 5 may then be distinguished by employing the method used for Eqs. 1 and 2.

Wurster and Taylor (11) in their studies of the dissolution rate behavior of prednisolone employed Eq. 4 and Eq. 1. These investigators suggested that the double-barrier mechanism (Eq. 4) better described their data on the influence of agitation upon the dissolution rates. Some recent single crystal studies by Tawashi (12) with cholesterol monohydrate and by Mehta (13) with methylprednisolone show that under certain conditions single crystals of these substances of about 100-μ dimensions dissolve by some interfacially controlled process in aqueous media.

Small Particle Problems—Goyan (14) derived a relationship for the dissolution rate of a small spherical particle involving the surface renewal mechanism. In one form it may be written

$$G = \left[\frac{D}{a} + S^{1/2}D^{1/2}\right](C_s - C) \qquad \text{(Eq. 7)}$$

where a is the particle radius (equivalent volume sphere) and the other symbols have been defined. Goyan has suggested that Eq. 7 rather than Eq. 1 better describes the data (15) on the dissolution rate of salicylamide particles in water at high agitation rates.

Equation 7 nicely reduces to the purely diffusion controlled case when $S \to 0$ or when $a \to 0$, *viz.*,

$$G = \frac{D}{a}(C_s - C) \qquad \text{(Eq. 8)}$$

It is noteworthy (compare Eq. 8 with Eq. 1) that, for small particles, $h \simeq a$ even with *no* agitation.

For micron size particles at low to moderate agitation rates, Eq. 8 should be applicable if interfacial barrier effects are absent. The dissolution rate behavior of dibutyl phthalate droplets in water agreed very well with this theory (16).

If interfacial barrier effects are not negligible, a double-barrier relation may be written,

$$G = \frac{D}{a}\left[\frac{C_s - C}{1 + \dfrac{D}{ak_i}}\right] \qquad \text{(Eq. 9)}$$

which is identical to Eq. 4 when $a = h$.

Particle size distribution effects may be taken into account by selecting a particle size distribution function (17, 18) that is time dependent and by combining it with the appropriate Eqs. 7, 8, or 9. For example, if the particle size distribution may be expressed by the function $f(a)$, where a is a function of time and where $f(a)da$ is the number of particles between the sizes a and $a + da$, we may write for the total dissolution rate, J, of the suspension,

$$J(t) = \int_{a_s}^{a_e} f(a)G(a)da \qquad \text{(Eq. 10)}$$

where a_s and a_e are, respectively, the smallest and the largest particles in the distribution. If $f(a)$ is known by a particle size distribution measurement, then Eqs. 7, 8, or 9 may be employed for G to provide an equation for J explicit in time. This procedure was used employing Eq. 8 to analyze data on the dissolution rate of a steroid suspension in water (18).

Dissolution Rates with Simultaneous Solution Interactions Involving Additives in the Solvent—In many practical situations the dissolving drug may become involved in an acid–base reaction, in complex formation, or in some other kind of solubilization interaction. In these instances the three basic models (Fig. 1) still apply in a qualitative sense. However, detailed consideration of the move-

ment of all solution species becomes necessary, resulting in equations that are generally different from those for the one component problem.

As an illustrative example, let us choose the case where the dissolving molecule, A, reacts with an additive molecule, B, present in the solvent to form a complex, AB, according to $A + B = A \cdot B$, with

$$K = \frac{(A \cdot B)}{(A)(B)} \qquad \text{(Eq. 11)}$$

Assume that equilibrium is rapid compared to diffusion over distances of importance ("film" thickness, packet dimensions, etc.). This is a reasonable assumption for most acid–base reactions and for most interactions leading to complex formation. Assume also that no new phases may precipitate. Then the diffusion layer theory gives for this situation (19–21)

$$G = \frac{D_A}{h}\left[1 + \frac{D_B B_h}{D_A\left(A_0 + \frac{D_B}{D_{AB}K}\right)}\right](A_0 - A_h) \qquad \text{(Eq. 12)}$$

D_A, D_B, and D_{AB} are the diffusion coefficients for A, B, and AB. A_0 and A_h are the concentrations of A at $x = 0$ and $x = h$. B_h is the concentration of B in the solvent ($x \geq h$).

Physically the situation regarding the species leading to Eq. 12 may be described as follows. Species A is diffusing from $x = 0$, where $A_0 =$ solubility of A, to $x = h$, where $A = A_h$. Species B diffuses in the opposite direction from $x = h$, where $B = B_h$, to $x = 0$. Along the way B complexes with A according to Eq. 11 and the complex $A \cdot B$ diffuses out along with free A in the same direction as A. The net effect is a "facilitation" of the transport of A into solution, resulting in the factor

$$\left[1 + \frac{D_B B_h}{D_A\left(A_0 + \frac{D_B}{D_{AB}K}\right)}\right]$$

multiplying the rate given by Eq. 1.

The Danckwerts theory does not give differential equations that can be solved analytically for the situation (19) involving this equilibrium between A, B, and $A \cdot B$. However, Olander has solved the special case, when $D_A = D_B = D_{A \cdot B} = D$, in which

$$G = S^{1/2}D^{1/2}\left[1 + \frac{B_h}{A_0 + \frac{1}{K}}\right](A_0 - A_h) \qquad \text{(Eq. 13)}$$

It is noteworthy that, when $D_A = D_B = D_{A \cdot B} = D$, the diffusion layer theory (Eq. 12) reduces to

$$G = \frac{D}{h}\left[1 + \frac{B_h}{A_0 + \frac{1}{K}}\right](A_0 - A_h) \qquad \text{(Eq. 14)}$$

As Olander points out (20), Eqs. 13 and 14 are identical except for the dependence on D and the hydrodynamics. It is further noteworthy that both Eqs. 13 and 14 reduce to Eqs. 1 and 2, respectively, if one notes that

$$(C_s - C) = (A_0 - A_h)\left[1 + \frac{B_h}{A_0 + \frac{1}{K}}\right] \qquad \text{(Eq. 15)}$$

where $C_s - C$ is the "total" concentration differential for A between the solid–solvent interface and the bulk solvent.

It follows from the above that, when all the diffusion coefficients are equal, the Noyes-Whitney law should apply regardless of whether the diffusion layer theory or the Danckwerts theory is appropriate. These conclusions are not restricted to the reaction, $A + B = A \cdot B$. Situations involving other kinds of equilibria have also been worked out (19–21). Because the diffusion coefficients of molecules and ions vary approximately as the cube root of the molecular weight, the Noyes-Whitney law should be frequently applicable as long as interfacial barrier effects or the precipitation of new phases are absent. Extensive experimental studies by Nelson (22, 23) and by Hamlin *et al.* (24) substantiate this.

Situations where significant deviations from the Noyes-Whitney law should occur, except when phase changes take place, are those involving either very small or very large diffusion coefficients. A case in point is the dissolution rate behavior of a basic amine drug in HCl solutions (25). Here the large diffusion coefficient of the HCl apparently caused the dissolution rate to be as much as 3 times greater than the Noyes-Whitney law predictions.

The studies by Desai *et al.* (10) on the initial dissolution rate behavior of benzocaine in aqueous polysorbate 80[2] solutions are particularly noteworthy. Their experiments carried out under constant hydrodynamic conditions provided data that could be used to simultaneously test the diffusion layer theory, the Danckwerts theory, and the Noyes-Whitney law. For this situation the diffusion layer theory gives the following equation (10, 26)

$$G = \frac{D}{h}C_s + \frac{D^1}{h}C^1_s \qquad \text{(Eq. 16)}$$

where D^1 is the diffusion coefficient of the micelle-

[2] Marketed as Tween 80 by Atlas Chemical Industries, Wilmington, Del.

solubilized drug and C_s^1 is the solubility increase due to solubilization. All other terms are the same as in Eq. 1.

In contrast to Eq. 16, Danckwerts theory (10) leads to the following equation for the dissolution rate of benzocaine in polysorbate solutions.

$$G = S^{1/2} \times \sqrt{(C_s + C^1_s)(DC_s + D^1C^1_s)} \quad \text{(Eq. 17)}$$

The symbols have the same meanings as before.

Finally, according to the Noyes-Whitney law, we have for this situation

$$G = \text{constant } x(C_s + C^1_s) \quad \text{(Eq. 18)}$$

The comparison of the experimental data with Eqs. 16, 17, and 18 is shown in Fig. 2. Clearly, in this example, the diffusion layer theory agrees best with the experimental data. Both Eqs. 17 and 18 show discrepancies with data that are far greater than the scatter of the data.

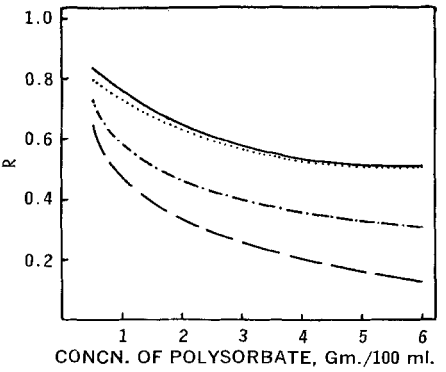

Fig. 2—Data and theory on the influence of polysorbate 80 solubilization on the dissolution rate behavior of benzocaine. R is ratio of rate in polysorbate solution to that without polysorbate (from Desai et al.). *Key: ———, experimental; · · · · · · · , diffusion layer theory; – · – · –, Danckwerts theory; – – – –, Noyes-Whitney theory.*

The reviewer believes that studies by Desai *et al.* represent the first clear-cut demonstration of mechanism differentiation. This technique should have extensive application in the future—particularly in studying the effects of hydrodynamic factors on mechanisms.

Some Comments on the Influence of Additives at the Interface—An interfacially adsorbing agent may help in increasing the dissolution rate. A surfactant may improve the wetting of the surface and effectively increase the available area (27, 28). It may also increase the interfacial rate constant k_i (Eq. 3) by assisting in the release of surface molecules through interfacial tension lowering.

Surface-active agents may play other roles. For example, the formation of a surface adsorbed layer of aliphatic long chain ammonium ions retards the dissolution rate of apatite crystals (29). Also it is expected on theoretical grounds (30) that for very water insoluble drugs ($C_s \lesssim 10^{-8}$ Gm. ml.$^{-1}$) the intrinsic rate of micellar solubilization of a drug may be very low, and the dissolution rate may be much slower than that predicted by Eq. 16. This might occur if, for example, the surfactant micelles have the same charge as the crystal surface (due to, say, the adsorbed surfactant), and the close approach of the micelle to the surface is improbable.

Dissolution Rates Involving Simultaneous Phase Changes—There have been a number of reports in the literature (31, 32) where the formation of a new surface phase was noted during the dissolution of the drug. Invariably the formation of such phases leads to slower dissolution rates than if it did not occur.

The physical model approach involving the consideration of simultaneous diffusion, chemical equilibria, and new phase precipitation has now been employed in a number of instances. The dissolution rate behavior in phosphate buffers of the sodium salt of a relatively water-insoluble weak acid drug was analyzed (33) by this technique. The data were found to be consistent with the model in which a surface coating of the weak acid was formed under certain conditions.

The pamoate salt of an amine drug forms a coating of pamoic acid during its dissolution in HCl solutions (32). Assuming that the diffusion of the protonated amine through this coating is rate determining, a model was constructed and compared to data (34).

The dissolution rate behavior of apatites is important because of its relation to bone and tooth mineral dynamics (35, 36). The possibility of dicalcium phosphate surface phase deposition during apatite dissolution in aqueous lactate buffers was considered (35). More recently (37, 38) the influence of the fluoride ion on the dissolution rate behavior of apatites has been examined by means of models involving surface phases of fluorapatite and CaF_2. The questions of what effects phosphate, calcium, and fluoride ions and pH have on these mechanisms are being answered by these models and the appropriate experiments.

Recently Bernardo (39) examined the problem of the anomalous dissolution rate behavior (40) of the polymorphs of methylprednisolone. A model was considered in which it was assumed that simultaneous surface reversion of polymorph II (the higher energy one) to polymorph I

occurred during the dissolution of polymorph II. This led to equations which were consistent with the experimental observation that at high stirring rates the dissolution rates for forms I and II were indistinguishable.

Dissolution Rates from Mixtures—Recently a mathematical analysis based on a physical model was presented (41) to describe the dissolution rate behavior of polyphase mixtures. For a two phase mixture in which the two components, A and B, do not interact in any way with each other, we may describe the model in the following way. Upon exposure to solvent, both components of the mixture should tend to dissolve at rates proportional to their solubilities and their diffusion coefficients. After some time, usually one of the phases would become depleted at the solid–liquid interface region because N_A/N_B may not be equal to $(D_A C_{SA})/(D_B C_{SB})$, where N_A and N_B are the original amounts of A and B in the mixture, D_A and D_B are the diffusion coefficients, and C_{SA} and C_{SB} are the respective solubilities. As a result, a surface layer is formed that is composed of only one of the phases. The three possible situations after zero time are illustrated in Fig. 3 for the one-dimensional, two-phase mixture problem.

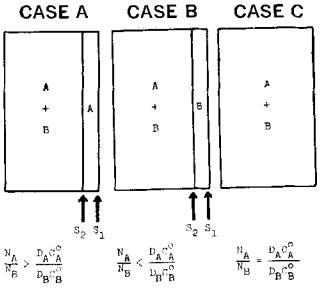

Fig. 3—Dissolution behavior of two-phase mixture of A *and* B. *In case* A, *phase* B *dissolves fast enough to leave a layer of pure* A *behind; in case* B, *the reverse is true; while in case* C, *dissolution rates of* A *and* B *are proportional to their relative amounts in the mixture.*

The following dissolution rate equations based on this model were derived[3] for each of the situations given in Fig. 3.

When

$$N_A/N_B > (D_A C_{SA})/(D_B C_{SB}),$$

$$\left.\begin{aligned} G_A &= \frac{D_A C_{SA}}{h} \\ \text{and} \\ G_B &= \frac{N_B}{N_A} G_A \end{aligned}\right\} \quad \text{(Eq. 19)}$$

When

$$N_A/N_B < (D_A C_{SA})/(D_B C_{SB}),$$

$$\left.\begin{aligned} G_B &= \frac{D_B C_{SB}}{h} \\ \text{and} \\ G_A &= \frac{N_A}{N_B} G_B \end{aligned}\right\} \quad \text{(Eq. 20)}$$

When

$$N_A/N_B = (D_A C_{SA})/(D_B C_{SB}),$$

$$\left.\begin{aligned} G_A &= \frac{D_A C_{SA}}{h} \\ \text{and} \\ G_B &= \frac{D_B C_{SB}}{h} \end{aligned}\right\} \quad \text{(Eq. 21)}$$

Equations 19–21 were applied (41) to the data on benzoic acid–salicylic acid tablet mixtures dissolving in water. Excellent agreement between data and theory was found in this case.

The above equations have a restriction in that they are quantitatively applicable in the steady state only. This requires that the C_{SA} and C_{SB} do not differ too greatly, say no more than a factor of 100 if, for example, the tablet thickness is on the order of millimeters.

If one of the components is very much less soluble than the other, *i.e.*, if either $C_{SA}/C_{SB} \to 0$ or ∞, then the problem reduces to that of solute release from an inert matrix which is discussed under *Drug Release Out of Matrix Systems*. The intermediate ranges have been treated also (41).

This two-phase model has been extended (41) to the case in which the components, A and B, may interact to form a complex, $A \cdot B$, in solution. The resulting equations for this case very nicely agreed with data on the dissolution rate behavior of caffeine–benzocaine mixtures in water. The same basic model was used (39) to derive equations that accurately described the dissolution rate behavior of mixtures of different crystalline forms of drugs. Experimental data with sulfathiazole forms I and II and with methylprednisolone polymorphs agreed well with the theory. The model was also employed in the re-examination of Nelson's data (42) on the dissolution rate behavior of benzoic acid–trisodium phosphate mixtures in water.

The simple nature of this model should allow extension to mixture problems involving more than two phases.

DRUG RELEASE OUT OF MATRIX SYSTEMS

General Considerations—This portion of the

[3] While the diffusion layer theory was used to express the dissolution rate behavior of the surface phases in Eqs. 19–21, the Danckwerts theory could have been used instead.

review[4] is concerned with drug release problems in which the external geometry of the dosage form remains essentially unchanged during drug release. Therefore, cases in this category include drug release from ointments, nondisintegrating tableted matrices, and perhaps from injections of the depot type. The discussion is directed toward the recent *in vitro* type work where attempts have been primarily made to understand the roles played by those factors associated with the dosage form itself. The question of whether conclusions from studies such as these truly reflect the *in vivo* availability is not under scrutiny here.

Special mention should be made that the most significant applications of the physical model approach in this area in recent times are those presented in the reports by T. Higuchi (44–47). These studies form the basis for much of the discussion here. They are also reflected in much of the thinking and research being done today on diffusion controlled release of drugs.

Diffusion Controlled Solute Release Obeying Fick's Law—When Fick's law is obeyed, the diffusion coefficient, D, is constant. For the one-dimensional diffusion of a single solute, we may write

$$\frac{\partial C}{\partial t} = D\frac{\partial^2 C}{\partial x^2} \qquad \text{(Eq. 22)}$$

Here C is the solute concentration at time t and at position x.

Various mathematical solutions to Eq. 22 have provided useful quantitative methods for studying the drug release problem. For planar diffusion to a perfect sink at $x = 0$ from a region, $0 \angle x \angle h$, at a uniform initial ($t = 0$) concentration of C_0, the solution to Eq. 22 is (45, 48–50)

$$Q = hC_0\left[1 - \frac{8}{\pi^2}\sum_{m=0}^{\infty} \times \frac{1}{(2m+1)^2}\exp.\left(\frac{-D(2m+1)^2\pi^2 t}{4h^2}\right)\right] \qquad \text{(Eq. 23)}$$

where Q = amount of drug released to the sink per unit area. It can be shown (51) that Eq. 23 may be approximated rather well by Eq. 24 up to about 30 to 50% drug release,

$$Q = 2C_0\left(\frac{Dt}{\pi}\right)^{1/2} \qquad \text{(Eq. 24)}$$

where Eq. 24 is the solution to the case for h at infinity.

Figure 4 shows how the drug concentration profiles may change with time in the region, $0 < x < h$. It is noteworthy that the slopes of these curves at $x = 0$ give the rate of release at the various times, *i.e.*,

$$\text{rate} = \frac{dQ}{dt} = D\left(\frac{dC}{dx}\right)_{x=0} \qquad \text{(Eq. 25)}$$

and may be obtained by simply differentiating Eqs. 23 or 24 with times.

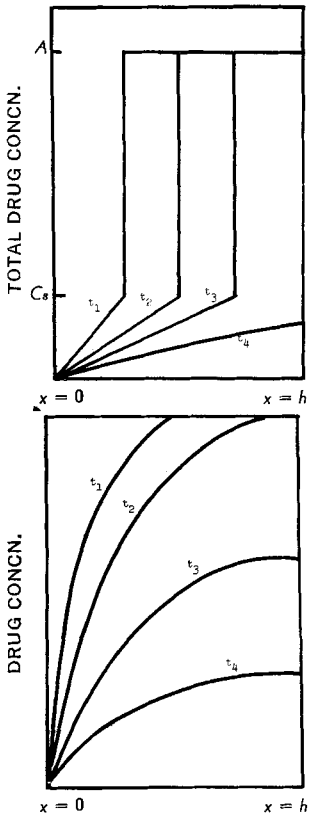

Fig. 4—Concentration profiles for the two situations during drug release to a perfect sink. Solid in matrix (top); solution in matrix (bottom).

It can be seen that if D is known we may easily predict the release rate behavior by means of Eqs. 23–25. While D may always be determined experimentally, it is of interest from the mechanism standpoint to consider the various theoretical methods for predicting D for the different situations.

First of all, there is the well known Stokes-Einstein relation,

$$D = \frac{kT}{6\pi na} \qquad \text{(Eq. 26)}$$

where k is the Boltzmann constant, T is temperature, n is the viscosity of the matrix, and a is the hydrodynamic radius of the diffusing drug molecule. This equation is practically quantitatively applicable when the matrix is composed

[4] The readers are referred to an earlier review (43) on this subject for background.

of solvent molecules that are comparable to or smaller than the diffusing drug molecules so that the microscopic viscosity is close to the macroscopic viscosity. The case when the situation is reversed, *i.e.*, drug diffusion out of polymer solutions or gels, will be discussed later.

The meaning of D when the matrix is heterogeneous has received much attention recently (51–57). A number of approximate relationships have been considered and compared with experimental data.

When the matrix is a suspension or an emulsion, the effective diffusion coefficient, D_e, must be used instead of D in Eqs. 23 and 24. D_e may be obtained from mixture formulas based on analogous electrostatic situations (52, 58–61). Equations 27 and 28 are, respectively, the Bruggeman (59) and the Maxwell-Rayleigh-Lorentz-Clausius-Mosotti-Wagner-Wiener relations for the effective permeability constant, P_e, for a two-phase system consisting of an internal phase of spherical particles dispersed in a continuous phase.

$$\left(\frac{P_e - P_i}{P_c - P_i}\right)\left(\frac{P_c}{P_e}\right)^{1/3} = V_c \qquad \text{(Eq. 27)}$$

and

$$\frac{P_e - P_c}{P_e + 2P_c} = \left(\frac{P_i - P_c}{P_i + 2P_c}\right) V_i \qquad \text{(Eq. 28)}$$

Here the P's are the permeability constants and the V's are the volume fractions of the phases. The subscripts i and c refer to the internal phase and the continuous phase, respectively. Equations 27 and 28 are the two most popular mixture formulas discussed in the literature. Other formulas are available (52), including those which take into account shape effects and the effects of a "coating" of the internal phase. Higuchi (52) considered a semiquantitative mixture relationship that correlated well with literature data.

