The antiviral 5-trifluoromethyl-2′-deoxyuridine, F_3TdR, is hydrolyzed by hydrogen ions and solvent to 5-trifluoromethyluracil, F_3T, and deoxyribose. The F_3T is readily hydrolyzed to 5-carboxyuracil by hydroxyl ion attack on the undissociated and anionic species. At elevated temperatures, 5-carboxyuracil is decarboxylated by hydroxyl ion catalysis to uracil. The F_3TdR is readily hydrolyzed to 5-carboxy-2′-deoxyuridine by hydroxyl ion attack on the undissociated and anion species through an observable kinetic intermediate at high alkalinity, probably 5-hydroxydifluoromethyl-2′-deoxyuridine. The optimum pH range for stabilization is 1–4 where the half-life at 30° is 280 days. The material is readily degraded at pH 7.4 where 1.5 days is the half-life at 30°.

THE KNOWN antitumor and antiviral activity of the 5-halogenated uracils and 5-halogenated pyrimidine nucleosides (1) initiated the synthesis of 5-trifluoromethyl-2′-deoxyuridine (trifluorothymidine, F_3TdR, I) (2). The structure I sterically resembles 5-iodo-2′-deoxyuridine, IDU, which is active against *Herpes simplex* in human keratitis (3). The van der Waals radius of iodine is 2.15 Å. and that of the trifluoromethyl group is 2.44 Å. (4). Since a degradation product of IDU, 5-iodouracil tends to antagonize its activity (5), complete studies of its kinetics of solvolysis were performed in order to determine optimum conditions for pharmaceutical stabilization (6–9).

Preliminary experiments with F_3TdR, I, have

Received January 22, 1968, from the College of Pharmacy, University of Florida, Gainesville, FL 32601
Accepted for publication March 15, 1968.

† To whom inquiries concerning this manuscript should be addressed.

indicated that it is about 100 times as potent against *Herpes simplex* infections as IDU (10). Intrinsic potency is about 10 times greater but the solubility enhancement is also 10-fold. It also appears that its use is less conducive to the development of resistance (10).

Since the degradation products of nucleosides frequently interfere with the biological activity of its precursors (5, 11, 12), a full study of the kinetics of solvolysis of F_3TdR, I, is necessary to determine the optimum stability conditions for its pharmaceutical formulation and the products of its hydrolysis over the entire pH range. The comparative solvolytic rates of F_3TdR may also provide information on the contributory effects of strongly electronegative 5-substituents to the solvolysis of pyrimidine nucleosides which has been recently discussed in detail (13).

EXPERIMENTAL

Materials—5 - Trifluoromethyl - 2′ - deoxyuridine, F_3TdR, was obtained from P-L Biochemicals, Inc. and 5-trifluorothymine, F_3T, from Merck Sharp and Dohme. All solutions were made up in nitrogen-purged distilled water. Stock solutions of F_3TdR and F_3T were 0.7×10^{-2} *M* and 0.35×10^{-2} *M*, respectively, and were always prepared shortly before using. The pH values of buffer solutions were read at the temperature of the kinetic experiments. The pH values of NaOH and HCl solutions were obtained by calculation and extrapolation from the data of Harned and Owen (14). Ionic strength in all buffer solutions was adjusted to 0.1 with NaCl.

Instruments—A Cary model 15 spectrophotometer equipped with a repetitive scan accessory, automatic sample changer, and a thermostatically controlled cell compartment, and a Beckman DU spectrophotometer, DU-2 were used for ultraviolet absorbance readings. The pH was read on a Radiometer (Copenhagen, Denmark) pH meter equipped with a Beckman high temperature (pH range 1–14) glass electrode with a calomel reference electrode. For potentiometric titrations a Sargent automatic titrator model D was used.

Acid Solvolysis of F_3TdR—An aliquot (2.00 ml.) of F_3TdR stock solution was added to 98 ml. of thermally equilibrated HCl or acetate buffer to produce concentrations of 1.4×10^{-4} *M*. Samples were taken at appropriate time intervals, chilled to room temperature, and an equal volume of 1 *N* NaOH added. After 24 hr. at room temperature the increasing absorbance, *A*, to its asymptotic value A_∞ was read at 300 mμ (Fig. 1). From the slope of the plot $\log/A_\infty - A/$ *versus* time the apparent first-order rate constants were calculated for the temperatures listed in Table I.

Alkaline Solvolysis of F_3TdR—The initial transformation of F_3TdR to a presumed 5-hydroxydifluoromethyl-2′-deoxyuridine intermediate (VIII) was followed at 29.5° by adding 0.5 ml. of F_3TdR stock solution to 10 ml. of NaOH solutions to yield a 3.34×10^{-4} *M* solution. The spectral absorbance increased at 298.4 mμ to a readily obtainable asymptotic value (Fig. 2) prior to further reaction,

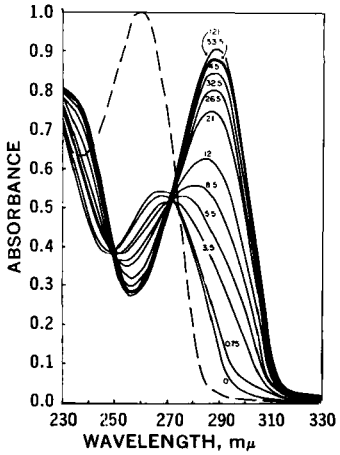

Fig. 1—Typical spectral changes of alkaline-treated (0.5 N NaOH, 24 hr. at room temperature) 5-trifluoromethyl-2′-deoxyuridine, F_3TdR, after the labeled hr. of degradation in 0.002 N HCl at 80.0°. The acid solutions of 1.4×10^{-4} M F_3TdR were diluted 1:1 with 1.0 N NaOH. The spectral end-product, $\lambda_{max.}$ 288 mμ, is 5-carboxyuracil anion. Key: ——, hr.; - - -, spectrum of 5-trifluoromethyluracil in 0.5 N NaOH.

and permitted the first-order rate constants at the cited NaOH concentrations of Table I to be determined. Similar studies were conducted in borate and phosphate buffers but valid asymptotic values for this first transformation were not easily obtained, probably because of the greater relative speed of the subsequent transformation.