Now D_e may be calculated (52, 53) with either Eqs. 27 or 28 if we note further that

$$D_e = \frac{P_e}{K_e} \qquad \text{(Eq. 29)}$$

and

$$K_e = K_i V_i + V_c \qquad \text{(Eq. 30)}$$

where K_i is the partition coefficient of the solute between the internal and the external phases.

Koizumi (53) has tested Eqs. 23 and 24 and 27–30 with data on pyridine release from water-in-oil emulsions into an aqueous sink. Agreement of both Eqs. 27 and 28 with data was satisfactory. However, Koizumi's more critical tests were carried out with solute mixtures of pyridine and pyridine hydrochloride to be discussed later.

Higuchi analyzed data on drug release from oil-in-water emulsions. Good consistency of the data (62) with Eqs. 23 and 24 and with the Higuchi mixture formula (52) was found in this instance.

Drug release from inert plastic matrices initially saturated with a drug solution of concentration, C_0, may follow equations similar to Eqs. 23 and 24. Here, for example, instead of Eq. 24 we may write (54)

$$Q = 2\epsilon C_0 \left(\frac{Dt}{\tau\pi}\right)^{1/2} \qquad \text{(Eq. 31)}$$

where $\epsilon \equiv V_c$ = porosity, and τ = tortuosity. The quantity τ may be calculated by means of Eqs. 27 or 28 if the internal phase particles are spherical and impermeable. Thus, if $V_i = V_c = 0.5$, we get $P_e = 0.35P_c$ and $\tau = 1.43$, according to Eq. 27, and $P_e = 0.40P_c$ and $\tau = 1.25$ according to Eq. 28. The Higuchi mixture formula (52) gives $P_e = 0.35P_c$ and $\tau = 1.43$ for this situation.

Desai *et al.* (55) employing Eq. 31 found experimental τ values mainly in the range of 1.3 to 3.0 for polyvinyl chloride compressed tablet matrices when $V_i \simeq 0.60$ to 0.70. This is in very good agreement with the expected values of about 1.4 to 2.0 according to Eqs. 27, 28, and the Higuchi formula (52). When polyethylene plastic tablet matrices were used (55),[5] higher τ values of 6 to 10 were found. This difference in general behavior has been explained (55) on the basis of the much greater plasticity of the polyethylene and the much greater elasticity of the polyvinyl chloride influencing the structures of their respective matrices when the materials are subjected to compaction.

It is worthwhile to point out that both Eqs. 27 and 28 lead to Eq. 32 when V_i is small.

$$D_e = \frac{D_1}{V_c + K_i V_i}\left[1 + 3V_i \frac{K_i D_i - D_c}{K_i D_i + 2D_c}\right] \qquad \text{(Eq. 32)}$$

This equation is not only useful in estimating accurate values of D_e for dilute suspensions and emulsions but also when the matrix is a dilute polymer solution or a gel.

If a gel forming polymer does not bind the drug but acts only to provide some "mechanical" resistance to drug diffusion, Eq. 22 becomes

$$D_e = \frac{D_1}{V_c}\left(1 - \frac{3}{2} V_i\right) \qquad \text{(Eq. 33)}$$

Equation 33 appears to accurately describe (63)

[5] See also Desai, S. J., Ph.D. thesis, University of Michigan, Ann Arbor, Mich., 1966.

the diffusion of sodium and cesium ions in aqueous agar gels.

Suppose a viscous but dilute polymer solution is the matrix with the polymer binding the drug according to a linear law, *i.e.*,

$$M = k_0 C_c \qquad \text{(Eq. 34)}$$

where M = amount of drug bound per unit volume of polymer, C_c = concentration of the drug in the "continuous" phase, and k_0 = constant. Then Eq. 32 should be used with $D_i = 0$ and

$$K_i = \frac{M}{C_c} \qquad \text{(Eq. 35)}$$

If the binding does not obey Eq. 34, then Fick's law will not be obeyed and other methods must be considered. (See under *Diffusion Controlled Release Not Obeying Fick's Law.*)

If a suspension type matrix with $D_i = 0$ is able to adsorb drug according to a linear relation similar to Eq. 34, then equations analogous to 34 and 35 may be used (43) with Eqs. 32, 27, or 28 and Q calculated with Eqs. 23 or 24. Again if the adsorption isotherm is not linear, then the mathematics cannot be handled analytically and numerical methods become necessary. (See under *Diffusion Controlled Release Not Obeying Fick's Law.*)

In all of the preceding discussion involving Eqs. 23 and 24 and the mixture relations, Eqs. 27–30, we have assumed that local equilibrium (52) is maintained, *i.e.*, partitioning or binding occurs rapidly. If local equilibrium is not maintained the equations may not be correct. In this connection, Koizumi (64) has theoretically treated the case where the rate of oil–water interfacial transport becomes important in influencing the rate of drug release from emulsions. It appears safe to state (52) that in most situations the assumption of local equilibrium will be a good one for the small particle sizes normally involved in most emulsions.

Diffusion Controlled Release Not Obeying Fick's Law—For many situations in drug release rate problems, Eq. 22 alone cannot describe the process. In the following we shall consider some of those cases that have been studied.

Diffusion controlled drug release when the drug is dispersed as a solid in a matrix was first studied by Higuchi (45–47). If the matrix is a homogeneous liquid, the one-dimensional theory (planar release) gives

$$Q = \sqrt{D(2A - C_s)C_s t} \qquad \text{(Eq. 36)}$$

where D is the drug molecule diffusion coefficient in the matrix, A is the total amount of drug present in the matrix per unit volume, and C_s is the solubility of the drug in the matrix substance.

If the matrix is heterogeneous and diffusion takes place in the intergranular pores, *e. g.*, drug dispersed in an inert plastic matrix with aqueous pores, instead of Eq. 36 we get

$$Q = \sqrt{\frac{D\epsilon}{\tau}(2A - \epsilon C_s)C_s t} \qquad \text{(Eq. 37)}$$

where D is the diffusion coefficient in the solvent, ϵ = porosity of the matrix, and τ, as before, is the tortuosity.

Figure 4 shows the drug concentration profiles in the matrix at different times in accordance with the theory leading to Eqs. 36 and 37. The concentration gradients from the solid-drug boundary ($x = s$) to the matrix boundary ($x = 0$) are linear as long as $2A \gg C_s$ (for Eq. 36) or $\epsilon C_s \ll 2A$ (for Eq. 37) which is the key assumption in the derivation of these two equations.

Desai *et al.* (54, 55) and Singh *et al.* (56) have made extensive experimental and further theoretical studies of Eq. 37. In their approach several different plastics and several drugs were involved. They independently determined the appropriate D (diffusion cell experiments), the solubility C_s, the appropriate ϵ (two ways), and τ by an independent experiment with the same matrix utilizing Eq. 31. Under the expected conditions (good penetration of the pores and when $\epsilon C_s \ll 2A$) Eq. 37 agreed quantitatively with the experimental data over a wide range of variables.

These investigators also showed (55) that in some instances (polyethylene matrices without surfactant in the solvent) wetting may be poor and therefore the effective τ values may be in the tens of thousands. More recent studies (56) show that in these cases the diffusion controlled model probably fails, and the release rate is determined by the channel penetration rate of the solvent. In other instances (polyvinyl chloride matrices in water) wetting was efficient, but air removal from the matrix significantly altered the drug release pattern.

Desai *et al.* (55) have extended Eq. 37 to take into account the hydrodynamic flow of the solvent in the pores. This refinement was necessary to explain the behavior of moderately soluble solutes.

These investigators have also further extended the same model taking into account the effect of a concentration dependent D and the possibility of linear binding of the drug onto the plastic during the release of drug.

Very recently Singh *et al.* (56) extended the theory to describe the release from mixtures of drugs in an inert matrix. They have derived equations which also take into account the possibility of complex formation between the

components of the phases. The theory is being used to evaluate the data on mixtures currently being gathered in these laboratories.

A very important situation where Eq. 22 fails is in the release of drugs when the partition coefficient, K_i (see Eqs. 30 and 35), is not constant but is dependent on the drug concentration. K_i may vary with drug concentration if (*a*) the drug is a weak acid or a weak base and therefore K_i would be pH dependent, (*b*) the drug molecule associates as carboxylic acids do in mineral oil, or (*c*) the drug binds or complexes according to some nonlinear law, *e.g.*, Langmuir binding, to some component in the system.

Koizumi (53) has investigated the theoretical and experimental methods for handling this situation. By applying Boltzmann's method (48, 49) and employing Eqs. 27 and 28, he numerically computed the drug release rates from emulsions into aqueous sinks when Eq. 37

$$\frac{\partial C}{\partial t} = \frac{\partial}{\partial x}\left(D\frac{\partial C}{\partial x}\right) \qquad \text{(Eq. 37)}$$

rather than Eq. 22 was obeyed. The theoretical predictions agreed very well with experimental data on the release of solute from pyridine–pyridine hydrochloride solute mixtures in water-in-oil emulsions. As expected, the Bruggeman Eq. 27 agreed better with the data than Eq. 26 over a wide range of the solute mixture ratio. The agreement of theory with data was particularly significant because all parameters entering into the theory were determined independently of the rate experiments themselves.

Koizumi also investigated theoretically and experimentally the effect of a membrane (*e.g.*, cellophane) separating the emulsion from the aqueous sink. This is an important practical factor in many *in vitro* experimental methods. This modification gave better agreement of the data with theory under certain expected conditions.

The reviewer believes that with the use of such numerical methods in conjunction with modern computers there is practically no problem that is inaccessible to theoretical analysis. There will be many examples of such attacks on diffusion problems in the future.

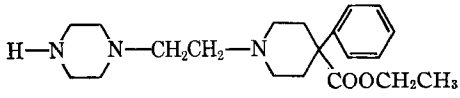
Synthesis of Some *N,N'*-Disubstituted Piperazines as Potential Analgesics

By DOUGLAS C. KRIESEL and OLE GISVOLD

The synthesis and pharmacological screening of some *N,N'*-disubstituted piperazinonorpethidines is described. Certain members were prepared by *N*-alkylating norpethidine, while other analogs were made by condensing an appropriate *N*-monosubstituted piperazine with *N*-(2-chloroethyl)-norpethidine. Two compounds possessed significant analgesic activity although of a lower order than pethidine.

RECENT INVESTIGATIONS have demonstrated that certain *N,N'*-disubstituted piperazines possessed antihypertensive, adrenolytic, and anti-inflammatory properties (1). Some bicyclic structures containing a piperazine moiety have been shown to have analgesic activity (2). It previously had been reported that the *N*-piperazinoethyl analog of norpethidine (I) had ex-



I

hibited no demonstrable analgesic activity when tested in doses of at least 50 mg./Kg. in rats. However, hetero atoms in the four position of a six membered ring analog do not necessarily lead to lowered activity, for *N*-morpholinoethylnorpethidine and *N*-1,4-thiazinoethylnorpethidine were found to be more potent than pethidine (3).

This communication deals with the synthesis of certain *N,N'*-disubstituted piperazines in an attempt to prepare suitable analgesics. The rationale for introducing some selected groups to form some of the desired analogs was drawn from the area of the phenothiazine tranquilizers. The substitution of β-acetoxyethyl and β-hydroxyethyl moieties on one nitrogen of the piperazino group in the 2-chloro-10-piperazinopropylenephenothiazines gave drugs possessing both ataractic and antiemetic properties. The incorporation of these substituents into the piperazinonorpethidines was carried out in order to determine their contributions to analgesic and other activities.

Received August 24, 1966, from the School of Pharmacy, Southwestern State College, Weatherford, OK 73096
Accepted for publication January 3, 1967.
Abstracted from a portion of the thesis submitted by Douglas C. Kriesel to the Graduate School, University of Minnesota, Minneapolis, Minn., in partial fulfillment of Doctor of Philosophy degree requirements.

DISCUSSION

Ethylene oxide was distilled into a solution of *N*-benzylpiperazine in methanol to yield 1-(2-hydroxyethyl)-4-benzylpiperazine, which has been reported by Baltzly (4). The synthesis of 1-(2-chloroethyl) - 4 - benzylpiperazine dihydrochloride (II) was completed by refluxing the substituted alcohol with thionyl chloride. Amination with norpethidine in dimethylformamide afforded the wanted product (XI) which was characterized as the trimaleate. All of the 1-substituted norpethidines were isolated as their trimaleates.

The preparation of 1-(3-hydroxy-*n*-propyl)-4-methylpiperazine was accomplished by following the procedure of McElvain and Bannister (5), *i.e.*, monoalkylation of piperazine with trimethylene chlorohydrin, followed by reductive formylation. Treatment of this product with 48% HBr gave the desired alkyl halide, 1-(3-bromo-*n*-propyl)-4-methylpiperazine (III). Condensing this product with norpethidine yielded *N*-(4-methyl-1-*n*-propylenepiperazino)-norpethidine (XII).

Alkylation of norpethidine with 1-(2-chloroethyl)-4-methylpiperazine[1] in dimethylsulfoxide at 100° for 18 hr. yielded *N*-(4-methyl-1-ethylenepiperazino)-norpethidine (XIII).

Some of the desired compounds were prepared *via* the condensation of β-chloroethylnorpethidine with an *N*-monosubstituted piperazine. A modification of the procedure of Anderson *et al.* (6) gave the desired β-haloamine. One of the monosubstituted piperazine intermediates, 1-(2-hydroxyethyl)-piperazine, was prepared according to the procedure of McElvain and Bannister (5), *i.e.*, by reacting piperazine with ethylene oxide.

A second *N*-substituted piperazine intermediate, 1-(2-ethoxyethyl)-piperazine, was synthesized in two steps as follows: *N*-benzylpiperazine was refluxed in benzene with an equivalent amount of β-bromoethyl ethyl ether to give 1-(2-ethoxyethyl)-4-benzylpiperazine (IV). It was obtained as an oil by fractional distillation and was analyzed as the dihydrochloride (V). Catalytic hydrogenation debenzylated the substituted piperazine yielding the dihydrochloride of 1-(2-ethoxyethyl)-piperazine (VI).

The synthesis of 1-(2-acetoxyethyl)-piperazine (IX) was carried out in a manner similar to that of

[1] Purchased as the dihydrochloride from Aldrich Chemical Co., Milwaukee, Wis.

the ethoxyethyl analog with the exception that debenzylation by catalytic hydrogenation was done in the absence of any aqueous acid in order to prevent any possible hydrolysis of the ester.

β-Chloroethylnorpethidine was condensed with 1-(2-hydroxyethyl)-piperazine, 1-(2-ethoxyethyl)-piperazine, and 1-(2-acetoxyethyl)-piperazine to yield, respectively, products XIV, XV, and XVI.

EXPERIMENTAL

All melting points were taken with a Thomas-Hoover Uni-Melt apparatus. The melting points and the boiling points are uncorrected. With the exception of products XI, XII, and XIII, which were microanalyzed by the Schwarzkopf Microanalytical Laboratory, Woodside, N. Y., all of the elemental analyses were performed by the Microanalytical Laboratory, School of Chemistry, University of Minnesota, Minneapolis, Minn.

1 - (2 - Chloroethyl) - 4 - benzylpiperazine Dihydrochloride (II)—A stirred ice-cold solution of 1-(2-hydroxyethyl)-4-benzylpiperazine (4.0 Gm., 0.018 mole) in 50 ml. of benzene was treated with dropwise addition of thionyl chloride (4.6 Gm., 0.038 mole). The mixture was refluxed for 30 min., cooled, 50 ml. of dry ether added, and the tan solid filtered. After recrystallization from methanol–ether, white crystals resulted. Yield: 2.6 Gm. (46.5%). (Table I.)

1 - (3 - Bromo - n - propyl) - 4 - methylpiperazine Dihydrobromide (III)—A solution of 1-(3-hydroxypropyl)-4-methylpiperazine (3.5 Gm., 0.022 mole) in 160 ml. of 48% aqueous hydrogen bromide was slowly distilled from an all-glass apparatus until 80 ml. of distillate had been collected. After refluxing overnight, the reaction mixture was concentrated to dryness under reduced pressure, and the oily precipitate was triturated in acetone, which rapidly transformed it into a fine brownish powder. The solid was recrystallized from 95% ethanol giving white crystals. Yield: 8.0 Gm. (95.0%). (Table I.)

1 - (2 - Ethoxyethyl) - piperazine Dihydrochloride (VI)—1-(2-Ethoxyethyl)-4-benzylpiperazine (IV) (5.0 Gm., 0.02 mole) was dissolved in a mixture of 15 ml. of 10% aqueous HCl and 45 ml. of 95% ethanol and to it was added 1 Gm. of 10% palladium on charcoal. The mixture then was hydrogenated at 40 p.s.i. for 24 hr. The reaction mixture was filtered through a diatomaceous earth[2] filter bed, and the filtrate was concentrated to dryness *in vacuo*. The resulting white powder was crystallized from a mixture of absolute ethanol and ether. Yield: 2.25 Gm. (48.5%). (Table I.)

1 - (2 - Acetoxyethyl) - 4 - benzylpiperazine Dimaleate (VIII)—To 20 ml. of dimethylformamide was added *N*-benzylpiperazine (10 Gm., 0.057 mole) and β-chloroethyl acetate (7.0 Gm., 0.057 mole). Five grams of anhydrous sodium carbonate was added and the mixture was stirred at 100° for 16 hr. After cooling, 50 ml. of water was added, and the aqueous mixture was extracted three times with ether. The ethereal extracts were dried over anhydrous sodium sulfate, the solvent removed on a rotating evaporator, and the residue fractionally distilled. Yield: 10.0 Gm. (67.5%) (VII). (Table I.) The dimaleate salt was prepared by dissolving the product (0.5 Gm., 0.0019 mole) in 5 ml. of absolute ethanol and adding it to a solution of maleic acid (0.44 Gm., 0.0038 mole) in 5 ml. of absolute ethanol. The white crystals that formed on standing were recrystallized from 85% ethanol. Yield: 0.5 Gm. (53%). (Table I.)

1 - (2 - Acetoxyethyl) - piperazine Dimaleate (X)—1 - (2 - Acetoxyethyl) - 4 - benzylpiperazine (VII) (7.0 Gm., 0.019 mole) was dissolved in 50 ml. of absolute ethanol and to it was added 1 Gm. of 10% palladium on charcoal. The mixture was hydrogenated in a Parr hydrogenating apparatus at 40 p.s.i. for 24 hr. The reaction mixture was filtered through a diatomaceous earth filter bed, and the ethanol removed on a rotating evaporator. The residual oil was fractionally distilled under reduced pressure. Yield: 3.0 Gm., (65.2%) (IX). (Table I.) A portion of the oil (0.5 Gm., 0.0029 mole) was dissolved in 5 ml. of absolute ethanol and added to a solution of maleic acid (0.68 Gm., 0.006 mole) in 5 ml. of absolute ethanol. The white crystals that resulted upon cooling were recrystallized from absolute ethanol–ether. (Table I.)

[a] Calculated as the free base; NA, no activity at 50 mg./Kg.

N - (4 - Methyl - 1 - n - propylenepiperazino)-norpethidine Trimaleate (XII)—Norpethidine[3] (0.5 Gm., 0.002 mole) was dissolved in 10 ml. of dimethylformamide and to it was added 1-(3-bromo-*n*-propyl)-4-methylpiperazine dihydrobromide (III) (0.83 Gm., 0.0022 mole) dissolved in 1 ml. of 20% aqueous sodium hydroxide. The mixture was dried over anhydrous sodium sulfate, anhydrous sodium carbonate (0.39 Gm., 0.003 mole) was added, and the mixture was stirred at 100° for 18 hr. After filtration, the solvent was removed *in vacuo*. The residue, dissolved in 10 ml. of absolute ethanol, was added to maleic acid (0.75 Gm., 0.006 mole) in 5 ml. of absolute ethanol. The white crystals which separated were recrystallized from 95% ethanol. Yield: 0.45 Gm. (31%). (Table II.)

N - [4 - (2 - Ethoxyethyl) - 1 - ethylenepiperazino] - norpethidine Trimaleate (XV)—*N* - (2-Chloroethyl)-norpethidine hydrochloride (0.5 Gm., 0.0015 mole) and 1-(2-ethoxyethyl)-piperazine dihydrochloride (VI) (0.35 Gm., 0.0015 mole) were dissolved in 3 ml. of water and the solution was basified with 5% aqueous sodium hydroxide. Dimethylformamide (10 ml.) was added along with anhydrous sodium carbonate (2.0 Gm.) and the mixture was stirred at 100° for 18 hr. After filtration of the solid, the filtrate was concentrated on a rotating evaporator to an oily residue. The oil was dissolved in 10 ml. of absolute ethanol and added to maleic acid (0.52 Gm., 0.0045 mole) dissolved in 5 ml. of absolute ethanol. The white solid was filtered and recrystallized from 85% ethanol. The yield of white microcrystals was 0.45 Gm. (39%). (Table II.)

[3] Prepared according to the procedure of Thorp, R., and Walton, E., *J. Chem. Soc.*, **1948**, 559.

BIOLOGICAL DATA

Preliminary screening for analgesic activity was carried out using a modification of the procedure described by Eddy and Leimbach (7). Mixed white mice were placed on a metal plate kept at 53° by floating it on top of a circulating hot water bath. Those animals whose reaction time increased to at least twice the mean reaction time for the control animals were assumed to show significant pain relief. The reaction time was the interval from the time the animal was placed on the plate to the time it licked its hind feet or attempted to jump off the container. The test was conducted 30 min. after the required dose was given subcutaneously. The test animals were kept on the plate for a maximal period of 60 sec. The ED_{50} levels were calculated according to the method of Miller and Tainter (8). Pethidine, according to this method, had an ED_{50} of 9 mg./Kg.

Syntheses of Some New Mannich Bases Using 2,6-Dimethylmorpholine as Amine Moiety

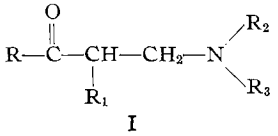
By K. K. KHULLAR and L. G. CHATTEN

The use of 2,6-dimethylmorpholine as an amine moiety in Mannich reaction has been investigated. Nine new Mannich bases have been synthesized using nine different ketones. The salts of β-amino esters have also been synthesized by Mannich reaction using *p*-nitrophenylacetic acid, formaldehyde solution (37 per cent), and three different amines (2,6-dimethylmorpholine, piperidine, and 4-methylpiperidine) followed by esterification. The structures of these compounds have been established by infrared spectra, mass spectra, and elemental analyses.

In their studies on the synthesis of antispasmodics by Mannich reaction (1), Denton and co-workers (2) observed that the most effective amino group in their series from a pharmacological standpoint was piperidyl.

Compounds containing this amine moiety possessed outstanding properties when the acyl group belonged to the propiophenone series which possessed no ring or side chain substituents. In addition, piperidyl was as effective as any other amino group in the propionaphthone series. On the other hand, morpholinyl derivatives generally were the least active. The changes in activity which resulted from structural variations prompted the investigation of the use of substituted morpholines in the Mannich reaction to determine whether the resulting compounds possessed improved activity.

Although Mannich bases containing the morpholine ring as in structure I are known to possess low activity (2), their basic esters have pronounced antispasmodic activity and in general are less toxic than their diethylamine analogs (3). Synthesis of the β-amino acid (Scheme I) has been successfully attempted by Mannich reaction of *p*-nitrophenylacetic acid, formaldehyde (37%), and 2,6-dimethylmorpholine in aqueous medium (4), and the salt of the β-amino ester has been synthesized (Scheme II) by esterification of the appropriate acid by thionyl chloride and methanol (5).



I

For the purpose of comparison of pharmacological activities, salts of β-amino esters have also been synthesized using piperidine and 4-methylpiperidine as amine moieties.

Received August 16, 1966, from the Faculty of Pharmacy, University of Alberta, Edmonton, Alberta, Canada.
Accepted for publication November 7, 1966.
The authors thank Mrs. Pauline Mudry for determining the infrared spectra of the compounds reported here.

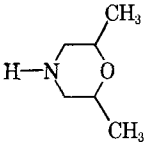
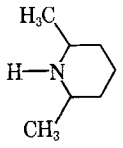
DISCUSSION

2,6-Dimethylmorpholine, b.p. 144–146°/758 mm., was converted into its hydrochloride by passing dry hydrogen chloride gas through a solution of 2,6-dimethylmorpholine in ether. The Mannich bases of type I were obtained by *Method A* (6) (see under *Experimental*). Where a solid product did not separate on cooling, the solvent and unreacted acetone were removed on the evaporator. The resulting residue was recrystallized from acetone. These reactions, in addition to their use in the preparation of compounds which may have antispasmodic activity, will permit speculation on the steric requirements of the Mannich reaction. It is noteworthy that, whereas the reaction proceeds easily and gives crystalline products with sharp melting points with 2,6-dimethylmorpholine, the reactions

fail with 2,6-dimethylpiperidine under similar conditions.



2,6-Dimethylmorpholine



2,6-Dimethylpiperidine

Furthermore, as illustrated by Scheme III, it is intended to convert the morpholino Mannich bases into compounds of type IV by stirring the Mannich base with potassium cyanide and piperidine hydrochloride at room temperature (7). The resulting compounds would appear to possess interesting possibilities as antiperistaltic agents (8) and/or analgesics (9).

Mass spectra of the salts of Mannich bases of type I, recorded by direct probe introduction method using the MS9 mass spectrometer, permit ready elucidation of their structure. In addition, it is hoped to be able to correlate mass spectral data of these bases with their structure-activity relationship as antispasmodics. Since more information is required to substantiate our viewpoint, this report will appear at a later date.

Infrared spectra (10) of the salts of Mannich bases of type I performed on a Perkin-Elmer instrument using Nujol mull appear in Table I. The

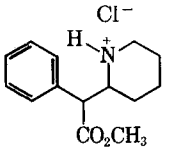
Scheme III

Mannich bases of type II were obtained by *Method B* (see under *Experimental*) (4). Infrared spectra of this type of compound are reported in Table II.

The β-amino acids formed from *p*-nitrophenylacetic acid through the Mannich reaction (type II) are insoluble in water and most organic solvents. These compounds exist as zwitterions, and since zwitterions are usually rather inert pharmacologically, no special attempt was made to purify these amino acids.

The salts of the β-amino esters (type III) were prepared from the amino acids by *Method C* (see under *Experimental*) (5). (Table III.) This type of compound, in addition to being antispasmodic, may also have mild psychomotor stimulant properties for minor neuroses, psychoneuroses, psychoses, and also for narcolepsy, as indicated by its structural similarity to methylphenidate HCl.

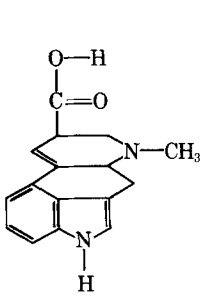
The $-NO_2$ group may increase the toxicity, but the compound without the nitro group may easily



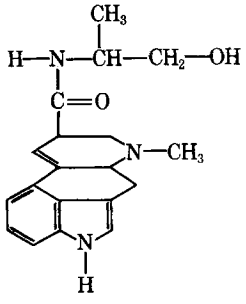
Methylphenidate HCl

be obtained by using phenylmalonic acid in place of *p*-nitrophenylacetic acid.

All the naturally occurring ergot alkaloids are derivatives of lysergic acid. They have been widely



Lysergic Acid



Ergometrine

used as oxytocics, vasoconstrictors, and sympatholytics (11). Bovet and his co-workers (12), through the ingenious design of a series of analogs utilizing the method of disjunction, have provided an answer to the very important and interesting question—whether the three actions of these alkaloids depend on a single pharmacomorphic moiety or whether there are distinct moieties responsible for each type of action. According to them, these actions are indeed separable. They visualized the presence of a sympathomimetic amine structure embedded in the lysergic acid nucleus as in V and VI.

[a] Prepared by *Method C*.

obtained from commercial sources unless otherwise reported.

Method A—A mixture of a ketone (0.10 mole), 2,6-dimethylmorpholine hydrochloride (0.10 mole), paraformaldehyde (0.20 mole), and concentrated hydrochloric acid (0.50 ml.) in 50 ml. of absolute ethanol was heated under reflux. After refluxing for 3 hr., another 0.10 mole of paraformaldehyde was added and refluxing continued for an additional 6 hr. Boiling acetone (200 ml.) was added to the hot mixture with shaking. The resulting solution was allowed to cool overnight, and then in the refrigerator for 3 hr. The crystalline product thus precipitated was filtered. Ethanol–acetone is a suitable solvent pair for crystallization.

Method B—The β-amino acids were prepared according to the procedure of Mannich and Stein (4). A white solid started separating after about 4 hr. The crystalline product thus precipitated after 24 hr. was filtered. The residue was washed twice with absolute ethanol (50-ml. portions) and dried. Some of these acids turn red on standing, probably due to air oxidation.

Method C—Thionyl chloride (20 ml.) was added to the β-amino acid (0.025 mole) dropwise with cooling and shaking. After the completion of addition, the mixture was allowed to stand at room temperature for about 16 hr. During this period, the entire solid went into solution. The unreacted thionyl chloride then was removed on the evaporator. The residue then was taken up in carbon tetrachloride (100 ml.), methanol (20 ml.) was added slowly, and the resulting mixture was refluxed on a steam bath. After about 6 hr., the solvent and unreacted methanol were removed on the evaporator, and a portion of the resulting residue was recrystallized from acetone.

Stability of Metal Complexes of Salicylic Acid Derivatives and Analogs III

3,6-Dialkyl Derivatives and Pyridine Analogs

By WILLIAM O. FOYE, MARTIN D. BAUM, and DAVID A. WILLIAMS

Stability constants are reported for the complexation of a series of 3,6-dialkylsalicylic acids and pyridine analogs of salicylic acid with Cu (II), Fe (III), and Al (III) ions. These compounds were selected in an attempt to increase the affinity of salicylates for ferric ion. The 3,6-dialkyl substituents lowered metal complex stabilities, but the presence of a ring-nitrogen adjacent to the phenolic group increased complex stabilities considerably. The 3,6-dialkylsalicylic acids revealed somewhat greater analgesic effects than salicylic acid, but less anti-inflammatory action.

THE AVIDITY of salicylic acid for complex formation with transition metals has suggested that some, if not all, of the biological effects of salicylates may be due to complexation of metalloenzymes (1). Ample evidence may be found in the literature that salicylic acid or its derivatives become involved in enzymatic reactions; some references of this nature were cited in a previous paper (1), and other examples have appeared since (2–6). Since salicylates apparently affect cellular oxidations, salicylate derivatives which show a greater affinity for iron might be expected to show enhanced biological effects. Increased affinity for iron could be realized in two ways. Introduction of bulky substituents in the 3,6-positions of salicylic acid would tend to crowd the chelating groups together and thus provide a better fit for the ferric ion, which is a relatively small ion (7). Or the introduction of nitrogen into the ring in positions adjacent to the chelating groups might also provide molecules

Stability of Metal Complexes of Salicylic Acid Derivatives and Analogs III

3,6-Dialkyl Derivatives and Pyridine Analogs

By WILLIAM O. FOYE, MARTIN D. BAUM, and DAVID A. WILLIAMS

Stability constants are reported for the complexation of a series of 3,6-dialkylsalicylic acids and pyridine analogs of salicylic acid with Cu (II), Fe (III), and Al (III) ions. These compounds were selected in an attempt to increase the affinity of salicylates for ferric ion. The 3,6-dialkyl substituents lowered metal complex stabilities, but the presence of a ring-nitrogen adjacent to the phenolic group increased complex stabilities considerably. The 3,6-dialkylsalicylic acids revealed somewhat greater analgesic effects than salicylic acid, but less anti-inflammatory action.

THE AVIDITY of salicylic acid for complex formation with transition metals has suggested that some, if not all, of the biological effects of salicylates may be due to complexation of metalloenzymes (1). Ample evidence may be found in the literature that salicylic acid or its derivatives become involved in enzymatic reactions; some references of this nature were cited in a previous paper (1), and other examples have appeared since (2–6). Since salicylates apparently affect cellular oxidations, salicylate derivatives which show a greater affinity for iron might be expected to show enhanced biological effects. Increased affinity for iron could be realized in two ways. Introduction of bulky substituents in the 3,6-positions of salicylic acid would tend to crowd the chelating groups together and thus provide a better fit for the ferric ion, which is a relatively small ion (7). Or the introduction of nitrogen into the ring in positions adjacent to the chelating groups might also provide molecules

Received October 31, 1966, from the Department of Chemistry, Massachusetts College of Pharmacy, Boston, MA 02115
Accepted for publication December 8, 1966.

This project was supported in part by a grant awarded by The Dow Chemical Co., Midland, Mich.

with an increased affinity for iron, which has a greater affinity for nitrogen than oxygen (7).

Both types of salicylate derivatives were therefore prepared, and their complex forming abilities with Fe (III), Al (III) (a still smaller ion), and Cu (II) (a larger ion, but also involved in cellular oxidations) ions have been determined. Some of the characteristic biological effects of salicylates were then determined, and possible correlations with metal-binding strengths were sought. In this way, evidence for a possible mode of salicylate action might be obtained, or more potent salicylate derivatives found.

METHODS

Analytical reagent grade $Fe(NO_3)_3 \cdot 9H_2O$, $AlCl_3 \cdot 6H_2O$, and $CuCl_2 \cdot 2H_2O$ were used, and carbonate-free 0.01 *M* sodium or potassium hydroxide solution was prepared according to Armstrong (8).

The solutions were stored in polyethylene bottles under nitrogen and diluted quantitatively with boiled distilled water just prior to use. The normality was checked against potassium diphthalate. The organic ligands were prepared as described below, and their purity was ascertained by thin-layer chromatography. The method of Reio (9) was used, in which the developing solvent contained methyl ethyl ketone, acetone, formic acid, and water in the ratio of 40:2:1:6. The plates were sprayed with a solution of bromophenol blue in ethanol (0.06%) containing 1 drop of 10% sodium hydroxide solution, and the presence of one spot confirmed the absence of isomers or other impurities.

Melting ranges were determined with a Mel-Temp apparatus and are corrected. Elemental analyses were obtained from Weiler and Strauss, Oxford, England. 3,4-Pyridinedicarboxylic acid was obtained from Aldrich Chemical Co. and was recrystallized to constant melting point (260°) from water.

2 - Hydroxy - 3,6 - dimethylbenzoic Acid—The method of Moody (10) was modified. 2,5-Dimethylphenol (25 Gm., 0.204 mole) dissolved in 200 ml. of xylene was placed in a 1000-ml. Parr autoclave. Granular sodium (9.5 Gm., 0.41 mole) was added and the bomb was sealed and heated at 160° for 3 hr. Xylene (300 ml.) and dry ice (50 Gm.) were added to the cooled contents, and the bomb was resealed and heated at 160° for 10 hr. with periodic shaking. Water (300 ml.) was then cautiously added to the cooled contents, and the mixture was heated, cooled, and separated. The aqueous layer was acidified, and the resulting precipitate was collected and dried. The crude product was purified by complexation with copper sulfate in aqueous solution, filtering, acidifying the filtrate, and collecting the precipitate. The yield was 24 Gm. (90%), m.p. 197–198°. [Lit. m.p. 193° (10).] Further purification resulted by dissolving the product in aqueous sodium bicarbonate, boiling with activated charcoal, filtering, acidifying, and collecting the precipitate, m.p. 200–201°.

Anal.—Calcd. for $C_9H_{10}O_3$: C, 65.05; H, 6.08. Found: C, 65.36; H, 6.41.

2 - Hydroxy - 3 -methyl - 6 - isopropylbenzoic Acid—A modification of the method of Sondern (11) was used. 2-Methyl-5-isopropylphenol (50 Gm., 0.33 mole) was dissolved in 300 ml. of xylene, which was stirred and refluxed, and carbon dioxide was admitted continuously. Granular sodium (15.3 Gm., 0.67 mole) was added during 1 hr., and the mixture was stirred for 5 hr. and cooled. Water was then added slowly until all sodium was spent. The mixture was heated, cooled, and separated, and the aqueous layer was acidified. The precipitate was collected, dissolved in hot alcohol, and the phenol was removed by addition of water. The hot supernate was allowed to cool, and crystals were collected and dried. After recrystallization from ethanol–acetic acid (1:1), a 16% yield was obtained, m.p. 157–158°. [Lit. m.p. 134° (12).]

Anal.—Calcd. for $C_{11}H_{14}O_3$: C, 68.10; H, 7.22 Found: C, 67.81; H, 7.22.

2 - Hydroxy - 3 - tert - butyl - 6 - methylbenzoic Acid—The above procedure was followed, and from 50 Gm. (0.304 mole) of 2-*tert*-butyl-5-methylphenol was obtained a 19% yield of product, m.p. 183–184°. [Lit. m.p. 182° (10).]

Anal.—Calcd. for $C_{12}H_{16}O_3$: C, 69.28; H, 7.75. Found: C, 69.09; H, 7.69.

2 - Hydroxy - 3,6 - dimethyl - 5 - nitrobenzoic Acid—Ten grams (0.06 mole) of 2-hydroxy-3,6-dimethylbenzoic acid was nitrated according to the method of Sondern (11). The crude product was washed several times with ethylene dichloride, dissolved in aqueous sodium bicarbonate, boiled with activated charcoal, filtered, acidified, and collected. A 16% yield was obtained, m.p. 202–205° dec. [Lit. m.p. 182–184° dec. (10).]

Anal.—Calcd. for $C_9H_9NO_5$: C, 51.30; H, 4.26; N, 6.64. Found: C, 51.36; H, 4.47; N, 6.70.

2 - Hydroxy - 3,6 - dimethyl - 5 - aminobenzoic Acid Hydrochloride—The previous product (1 Gm., 0.0047 mole) was dissolved in absolute ethanol (50 ml.) in a hydrogenation bottle, and 1.1 equivalents of dry hydrogen chloride were added. Ten per cent palladium-on-charcoal (0.5 Gm.) was added, and the compound was hydrogenated at 2–3 atm. After reduction was complete, the catalyst was removed, and the alcohol was evaporated. The residue was washed with ethyl acetate, dissolved in hot glacial acetic acid, and precipitated with benzene. The resulting crystals (0.4 Gm., 40%) melted at 245–246° dec.

Anal.—Calcd. for $C_9H_{12}ClNO_3$: C, 49.66; H, 5.56; N, 6.44. Found: C, 49.80; H, 5.27; N, 6.18.

2 - Hydroxypyridine - 3 - carboxylic Acid—The method of Feibel and Spoerri (13) was used. The product melted at 256–257°. [Lit. m.p. 255° (13).]

Anal.—Calcd. for $C_6H_5NO_3$: C, 51.80; H, 3.62; N, 10.07. Found: C, 51.32; H, 3.75; N, 10.20.

3 - Hydroxypyridine - 4 - carboxylic Acid—The method of Bachman and Barker (14) was used. The product melted at 315–316° dec. [Lit. m.p. 315° dec. (14).]

Anal.—Calcd. for $C_6H_5NO_3$: C, 51.80; H, 3.62; N, 10.07. Found: C, 51.52; H, 3.90; N, 10.26.

Ionization Constants—The methods employed were a spectrophotometric procedure for groups having a pKa value below 2 or above 11 and a potentiometric procedure for groups having a pKa

value between 2 and 11. Both methods are fully described by Albert and Serjeant (15).

Stability Constants—Potentiometric titrations were carried out under nitrogen either in 95% ethanol or in distilled water. Fifty-milliliter volumes of 0.001 *M* solutions of the organic acid were titrated with 0.01 *N* sodium or potassium hydroxide in 0.5-ml. portions first in the absence of metal ions and then in the presence of 0.000025 mole of a divalent metal salt or 0.0000167 mole of a trivalent metal salt. Fifty-milliliter volumes of the same quantities of the metal salts were also titrated with 0.01 *N* alkali. The aqueous solutions titrated were first brought to a constant ionic strength with 0.1 *M* potassium chloride. In several instances, titration with alkali did not uncover all the values necessary for calculation of the constants, so resort was made to back titration with 0.01 *N* hydrochloric acid.

In the case of the titrations done in 95% alcohol, pH values were recorded with a Vibron Electrometer (model 33B, Electronic Instruments Ltd.) with a pH attachment and glass (type GG 33) and calomel (type RJ 23) electrodes, as described by Albert and Serjeant (16). After each addition of alkali, the solution was mixed for 2 min. before the reading was made. For the titrations in water, pH values were measured with a Beckman research pH meter using glass and calomel electrodes.

When 3-hydroxypyridine-4-carboxylic acid was mixed with cupric chloride in the above concentrations, precipitation occurred. This required a 0.0002 *M* solution of the acid and 0.0001 *M* solution of cupric chloride to be titrated with 0.002 *N* alkali.

Calculations were done as previously (17), except that $[L^-]$ has been substituted for [Sc] (concentration of free chelating species), βnm for Ks, and P and Q for β and α, respectively, in conformance with present convention. This gives the following equations for the solution of values of $[L^-]$:

$$\log [L^-] = \log([Lo] - [KOH] - [H^+] + [OH^-]) - \log P \quad \text{(Eq. 1)}$$

$$\log [L^-] = \log(2[Lo] - [KOH] - [H^+] + [OH^-]) - \log P \quad \text{(Eq. 2)}$$

The term $[OH^-]$ was generally dropped, since the titrations were not usually carried to a pH of 10, and the term was therefore insignificant. Values of $\bar{n}$ were calculated from:

$$\bar{n} = \frac{[Lo] - Q[L^-]}{[Mo]} \quad \text{(Eq. 3)}$$

If the pH in the presence of metal ion more closely approximated the pH value obtained with the organic acid alone at one equivalent, then Eq. 1 was used; at two equivalents, Eq. 2. Equation 1 was used for the 2-hydroxypyridine-3-carboxylic acid systems, where one proton was apparently picked up by the ring nitrogen, and only one proton was liberated; Eq. 2 was used for the others. Formation curves were also plotted ($\bar{n}$ against $-\log [L^-]$) to show whether stepwise complexation had taken place (18).