At higher temperatures, *e.g.*, 47°, this first reaction was a fast process so that initial spectra (see 295 mμ in Fig. 3) already represented the complete transformation to the probable 5-hydroxydifluoromethyl-2′-deoxyuridine intermediate. The reaction was studied at a concentration of 1.05×10^{-4} *M* in various NaOH, borate, and phosphate buffer solutions listed in Table I with their pH values at 280 mμ and the rate constants determined. In buffer solutions below pH 8 the initial changes due to the first reaction were not as readily observable, and thus estimates of these rate constants were not as valid as the rate constants for the formation of 5-carboxy-2′-deoxyuridine from degrading F_3TdR.

Decarboxylation of 5-Carboxy-2′-deoxyuridine—The spectrum of 5-carboxy-2′-deoxyuridine was obtained very quickly at 80° in NaOH and borate buffers from F_3TdR. The spectrum then changed slowly to $\lambda_{max.}$ 261 mμ in base and 262 mμ in acid; these spectra are inidcative of 2′-deoxyuridine as the product. The reaction appeared to be pH independent in the alkaline region. 2′-Deoxyuridine was relatively stable in buffer below pH 9, but slowly degraded in strong NaOH with loss of absorbance.

Degradation of Trifluoromethyluracil, F_3T—An aliquot (2.00 ml.) of F_3T stock solution was added to 98 ml. of various NaOH and buffer solutions, preequilibrated at 34°. The reaction to 5-carboxyuracil was followed by monitoring the increasing absorbance at 290 mμ attributed to the 5-carboxyuracil anion. The derived first-order rate constants, solvent conditions, and pH values are given in Table II. This reaction is completed almost instantaneously at 80°. The subsequent

[a] The pH values were calculated from pH = $-\log a_{HCl}$ [HCl] and pH = $pK_w - \log a_{NaOH}$ [NaOH], respectively, where the activity coefficients for the respective [HCl] and [NaOH] and the pK_w values at the several temperatures (12.63, 80.0°; 13.35, 47.0°; 13.83, 29.5°) were obtained from the literature (14). The pH values in the buffer solutions were measured at the stated temperatures and the ionic strengths of these buffer solutions were adjusted to 0.1 with NaCl. [b] These rate constants at 80.0° were obtained for the acid-catalyzed solvolysis of 1.40×10^{-4} *M* 5-trifluoromethyl-2′-deoxyuridine, I, to 5-trifluoromethyluracil, II, and deoxyribose by monitoring the appearance of 5-carboxyuracil, IV, derived from II after 24 hr. in 0.5 *N* NaOH at room temperature. Additional rate constants obtained for this transformation were: °C., [HCl], 10^5k; 70.0°; 2.54, 2.55; 60.0, 2.54, 0.570; 47.0, 2.54, 0.0994; 75.0°, 0.100, 1.1; 70.0°, 0.100, 0.617; 60.0°, 0.100, 0.253. [c] The rate constants at 47.0° in NaOH solutions were obtained for the hydroxyl ion catalyzed solvolysis of the anion of 5-hydroxydifluoromethyl-2′-deoxyuridine, VIII, to 5-carboxy-2′-deoxyuridine, IX ($\lambda_{max.}$ 272 mμ) after the rapid spectral changes at 295 mμ denoted completion of the formation of VIII from 1.05×10^{-4} *M* 5-trifluoromethyl-2′-deoxyuridine, I. Additional rate constants for the hydrolysis of VIII to IX were °C., [NaOH], pH, 10^5k; 38.0, 0.485, 13.1, 8.70; 26.2, 0.535, 13.6, 1.73. The buffer studies were conducted *in situ* and no significant amount of VIII could be observed indicative that these rate constants in the buffer solutions are for I → VIII with rapid degradation to IX. [d] Additional rate constants obtained at 60.0° for hydrolysis of I to IX through the intermediate VIII were: pH, 10^5k; 5.90 (phosphate), 1.24; 5.30 (acetate), 0.49. The rate constants at 29.5° in NaOH solution were obtained for the formation of the probable anion of 5-hydroxydifluoromethyl-2′-deoxyuridine, VIII, from 3.34×10^{-4} *M* trifluoromethyl-2′-deoxyuridine, I, a rapid reaction which is completed much before the hydrolysis of VIII to IX becomes significant as indicated by the monitoring of spectral absorbance at 295 mμ *in situ*. In the borate and phosphate buffer regions, there is no indication from the 290 and 295 mμ absorbances that VIII has more than a transitory existence and that its transformation to IX is very rapid. Thus, these rate constants in the buffer solutions are for I → VIII with rapid degradation to IX.

slower decarboxylation of 5-carboxyuracil to uracil ($\lambda_{max.}$ 283 mμ) was monitored spectrophotometrically.

Isolation of 5-Carboxyuracil—F_3T (200 mg.) was dissolved in 10 ml. of 0.5 *N* NaOH and heated for 30 min. at 50°. The cooled solution was adjusted to pH 3.0 with 2.5 *N* HCl. The refrigerated crystals were filtered after 3 days and dried under high vacuum at 60° for 3 hr. The yield was 180.8 mg., m.p. 284–285° dec. [lit. (15) m.p. 278° dec.]. The product was recrystallized from 50% aqueous ethanol; yield 62 mg., m.p. 285° dec. The com-