Values of K_1, K_2, and K_3 were calculated as before (17) where the difference between log K_1 and log K_2 was at least 2.5. In those cases where the values of log K_1 and log K_2 were closer, K_1 and β_2 were evaluated from Eq. 4 using the method of least squares (15).

$$\frac{\bar{n}}{(\bar{n} - 1)[L^-]} = \frac{(2 - \bar{n})[L^-]}{(\bar{n} - 1)} \beta_2 - K_1 \quad \text{(Eq. 4)}$$

RESULTS AND DISCUSSION

Table I lists the ionization constants determined for the salicylate analogs and derivatives, and Tables II–IV list the stability constants for the complexes with Cu (*II*), Fe (*III*), and Al (III) ions. The values of the stability constants obtained in aqueous alcohol (final concentration approximately 79% ethanol) cannot be considered valid for some purposes, but for comparison of metal-binding abilities with biological effects, these values should suffice. (For a discussion of the irregularities in ionization constants, and consequently in metal-binding constants, to be expected in nonaqueous or mixed solvents, see *Reference 15*, pp. 66–68.) However, the same sequence of complexing abilities should be found in water as in aqueous alcohol. The complexes of these dialkyl-substituted salicylic acids were too insoluble in water to permit pH measurements in meaningful concentrations, despite the use of the more sensitive instrument employed.

Not all values of K_1, K_2, or K_3 could be obtained by titration with alkali, either because of precipitation of the metal complexes, or because in several cases values of $\bar{n}$ less than 1 were not realized. In the latter cases, high affinity of the metal for the ligand probably prevented part of the titration curve from being revealed, and no complexation was evident until one equivalent of alkali had been added (as in the case of the cupric complexes of the 3,6-dimethyl and 5-nitro-3,6-dimethyl derivatives in water). The latter situation was corrected by back titration with acid.

Table I—Ionization Constants (25°)

Acid	Solvent	pKa^1	pKa^2	pKa^3
2-Hydroxy-3,6-dimethylbenzoic	EtOH	6.07	13.20	
2-Hydroxy-3-*tert*-butyl-6-methylbenzoic	EtOH	5.77	13.05	
2-Hydroxy-3-methyl-6-isopropylbenzoic	EtOH	5.70	13.00	
2-Hydroxy-5-amino-3,6-dimethylbenzoic	EtOH	6.37	11.55	
2-Hydroxybenzoic[a]	H_2O	3.00	13.82

3,4-Pyridinedicarboxylic	0.1 *M* KCl	4.06	4.02	3.73	11.81

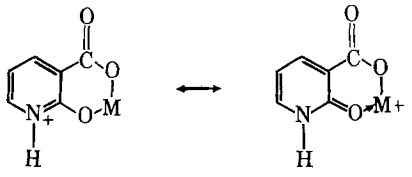
[a] *Reference 17.*

The sequence of complexing abilities found was essentially the same for either the cupric, ferric, or aluminum complexes.

With the 3,6-dialkyl-substituted salicylic acids, the 3,6-dimethyl compound showed more avidity for the metal ions than the more bulky isopropyl or *tert*-butyl derivatives. It also showed less metal-complexing ability in water than salicylic acid itself, so the entire series of 3,6-dialkylsalicylic acids may be considered as having lower complexing ability not only for iron but for the other metal ions observed. Apparently, increased bulk around the chelating carboxyl and hydroxyl functions did not contribute to increased stability, but led instead to increased steric hindrance. Introduction of the 5-amino group also lowered stability, possibly by quinoid contributions by the phenolic group which lowered its basicity. The 5-nitro group lowered stability as would be predicted from its electron withdrawing effect. The presence of a ring-nitrogen atom adjacent to the phenolic group did, however, augment complex stability considerably.

Comparison of the complex stability constants with the ionization constants shows the complex stabilities paralleled by the phenolic ionizations, the greater the basicity of the phenolic group, the greater the stability of the complex. An apparent exception to this may be seen with 2-hydroxypyridine-3-carboxylic acid, where the presence of the ring nitrogen adjacent to the phenolic group would be expected to increase its acidity and thus lower, in some cases, the complex stability constants. The fact that both the phenolic ionization and complex stabilities are greater than those of the 3-hydroxypyridine-4-carboxylic acid suggests that the 2-hydroxy group may undergo tautomerism leading to increased resonance (see structures I and II) and thus increased stability, in the chelate ring. The 3-hydroxy compound is structurally incapable of this tautomerism. That the 5-amino group in the 3,6-dimethylsalicylic acid, also capable of tautomerism, did not show the same enhancement of complex stability may be attributed to the π-excessive character of the 5-amino-substituted ring

and the π-deficient character of the pyridine ring.



I II

Biologic Activities—Results of analgesic testing[1] of the 3,6-dialkyl-substituted salicylic acids showed that both the 3,6-dimethyl and 3-methyl-6-isopropyl derivatives had about 40% greater activity than aspirin, while the 3-*tert*-butyl-6-methyl derivative had about 20% more activity. Analgesic testing was carried out in rats (20 per compound) at compound dosages of 300 mg./Kg. by heating the rat's tail. Because of the lower metal-binding abilities of these acids in water in comparison to that of salicylic acid, it cannot be concluded that greater avidity for metal ions confers greater analgesic effects. It is significant, however, that *o*-thymotic acid also claimed to have a greater analgesic effect than salicylate (19) has also somewhat lower metal-binding constants (1).

Tests for anti-inflammatory and antierythemic effects[2] were also positive for 3,6-dimethylsalicylic acid. In this test, carried out by the method of Winder *et al.* (20), a dosage level of 80 mg./Kg. in guinea pigs produced a decrease in response to U.V.-induced erythema in $^7/_8$ animals, compared to the same response from 100 mg./Kg. of aspirin. In comparison, 3,5-diisopropylsalicylic acid (1) reduced these effects in only $^2/_8$ animals, and both 2-hydroxypyridine-3-carboxylic acid and 3-hydroxypyridine-4-carboxylic acid showed no effects at 80 mg./Kg.

[1] Carried out under the direction of Dr. Howard J. Jenkins.

Constituents of the Rhizome of *Asarum canadense*

By LUDWIG BAUER, CHARLES L. BELL, JAMES E. GEARIEN, and HIROSHI TAKEDA

A pentane extract from the rhizomes of *Asarum canadense* was separated first by means of steam distillation, and then by column and gas chromatography. From the steam-volatile oil the following constituents were isolated (percentages are shown in parentheses): methyleugenol (44.5), linalyl acetate (41.1), geraniol (7.4), linalool (5.3), limonene (0.8), α-terpineol (0.4), bornyl acetate (0.3), aristolone (0.1), elemicin (0.1), 2,3,4,5-tetramethoxyallylbenzene (0.05), 2,4-dimethoxycinnamaldehyde (0.05), and two unidentified compounds (0.01 each). The steam-nonvolatile residue contained some of the above and also β-sitosterol.

THE FRAGRANT essential oil of *Asarum canadense* (Canada snakeroot, wild ginger) has not been investigated since 1902 when Power reported it to contain mainly methyleugenol (3,4-dimethoxyallylbenzene), pinene, and (after saponification) linalool, borneol, terpineol, geraniol, and several unidentified compounds (1, 2). This work set out to re-examine this oil and, in particular, search for minor constituents. Instead of subjecting the ground rhizomes immediately to steam distillation (1, 2), it was advantageous to obtain a pentane extract first which then was separated into a steam-volatile fraction (oil *A*) and a residue (oil *B*). Examination of oil *A*, by gas chromatography (GC) revealed the presence of at least 13 components (Fig. 1, Table

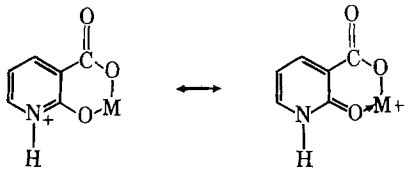
Stahl, Universität des Saarlandes, Saarbrücken, Germany; β-sitosterol from Dr. Percy L. Julian, Julian Associates, Inc., Franklin Park, Ill.

and the π-deficient character of the pyridine ring.



I II

Biologic Activities—Results of analgesic testing[1] of the 3,6-dialkyl-substituted salicylic acids showed that both the 3,6-dimethyl and 3-methyl-6-isopropyl derivatives had about 40% greater activity than aspirin, while the 3-*tert*-butyl-6-methyl derivative had about 20% more activity. Analgesic testing was carried out in rats (20 per compound) at compound dosages of 300 mg./Kg. by heating the rat's tail. Because of the lower metal-binding abilities of these acids in water in comparison to that of salicylic acid, it cannot be concluded that greater avidity for metal ions confers greater analgesic effects. It is significant, however, that *o*-thymotic acid also claimed to have a greater analgesic effect than salicylate (19) has also somewhat lower metal-binding constants (1).

Tests for anti-inflammatory and antierythemic effects[2] were also positive for 3,6-dimethylsalicylic acid. In this test, carried out by the method of Winder *et al.* (20), a dosage level of 80 mg./Kg. in guinea pigs produced a decrease in response to U.V.-induced erythema in $^7/_8$ animals, compared to the same response from 100 mg./Kg. of aspirin. In comparison, 3,5-diisopropylsalicylic acid (1) reduced these effects in only $^2/_8$ animals, and both 2-hydroxypyridine-3-carboxylic acid and 3-hydroxypyridine-4-carboxylic acid showed no effects at 80 mg./Kg.

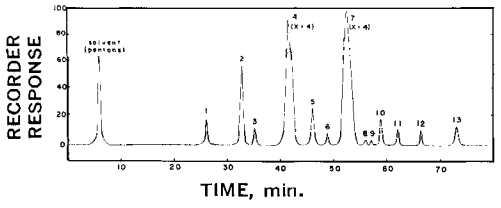

Fig. 1—Vapor-phase chromatogram of the steam-volatile oil, A, from a pentane extract of the rhizomes of Asarum canadense *(20 ft. × 3/8-in. o.d. coiled aluminum column), packed with 20% SE-30 on Chromosorb W, nonlinearly programmed from 90 to 250° over 54 min. using the Autoprep model A-700, the helium flow rate being 200 ml. per minute measured at the outlet of the apparatus. Table I lists the constituents associated with the numbered peaks.*

I) of which two were present in about equal amounts and composed 85% of the oil. Although column chromatography failed to separate the components of oil *A*, this technique served to concentrate the minor constituents somewhat more effectively (see Table II). Each eluate was resolved by means of preparative GC, and the pure components were identified by comparing their various spectra with those of authentic samples and those in the literature. The constituents of the steam-volatile oil *A* are discussed first (Fig. 1, Table I).

DISCUSSION

Monoterpene Hydrocarbons—The first fraction in the GC of *A* was identified as limonene by its mass spectrum (molecular ion *m/e* 136, base peak *m/e* 68), identical to the published spectrum (3), and to that of an authentic sample of dipentene. Since pinene was reported to be present in this oil (2), attempts were made to find this hydrocarbon by examining the mass spectra of all GC fractions before and after chromatography of *A*. Although the retention times (under the conditions for the separation of *A*) and mass spectra of pure α- and β-pinenes were in hand, these hydrocarbons could not be detected. It was observed that after chromatography of *A*, β-myrcene was found in fraction *A*-I which was identified by its NMR (4, 5) and mass spectra (3, 5, 6). This hydrocarbon was definitely not present in oil *A* and it was found that at the same time, the amount of linalyl acetate in *A* decreased from 44 in *A* to 1.8% after chromatography. The suspicion that linalyl acetate underwent elimination was confirmed when a sample of the ester was chromatographed under similar conditions to give β-myrcene, linalool, and unchanged ester in the ratio of 2:1:2. It was interesting to note that alumina acted as a basic catalyst promoting the elimination of acetic acid from linalyl acetate to give β-myrcene only, uncontaminated by *cis*- and *trans*-β-ocimene (5). This reaction is so different from the catalytic pyrolysis of linalyl acetate (7) over acid-washed Chromosorb P at 140–150° to give β-myrcene, *cis*- and *trans*-β-ocimene, and dipentene in the ratio of 43:20:35:2. The conversion of the linalyl acetate to linalool during the chromatography can be explained by either a hydrolytic process due to adsorbed water or by ester interchange during elution with a mixture of chloroform and ethanol.

TABLE I—COMPONENTS OF THE VAPOR-PHASE CHROMATOGRAM SHOWN IN FIG. 1

Peak No.	Component	Retention Time, min.	Compn. Vol., %
1	Limonene	25.4	0.8
2	Linalool	32.5	5.3
3	α-Terpineol	35.0	0.4
4	Linalyl acetate	41.6	41.1
5	Geraniol	46.0	7.2
6	Bornyl acetate	48.5	0.3
7	Methyleugenol	52.0	44.5
8	Unidentified	56.0	0.01
9	Unidentified	57.0	0.01

			Linalyl acetate	10
			Geraniol	40

Monoterpene Alcohols and Esters—In identifying these components, it was possible to make use of the recently published mass spectra of a number of monoterpene alcohols and esters (8, 9). Cognizance was taken of the fact that in a number of instances the mass spectra of alcohols or their esters did not show the parent peak (8), the first peak for the alcohols being at M-18 and for the esters being either (M-RCO-1) or at (M-RCO_2H) (9).

Of the terpene alcohols in the steam-volatile oil *A*, geraniol was found in largest abundance and

was identified by its mass spectrum, which was identical to that of a purified authentic specimen and to the published spectrum (6, 8). Its NMR spectrum ($CDCl_3$) also matched the published one (10), except it was possible to observe the exchangeable OH proton as a singlet at 2.53 δ. α-Terpineol was also present and was identified by its mass spectrum (8) and its NMR spectrum ($CDCl_3$) which showed the vinyl proton at 5.48 δ, a singlet for one CH_3 at 1.75 δ, one for two CH_3's at 1.27 δ. In the steam-volatile oil *A*, linalool was found only in about 4%, but after chromatography its percentage rose to 15.6% (see above). The NMR spectrum of linalool in $CDCl_3$ showed three CH_3 singlets at 1.26, 1.60, and 1.68 δ, the exchangeable OH proton at 2.05 δ, and the alkene protons as complex multiplets between 4.9 and 6.3 δ. The mass spectrum of this sample of linalool also showed a peak at *m/e* 155 (M + 1) which had been noted previously (8) and been the subject of considerable discussion.[1]

Linalyl acetate was the major ester fraction of this essential oil and was found to be quite stable to steam distillation and to GC under the conditions described, but did react on alumina (see above). Its mass spectrum was not included among the terpene esters studied by Sydow (9) and is appended (Fig. 2). Like most terpene esters, it lacked the molecular ion peak at *m/e* 196, and the first fragment appeared at *m/e* 136 (M-60, M-CH_3-CO_2H). At first glance the fragmentation pattern appeared almost like that of β-myrcene—with some additional peaks and changes in relative intensities (see Table III). The peak *m/e* 60 is attributed to acetic acid, a fragment which was observed sometimes in the mass spectra of terpene acetates (9).

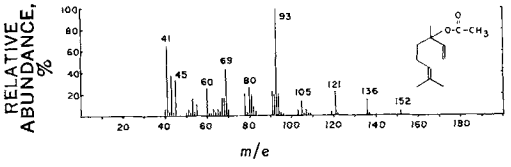

Fig. 2—The mass spectrum of linalyl acetate.

The only other ester which was isolated was bornyl acetate whose NMR and mass spectra matched those of an authentic sample. Although the mass spectra of bornyl and isobornyl acetates are almost identical (9), Biemann (11) was able to distinguish between these two isomers on the basis of the ratio of the abundance of the M and (M-60) ions. The identity of the ester isolated here was established here on the basis of its NMR spectrum ($CDCl_3$), which showed the methine proton as a doublet of quartets at 4.91 δ [previously reported at 5.19 δ, in CCl_4 (12)] which distinguished this ester from isobornyl acetate. Furthermore, the infrared spectrum of the isolated ester matched that of bornyl rather than isobornyl acetate, particularly due to differences in the 1000–1100 cm.$^{-1}$ region.

Aromatic Compounds—Since a number of different alkoxy substituted allyl- and propenylbenzenes have been discovered in several *Asarum* species (13), *e.g.*, asarone [*trans*-1-(2,4,5-trimethoxyphenyl)-1-propene] and *trans*-methylisoeugenol, the predominant ethers in *Asarum europeum* (14), safrole, the principal component of *A. arifolium*, and mainly methyleugenol in *A. caduatum* and *canadense*, a particular effort was made to determine the nature of the aromatic constituents in *A. canadense*.

The major component of the steam-volatile oil *A* was proved to be methyleugenol whose spectra matched those of an authentic sample. It was oxidized by potassium permanganate to veratric acid (see under *Experimental* for the oxidation of elemicin). Its NMR spectrum (neat) showed the benzyl protons as a doublet (with fine structure) at 3.27 δ (J = 6 c.p.s.), the two OCH_3 resonances at

[1] It was suggested by Willhalm, B., Thomas, A. F., and Stoll, M., *Acta Chem. Scand.*, **18**, 1573(1964), that the peak *m/e* 155 stems from contamination of samples of linalool by (*cis* and *trans*) linalool oxides which are almost impossible to separate from the alcohol by chromatography. Since the mass spectra of the oxides [Felix, D., Melera, A., Seibl, J., and Kovats, E., *Helv. Chim. Acta*, **46**, 1513(1963)] contain fragments also present in the mass spectrum of linalool, the origin of the *m/e* 155 peak remains to be discovered.

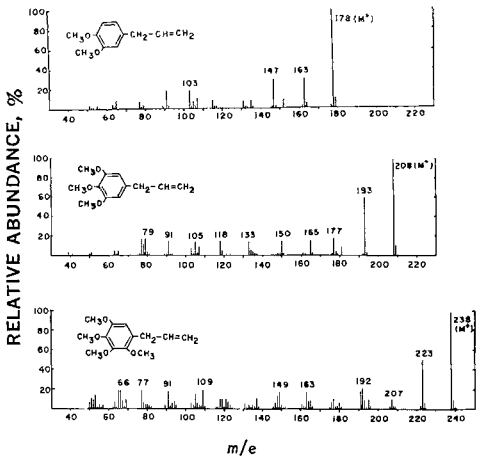

Fig. 3—The mass spectra of methyleugenol (top), elemicin (middle), and 2,3,4,5-tetramethoxyallylbenzene (bottom).

m/e 135.[2] The loss of a methoxy radical from the molecular ion showed the peak at *m/e* 147 (confirmed by the metastable ion at 69.5). The formation of a fragment *m/e* 151 by the loss of a vinyl radical from the molecular ion (M-27) would be expected to produce a substituted tropylium ion whose stability would overcome the relatively unstable vinyl radical. It should be noted that the mass spectrum of methylisoeugenol was quite similar to that of methyleugenol except for the absence of the peak at *m/e* 151 (M-27) in the former.

A small amount of elemicin (3,4,5-trimethoxyallylbenzene) was isolated from oil *A* and was identical to an authentic sample (15). Its structure was proved also by permanganate oxidation to 3,4,5-trimethoxybenzoic acid. Its NMR spectrum ($CDCl_3$) showed one aromatic proton at 6.41δ and the nine OCH_3 protons as a singlet at 3.82δ. The mass spectrum of elemicin (Fig. 3, Table IV) showed that the parent peak (208) was the base peak and the next most intense peak (61%) was *m/e* 193 (M-15) due to loss of a methyl radical,

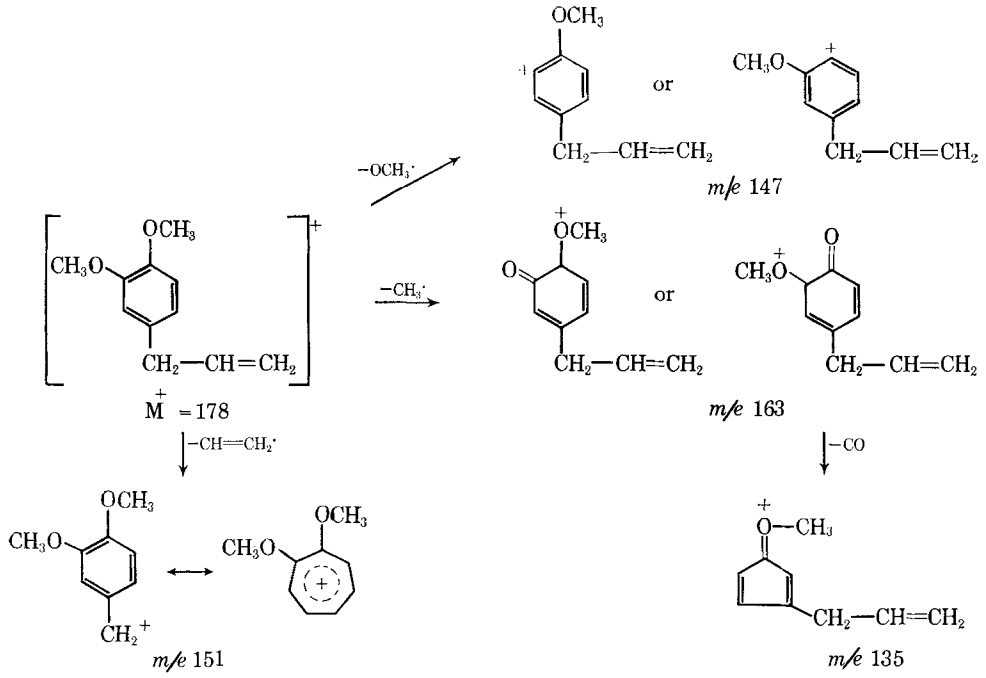
3.66 and 3.67 δ, and the aromatic protons as a singlet at 6.72 δ. The vinyl protons formed an ABC spin system, and that portion of the spectrum resembled the pattern for eugenol and safrol (10). The mass spectrum of methyleugenol (Fig. 3 and Table IV) showed that the parent peak, $M^+ = 178$, was the base peak. Several schemes are suggested to explain some of the peaks observed (Scheme I). Loss of a CH_3 radical produced the peak at *m/e* 163 (confirmed by a metastable ion at 149.2) which might be expected to lose CO to give a fragment (corresponding metastable peak at 179). The peak at *m/e* 184 (M-27) indicated the loss of a vinyl radical (4%), and *m/e* 177 (M-31) also appeared in 15% which is considerably lower compared to that of methyleugenol (25%). The successive loss of a methyl group and carbon monoxide, *m/e* 165 (M-15-28), was confirmed from the metastable peak at 141. A further loss of a methyl radical

[2] It was reported that the mass spectra of *o*- and *p*-dimethoxybenzenes showed peaks at *m/e* 123 (M-15) and *m/e* 95 (N-15-28) due to the successive loss of a CH_3 radical and then CO (*Reference 17*, p. 179).



Scheme I

from 165 produces a peak *m/e* 150, and the corresponding metastable peak at 136.3 was also observed. The initial fragmentation of elemicin may proceed by an analogous path to that of methyleugenol.

A minute quantity of 2,3,4,5-tetramethoxyallylbenzene was isolated whose NMR and mass spectra (Fig. 3, Table IV) were identical to an authentic sample obtained from parsley (16). Its NMR spectrum ($CDCl_3$) showed only three OCH_3 singlets at 3.80, 3.87, and 3.93δ, (in the ratio of 2:1:1) and the aromatic proton at 6.48δ and the pattern usually associated with the allyl group.

The only other aromatic compound which was isolated at this time was methylconiferaldehyde (3,4-dimethoxycinnamaldehyde), which was identical to an authentic sample. Its NMR spectrum ($CDCl_3$) showed the OCH_3 protons as a singlet at 3.80δ, the aldehyde proton at 9.6δ (J = 8 c.p.s.), and the rest of the spectrum similar to that of cinnamaldehyde. Its mass spectrum (Fig. 4, Table IV) showed the base peak at M^+ = 192, and the successive loss of a CH_3 radical (M-15, *m/e* 177, metastable peak at 163.1) followed by the loss of CO (M-15-28, *m/e* 149 metastable peak at 125.4). The successive loss of a OCH_3 radical (M-31, *m/e* 161, metastable at 135) and then CO (M-31-28, *m/e* 133, metastable at 109.1) was also confirmed, this CO stemming probably from the aldehyde side chain, a behavior observed previously in aromatic aldehydes (17).

Safrole could not be detected in any of the fractions collected, nor could there be found any propenylbenzenes. The latter would have shown up readily in the NMR spectra, since the CH_3 doublet of the CH_3CH=CH—group would have been readily discernible.

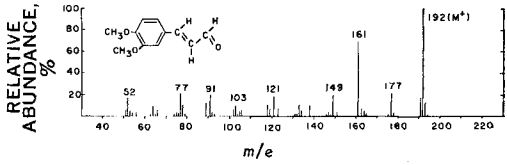


Fig. 4—The mass spectrum of 2,4-dimethoxycinnamaldehyde.

Aristolone—This sesquiterpene ketone was isolated from the steam volatile oil and the nonvolatile residue. It was shown to be identical to a sample previously isolated from *Aristolochia debilis* (18) and to an enantiomer, ferulone, obtained after air-oxidation of ferulene which was found in *Ferula communis* (19).

The structure and stereochemistry of aristolone had been established and the ketone shown to possess a cyclopropane ring (18). Although the cyclopropane protons were identified clearly in the NMR spectra of a number of hydrocarbons possessing the aristolane skeleton (19, 20), these protons were not clearly discernible in our 60-Mc. spectra of aristolone but were identified clearly in the 100-Mc. NMR spectrum[3] in C_6D_6 (Fig. 5, see under *Experimental*).

The mass spectrum of aristolone (Fig. 6) showed the molecular ion peak to be the base peak at *m/e* 218. The major fragmentation peaks were those resulting from loss of 15 (CH_3), 29 (C_2H_5), 43 (C_3H_7), 57 (C_4H_9), 71 (C_5H_{11}), 85 (C_6H_{13}), and 99 (C_7H_{15}) from the molecular ion, the charge remain-

[3] Determined on a Varian HA-100 NMR spectrometer by LeRoy F. Johnson, Varian Associates, Inc., Palo Alto, Calif. The authors thank Mr. Johnson for obtaining this spectrum and also for performing the decoupling experiments.

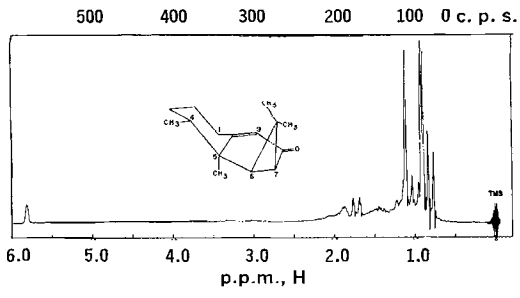

Fig. 5—The NMR spectrum of aristolone in C_6D_6 at 100 Mc.

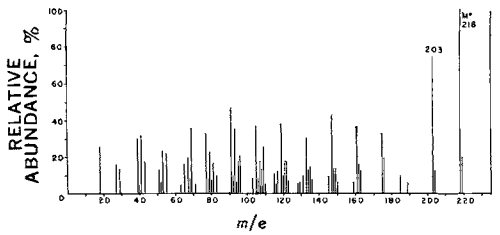

Fig. 6—The mass spectrum of aristolone.

ing with the oxygen-containing fragment. The corresponding metastable peaks for production of the seven fragments were also observed.

β-Sitosterol—This steroid was isolated from the steam-nonvolatile fraction *B* and identified by comparison with an authentic sample. This steroid is widely distributed in plants (21) and interestingly enough has just been found in *A. europeum* (22).

EXPERIMENTAL

Boiling and melting points are uncorrected. Mass spectra were obtained by means of the Hitachi RMU-6D mass spectrometer, ionizing voltage was 75 e.v., inlet temperature for the terpene derivatives being kept to a minimum. In recording the spectra, relative intensities of each fragment above 5% of the strongest line are shown except in the region of the molecular ion where all lines are included. NMR spectra were determined by means of the Varian A-60 spectrometer using tetramethylsilane (TMS) as internal reference, all signals being recorded in parts per million (δ) downfield from TMS. Infrared spectra were taken between salt plates or in $CHCl_3$ solution on a Perkin-Elmer model 337 spectrophotometer.

Gas Chromatography—Preparative GC was carried out by means of the Aerograph Autoprep model A-700 chromatograph using 20-ft. × $^3/_8$-in. o.d. coiled aluminum columns packed with either 20% silicon gum rubber (SE-30) on Chromosorb W (40–60 mesh), or with 20% diethyleneglycol succinate (DEGS) on firebrick (40–60 mesh), both purchased from Wilkins Instrument and Research Co., Inc. All runs were nonlinearly temperature programmed at the "50" power setting, helium was used as the carrier gas, the flow rate was 200 ml./min. as measured at the outlet. For preparative runs, 0.4 to 0.6-ml. aliquots were injected repeatedly, the fractions trapped in 5-ml. glass traps, and cooled in dry ice and 2-propanol. After collection, the fractions were permitted to come to room temperature and reinjected in 1–5-μl. aliquots into a 150-ft. × 0.01-in. o.d. analytical column coated with castorwax (isothermal runs) in a Perkin-Elmer model 800 chromatograph, the flow of helium being 5 ml./min. as measured at the outlet.

Authentic Samples—The following samples were obtained commercially: β-myrcene (Aldrich Chemical Co.), α-pinene and dipentene (K and K Laboratories), geraniol and linalool (Eastman Chemicals), α-terpineol and linalyl acetate (Matheson Scientific Co.), bornyl acetate (Baker Chemical Co.). These were either distilled *in vacuo* or steam distilled and then purified by preparative GC (SE-30 column, Autoprep) under the general conditions described above and the required fraction collected. If the cut was not pure, it was then passed through a column of 30% FFAP on Chromosorb W column (Autoprep) until a pure fraction was obtained.

Methyleugenol was prepared from eugenol in a fashion described for the synthesis of anisole (23), b.p. 156–159° at 40 mm. [Lit. (24) b.p. 237–239°.] Isomethyleugenol was prepared by the isomerization of methyleugenol (10 Gm.) with hot saturated alcoholic KOH (10 ml.) instead of sodium (25) at 200° for 1 hr., b.p. 163–168° at 38 mm. [Lit. (26) b.p. 263°.]

3,4-Dimethoxycinnamaldehyde was prepared (27) from veratraldehyde and acetaldehyde and purified finally by GC, m.p. 84–85°. [Lit. (27) m.p. 82–83°.]

Isolation of Steam-Volatile Oil A—The plants grew in dense patches in shaded areas along the Des Plaines River in the Dam IV Forest Preserve (about 25 miles northwest of Chicago, Ill.) and were harvested (in small samples from each patch) during May 1960 and 1961.[4] Dry rhizomes were also purchased from the Meer Corp. in 1964.[5]

Eight kilograms of dried milled rhizomes were extracted continuously with hot pentane (b.p. 35–36°) for 1 week and the solvent removed (Vigreux column) on the steam bath. The residue (210 Gm., 2.6%) was steam distilled (5 hr.), and the distillate extracted with pentane. Evaporation of the solvent yielded 100 Gm. of a fragrant light yellow oil (*A*) which was examined immediately by GC. (Fig. 1, Table I).

Column Chromatography of Steam-Volatile Oil A—The oil *A* (50 Gm.) was placed on neutral alumina (750 Gm., Woelm, grade I) and eluted with various solvents until no further oil was obtained with a particular solvent (usually about 1.5 L.). Pentane was distilled through a Vigreux column at 760 mm., but other solvents were removed *in vacuo* using a rotatory flash evaporator at the lowest possible temperature, and the residue weighed. Each fraction then was subjected to preparative

[4] The authors thank Mr. Roland F. Eisenbeis, Superintendent of Conservation, Forest Preserve District, for permission to harvest the plants. The authors thank Mr. Floyd A. Swink, Morton Arboretum, Lisle, Ill., who identified the specimens as *Asarum canadense*, the plants usually found in this area, and who pointed out to us that *Asarum canadense* is polymorphic, *sensu latu*. A detailed discussion of the minute differences distinguishing four varieties of *A. canadense* L. is given by J. Steyermark ("Flora of Missouri," Iowa State University Press, Ames, Iowa, 1963, p. 572).

[5] Dr. William A. Meer reported to us that this material was collected during the spring and summer in northwestern Ohio and met the requirements of the N.F. VII.

GC under the conditions described in Fig. 1. The results of these separations are summarized in Table II.

Oxidation of Elemicin—A suspension of elemicin (0.1 Gm.) in aqueous $KMnO_4$ (0.5 Gm. in 10 ml.) was stirred and boiled under reflux for 1 hr. On cooling, $NaHSO_3$ (0.4 Gm.) was added, the mixture acidified with concentrated HCl, and extracted with $CHCl_3$. There was isolated 3,4,5-trimethoxybenzoic acid (0.05 Gm., 50%), m.p. 165°, M^+ 212, and whose infrared spectrum was identical to an authentic sample, m.p. 168° (Eastman Chemicals).

Chromatography of Linalyl Acetate—The ester (1 Gm.) was placed on neutral alumina (20 Gm.), and the following components were eluted and their identity proved by GC (enrichment method): β-myrcene (0.2 Gm., by pentane), unchanged ester (0.2 Gm., by ether), and linalool (0.1 Gm., by chloroform–ethanol, 9:1).

Separation of Steam-Nonvolatile Oil B—The steam-nonvolatile residue (after 5-hr. distillation) was taken up in pentane and the solvent removed. The residual oil (50 Gm.) was placed on basic alumina (750 Gm., Alcoa grade F-20) and eluted by each of the solvents shown in Table V. Some of the fractions then were distilled *in vacuo* and the distillates examined by GC.

Aristolone—The ketone was conveniently isolated from fraction *B*-VI. Short-path distillation of a portion of this fraction (1.5 Gm.) between 100–105° at 0.15 mm. afforded a viscous oil which slowly solidified. Sublimation of this solid at 100–110° at 0.075 mm. yielded the ketone (0.4 Gm.), m.p. 100–101° [lit. (18) m.p. 100–101°], undepressed on admixture with an authentic sample (18). $[\alpha]_D^{25}$ −321.3° (c, 1.5, $CHCl_3$), ν C=O in $CHCl_3$ 1640 $cm.^{-1}$. [Lit. (18) ν C=O in $CHCl_3$ 1658 $cm.^{-1}$.] $\lambda_{max.}^{EtOH}$ 234 (log ϵ 4.18), 310 mμ (log ϵ 2.15). [Lit. (18) $\lambda_{max.}^{EtOH}$ 235 (log ϵ 4.11), 310 mμ (log ϵ 2.07).]

The chemical shifts of aristolone in CCl_4 did not quite agree with those reported (20) (see Table VI), and in particular the cyclopropane resonances were not clearly discernible. However, the 100 Mc. spectrum[4] in C_6D_6 (Fig. 5) showed the resonances of H-6 and H-7 as two doublets, and, as expected, H-7 was considerably more shielded due to the inductive and anisotropic effect of the C=O group. The chemical shifts of H-7 and H-6 compared well with those observed for the α- and β-protons of cyclopropyl ketones (28, 29), and the magnitude of the coupling constant was of the order expected for adjacent *cis* cyclopropane protons (29).

The signal arising from the cyclopropane proton adjacent to the C=O group (H-7) showed fine splitting (J = 1.1 c.p.s.) which was traced to spin–spin interaction with the vinyl proton. This coupling through the carbonyl group (30) was proved by irradiating the vinyl signal (H-9) at 5.77 δ (in C_6D_6) while sweeping the rest of the spectrum which changed the signal at 1.72 δ to a simple doublet. Irradiation of the signal at 1.72 δ (H-7) sharpened the unresolved multiplet at 5.77 δ, and turned the doublet at 0.99 δ to a singlet, thus establishing the chemical shift of H-6. The only other change which was observed by irradiating at 1.72 δ was the collapse of the methyl doublet at 0.80 δ to an ill-defined broad signal, which suggests that the chemical shift of the methine proton at C-4 was in the vicinity of 1.72 δ. A considerable solvent effect

TABLE VI—NMR SPECTRAL DATA FOR ARISTOLONE

Protons and Coupling Constants Involved	C_6D_6 100 Mc.	C_6H_6 60 Mc.	$CDCl_3$ 60 Mc.	CCl_4 60 Mc.	CCl_4[a]
CH_3 Doublet at C-4	0.80	0.81	1.10	1.07	0.93
$J_{CH_3,H-4}$	(6.7)	(6.5)	(6.2)	(6.0)	(6)

[a] Data from *Reference 20.* [b] Doublet not clearly observable. [c] This chemical shift was calculated on the assumption that in this solvent H-6 and H-7 were observed as an AB quartet. However, the fourth line necessary to compute this value would be hidden underneath the CH_3 singlets at 1.22 δ.

TABLE V—CHROMATOGRAPHY OF OIL *B*

Fraction	Eluting Solvent	Yield, Gm.	Comments
B-I	Pentane	9.4	Fractions, b.p. 70–135° at 0.4 mm. (5 Gm.), contained varying quantities of linalool, bornyl acetate, methyleugenol, and elemicin; fractions, b.p. 130–170° at 0.1 mm. (4.0 Gm.), could not be separated and identified.
B-II	Pentane–benzene (9:1)	6.7	Methyleugenol (99%)
B-III	Benzene	12	Fractions, b.p. 80–105° at 0.1 mm. (3 Gm.), consisted of varying mixtures of methyleugenol, elemicin, and 2,3,4,5-tetramethoxyallylbenzene; b.p. 106–125° at 0.1 mm. (1 Gm.) contained aristolone in addition to the ethers.
B-IV	Benzene–ether (9:1)	5.5	Aristolone (see under *Aristolone*)
B-V	Ether	0.5	Not examined further.
B-VI	Ether–chloroform (9:1)	2.0	β-Sitosterol (see under *β-Sitosterol*)
B-VII	Chloroform	2.0	β-Sitosterol (see under *β-Sitosterol*)
B-VIII	Chloroform–ethanol (9:1)	3.0	Linalool (88%)
B-IX	Ethanol	—	

was noted for the chemical shifts of one of the cyclopropane protons (H-7) and that of the CH_3 resonances in benzene and chlorinated solvents. (Table VI). These shifts are attributed to benzene–carbonyl solvent complexes (31) but in the absence of model compounds, no assignment for the chemical shifts of different CH_3 groups is made at present.

Anal.[6]—Calcd. for $C_{15}H_{22}O$: C, 82.51; H, 10.15. Found: C, 82.26; H, 10.29.

Its 2,4-dinitrophenylhydrazone crystallized from ethanol, m.p. 165°. [Lit. (18) m.p. 169–170°.]

Anal.[7]—Calcd. for $C_{21}H_{26}N_4O_4$: N, 14.06. Found: N, 13.90.

β-Sitosterol—Rechromatography of fraction *B*-VI (2 Gm.) on basic alumina (50 Gm.) gave in the ether–chloroform (9:1) eluent a light yellow solid (1 Gm.) which was extracted with hot pentane. The pentane solution was evaporated and the residue recrystallized from ethanol to give the product (0.5 Gm.), m.p. 137°. [Lit. (32) m.p. 137°.] It was undepressed by an authentic sample. $[\alpha]_D^{24}$ −37.07° (c, 0.47 in $CHCl_3$). [Lit. (32) $[\alpha]_D^{25}$ −37.0 ($CHCl_3$).] ν OH in $CHCl_3$ at 3600 cm.$^{-1}$. Its NMR spectrum showed one vinyl proton at 5.38 δ and the >CH—O— proton as a multiplet at 3.50 δ, and the rest of the spectrum was like that published previously (33). Its mass spectrum is reproduced in Fig. 7 and showed *m/e* 414.

Anal.[6]—Calcd. for $C_{29}H_{50}O$: C, 83.98; H, 12.15. Found: C, 83.83; H, 12.26.

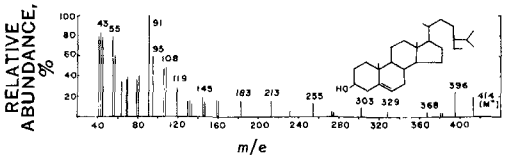

Fig. 7—The mass spectrum of β-sitosterol.

β-Sitosterol Benzoate—A solution of β-sitosterol (0.2 Gm.) in pyridine (1.5 ml.) was treated with benzoyl chloride (0.2 Gm.) and heated over a free flame for 1 min. The solution was poured into ice water, the solid filtered, and washed with 5% K_2CO_3 solution. After crystallization, the solid melted at 143°. [Lit. (32) m.p. 146°.] ν C=O in $CHCl_3$ at 1740 cm.$^{-1}$, M^+ at *m/e* 518.

Absorbance-Stat Method for the Study of Reaction Kinetics in Solution

By KENNETH A. CONNORS and JULIUS H. FAVILLA

A method is described for the kinetic study of reactions in which the concentration of one reactant is held essentially constant by addition of that reactant throughout the course of the reaction; this condition of constancy is attained by maintaining the solution absorbance, which is made a function of reactant concentration, at a constant value. This technique, the absorbance-stat method, is exemplified by alkaline ester hydrolysis, an acid-base indicator being added to the solution. By titrating with alkali to keep the absorbance of the indicator constant, the hydroxide-ion concentration is held constant. The principles of this technique are developed, and the method is compared with the conventional pH-stat procedure. The second-order rate constants of alkaline hydrolysis of methyl and ethyl acetates have been determined. The method is satisfactorily accurate and precise.

In the "continuous-titration" method of studying reactions that produce or consume hydrogen or hydroxide ion, a poorly buffered solution of the reacting substrate is titrated with acid or alkali to keep the pH at an essentially constant value. The rate of addition of titrant is related to the rate of the chemical reaction. As commonly carried out, the procedure utilizes potentiometric detection of the solution pH by means of a glass electrode–saturated calomel electrode system. The titrant can be added manually while its volume and the corresponding time are recorded. During the past decade, however, instruments have been designed to carry out the pH measurement, titration, and recording steps automatically; several of these instruments, called pH-stats, are available commercially. The pH-stat method for studying reaction rates has been reviewed by Jacobsen *et al.* (1). Throughout the present paper the term "pH-stat" will be applied to the continuous-titration method with potentiometric pH detection, whether carried out manually or instrumentally.

The continuous-titration technique appears to have been introduced in 1922 by Knaffl-Lenz (2), who studied rates of enzyme-catalyzed ester hydrolyses. Knaffl-Lenz added an acid-base indicator to the reaction solution to function as a visual pH detector, by titrating to keep the solution a definite color, the pH was maintained constant. Later development of this technique utilized electrometric pH determination, as described above. With the present availability of highly sensitive and stable spectrophotometers, the original colorimetric procedure regains its attractiveness, and in this paper the theory and practice of this technique, which will be called the "absorbance-stat" method, are explored.