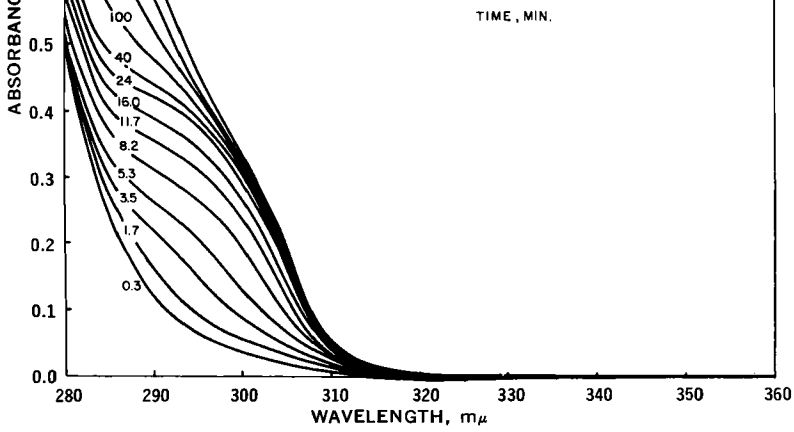

Fig. 2—Typical initial spectral changes for the degradation of 5-trifluoromethyl-2′-deoxyuridine, F_3TdR, in alkaline solution. The conditions were F_3TdR, 3.34×10^{-4} M in 0.126 N NaOH at 29.5°. Key: curves, min. after the start of the reaction; insert, typical plots of the absorbance at 295 mμ against time for the production of the probable 5-difluorohydroxymethyl-2′-deoxyuridine at several NaOH concentrations: ▲, 0.0485 N; ×, 0.097 N; Δ, 0.0049 N.

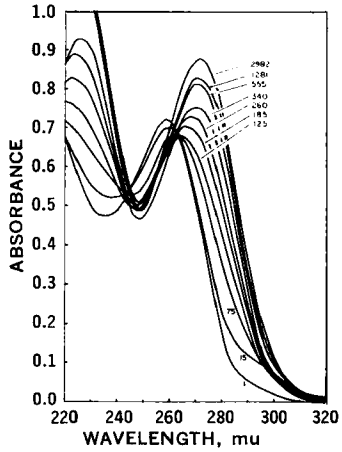

Fig. 3—Typical spectral changes of 5-trifluoromethyl-2′-deoxyuridine, F_3TdR, in alkaline solution. The conditions were F_3TdR, 1.05 × 10^{-4} M, in 0.020 N NaOH at 47.0°. Key: curves, min. after the start of the reaction. The rapid increase in absorbance in the range 290–310 mμ within the first 15 min. may be attributed to the production of a difluoro-monohydroxy intermediate.

pound is claimed to crystallize as the monohydrate (15), mol. wt. 174.1 + 18.0.

Anal.—Calcd. for $C_5H_4N_2O_4 \cdot H_2O$: C, 31.1; H, 3.12; N, 14.6. Calcd. for $C_5H_4N_2O_4$: C, 34.5; H, 3.45; N, 16.1. Found: C, 33.34; H, 3.22; N, 15.76.

Equivalent weight found by titration was 176.5, $pKa_1' = 4.25$, $pKa_2' = 8.90$.

Isolation of 5-Carboxy-2′-deoxyuridine—F_3TdR (200 mg.) was dissolved in 10 ml. of 1 *M* NaOH and heated for 7 hr. at 47°. The pH was adjusted to 6.8 with concentrated HCl. The solvent was removed *in vacuo*. The white residue was triturated with ethanol to which a few drops of concentrated HCl had been added. After filtering off the NaCl, the separated yellow filtrate was evaporated *in vacuo* at 60°. The yield was 115 mg. of yellow crystals, m.p. 165°. Repeated recrystallization from absolute ethanol yielded 31 mg. of a chloride-free product, m.p. 170° dec. The elementary analysis, mol. wt. 272.2, was as follows.

Anal.—Calcd. for $C_{10}H_{12}N_2O_7$: C, 44.12; H, 4.44; *N*, 10.29. Found: C, 44.64; H, 4.48; N, 10.20.

Paper Chromatography—Paper chromatography was used to monitor the basic degradation reactions from F_3TdR to 5-carboxy-2′-deoxyuridine, DU-5-COOH, and from F_3T to 5-carboxyuracil, U-5-COOH. Aliquots (25 μl.) of approximately 10^{-2} *M* aqueous solutions were spotted on Whatman No. 1 paper and developed with a mixture of ethyl acetate, formic acid, and water (21:3:1.5) (16). The substances were visualized by UV light (254 mμ). The acids were detected by spraying the dried chromatogram with alcoholic bromocresol green solution and gave yellow spots against a blue background. F_3TdR and F_3T move with the solvent front while the acids DU-5-COOH and U-5-COOH have an R_f value of ~0.5.

Table III lists the principal UV spectra and pKa′ values determined by potentiometric or spectrophotometric titration.

[1] The synthesis of this compound has been reported recently (Isenberg, N., and Heidelberger, C., *J. Med. Chem.* 10, 970(1967), colorless crystals, m. p. 158–159,° ε = 11,400 ($\lambda_{max.}$ 276 mμ, 0.1 *N* HCl), ε = 6,810 ($\lambda_{max.}$ 271 mμ, 0.1 *N* NaOH).

0.049	12.35	162
0.0194	11.95	78
0.0049	11.40	44.5

[a] Hydrolysis to 5-carboxyuracil. In borate buffer at pH 9.70 at 34.0°, $k = 5.17 \times 10^{-5}$. [b] Calculated from activity coefficients in the literature (14) where pH = pK_w − log a_{NaOH}[NaOH].

RESULTS AND DISCUSSION

Degradation in Mineral Acid—The glycoside bond of 5-trifluoromethyl-2′-deoxyuridine (F_3TdR), I, is readily cleaved in acid (Scheme I) in a manner common to pyrimidine deoxyribosides (13). The initial products are 5-trifluoromethyluracil (F_3T) (II) and deoxyribose, III. Deoxyribose is not stable under these acidic conditions; it is transformed in part to 5-methyl-3(2*H*)-furanone (17, 18), V, and levulinic acid (VI) (19). The absorbance of the former compound, V, $\lambda_{max.}$ 261 mμ which would interfere with the spectrophotometric monitoring of the F_3TdR, $\lambda_{max.}$ 261 mμ in 0.1 *N* HCl and $\lambda_{max.}$ 259 mμ in 0.1 *N* NaOH, can be removed (13, 17) by degradation of the reaction mixture in 0.5 *N* NaOH at room temperature for 24 hr.