Consider the reaction between a substrate S and a reagent R, in which reagent is consumed on a stoichiometric basis.

$$S + R \rightarrow \text{products}$$

The velocity of this reaction is given by the rate equation $v = k\,[S][R]$, where k is the second-order rate constant. When [R] is maintained constant, this takes the first-order form $v = k_{app.}\,[S]$, where $k_{app.}$, the apparent first-order rate constant, is equal to $k[R]$. The absorbance-stat method permits the evaluation of $k_{app.}$ for reactions of two general types. (*a*) Reactions in which R possesses an absorption spectrum such that at a selected wavelength R is the only reaction component that absorbs radiation. Then the absorbance due to R is maintained constant by continuous titration with a solution of R. (*b*) Reactions in which an indicator is added whose absorption intensity is a function of the R concentration; the reaction mixture is titrated with a solution of R to keep the absorbance constant.

The first of these possibilities might be exemplified by oxidations with permanganate or by bromine-addition reactions. The second class includes, as its most important examples, some reactions in which R is hydrogen ion or hydroxide ion. Thus acid-catalyzed amide hydrolysis or alkali-catalyzed ester hydrolysis might be studied by the absorbance-stat method.

In this paper the potentialities of this technique have been investigated by applying it to hydroxide ion-catalyzed ester hydrolyses. The theoretical treatment is also based upon this reaction. With suitable modification the theory can be adapted to other reactions.

PRINCIPLES

Dependence of Titrant Volume on Time—The relationship between the rate of addition of titrant and the rate of chemical reaction must be established to permit evaluation of the reaction rate constant. The reaction is written

Received September 19, 1966, from the School of Pharmacy, University of Wisconsin, Madison, WI 53706
Accepted for publication December 7, 1966.

$$E + OH^- \xrightarrow{k_{OH}} \text{products}$$

with 1 equivalent of hydroxide being consumed per mole of ester hydrolyzed. The solution buffer capacity is assumed to be negligible and the volume change of mixing upon the addition of titrant is neglected. The volume change resulting from conversion of E and OH^- to reaction products also is neglected. The temperature is assumed constant. Then the ester concentration can change through chemical reaction and by dilution with titrant.

$$d[E] = (\delta[E]/\delta t)_V dt + (\delta[E]/\delta V)_t dV \quad \text{(Eq. 1)}$$

The first of these derivatives is given by the rate equation:

$$(\delta[E]/\delta t)_V = -k_{OH}[E][OH] \quad \text{(Eq. 2)}$$

The dilution effect is found by differentiating the definition of concentration, $[E] = q_E/V$, where q_E is the milliequivalents of ester contained in V milliliters of solution. The result is

$$(\delta[E]/\delta V)_t = -[E]/V \quad \text{(Eq. 3)}$$

The differential dV in Eq. 1 can be evaluated from a consideration of the effects of the reaction and the titration on the hydroxide-ion concentration.

$$d[OH] = (\delta[OH]/\delta t)_V dt + (\delta[OH]/\delta V)_t dV = 0 \quad \text{(Eq. 4)}$$

In Eq. 4 the differential $d[OH]$ is set equal to zero, expressing the experimental objective of the continuous-titration method. From the rate equation, the time effect can be found:

$$(\delta[OH]/\delta t)_V = -k_{OH}[E][OH] \quad \text{(Eq. 5)}$$

To find the titration effect, the hydroxide-ion concentration is written

$$[OH] = (\text{meq. of } OH^- \text{ present initially} + \text{meq. of } OH^- \text{ added})/V$$

$$[OH] = (q_{OH} + NV_t)/V \quad \text{(Eq. 6)}$$

where q_{OH} represents the milliequivalents of hydroxide present in the initial sample solution, N is the titrant normality, V_t is the volume of titrant added, and V is the total volume of reaction solution. Therefore, $V = V_0 + V_t$, if V_0 is the volume of sample solution before any titrant is added. Equation 6 is differentiated to give

$$(\delta[OH]/\delta V)_t = 1/k'V \quad \text{(Eq. 7)}$$

where $k' = 1/(N - [OH])$. Equations 4, 5, and 7 can be combined, yielding Eq. 8.

$$dV = k'k_{OH}V[E][OH]dt \quad \text{(Eq. 8)}$$

Substitution of Eqs. 2, 3, and 8 into Eq. 1 gives

$$\frac{d[E]}{[E](1 + k'[E])} = -k_{obs.}dt \quad \text{(Eq. 9)}$$

where a later result has been anticipated by defining $k_{obs.} = k_{OH}[OH]$. Equation 9 gives, on integration,

$$\ln \frac{[E](1 + k'[E]_0)}{[E]_0(1 + k'[E])} = -k_{obs.}t \quad \text{(Eq. 10)}$$

in which $[E]_0$ represents the ester concentration at time zero, and $[E]$ is its concentration at time t. An equation similar to Eq. 10 has been presented by Breuer and Jenkins (3), who, however, give $1/N$ as the value of k'.

The number of milliequivalents of ester initially present is equal to $V_0[E]_0$, which is equal to the number of milliequivalents of hydroxide consumed in the entire reaction, or $V_\infty N$.

$$[E]_0 = V_\infty N/V_0 \quad \text{(Eq. 11)}$$

V_∞ is the volume of titrant added at $t = \infty$. The number of milliequivalents of ester unreacted at time t is equal to the total meq. added minus the meq. hydrolyzed, leading to Eq. 12 for the concentration $[E]$.

$$[E] = N(V_\infty - V_t)/V \quad \text{(Eq. 12)}$$

With Eqs. 11 and 12, Eq. 10 can be expressed in terms of titrant volumes:

$$\ln \left[\frac{V_\infty - V_t}{V_\infty}\right] \left[\frac{V_0 + k'NV_\infty}{(V_0 + k'NV_\infty) + V_t(1 - k'N)}\right] = -k_{obs.}t \quad \text{(Eq. 13)}$$

When $V_t(1 - k'N) <<< (V_0 + k'NV_\infty)$, Eq. 13 becomes

$$\log \left[\frac{V_\infty - V_t}{V_\infty}\right] = -\frac{k_{obs.}t}{2.303} \quad \text{(Eq. 14)}$$

Equation 14 is therefore a satisfactory approximation when $(N - [OH]) \cong N$ or when $V_t <<< V_0$. Though these are separate conditions, they are usually both satisfied by employing a very concentrated titrant solution.

The above considerations apply to both the pH-stat and the absorbance-stat methods. According to Eq. 14, a plot of $\log(V_\infty - V_t)$ against time should be linear with slope equal to $-k_{obs.}/2.303$.

Effect of Volume Change on Indicator Concentration—During the course of the reaction a volume change in the range 1–5% will usually result from the addition of titrant. The case for keeping this change as small as possible was presented in the preceding paragraphs. In the absorbance-stat method this volume change can exert a secondary effect by reducing the total indicator concentration in the reaction solution. This reduction in indicator concentration will lead to an absorbance decrease. Since the absorbance is the quantity that is maintained constant in this technique, the reduction in indicator concentration will be compensated for by a further addition of titrant, which will convert some of the indicator to the more highly absorbing form and thus restore the absorbance to its initial value. (This description supposes that the basic form of the indicator is responsible for the light absorption.) But this means that the pH has changed, because an alteration in the ratio of acid to base forms of the indicator is a reflection of a pH change. Thus, the hydroxide-ion concentration will undergo a small but possibly significant shift during the reaction because of this dilution effect on the indicator.

The possible error from this source has not been analyzed quantitatively because it is easily eliminated. The remedy is simply to add to the titrant the same concentration of indicator that is present in the initial sample solution. Then no matter how much titrant is added, the total indicator concentration will remain constant. By holding the absorbance at a constant value, the pH will

remain unchanged. The experimental problem is not difficult. Proportional amounts of an indicator stock solution are added to the titrant and to the sample solution. The new titrant normality can be calculated from the initial normality and volumes.

Calculation of Second-Order Rate Constants—The preceding considerations provide a basis for the evaluation of the first-order rate constant, $k_{obs.}$ The goal of the kinetic measurements usually is the second-order constant, k_{OH}, which is given by $k_{OH} = k_{obs.}/[OH]$. An estimate must therefore be made of [OH] in the reaction solution. This can be made in two general ways. (*a*) The *concentration* of hydroxide ion, which will be symbolized as c_{OH}, can be obtained; this is based ultimately upon titration data. (*b*) The conventional *activity* of hydroxide ion, a_{OH}, may be found; this is ultimately based upon a potentiometric determination of pH. Writing for the experimental first-order constant the two equivalent expressions

$$k_{obs.} = (k_{OH})^c c_{OH}$$

$$k_{obs.} = (k_{OH})^a a_{OH}$$

shows that the second-order rate constants expressed on the concentration and activity scales are related by Eq. 15,

$$(k_{OH})^c/(k_{OH})^a = a_{OH}/c_{OH} = y_{OH} \quad \text{(Eq. 15)}$$

where y_{OH} is the apparent molar activity coefficient, which in its present use simply has the significance that it is a factor relating the rate constants calculated on these two bases. y_{OH} depends upon the ionic strength of the solution. In most practical situations y_{OH} is appreciably different from unity, and it is essential to distinguish between the rate constants $(k_{OH})^c$ and $(k_{OH})^a$.

pH can be measured potentiometrically at any time during the reaction; then the quantity a_{OH} can be calculated with the use of pKw at the appropriate temperature. (It is assumed here that the reaction mixture is a fully aqueous solution.) In the calculation of second-order hydrolytic rate constants based on pH measurements, the pH determination usually contributes a greater share of error than does the measurement of $k_{obs.}$ The accuracy inherent in the kinetic measurements may be preserved by basing the second-order constant on the concentration, c_{OH}, which can often be established with greater accuracy than can a_{OH}.

If c_{OH} is not to be calculated for the absorbance-stat reaction solution, the exact value of absorbance selected as the static value is not of great importance, and immediately after the reaction is initiated a suitable value can be adopted. But if c_{OH} is to be estimated, the absorbance becomes critical. Suppose the sample solution is prepared with V_S ml. of solvent, V_I ml. of indicator stock solution, and V_A ml. of a standard solution of alkali of normality N_A. At the cell path length and wavelength selected for the kinetic experiment, this solution possesses an absorbance, A'. The reaction is next initiated by adding V_E ml. of ester (either neat or in a stock solution). The absorbance immediately changes because of three effects: (*a*) dilution of the indicator; (*b*) conversion of some indicator from the base to the acid form because of the dilution effect on the hydroxide ion; (*c*) hydrolysis of the ester to reduce the hydroxide-ion concentration. The third effect does not enter the argument because the present concern is to select the proper absorbance value at $t = 0$ before any ester has hydrolyzed, this then being the absorbance value at which the solution will be maintained throughout the reaction. The correct absorbance is obtained by taking the dilution of the indicator into account (Eq. 16),

$$A = A'(V_S + V_I + V_A)/V_0 \quad \text{(Eq. 16)}$$

where $V_0 = V_S + V_I + V_A + V_E$. Even in the absence of the ester hydrolysis, however, the observed absorbance would be less than A because of the dilution effect on hydroxide ion, so the solution is immediately titrated to achieve the absorbance, A, and this value is maintained through the reaction. In effect, this procedure restores c_{OH} to the value it had before addition of the ester. Then the quantity, c_{OH}, to be used in converting $k_{obs.}$ to $(k_{OH})^c$, is obtained with Eq. 17.

$$c_{OH} = V_A N_A/(V_S + V_I + V_A) \quad \text{(Eq. 17)}$$

Sensitivity of the Absorbance-Stat Method—The acid-base indicator equilibrium is

$$HI \rightleftarrows H^+ + I^-$$

and the acid dissociation constant for the indicator may be written $K_I = a_H[I]/[HI]$. The indicator ratio is given by

$$[I]/[HI] = (A - A_{HI})/(A_I - A)$$

where A_{HI} is the absorbance of a solution containing indicator transformed totally to its acid form, A_I is the absorbance when the indicator is in its base form, and A is the absorbance when it is present in any mixture of the two forms; all of these quantities refer to the same total concentration of indicator. The hydrogen-ion activity can be expressed in terms of these absorbances as in Eq. 18.

$$a_H = K_I(A_I - A)/(A - A_{HI}) \quad \text{(Eq. 18)}$$

From Eq. 18 the derivative da_H/dA can be found, and this can be transformed with the relation $d\text{pH} = -da_H/2.3a_H$ to give (in incremental form) Eq. 19.

$$\Delta\text{pH} = \frac{(A_I - A_{HI})\Delta A}{2.3(A_I - A)(A - A_{HI})} \quad \text{(Eq. 19)}$$

This equation provides a basis for evaluating the relative sensitivities of the pH-stat and absorbance-stat methods. Sensitivity in these continuous-titration procedures may be expressed as the smallest change in detector signal that will elicit a response from the titrator mechanism. It will be clear from Eq. 19 that the sensitivity in the absorbance-stat method depends upon the solution absorbance, increasing with concentration of the indicator; moreover, sensitivity is maximal when $\text{pH} = \text{pK}_I$, which corresponds to the condition $A = (A_I - A_{HI})/2$. The relationship of A to pH for any indicator suggests, however, that good sensitivity can be achieved in the approximate range $\text{pH} = \text{pK}_I \pm 1$.

The comparative sensitivities of potentiometric and spectrophotometric control of pH can be demonstrated with Eq. 19 and some hypothetical but reasonable values for the experimental quantities. Suppose $A_I = 2.00$, $A_{HI} = 0.00$, $A = 0.90$, and

ΔA = 0.005. Then Eq. 19 yields ΔpH = 0.0044. Since ΔA = 0.005 seems to be a conservative estimate of attainable spectrophotometric sensitivity, while ΔpH = 0.0044 probably is an optimal sensitivity for the pH-stat, it appears that the absorbance-stat should be capable of more sensitive response to the changing solution conditions than is the pH-stat.

EXPERIMENTAL

Materials—Ethyl acetate (Baker and Adamson reagent grade) was distilled, b.p. 76–77°. Methyl acetate (Matheson Coleman & Bell) was distilled, b.p. 55–56°. Alizarin yellow R (Coleman & Bell) was used directly. Other chemicals were of reagent or primary standard grade. All water was redistilled from alkaline permanganate.

Indicator stock solution was prepared by dissolving 25 mg. of alizarin yellow R in 0.5 ml. of 1.0 *N* sodium hydroxide; this was diluted to 50 ml. with water, the solution was allowed to stand overnight in a refrigerator, it was filtered, and 25 ml. of the filtrate was diluted to 50 ml. with water.

Apparatus—Reactions were carried out in a flask originally designed for photometric titrations (4). The flask (capacity about 120 ml.) was constructed with a jacket through which water was circulated from a constant-temperature water bath. This apparatus was mounted directly over an air-driven magnetic stirrer, the entire assembly being placed near the thermostated cell compartment of a Cary model 14 recording spectrophotometer. Short lengths of rubber tubing connected the inlet and outlet of the reaction flask to a flow-through spectrophotometer cell that was firmly positioned in a cell holder in the sample cell compartment. A Teflon-covered stirring bar provided the stirring and pumping action. The reaction flask was tightly closed with a rubber stopper, through which passed the tip of a 2-ml. micrometer buret (Roger Gilmont Instruments); the buret tip extended below the surface of the reaction solution.

pH measurements were made with a Sargent model DR pH meter equipped with a wide-range glass electrode.

Procedure—A typical experiment was conducted as follows. To the reaction flask 75.0 ml. of freshly boiled water, 3.0 ml. of indicator stock solution, and 5.0 ml. of standard 0.1 *N* sodium hydroxide were added. This solution was allowed to reach temperature equilibrium. The spectrophotometer wavelength selector was set at 495 mμ (the absorption maximum of the base form of the indicator), and the recorder was activated. About 2 meq. of ester was added to initiate the reaction. From the buret 1 *N* NaOH was added to keep the absorbance as constant as possible; the chart tracing is a helpful aid in minimizing the fluctuations about the mean absorbance value. The titrant volume was recorded as a function of time; reactions were followed until no further change in absorbance was observed. All reactions were carried out at 25.0°.

RESULTS AND DISCUSSION

Ethyl acetate was selected as the ester for the developmental stage of this investigation because its hydrolysis is uncomplicated, it is water soluble, and many other studies of its alkaline hydrolysis have been made; its volatility is a disadvantage. Alizarin yellow R was found to be a suitable indicator in the pH range required to give a convenient rate of reaction. This indicator possesses good sensitivity from pH 9.8 to 11.8, and it is adequately stable under these conditions.

The volatility of ethyl acetate prevented the use of a nitrogen stream as protection against atmospheric contamination, and it was necessary to stopper tightly the reaction flask to prevent absorption of carbon dioxide from the atmosphere as well as loss of ethyl acetate to the atmosphere. After such sources of error were eliminated, very well-behaved kinetic data were obtained. Figure 1 shows a characteristic plot of titrant volume as a function of time. The first-order plot according to Eq. 14 is shown in Fig. 2; the line is straight over about 4 half-lives, and this behavior could be reproduced at will. The V_∞ value tended to rise slightly with unrealistically long periods of waiting, probably because of a slight decomposition of the indicator, so the V_∞ value used in the calculations was taken after the expiration of 7 to 9 half-lives. With the conditions described here, it was found unnecessary to incorporate indicator in the titrant.

The mean value of $(k_{OH})^c$ for ethyl acetate at 25.0° was found, from such measurements, to be 0.103 L./mole-sec., with a standard deviation of 0.0013 L./mole-sec. This must be considered

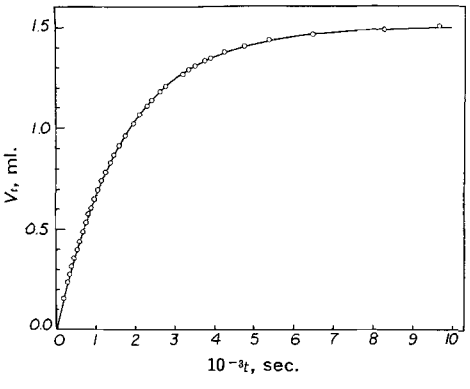

Fig. 1—Plot of titrant volume against time for the absorbance-stat study of the alkaline hydrolysis of ethyl acetate at 25°; c_{OH} = *0.00569* N, *absorbance = 0.64.*

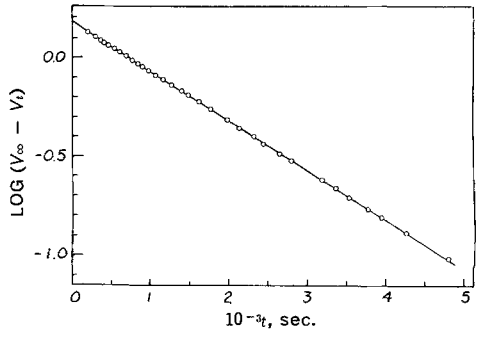

Fig. 2—First-order plot of the data shown in Fig. 1.

excellent precision, and it reflects the very good reproducibility of the observed first-order rate constants. The mean value of $(k_{OH})^a$, from these same determinations, was 0.126 L./mole-sec., with a standard deviation of 0.012 L./mole-sec., and this poorer precision is a result of the difficulty in obtaining precise pH measurements. In these studies the pH was in the range 11.6–11.8.

Literature values of $(k_{OH})^c$ for ethyl acetate at 25° vary widely. Terry and Stieglitz (5) give the value 0.113 L./mole-sec. with a claimed accuracy of 0.75%; they also review earlier reports, with the mean value of six workers being 0.110 L./mole-sec. (ranging from 0.106 to 0.114). Salmi and Kantola (6) found 0.109 L./mole-sec., Shrivastava (7) reported 0.091 L./mole-sec., Myers *et al.* (8) gave 0.111 L./mole-sec., and Flom and Elving (9) found 0.110 L./mole-sec. (standard deviation 0.010). Wilson and Terry (10) observed a progressive decrease of the rate constant with increase in ionic strength (NaCl), with the constant dropping from 0.113 with no NaCl present (initial NaOH 0.01 molal) to 0.102 L./mole-sec. at 0.51 *M* NaCl. Bell and Waind (11), however, found that increasing concentrations of NaCl up to 0.5 *M* had no significant effect on the rate constant; they reported values in the range 0.099–0.101 L./mole-sec. The value of 0.103 L./mole-sec. obtained in the present study, therefore, lies close to many reliable literature values, though it may be slightly lower than the best value.

Methyl acetate was also studied by the absorbance-stat method. The mean $(k_{OH})^c$ for this ester at 25° was 0.186 L./mole-sec., with a standard deviation of 0.0075 L./mole-sec. [Gooch and Terry (12) give 0.195 L./mole-sec. for this constant.] The same data yielded, for $(k_{OH})^a$, the mean value 0.226 L./mole-sec. (standard deviation 0.067).

Guggenheim's method (13) of plotting first-order rate data was also applied to all experiments, and the rate constants obtained from these plots agreed closely with those from the conventional graphs. The Guggenheim method obviates the necessity of obtaining a value for V_∞, which may be subject to small errors caused by indicator instability, carbon dioxide absorption, or spectrophotometer base line drift.

Other indicators could doubtless be used, especially in the less alkaline pH ranges. Attempts to locate suitable indicators for use above pH 12 were unsuccessful, the substances studied being too unstable for practical use.

The absorbance-stat method for studying reaction rates appears, on the basis of the analysis and results reported in this paper, to be a useful technique for the precise and accurate determination of rate constants in suitable systems. The procedure could easily be placed on an automatic basis by substituting a photometer for the pH meter as the detector in a conventional pH-stat. The absorbance-stat is potentially more sensitive than is the pH-stat. These two techniques will probably complement each other, for the absorbance-stat method will not be successful in heterogeneous systems where the pH-stat might perform satisfactorily, while the absorbance-stat will function in systems (such as low dielectric constant solutions) that might vitiate measurements with the glass electrode; moreover, the absorbance-stat is not limited to reactions involving solvent ions.

Colorimetric Analysis of Organic Hydroxyl Groups

By GERALD R. UMBREIT* and RONALD L. HOUTMAN

The reaction of 3,5-dinitrobenzoyl chloride with organic hydroxyl groups has been adapted to provide a colorimetric method of analysis. The ester formed by this reaction is subjected to conditions of controlled basicity after hydrolysis of the excess reagent. A red color is formed by the ester which is stable after 30 min. for an additional 20 min. or more, and is measured at 555 mμ *versus* a reagent blank. Tertiary alcohols react too slowly to interfere, and tertiary amines do not react. Phenols, primary and secondary amines, and certain thiols react similarly to hydroxyl groups and can be determined by this method. The procedure is rapid, simple, and accurate.

THE PRODUCTION of color on the addition of base to polynitroaromatics is well known. It has been used as a means of qualitative and quantitative determination of nitroaromatics by Porter (1). Berezin (2) and Robinson, Cundiff, and Markunas (3) have described the use of 3,5-dinitrobenzoyl chloride for the determination of alcohols in which the excess reagent is hydrolyzed and titrated with base. The end point of the titration is indicated by color formation due to the 3,5-dinitrobenzoate ester of the alcohol and the 3,5-dinitrobenzoate anion. Robinson, Cundiff, and Markunas (3) also pointed out that the ester could be determined directly by potentiometric titration since the end point potential is sufficiently removed from that for the anion to allow a differentiating titration.

A number of other excellent methods are available for the titrimetric analysis of hydroxyl compounds on a milligram or larger scale (5, 10–12). At the sensitivity level of colorimetric analyses several methods are available for specific hydroxyl types. As examples, those of Dal Nogare and Mitchell (4), Schreiber and Eschenmoser (5), and Critchfield and Hutchinson (6) may be cited.

However, few generally applicable colorimetric hydroxyl methods are available. The method of Baggett, Engel, and Fielding (7) may be adapted to general use for all hydroxyl compounds which are subject to acetylation. Acetylation is also the basis of a method proposed by Gutnikov and Schenk (8) which utilizes the ferric hydroxamate reaction after acid-catalyzed esterification of the hydroxyl functions. The sequence of reactions involved necessarily makes this a complex procedure, though it has the compensating advantage of allowing analyses of tertiary alcohols and avoids interference by amines. The method of Johnson and Critchfield (9) utilizes the 3,5-D reaction. It also has the advantage of eliminating amine interferences because of an extraction step, but has several disadvantages when compared to the method described here. Satisfactory response was not obtained by these investigators with diols. Larger volumes and more complex treatment are required, and the color produced is not stable for more than 4 min. The method proposed here is markedly superior on each of these points.

The information reported by Robinson, Cundiff, and Markunas (3) indicated the possibility that the 3,5-dinitrobenzoate esters become colored in a system of lower basicity than that required to produce color with 3,5-dinitrobenzoic acid. The problem of capitalizing on this differential color development was then to devise a system wherein the ester was primarily in the colored state, and the acid was not, and to maintain this condition long enough for convenient measurement. The method described here presents an approach based on this concept.

The method involves formation of the 3,5-dinitrobenzoate ester by reaction of the hydroxyl compound under study with a large excess of 3,5-dinitrobenzoyl chloride in pyridine–dimethylformamide. The excess reagent is hydrolyzed, the resulting mixture buffered with a saturated solution of ammonium acetate in acetone, and concentrated ammonia is added. Final dilution is made with acetone. Under these circumstances only faint color is developed with a reagent blank, and is probably due to impurities in the solvents used. The measurement is made at 555 mμ with a suitable spectrophotometer or colorimeter.

EXPERIMENTAL

Reagents and Apparatus—3,5-Dinitrobenzoyl chloride (Eastman White Label reagent), 540 mg., is dissolved in 2 ml. of dry dimethylformamide. This solution is stable for at least 72 hr. A saturated solution of ammonium acetate is prepared in dry acetone at 25° to 29°. The Cary model 11, Beckman DU, and Beckman B spectrophotometers were used in this study.

Procedure—One milliliter of the sample solution (25–300 mcg./ml. in dry pyridine) is transferred to a 10-ml. volumetric flask. One-tenth milliliter of the

Received October 12, 1966, from the Research Laboratories, The Upjohn Co., Kalamazoo, MI 49002
Accepted for publication December 20, 1966.
* Present address: Greenwood Laboratories, Chadds Ford, PA 19317

3,5-dinitrobenzoyl chloride solution is added, and the mixture is allowed to stand for 15 min. at room temperature. Approximately 0.25 ml. (5 drops) of water is then added, and hydrolysis of the excess reagent is carried out by heating on a steam bath for 5 min. When the sample has cooled (5 to 15 min.), 2 ml. of the buffer solution and 0.5 ml. of concentrated (15 *N*) ammonium hydroxide reagent are added. After 30 min. the mixture is diluted to 10 ml. with acetone and the absorbance measured at 555 mμ *versus* a similarly prepared reagent blank. The color is stable for at least an additional 20 min.

DISCUSSION

Table I summarizes analytical data obtained for a variety of compound types by this method. In every case, except the tertiary hydroxyl compound (*tert*-butyl alcohol), the response is linear over the normally useful absorbance range. The absorption spectrum as shown in Fig. 1 for ethanol is essentially identical for all compounds listed in the table.

All the listed compounds were determined using the procedure exactly as described above. It is possible that increased reaction time or temperature for the esterification may result in a satisfactory response for tertiary hydroxyls. Careful limitation of reaction time will permit the determination of primary or secondary alcohols in the presence of approximately equivalent amounts of tertiary alcohols (9).

The failure of 2-mercaptobenzothiazole to react may be due to a possible opening of the lactone ring resulting in a nonreactive structure. Mercaptoacetic acid yielded color immediately upon addition of the dinitrobenzoyl chloride reagent. However, this color remained stable throughout the balance of the analytical procedure and presented no difficulties.

The problem of buffering at an appropriate level of basicity to provide reasonable sensitivity without excessive color in the blank solution was most critical. This was dealt with in the following manner.

Table I—Application of the Method

Compd.	Taken, mcg.	Found, mcg.	Error, mcg.
Ethanol	200	203	3
1-Propanol	200	193	7
1-Butanol	200	189	11
2-Butanol	200	204	4
1,3-Propanediol	100	97	3
Testosterone	200	196	4
11α-Hydroxytestosterone	100	101	1
11α-Hydroxyprogesterone	200	202	2

and 3,5-dinitrobenzoyl chloride reagent. The titration was carried out potentiometrically beyond the second break (titration of the benzoate ester) using a glass-saturated calomel electrode system and one of several different bases as titrant. Following this, solid sodium or ammonium acetate was added to determine whether the potential of the solution could be reversed partially and made to stabilize at the beginning of the second break. At this point, color development due to the ester is near a maximum, while color due to the 3,5-dinitrobenzoic acid is negligible. In this manner solvent systems involving pyridine, acetonitrile, dimethylformamide, acetone and chloroform alone, and some selected mixtures, were tested to arrive at the solvent mixture used in the procedure. Tetrabutylammonium hydroxide (1 *M* in methanol) and KOH (1 *M* in water) were tested as bases before turning to concentrated ammonia.

It is obvious that any of the reactive compound types would constitute a positive interference in the analysis of any other. Similarly, reactive acyl functions (anhydrides or halides) will tend to show negative interference depending on the efficiency with which they compete with the 3,5-D reagent for the available hydroxyl groups. The fact that both hydrochloric and 3,5-dinitrobenzoic acids are formed during the esterification reaction indicates that these types of compounds would not constitute interferences if present in small amounts. Water will react preferentially with 3,5-D, but will not interfere seriously unless present in sufficient quantity to consume a large proportion of the available reagent. Additional compounds which have been tested and shown not to interfere seriously in the determination of hydroxyl groups are summarized in the data of Table II. Note also in Table I that the multifunctional steroids imply a lack of interference by unsaturated moieties and by simple and conjugated ketones.

SUMMARY

A method has been presented and described for the colorimetric determination of organic alcohol, amine, and thiol groups. The method is free of interference from most common solvents and other functional groups. The procedure is rapid and the resulting products are adequately stable to provide ease of measurement.

Behavior of Erythrocytes in Various Solvent Systems III

Water–Polyethylene Glycols

By B. LESTINA SMITH* and DONALD E. CADWALLADER

Hemolytic behavior of human and rabbit erythrocytes in aqueous solutions of polyethylene glycol (PEG) 200, 300, 400, and 600 was investigated. Complete hemolysis occurred in all PEG 200 and 300 solutions, with discoloration occurring in $\geq$ 25 per cent PEG 200 and $\geq$ 15 per cent PEG 300 solutions. Sodium chloride was effective in preventing hemolysis in $\leq$ 25 per cent PEG 200 or $\leq$ 40 per cent PEG 300 solutions. When possible, *i* values were calculated for sodium chloride in the various water–PEG 200 and 300 solutions. PEG 400 and 600 protected blood cells from damage in > 10 per cent to < 40 per cent solutions, and *i* values were calculated for these PEG's. Solutions containing $\geq$ 40 per cent PEG 400 or 600 (with and without NaCl) were damaging to red cells. The ability of liquid PEG's to penetrate rabbit and human erythrocytes appeared to be 200 > 300 > 400 > 600.

PREVIOUS PAPERS in this series have reported the behavior of erythrocytes in various water–glycerin and water–propylene glycol systems (1, 2). Among other nonaqueous solvents that might be used in the preparation of parenterals would be the liquid polyethylene glycols.

Polyethylene glycols (PEG's) are products possessing a very low order of toxicity. Spiegel and Noseworthy (3) have reviewed the physical properties, toxicities, and parenteral applications of these liquids. Skin penetration studies on

many of these products show that they do not penetrate the skin in harmful amounts (4). Meyer and Sturmer (5) reported low oral and subcutaneous toxicities of PEG 200 and 600 in mice. Swanson and co-workers (6) found that sodium amobarbital in 60% PEG 200 and sodium secobarbital in 50% PEG 200 had approximately the same potency and toxicity as aqueous solutions of these barbiturates. Lee and Anderson (7) determined the toxicity of vancomycin in 50% PEG 200 and of PEG 200 alone. Their results indicated that PEG 200 produced no apparent toxic effects when given to dogs at 1.0 ml./Kg./day for 80 days intramuscularly, or 0.5, 1.0, 2.5, and 5.0 ml./Kg. as single intravenous doses.

The purpose of this investigation was to conduct experiments to study the behavior of red blood cells in aqueous polyethylene glycol solutions. Experiments were designed to determine the effect that aqueous solutions of PEG's 200, 300, 400, and 600 have in preventing hemolysis alone, and in the presence of sodium chloride.

EXPERIMENTAL

Materials—Polyethylene glycols 200, 300, 400, and 600, supplied by Union Carbide Chemical Corp., were used without further purification. The sodium chloride used was reagent grade.

Collection of Blood—Approximately 10 ml. of blood was obtained from rabbits by heart puncture. An 18-gauge, 2-in. needle attached to a 10-ml. syringe was used to make entrance into the heart. The blood was placed in a 50-ml. round-bottom flask which contained 10–15 glass beads. After gently rotating the flask for approximately 5 min., the defibrinated blood was decanted into a 50-ml. conical flask. The blood was aerated by gently swirling the flask for about 5 min.

The human blood used was obtained from the forearm veins of several 20–25-year-old healthy male Caucasians. The blood was treated in the same manner as the rabbit blood. Fresh blood samples were used in all experiments.

Preparation of Solutions—All of the polyethylene glycol and sodium chloride solutions were weight-in-volume percentage preparations.

Quantitative Determination of Per Cent Hemolysis—The method used to determine the degree of hemolysis in this investigation was dependent upon the fact that the amount of oxyhemoglobin liberated from the red corpuscles in hypotonic solutions is a direct function of the number of cells hemolyzed. A quantitative determination of partial hemolysis in any mixed solvent system was made by centrifuging solutions containing unhemolyzed cells and determining the oxyhemoglobin in the supernatant solutions by means of a photoelectric colorimeter.

The general method consisted of transferring 5 ml. of standard sodium chloride solutions (0.34, 0.36, . . ., 0.44, 0.46%) into each of two test tubes. Identical amounts of the mixed solvent systems were also transferred into each of two test tubes. Then 0.05 ml. of blood was added to each test tube and the tubes inverted several times to obtain complete mixing. After 45 min. at 37°, the blood mixtures were centrifuged. Because of the viscosity of the PEG solutions, especially in high concentrations, it was necessary to use centrifuge speeds of 2000–3000 r.p.m. to bring about complete settling of intact cells. After centrifuging, the light absorbance of the supernatant liquid was measured using a Klett-Summerson photoelectric colorimeter equipped with a No. 54 filter. These absorbance readings were divided by the absorbance readings for 0.05 ml. of blood in 5 ml. of distilled water (standard for 100% hemolysis) and multiplied by 100 to obtain per cent hemolysis occurring in each test solution. A blank, used to cancel any light absorbance inherent to the blood sample, was prepared by placing 0.05 ml. of blood in 0.9% sodium chloride solution, allowing to stand for 45 min., and centrifuging in a like manner.

Water–PEG solutions absorbed a small amount of light, and this absorbance increased with an increase in PEG content. This absorbance was determined for the various concentrations of PEG's used in the experiments, and these blank readings were subtracted from the colorimeter readings obtained at the end of the hemolysis experiments.

A battery-operated model M Beckman pH meter was used in all pH measurements.

Calculation of i Values—The i values (isotonic coefficients) for polyethylene glycols were calculated according to the equation of Grosicki and Husa (8) which was modified as follows.

$$\frac{\left(\begin{matrix}i\text{ value}\\ \text{for NaCl}\end{matrix}\right)\left(\begin{matrix}\text{Gm. of NaCl}\\ \text{in 100 ml.}\\ \text{soln.}\end{matrix}\right)}{(\text{Gm.-mol. wt. of NaCl})} = \frac{\left(\begin{matrix}i\text{ value for}\\ \text{PEG}\end{matrix}\right)\left(\begin{matrix}\text{Gm. of PEG}\\ \text{in 100 ml.}\\ \text{of soln.}\end{matrix}\right)}{(\text{Gm.-mol. wt. of PEG})} \quad \text{(Eq. 1)}$$

Concentrations of sodium chloride and polyethylene glycol causing the same degree of hemolysis (*e.g.*, 25, 50, and 75%) were used in the above equation to calculate i values for the polyethylene glycols.

Experiments were carried out to obtain data for calculating *apparent* i values for sodium chloride when the salt was present in a water–polyethylene glycol system in which the polyethylene glycol itself exhibited no protection to red blood cells, *e.g.*, sodium chloride in 10% PEG 200. In these calculations, it was necessary to assume that polyethylene glycol did not contribute to the osmotic behavior of the solutions and that sodium chloride was solely responsible for the tonicity of the solutions. Since the calculations were concerned with i values of only sodium chloride in different solvents, the molecular weights in Eq. 1 are identical and the equation becomes

$$\left(\begin{matrix}i\text{ value for}\\ \text{NaCl in water}\end{matrix}\right)\left(\begin{matrix}\text{Gm. of NaCl}\\ \text{in 100 ml. of}\\ \text{water}\end{matrix}\right) = \left(\begin{matrix}i\text{ value for}\\ \text{NaCl in PEG}\\ \text{soln.}\end{matrix}\right)\left(\begin{matrix}\text{Gm. of NaCl}\\ \text{in 100 ml.}\\ \text{PEG soln.}\end{matrix}\right) \quad \text{(Eq. 2)}$$

The value of i for sodium chloride was taken as 1.86, which is the accepted value of i for 0.9% sodium chloride in water (8).

Curves showing the degree of hemolysis in sodium chloride–water solutions and sodium chloride–water–PEG solutions were plotted on rectangular coordinate paper. From these curves the concentrations of sodium chloride in Gm./100 ml. of water and PEG, causing 25, 50, and 75% hemolysis, were determined. These values were inserted into Eq. 2, and the values of i for sodium chloride in a particular water–PEG solution at concentrations giving 25, 50, and 75% hemolysis were determined.

Preparation of Hemolysis Curves—Experiments employing human blood were carried out to determine *apparent* i values for sodium chloride in various PEG 200 and 300 solutions. The average readings of these experiments were used to construct a standard hemolysis curve. In constructing the hemolysis curves of the various PEG solutions the grams of sodium chloride per 100 ml. of solution causing 25, 50, and 75% hemolysis were calculated with reference to the standard hemolysis curve. By utilizing Eq. 2, the grams of sodium chloride per 100 ml. in a polyethylene glycol solution causing 25% hemolysis was calculated as

$$X = \frac{A \times B}{C} \qquad \text{(Eq. 3)}$$

where X = Gm. of sodium chloride in 100 ml. of polyethylene glycol solution causing 25% hemolysis, A = 1.86 as the i value for sodium chloride in water, B = Gm. of sodium chloride in 100 ml. of water causing 25% hemolysis (obtained from standard hemolysis curves), and C = previously calculated i value for sodium chloride in appropriate polyethylene glycol solution. Similar calculations were carried out to obtain i values at 50 and 75% hemolysis. With these three i values at 25, 50, and 75% hemolysis, the hemolysis curves for the various polyethylene glycol solutions were constructed.

RESULTS

Polyethylene Glycol 200 and 300—The hemolysis of rabbit and human erythrocytes after 45 min. at 37° in various water–PEG 200 and 300 solutions are shown in Figs. 1 and 2. All of the PEG 200 and 300 solutions void of sodium chloride caused complete hemolysis of rabbit and human erythrocytes; however, hemolysis of red blood cells in aqueous solutions containing more than 15–25% PEG 200 or 300 resulted in brown-green solutions instead of normal red solutions. The concentrations at which this discoloration occurred are shown in Table I.

The inclusion of 0.9% sodium chloride in aqueous solutions containing 0.0 to 25% PEG 200 or 300 afforded complete protection (no hemolysis) to rabbit and human erythrocytes. However, the inclusion of sodium chloride in solutions containing 25% and more of PEG 200 or 40% and more of PEG 300 did not prevent damage of blood cells. At these critical concentrations (see Table I) the red blood cells were destroyed resulting in brown-green solutions. The addition of 2, 3, or 5% sodium chloride to 25, 30, 40, and 50% PEG 200 and 300 solutions prevented hemolysis and discoloration of blood.

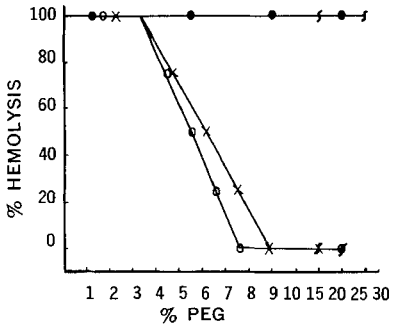

Fig. 1—Hemolysis of rabbit erythrocytes after 45 min. at 37° in various polyethylene glycol–water solutions. Key: ●, PEG 200 and 300; ×, PEG 400; ○, PEG 600; S, discoloration occurred.

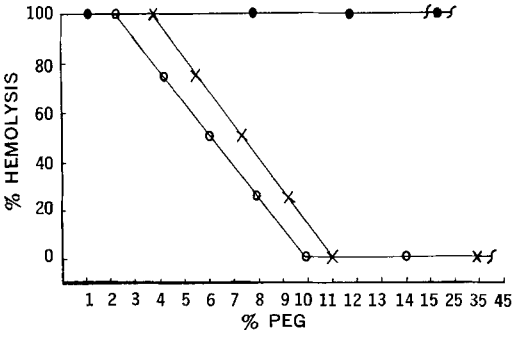

Fig. 2—Hemolysis of human erythrocytes after 45 min. at 37° in various polyethylene glycol–water solutions. Key: ●, PEG 200 and 300; ×, PEG 400; ○, PEG 600; S, discoloration occurred.

TABLE I—CONCENTRATIONS (Gm./100 ml.) OF PEG IN AQUEOUS SOLUTIONS AT WHICH DISCOLORATION OF BLOOD OCCURRED[a]

PEG	No NaCl		0.9% NaCl	
	Rabbit Blood	Human Blood	Rabbit Blood	Human Blood
200[b]	25	25	30	40
300[b]	15	15	25	25
400[c]	15	40	40	40
600[c]	20	40	40	40

[a] Each value represents an average of at least four blood samples. [b] Discoloration in PEG 200 and 300 solutions resulted in brown-green solutions. [c] Discoloration in PEG 400 and 600 solutions resulted in brown-black precipitates. The solutions were not colored.

The fragility of human erythrocytes in various water–PEG 200 and 300 solutions was modified or corrected by the addition of sodium chloride. It was possible to calculate i values for sodium chloride in various water–PEG 200 and 300 solutions. The average i values for sodium chloride in 5, 10, and 20% PEG 200 and 300 solutions are shown in Table II. The i values for sodium chloride in 10 and 20% PEG 200 solutions were less than 1.86 (the accepted value for 0.9% sodium chloride in water). The i values were greater than 1.86 for PEG 300 solutions.