The derived product of acidic solvolysis of I, which is F_3T, II, is completely hydrolyzed under these alkaline conditions to 5-carboxyuracil, IV ($\lambda_{max.}$ 289 mμ in 0.5 *N* NaOH) as shown in Scheme I. The acid-unreacted F_3TdR is also degraded under these alkaline conditions (Fig. 3). The 261 mμ $\lambda_{max.}$ shifts to 271 mμ $\lambda_{max.}$ in NaOH at room temperature in 24 hr., but contributes little to the change in the absorbance of IV at 295 mμ or 300 mμ in alkali. Thus the absorbance of IV at 295 mμ after 24 hr. at room temperature in 0.5 *N* NaOH may be taken as a measure of the extent of hydrolysis of I in acid solution. Typical spectra of the alkaline-treated acid degradations of I are given in Fig. 1. Typical first-order plots for the solvolysis of I in acid are given in Fig. 4 in accordance with the expression

$$\log |A_\infty - A| = -kt/2.303 + \log A_\infty \quad \text{(Eq. 1)}$$

where A is the absorbance with time, t, at 295 mμ after treatment for 24 hr. in 0.5 *N* NaOH at room temperature, A_∞ is the final absorbance, and k is the apparent first-order rate constant for the studies listed in Table I.

A plot of the apparent first-order rate constants (Table I) for the hydrolysis of F_3TdR, I, against [HCl] at 80.0° is linear with a finite intercept. This is indicative of a catalytic attack of hydrogen ion on the undissociated molecule, I, and a pH independent hydrolysis where

$$k = k_0 + k_{HCl}[HCl] \quad \text{(Eq. 2)}$$

where $k_0 = 2.0 \times 10^{-5}$ sec.$^{-1}$ and $k_{HCl} = 2.0 \times 10^{-5}$ L./mole/sec.

Degradation of F_3T—The 5-trifluoromethyluracil II, is known to produce 5-carboxyuracil, IV, in 0.1 *N* sodium bicarbonate and in 1.0 *N* NaOH solutions (2, 20). This can be followed readily by monitoring the absorbance at 290 mμ. Typical spectral changes in alkali with time are given in Fig. 5 and typical first-order rate constants are listed in Table II. Typical first-order plots are given in Fig. 6. At 34.0° the final absorbance was consistent with a stoichiometric yield of 5-carboxyuracil. Paper chromatographic monitoring of the reaction did not indicate any other processes but II → IV.

The rate constants can be well fitted by

$$k = k_{NaOH}'[NaOH]\, f_{u^-} \qquad \text{(Eq. 3)}$$

where $k_{NaOH}' = 4.5 \times 10^{-2}$ L./mole/sec. at 34.0°, where $f_{u^-} = [H^+]/([H^+] + K_a)$ is the fraction of 5-carboxyuracil that exists as the monoanion at the $[H^+]$ determined from the calculated pH (Table II). The K_{a_2}' is taken as 2.5×10^{-13}. This Eq. 3 indicates that the hydrolysis of F_3T, II, is effected by hydroxyl ion attack on the monoanion, or its kinetically equivalent water attack on the dianion at pH values more than one unit above the pK_{a_1}', 7.40 at 25.0°.

At elevated temperatures the anion of 5-carboxyuracil, IV, decarboxylates (19) to uracil, VII, but much more slowly than the production of IV from II. This is spectrally observable from the loss of absorbance at the 290 mμ $\lambda_{max.}$ in alkali of IV and the appearance of a 283 mμ $\lambda_{max.}$ with the lessened absorbance of the spectrum of VII.

At 80.0° in 0.02 *N* alkali the spectrum of 5-carboxyuracil, IV, is produced almost within 0.5 hr. from F_3T, II. The apparent first-order rate constants for the subsequent decarboxylation of IV were obtained from the slopes of typical first-order plots in accordance with Eq. 1. They were 8.17×10^{-7} and 2.07×10^{-7} sec.$^{-1}$ in 0.485 *N* (pH