The pH readings for PEG 200 and 300 solutions

TABLE II—VALUES OF *i* FOR NaCl IN VARIOUS WATER–PEG SOLUTIONS, CALCULATED FROM CONCENTRATIONS CAUSING 25, 50, AND 75% HEMOLYSIS OF HUMAN ERYTHROCYTES AT 37°[a]

% w/v	Hemolysis, % 25	50	75	Av.
PEG 200				
5[b]	1.8	2.1	2.2	2.0
10	1.7	1.7	1.9	1.8
20	1.6	1.6	1.7	1.6
PEG 300

10	2.6	4.4	6.9	4.6
20	2.8	3.1	3.4	3.1

[a] Unless otherwise indicated each *i* value represents an average of at least two blood samples. [b] Average of four blood samples.

before and after the addition of blood were within a range of 3.5 to 4.5.

Hemolysis curves showing the amount of laking that occurred when human blood was added to various water–PEG 200 and PEG 300–sodium chloride solutions are shown in Figs. 3 and 4. These curves were constructed in the manner described under *Experimental* utilizing the data presented in Table II. Unusual data were obtained for experiments using 5% PEG 200 solutions containing various amounts of sodium chloride and the results are shown in Fig. 5. Instead of the continual increase in hemolysis with decreasing sodium chloride concentration, hemolysis in 5% PEG 200 solutions decreased in those solutions containing 0.38 to 0.35% sodium chloride and then increased with further decrease in sodium chloride concentrations.

Polyethylene Glycol 400 and 600—The hemolysis of rabbit and human erythrocytes after 45 min. at 37° in various water–PEG 400 and 600 solutions is shown in Figs. 1 and 2. Hemolysis was prevented in various aqueous PEG 400 and 600 solutions up to critical concentrations where damage of red blood cells occurred resulting in brown-black precipitates (see Table I).

It was possible to calculate *i* values for PEG 400 and PEG 600. Average *i* values are shown in Table III.

The addition of 0.9% sodium chloride to solutions containing less than 40% PEG 400 or 600

PEG 600	1.2	1.4	1.6	1.4
	Human Blood			
PEG 400	0.5	0.6	0.8	0.6
PEG 600	0.9	1.2	1.6	1.2

[a] Each *i* value represents an average of two to seven blood samples.

afforded complete protection (no hemolysis) to rabbit and human erythrocytes; however, at critical concentrations (see Table I) damage of red blood cells occurred as in PEG 400 and 600 solutions void of sodium chloride. This damage was not prevented by the addition of 2, 3, or 5% sodium chloride to 40, 50, and 60% solutions of PEG 400 and 600.

The pH readings of all PEG 400 and 600 test solutions before and after the addition of blood was within a range of 3.5 to 4.5.

DISCUSSION

The concentrations of PEG 200, 300, 400, and 600 in water that are iso-osmotic with 0.9% sodium chloride, according to calculations using the osmotic factor equation (9),

$$\text{osmotic factor} = \frac{\left(\begin{matrix}\text{No. of particles}\\ \text{from 1 molecule}\\ \text{of solute}\end{matrix}\right)\left(\begin{matrix}\text{Gm. of solute}\\ \text{in 100 ml. of}\\ \text{soln.}\end{matrix}\right)}{\text{(Gm.-mol. wt. of solute)}} \quad \text{(Eq. 4)}$$

are 5.8, 8.7, 11.6, and 17.4%, respectively. Regardless of the polyethylene glycol content in aqueous solution, PEG 200 and 300 solutions failed to prevent hemolysis of rabbit and human erythrocytes. These experimental data point out that when water–PEG 200 or water–PEG 300 are used as vehicles for intravenous solutions, the finished product should not be assumed hypertonic with respect to blood, even when there is a high concentration of polyethylene glycol present. In experimental studies, tissue reactions have been observed following parenteral doses of undiluted polyethylene glycols which are severe enough to warrant very thorough study of safety before any parenteral applications are made (10). Hemolysis has resulted from high concentrations injected into the blood stream. Viscosity and lack of diffusion have resulted in discomfort or pain after subcutaneous injections of undiluted material and ischemic necrosis has also been seen after intramuscular injections. In a study of the polyethylene glycols as vehicles for intramuscular and subcutaneous injections by Carpenter and Shaffer (11), tissue reactions at the site of subcutaneous and intramuscular injections of undiluted PEG 300 in dosages 2.5 to 10 times that anticipated for human use caused blanching of the skin and scab formation in 48 hr. In a study by McCabe *et al.* (12), it was found that daily administration of 240 mg. of nitrofurantoin in PEG 300 to 30 patients caused severe metabolic acidosis and nephropathy in seven patients resulting in two deaths. These damaging effects were attributed to polyethylene glycol rather than nitrofurantoin.

Sodium chloride is effective in preventing hemolysis of human erythrocytes in aqueous polyethylene glycol solutions as long as the polyethylene glycol concentrations do not exceed 25 to 40%. At these higher polyethylene glycol concentrations, erythrocytes are not protected from discoloration by the addition of 0.9% sodium chloride. Concentrations of polyethylene glycols causing discoloration of human and rabbit erythrocytes are summarized in Table I. Higher concentrations of sodium chloride prevented discoloration in PEG 200 and 300 solutions but not in PEG 400 and 600 solutions. This damage does not appear to be hemolytic in character, but seems to be a chemical type of destruction. It appears that pH was not a factor since the pH of all concentrations of polyethylene glycol solutions remained within a range of 3.5 to 4.5 before and after the addition of blood.

The van't Hoff factor (i value or isotonic coefficient) is defined as the ratio of the colligative effect produced by a concentration (molal) of electrolyte divided by the effect observed for the same concentration of nonelectrolyte (13). In studying the effect of low concentrations of various substances on erythrocytes, previous workers (1, 2, 8) used molar concentrations in place of molal concentrations in their calculations. The use of molar instead of molal concentration would introduce only a small error at electrolyte concentrations of 0.1 M or less (8). However, in the present study, comparatively high concentrations of liquid polyethylene glycols (4–9%) were involved in calculation of i values. This meant that enough volume of the test solution was occupied by the polyethylene glycol to produce a substantial difference between molar and molal concentrations. Molal concentrations of the test solutions used in this study were calculated by direct proportion (no shrinkage was noticed when polyethylene glycols and water were mixed) and i values calculated using molal concentrations. They were found to be 12 to 15% lower than the i values calculated on a molar basis. However, it was decided to calculate *hemolytic* i values using molar concentrations since pharmaceutical calculations in the area of isotonic solutions are based on this concentration expression.

The i values for sodium chloride in most aqueous PEG 200 solutions were less than 1.86. These low i values indicate that PEG 200 offers no protection to red blood cells against osmotic hemolysis. In fact, there probably is some deleterious effect since more sodium chloride is needed to protect the red blood cells against hemolysis in aqueous PEG 200 solutions than in water. The higher values of i for sodium chloride in aqueous PEG 300 solutions indicate that PEG 300 contributes to the tonicity of aqueous solutions. The fact that i values could be calculated for PEG 400 and 600 shows that these polyethylene glycols have the ability to protect erythrocytes against osmotic hemolysis. Since i values for PEG 400 were less than i values for PEG 600, it can be assumed that PEG 600 gives greater protection to red blood cells than PEG 400. Therefore, the order in which the liquid polyethylene glycols protect rabbit and human erythrocytes against hemolysis is $200 < 300 < 400 < 600$. The ability of the liquid polyethylene glycols to contribute to the tonicity of aqueous solutions is dependent on the molecular weight. A possible explanation for this behavior might be that the lower molecular weight polyethylene glycols are able to penetrate the red blood cell membrane and therefore have little or no effective concentration in the extracellular solutions. It appears that increasing the molecular weight decreases the membrane penetrating properties of liquid polyethylene glycols.

Metabolite of 4-Amino-4-deoxy-N^{10}-methylpteroylglutamic Acid (Methotrexate)

By DAVID G. JOHNS and TI LI LOO

4-Amino-4-deoxy-N^{10}-methylpteroylglutamic acid (methotrexate; MTX) is rapidly metabolized by rabbit liver aldehyde oxidase. The MTX metabolite, on oxidative cleavage with permanganate, yields a simple pteridine having the spectrophotometric and chromatographic properties of 2,4-diamino-7-hydroxy-6-pteridinecarboxylic acid. Alkaline hydrolysis of the latter at 70° slowly converts it to 2-amino-4,7-dihydroxy-6-pteridinecarboxylic acid. The nonpteridine moiety of the MTX metabolite is identical with the nonpteridine moiety of MTX. The biological properties of the MTX metabolite are compatible with those of a 2,4-diamino derivative of pteroylglutamate. In view of these findings, the structure, 4-amino-4-deoxy-7-hydroxy-N^{10}-methylpteroylglutamic acid (7-hydroxy-MTX), is proposed for the MTX metabolite.

THE FOLIC ACID analog 4-amino-4-deoxy-N^{10}-methylpteroylglutamic acid (methotrexate; MTX), a compound of considerable clinical interest in the treatment of neoplastic diseases and of psoriasis, undergoes rapid biological inactivation by a flavin enzyme present in the supernatant fraction of rabbit liver homogenates (1, 2). A similar, but slower conversion occurs in the supernatant fraction of liver homogenates from guinea pig and several other species (3). Johns *et al.* (1) have identified the MTX-inactivating enzyme as aldehyde oxidase (aldehyde:O_2 oxidoreductase, EC 1.2.3.1) and have shown it to be identical with the enzyme catalyzing the inactivation of 3′,5′-dichloro-MTX and a number of other halogenated 4-amino analogs of pteroylglutamate (4). The structure of the MTX metabolite has not been established, although Redetzki and his co-workers (2), on the basis of elementary analyses, suggested that the compound is 4,7-dihydroxy-MTX (7-hydroxy-N^{10}-methylpteroylglutamic acid). Earlier studies by Loo and Adamson (5) with 3′,5′-dichloro-MTX, however, have shown that, in the latter compound, the 4-amino group remains intact during enzymic inactivation and that the 3′,5′-dichloro-MTX metabolite differs from the parent compound only in the presence of a hydroxyl group at the 7-position. Since the same enzyme system is responsible for the inactivation of both MTX and its 3′,5′-dichloro derivative, it appears unlikely that the 4-amino group of MTX would undergo hydrolysis while the 4-amino group of 3′,5′-dichloro-MTX would not. Furthermore, it is well known that elementary analytical data alone are rarely conclusive in establishing the structure of pteridines (5, 6). The studies described below strongly suggest that, with MTX, as with 3′,5′-dichloro-MTX, enzymic inactivation involves only 7-hydroxylation, and that the 4-amino group remains intact.

This work was supported by research grants CA-02817 and CA-08010 from the U. S. Public Health Service, and by contract PH 43-66-1156 with the National Cancer Institute, U. S. Public Health Service, Bethesda, Md.

EXPERIMENTAL

Preparation of the MTX Metabolite—Commercial grade MTX[1] was twice precipitated from aqueous solution with glacial acetic acid, washed with ice-cold acetone, and dried over phosphorus pentoxide; of the MTX powder thus obtained, 150 mg. was dissolved in 60 ml. of water with the aid of 1 *N* potassium hydroxide added dropwise. The pH of the solution was adjusted to 7.5 with 2 *N* phosphoric acid.

Frozen mature rabbit liver (600 Gm.; Pel-Freez Biologicals, Inc.) was allowed to thaw at 5° and homogenized in 2 vol. of distilled water. After centrifuging for 10 min. at 27,000 × g, the crude supernatant fraction was collected and immersed in a water bath at 60° for 10 min. Heat-precipitated protein was removed by centrifugation, and the supernatant fractionated with an ammoniacal solution of ammonium sulfate prepared by adding 60 ml. ammonium hydroxide solution (29%) to 940 ml. saturated solution of ammonium sulfate. For each 100 ml. of the supernatant, 59 ml. of the solution of ammoniacal ammonium sulfate was added with stirring, and the precipitate was removed by centrifuging. An additional 23 ml. of ammoniacal solution of ammonium sulfate was then added, and the precipitate was recovered. The precipitate was redissolved in sufficient ammoniacal ammonium sulfate solution of 10% saturation to give a protein concentration of about 30 mg./ml. A typical purification resulted in 28-fold concentration of aldehyde oxidase activity, as compared with that

[1] Kindly provided by Dr. J. M. Ruegsegger, Lederle Laboratories.

of the crude supernatant, and yielded 36 ml. of enzyme solution with a protein concentration of 31 mg./ml. Aldehyde oxidase activity was determined with *N*-methylnicotinamide as substrate (7), and protein concentration was determined by the method of Waddell (8).

To the enzyme solution were added 10,000 units of catalase[2] (Worthington Biochemical Corp.), 6 ml. of 0.4 *M* sodium phosphate buffer, pH 7.8, containing 0.005% iron chelating agent,[3] and 100 ml. of distilled water. The pH was adjusted to 8.4 by the addition of ammoniacal ammonium sulfate, and the MTX solution (prepared as described above) was added dropwise with stirring at room temperature, at a rate of 8 ml./hr. (20 mg. of MTX per hour). The solution was then allowed to stand at 5° overnight, and the yellowish-white flocculent precipitate was collected by centrifuging. The precipitate was suspended in 16 ml. of distilled water, and a 0.2-ml. aliquot was removed for chromatographic examination; the remainder was heated in a boiling water bath for 4 min., centrifuged, and the insoluble protein precipitate discarded. The supernatant fraction was cooled in an ice-bath, 0.8 vol. of glacial acetic acid was added, and the solution was allowed to stand overnight at 5°. The lemon-yellow precipitate was washed twice with cold acetone and dried at room temperature over phosphorus pentoxide. The yield in a typical preparation was 94 mg. Chromatography on DEAE-cellulose, as previously described (9), showed the product to migrate as a single peak, and to be free of MTX. The ultraviolet absorption characteristics of the product are: in 0.1 *N* hydrochloric acid, $\lambda_{max.}$ 218 mμ (log ε 4.48), 300 mμ (log ε 4.26), and 334 mμ (infl.) (log ε 4.07); at pH 7.6 in 0.05 *M* Tris buffer, $\lambda_{max.}$ 224 mμ (infl.) (log ε 4.23), 261 mμ (log ε 4.04), 303 mμ (log ε 4.29), and 340 mμ (infl.) (log ε 4.08); in 0.1 *N* sodium hydroxide solution, $\lambda_{max.}$ 223 mμ (log ε 4.54), 260 mμ (log ε 4.07), 308 mμ (log ε 4.31), and 337 mμ (infl.) (log ε 4.13).

Activity of the MTX Metabolite as an Inhibitor of Dihydrofolate Reductase—The MTX metabolite was tested for ability to inhibit the enzymatic conversion of dihydrofolate to tetrahydrofolate, using a partially purified preparation of dihydrofolate reductase from L1210 mouse leukemia cells (10). Data were plotted by the method of Zakrzewski (11). The MTX metabolite was of intermediate potency as an inhibitor of dihydrofolate reductase; the K_i was 6×10^{-9} *M* at pH 5.5. For comparison, the parent compound, MTX, a strong inhibitor of dihydrofolate reductase, has a K_i of $<3 \times 10^{-11}$ *M* (12), while pteroylglutamate, a weak inhibitor of the enzyme when dihydrofolate is used as substrate, has a K_i of 3×10^{-6} *M* (10).

Oxidative Degradation of the MTX Metabolite—The procedure was similar to that used for 3′,5′-dichloro-MTX (5). The MTX metabolite (50 mg.), dissolved in 10 ml. of 0.1 *N* sodium hydroxide, was oxidized with 1.5 ml. of 5% potassium permanganate added dropwise with vigorous stirring at 90° for 6 min. After all the potassium permanganate had been added, the reaction mixture was kept at 90° for an additional minute. The brown precipitate was removed by centrifugation, washed with water, and centrifuged again. The combined supernatant fractions were acidified with 1 ml. of glacial acetic acid and centrifuged. The weakly acidic supernatant from which the greenish-yellow gelatinous precipitate separated was saved for later investigation (see below). The precipitate was washed with water, redissolved in 6 ml. of 1 *N* sodium hydroxide, warmed with activated charcoal, and filtered. The filtrate was added slowly, dropwise, to hot dilute acetic acid (1 ml. of glacial acetic acid diluted to 20 ml. with water). On cooling, the pale yellow precipitate was collected by centrifugation and washed with water; this treatment was repeated. The product was then washed with acetone and dried in a vacuum desiccator. The pteridine acid (X) so obtained weighed 9 mg.

Anal.—Calcd. for $C_7H_6N_6O_3$ (2,4-diamino-7-hydroxy-6-pteridinecarboxylic acid; the diamino acid): N, 37.84; for $C_7H_5N_5O_4$ (2-amino-4,7-dihydroxy-6-pteridinecarboxylic acid; the dihydroxy acid): N, 31.39. Found: N, 38.15; 38.26.

The pteridine acid (X) showed ultraviolet absorption spectra identical to those of an authentic sample of the diamino acid (13) in 14.7 *N* sulfuric acid, in 0.1 *N* sodium hydroxide solution, and in 0.05 *M* Tris buffer, pH 8.0. Except in alkaline solution, the spectra of acid X bear little resemblance to those of the dihydroxy acid. The spectra of the three acids in 0.05 *M* Tris buffer, pH 8.0, are shown in Fig. 1.

When chromatographed on Whatman No. 1 paper, and developed with 0.5% sodium carbonate solution, ascending flow, the R_f values were 0.46–0.49 for pteridine acid (X), 0.46–0.49 for the diamino acid, and 0.71–0.73 for the dihydroxy acid. With 3% ammonium chloride solution as solvent, the R_f values were 0.19–0.20 for pteridine acid (X), 0.20–0.21 for the diamino acid, and 0.40–0.42 for the dihydroxy acid. All paper chromatograms were viewed under ultraviolet light of 254 mμ.

Alkaline Hydrolysis of Pteridine Acid (X)—Pteridine acid (X) was hydrolyzed at 70° in 2 *N* sodium hydroxide solution. Aliquots were removed at the times indicated in Table I, and ultraviolet absorption spectra determined in 0.05 *M* Tris buffer, pH 8.0. The maximum at 262 mμ displayed a gradual decrease in intensity, with a concomitant increase in intensity at 285 mμ, a change compatible with the conversion of the diamino acid to the dihydroxy acid (Table I).

Nonpteridine Moiety Derived from Permanganate Oxidation of the MTX Metabolite—The weakly acidic supernatant from which the pteridine acid (X) had been removed was further acidified with 3 ml. of concentrated hydrochloric acid, saturated with sodium chloride, and extracted first with 15 ml. of ethyl acetate, and then twice with 10 ml. of the same solvent. The combined extract was washed with 25 ml. of water and dried over anhydrous sodium sulfate. The ethyl acetate extract was then concentrated at 100° in an atmosphere of nitrogen. The reddish oil thus obtained defied all attempts at crystallization; however, its ultraviolet absorption spectra closely resembled that of *p*-methylaminobenzoylglutamic acid (14). When compared with the product obtained from a similar oxidative degradation of MTX, it showed identical *Rf* values on Whatman No. 1 paper, developed by

[2] The addition of catalase is necessary in order to prevent inactivation of the enzyme by hydrogen peroxide formed during the reaction.

Solvent: 0.05 M Tris buffer, pH 8.0.

TABLE I—CHANGES IN ABSORBANCE OF PTERIDINE ACID (X) ON ALKALINE HYDROLYSIS[a]

Time, hr.	$A_{263m\mu}/A_{358m\mu}$	$A_{285m\mu}/A_{358m\mu}$
0	0.808	0.306
2.5	0.749	0.309
13.5	0.746	0.359
21.5	0.696	0.437

[a] Hydrolysis was carried out at 70° in 2 *N* sodium hydroxide solution. Ultraviolet absorption spectra were determined in 0.05 *M* Tris buffer, pH 8.0.

ascending flow, in three solvent systems, as indicated in Table II. All paper chromatograms were viewed under ultraviolet light of 366 mμ.

RESULTS AND DISCUSSION

The demonstration by ultraviolet spectroscopy, by chromatography, and by elementary analysis, that the MTX metabolite gives rise to 2,4-diamino-7-hydroxy-6-pteridinecarboxylic acid on permanganate oxidation is compatible with the structure 7-hydroxy-MTX for the parent compound. It would appear, therefore, that the enzyme-catalyzed hydroxylation involves only position-7 of MTX, and that the 4-amino group is unaltered. While 7-hydroxylation is compatible with the known catalytic properties of rabbit liver aldehyde oxidase, this enzyme possesses no known deaminase activity. For the 2-amino-4,7-dihydroxy structure, therefore, one would have to postulate the presence of an MTX-4-deaminase in the reaction mixture, a remote possibility, since the reaction proceeds equally well

TABLE II—R_f VALUES OF THE NONPTERIDINE MOIETY OF MTX (*A*) AND OF MTX METABOLITE (*B*)

Chromatographic System	R_f Value *A*	*B*	Mixture of *A* + *B*
0.1 *M* acetate buffer, pH 4.4	0.83	0.82	0.82
0.5% sodium carbonate soln.	0.92	0.89	0.91
1:1 mixture of 5% ammonium sulfate soln. and isopropanol	0.59	0.63	0.58

with highly purified aldehyde oxidase. Alternatively, nonenzymic hydrolytic deamination might occur at the 4-position. This appears equally unlikely, since lengthy heating at 70° in 2 *N* sodium hydroxide solution is required to bring about the conversion of 2,4-diamino-7-hydroxy-6-pteridinecarboxylic acid to its 2-amino-4,7-dihydroxy analog.