TABLE III—SPECTRAL AND pKa′ VALUES

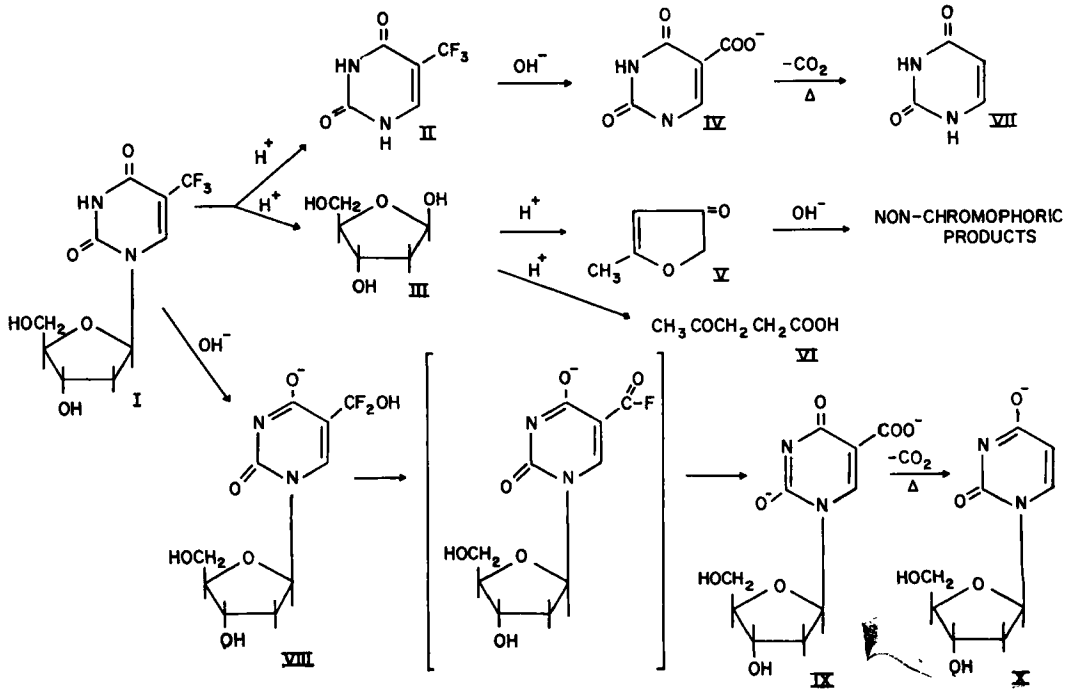

Scheme I

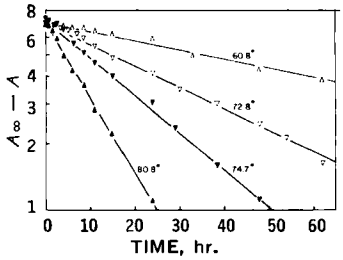

Fig. 4—Typical first-order plots for the degradation of 1.4 × 10⁻⁴ M 5-trifluoromethyl-2′-deoxyuridine in 0.1 N HCl at various temperatures. The absorbance values, A, were measured at 297.5 mμ for aliquots diluted 1:1 with 1.0 N NaOH and held for 24 hr. at room temperature where A_∞ is the asymptotic absorbance.

12.15) and 0.0218 *N* (pH 10.85) NaOH, respectively, at 80.0°. At 80.0° in pH 8.7 borate buffer, k = 2.0 × 10⁻⁷ sec.⁻¹ and in pH 6.7 phosphate buffer, k = 5.8 × 10⁻⁷ sec.⁻¹. At 80.0° in acetate buffers, k = 10.1 × 10⁻⁷ and 1.63 × 10⁻⁷ at pH values 4.75 and 3.75, respectively. It has been demonstrated that the major kinetic dependency for decarboxylation is by the attack of hydroxyl ion on the anion (21). Thus, it is probable from these rate constants that the specific catalytic rate constant for the attack of hydroxyl ion on the monoanion (or its kinetically equivalent water attack on the dianion) below the pKa_2' 9.0 (25.0°) but above the pKa_1' 4.2 (25.0°) of the carboxyl is of greater magnitude than the specific catalytic rate constant for the attack of hydroxyl ion on the dianion above the pKa_2'. The rate of decarboxylation most probably plateaus in the vicinity of this value and then decreases with solutions of decreasing pH values until values below the pKa_1' are reached. The values obtained in phosphate and acetate buffer solutions may be indicative of general base catalysis by phosphate and acetate ions where such catalysis has been reported for the decarboxylation of salicylic acids (21).

An expression consistent with the rate data excluding the values in acetate and phosphate buffers is

$$k = (k_0'' + k_{OH}''a_{NaOH}[NaOH])f_{u-} \quad \text{(Eq. 4)}$$

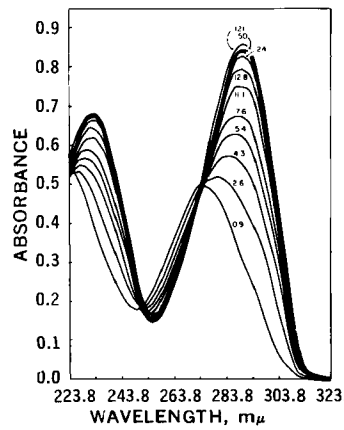

Fig. 5—Typical spectral changes for the degradation of 7.0 × 10⁻⁵ M 5-trifluoromethyluracil, in alkaline solution at low temperatures. The conditions were 0.200 N NaOH at 34.0°. Key: curves, min. after the start of the reaction.

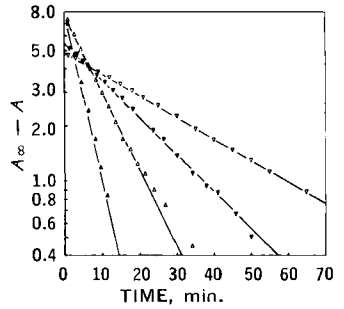

Fig. 6—Typical first-order plots for the degradation of 7.0 × 10⁻⁵ M 5-trifluoromethyluracil in various NaOH concentrations at 34.0°. Key: A, absorbance values were measured at 290 mμ where A_∞ is the asymptotic absorbance; curves and their respective N NaOH: ▽, 0.0049; ▼, 0.1094; Δ, 0.0485; ▲, 0.485.

where k_0'' = 2.0 × 10⁻⁷ sec.⁻¹, k_{OH}'' = 2.40 × 10⁻⁷ L./mole/sec., a_{NaOH} is the activity coefficient (14) for hydroxyl ion in [NaOH] solutions, and f_u = is the fraction of IV as the dianion at 80.0°.

The acid-catalyzed solvolysis of I in mineral acid at 80.0° produced the F_3T, II, or its hydrolytic product, IV, without any apparent decarboxylation. The alkaline-treated samples (room temperature, 24 hr.) from these studies produced a stoichiometric yield of the expected 5-carboxyuracil, IV. However, samples from the hydrolysis of I in acetate buffers at 80.0° at pH values of 3.7 and 4.7 when treated in alkali for 24 hr. did not produce a stoichiometric yield of desired 5-carboxyuracil. The presence of increasing amounts of uracil with time of acetate buffer degradation is consistent with the fact that 5-carboxyuracil is formed in these buffers at 80.0° and decarboxylated in the pH region of its pKa_1' 4.2 where it may exist in part as the carboxylate anion.

Since hydrolysis of II to IV and its subsequent decarboxylation to VII is a slow process with relation to the formation of II from I, an A_∞ corresponding to the theoretical yield of IV on alkaline treatment could be assumed. The initial points of the plot in accordance with Eq. 1 gave good estimates of the rate constants for hydrolysis of I in the acetate buffers at 80.0°.

Degradation of F_3TdR in Alkali—The facile degradation of F_3TdR, I, ($\lambda_{max.}$ 259 mμ) in alkaline solution is similar to that of F_3T in that the trifluoromethyl group is hydrolyzed to 5-carboxy-2′-deoxyuridine (DU-5-COOH), IX (272 mμ $\lambda_{max.}$ in 0.01 *N* NaOH), probably through alcohol, VIII, and acyl fluoride intermediates (Scheme I). The latter is most likely a highly reactive and transitory intermediate. This sequence is readily observable on changes in alkaline solution (Fig. 3). The spectra of alkaline-degrading I demonstrate a very fast initial increase in absorbance in the range 290–310 mμ (Fig. 3) which can be monitored with time at lower temperatures, *e.g.*, 30°. The apparent $\lambda_{max.}$ (260 mμ) of this intermediate is probably that of the curve for the 15-min. sample in 0.02 *M* NaOH at 47° and appears to be not very much different from the precursor, I (Fig. 3). This indicates that only minor changes in the electron patterns of the molecule are occurring, consistent with the structure of the 5-hydroxydifluoromethyl-2′-deoxyuridine, VIII, as the probable intermediate. The sub-

sequent production of a $\lambda_{max.}$, 272 mμ, is a slower process at these lower temperatures and the final absorbance and spectrum are consistent with the stoichiometric production of the anion of DU-5-COOH, IX, which was isolated from the alkaline-reacted solution and identified by elemental analysis and ultraviolet spectrum.

When the rapid increase of absorbance of higher concentrations of I in alkaline solutions is monitored at about 295 mμ at lower temperatures, *e.g.*, 30° (Fig. 2), plots of this absorbance against time permit the estimate of asymptotic values (Fig. 2 insert) before the further solvolysis to the carboxyl significantly affects the absorbance at this wavelength (Fig. 3). First-order plots of these data (Fig. 2 insert) in accordance with Eq. 1 permit estimates of the apparent first-order rate constants for the hydrolysis of I to VIII. These rate constants are listed in Table I and are consistent with the fact that the only significant process above pH 11 is the attack of hydroxyl ion on the monoanion where

$$k = k_{OH}' a_{NaOH}[NaOH] f_{u-} \quad \text{(Eq. 5)}$$

where k_{OH}' at 29.5° is 2.70 × 10^{-2} L./mole/sec., a_{NaOH} is the activity coefficient (14) for the specified [NaOH]. Above pH 11, the F_3TdR, I, exists as the monoanion since $pKa_1' = 7.85$ at 25°.

In the borate and phosphate buffer regions, first-order plots in accordance with Eq. 1 at both 280 and 290 mμ for data obtained at 47° were linear and of similar slopes for the complete duration of the reaction. No sequence of reactions could be observed at 30° and at these wavelengths in these buffer solutions, only the first-order process to IX. These facts are consistent with the premise that the intermediate, VIII, is rapidly hydrolyzed to IX in these lower pH regions by hydroxyl ion attack on the undissociated molecule (or its kinetically equivalent water attack on the monoanion) and that the rate-determining step is the hydrolysis to VIII.

At 80.0° in NaOH solutions, the hydrolysis of I to IX is too rapid to follow. However, it was spectrally observed that deoxyuridine (X) is rapidly produced by decarboxylation and slowly degrades subsequently.

Temperature Dependence—Rate constants for the several temperatures are given in Table I and its footnotes. The Arrhenius parameters were calculated from the plots of the logarithms of the rate constants in $sec.^{-1}$ against the reciprocal of the absolute temperature, T, in accordance with

$$\log k = \log P - (\Delta H_a/2.303R)(1/T) \quad \text{(Eq. 6)}$$

where R = 1.987 cal./degree/mole. The heats of activation, ΔH_a, in Kcal./mole and the log P values for the several conditions were: 2.54 N HCl, 29.7, 14.4; 0.100 N HCl, 26.9, 12.0; 0.485 N NaOH, 19.8, 9.78. The values in HCl are for hydrolysis of the nucleoside, I, to trifluoromethyluracil, II, and deoxyribose, III. The values in NaOH are for the hydrolysis of 5-hydroxydifluoromethyl-2′-deoxyuridine, VIII, to 5-carboxyl-2′-deoxyuridine, IX.

Log *k*-pH Profile—The log k-pH profiles for the degradation of F_3TdR, I, are given in Fig. 7 (solid lines) and are based on the data of Table I. They demonstrate maximum stability in the pH region 1–4 which may be assigned to solvent attack, k_0, on the undissociated molecule. The rising branch in

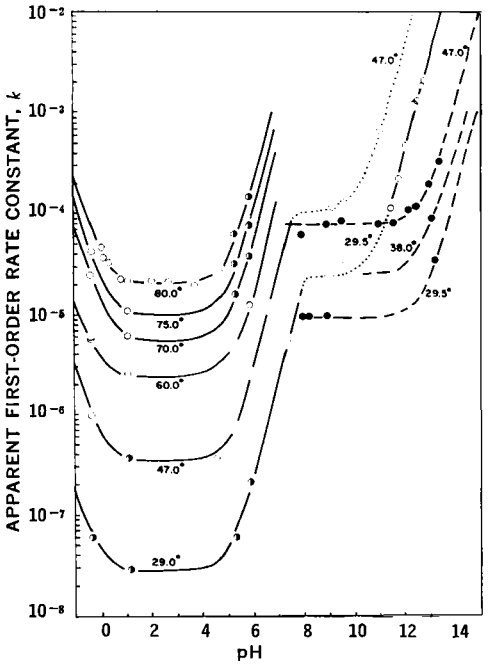

Fig. 7—Key: ——, *log k-pH profiles for the hydrolysis of 5-trifluoromethyl-2′-deoxyuridine and probable intermediate;* - - -, *5′-hydroxymethyl-2′-deoxyuridine where the lines are calculated;* ○, *represent data obtained from the loss of 5-trifluoromethyl-2′-deoxyuridine;* ◌, *estimated values with a degree of uncertainty;* ◑, *predicted from the Arrhenius relations; the dashed lines were calculated and fit the solid circles that represent data obtained for the formation of 5-carboxy-2′-deoxyuridine from the probable intermediate;* . . ., *estimated curves for the initial solvolysis of 5-trifluoromethyl-2′-deoxyuridine.*

the lower pH regions is consistent with hydrogen ion attack, $k_H[H^+]$, on the undissociated molecule. The products of these kinetic dependencies are F_3T, II, and deoxyribose, III (Scheme I).

The increasing rate constants with pH in the pH region 4–7.5 may be assigned to hydroxyl ion attack, $k_{OH}[OH^-]$ on the undissociated molecule and result in the 5-carboxyuracil-2′-deoxyribose, IX. Subsequent slow decarboxylation to X occurs at higher temperatures. No aberrations were observed in the spectra monitored in acetate or phosphate buffers (pH 4–7.5) as a function of time that could be assigned to a possible precursor, VIII, of the final product, IX. This can be explained on the basis of two possible premises. One explanation is that in the acetate and phosphate buffer regions, the HOF_2TdR, VIII, is more rapidly hydrolyzed than F_3TdR, I. Thus, the dashed lines (Fig. 7) for the presumed hydrolysis of HOF_2TdR, VIII to DU-5-COOH, IX by solvent attack on the dissociated molecule, k_0'' (or its kinetically equivalent hydroxyl ion attack on the undissociated molecule) may extend horizontally to lower pH values than the pKa′ of F_3TdR, I, *i.e.*, 7.9. This would imply that HOF_2TdR, VIII, has a significantly lower pKa_1' and that, even when it is completely undissociated, hydroxyl ion attack on this species is of much greater magnitude than hydroxyl ion attack, $k_{OH}[OH^-]$, on the undissociated F_3TdR, I.

TABLE IV—CATALYTIC RATE CONSTANTS[a] AND THERMODYNAMIC PARAMETERS[b] FOR THE CONSTRUCTION OF LOG k-pH PROFILES

	°C.							
	80.0	75.0	70.0	60.0	47.0	29.5	ΔH_a	log P
$10^6 k_0$	2.1	1.00	0.55	0.24	0.035	0.0028	27.1	16.2
$10^5 k_H$	2.2	1.45	0.80	0.13	0.029	0.00135	30.6	16.4
k_{OH}	430	460	250	130	48	14	17.0	13.3
k_{OH}'	—	—	—	—	0.13	0.026	18.2	11.6
$10^6 k_0''$	—	—	—	—	10.4[c]	2.5[c]	—	—
$10^5 k_0''$	—	—	—	—	7.85	0.97	22.3	11.1
$10^6 k_{OH}''$	—	—	—	—	25	10	10.3	3.5

[a] These catalytic rate constants may be used to predict the overall first-order rate constant for the hydrolysis of F_3TdR ($k = k_H[H^+] + k_0 + k_{OH}[OH^-]$ in the pH range -1 to 7.5 and $k = k_{OH}'[OH^-] + k_0'$ in the pH region >8) and of HOF_2TdR ($k = k_0'' + k_{OH}''[OH^-]$ in the pH region >8). [b] These values may predict the catalytic rate constant at other temperatures where $\log k = -(\Delta H_a/2.303R)(1/T) + \log P$. [c] These are estimated values based on approximations.

An alternative explanation is that in acetate and phosphate buffers, the spectrum of undissociated HOF_2TdR, VIII, is not significantly different than undissociated F_3TdR, I, and that the hydrolysis of the precursor I to VIII is much faster than the hydrolysis of VIII to IX so that the good first-order plots would still be obtained. This would lead to the conclusion that F_3TdR is more rapidly degraded than indicated in Fig. 7 for the pH range 5–7. However, in buffers about pH 10, there were no other spots observed on paper chromatographic monitoring that could be possibly assigned to a HOF_2TdR, VIII.

In the alkaline region the sequential steps could be readily analyzed kinetically. The data at 29.5° in the pH region > 11 (open circles, solid line, Fig. 7) is for the faster production of an asymptotic absorbance at 295–300 mμ (Fig. 2) than for the production of the spectrum assigned to DU-5-COOH, IX (Fig. 3) represented by the solid circles and dashed lines of Fig. 7. The intermediate is most probably HOF_2TdR, VIII, and is produced by hydroxyl ion attack, $k_{OH}'[OH^-]$, on the anion of F_3TdR, I. The dotted circles at 47.0° and 29.5° on the dotted lines are estimates of the rate constants in the borate buffer region, pH 8–11, and are not too accurate due to the small spectral difference at 295 mμ that had to be used. However, they do serve as a basis for estimating the stability of I in this intermediate pH region (dotted line, Fig. 7) where the rate constants for I and VIII are of the same order of magnitude.

The subsequent hydrolysis of the intermediate, the presumed VIII to IX, is represented by the dashed lines and the observed rate constants by the solid circles (Fig. 7). This obviously represents a solvent attack, k_0'', on the anion of VIII (or its kinetically equivalent hydroxyl ion attack on the undissociated molecule) and a hydroxyl ion attack, $k_{OH}''[OH^-]$, on the anion of VIII at higher pH values.

The basic expression used in the construction of the log k – pH profiles for the hydrolysis of F_3TdR (solid lines, Fig. 7) were

$$k = k_H[H^+] + k_0 + k_{OH}[OH^-] \qquad \text{(Eq. 7)}$$

in the pH region -1 to 7.5 (solid lines, Fig. 7), and

$$k = k_{OH}'[OH^-] + k_0' \qquad \text{(Eq. 8)}$$

in the pH region >8 (dotted and solid lines, Fig. 7). The expression used in the construction of the log k-pH profile for the appearance of DU-5-COOH, IX probably from the hydrolysis of HOF_2TdR, VIII was

$$k = k_0'' + k_{OH}''[OH^-] \qquad \text{(Eq. 9)}$$

in the pH region >8 (dashed lines, Fig. 7). The profiles of Fig. 7 were constructed from the $[H^+]$ and $[OH^-]$ in terms of their activities and the listed constants of Table IV. The drawn lines are calculated on the basis of the Eqs. 7–9 and are consistent with the experimental values of Fig. 7.

The half-life at 30° in the most stable pH range 1 to 4 is 280 days (580 days at 25°) and at pH 7.4 is 1.5 days (16 hr. at 37°). Thus solutions of F_3TR should be kept refrigerated. The products of degradation under the former conditions would be trifluorothymine and deoxyribose, and under the latter conditions would be fluoride ion, 5-carboxymethyl-2′-deoxyuridine and 5-hydroxydifluoromethyl-2′-deoxyuridine.

The obvious prediction is that F_3TdR incorporated into RNA or DNA will probably not remain as such. It should be readily transformed to the 5-carboxyl derivative at physiological pH values and temperatures. This would readily explain the fact that the use of F_3TdR is less conducive to the development of resistance than are the other nucleosidic antivirals (10).

Metabolism of β-Phenethylbiguanide

By PATRICK J. MURPHY and ARNE N. WICK

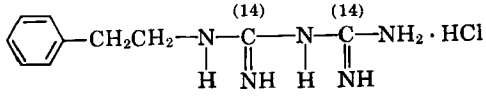
Carbon-14 labeled β-phenethylbiguanide (phenformin) was administered orally to male Sprague-Dawley rats. The radioactive material excreted in the urine was isolated and analyzed. The metabolic products were divided into "weak" and "strong" base components by their behavior on acidic ion-exchange resins. Chromatographic and spectroscopic evidence confirms the structure of the strong base fraction to be ρ-hydroxy-β-phenethylbiguanide. This hitherto unreported biguanide has been prepared synthetically for comparative purposes. The weak base metabolite has been shown to be the glucuronic acid conjugate of the phenolic biguanide. This fact was determined by acid hydrolysis to ρ-hydroxy-β-phenethylbiguanide and glucuronic acid. The more specific hydrolysis by β-glucuronidase confirmed the conjugate structure. The hydroxylated β-phenethylbiguanide along with its glucuronide conjugate were found to be present in the urine in approximately equal amounts. These two compounds seem to be the major metabolic products of β-phenethylbiguanide.

In diabetic humans, β-phenethylbiguanide hydrochloride has a hypoglycemic effect. Although this effect has been extensively studied, there is no unified concept which will explain the hypoglycemic action of this drug. Since the physiological activity of a chemotherapeutic agent is dependent in many cases (1) upon the mode of metabolism of the drug, an understanding of the metabolism of β-phenethylbiguanide may be helpful in elucidating the site and mode of action of the drug.

Preliminary studies in these laboratories have shown that the radioactivity of the labeled drug after administration is initially concentrated in the liver and gastric juice and is almost entirely eliminated in a 24-hr. period (2). Subsequent studies showed that the excreted metabolic products were chemically different from the ingested compound (3). The purpose of this study was the elucidation of the structure of the metabolic products excreted after the administration of β-phenethylbiguanide hydrochloride.

EXPERIMENTAL METHODS

In order to facilitate the metabolic studies, radioactive β-phenethylbiguanide hydrochloride synthesized by Walton (4), was used. The carbon-14 label was in the biguanide nucleus as depicted in the following:



Radioactivity was determined by the following means: (*a*) when the specific activity was to be determined the sample was oxidized to carbon dioxide by the "wet oxidation" method of Van Slyke and Folch (5) and precipitated as barium carbonate. The barium carbonate samples were mounted on planchets and counted for radioactivity in a Nuclear-Chicago gas-flow counter; (*b*) when relative radioactivity was desired, as in the case of column chromatography, aliquots were placed directly on the planchets, evaporated, and counted for radioactivity.

All paper chromatography was done by ascending technique on Whatman No. 1 paper. The spray

Received July 26, 1966, from Department of Chemistry, San Diego State College, San Diego, CA 93115, and California Metabolic Research Foundation, La Jolla, CA 92115

Accepted for publication May 2, 1968.

Taken in part from the thesis of Patrick J. Murphy, submitted in partial fulfillment of the Master of Science degree requirements, San Diego State College, August 1964.

This investigation was supported in part by the United States Public Health Service, grant AM05685-04, and The United States Vitamin and Pharmaceutical Corporation, New York, N. Y.

used for the detection of biguanide metabolites was prepared 30 min. prior to use by mixing 10% solutions of sodium nitroprusside, potassium ferricyanide, and sodium hydroxide in a 1:1:1 ratio and diluting the solution with 9 vol. of water. The reagent gives a bright red color with guanidines and biguanides (6).

Ultraviolet spectra were run on a Cary model 14 recording spectrophotometer. Infrared spectra were run in potassium bromide pellets on a Perkin-Elmer Infracord spectrophotometer. Nuclear magnetic resonance spectra were obtained on a Varian A-60 spectrometer.

ISOLATION OF METABOLIC PRODUCTS

β-Phenethylbiguanide hydrochloride was administered in water solution by means of a stomach tube to 24 hr. fasted male Sprague-Dawley rats in doses of 100 mg./kg. body weight. The urine of the rats was collected at 8-hr. intervals for a 24-hr. period during which time the rats had access only to water. The urine, which was approximately 25 ml. per rat, was frozen upon collection and subsequently lyophilized.

Ion-Exchange Chromatography—The lyophilized urine was slurried with water, in approximately $^1/_6$ the original volume of urine, and the insoluble material removed by centrifugation. The clear solution was then placed on a 20 × 1.25-cm. column of Amberlite CG-50 (carboxylic acid—H^+ form) ion-exchange resin. This column retained all of the inorganic cations as well as strong organic bases. The column was rinsed with water and the eluate passed over a 20 × 1.25-cm. column of Amberlite CG-120 (sulfonic acid — H^+ form). The CG-120 resin retains all weak organic bases. The eluate from this column contains the neutral and acidic components of the urine. All of the radioactive components of the urine were retained by these columns and a summary of the distribution of this radioactivity is given in Table I.

The two columns were then separately eluted, the CG-50 resin with 0–0.1 *N* hydrochloric acid in a gradient elution manner, and the CG-120 resin with 0–0.5 *N* ammonium hydroxide by similar methods. The eluate from the CG-50 column thus contained the strong organic bases while the eluate from the CG-120 resin contained the weak bases.

The remainder of the administered radioactivity (45%) was found to be present in the stools of the animals. This radioactive material was soluble in water and upon separation on a CG-50 (H^+) column (as above) was found to consist of 77% strong base material. These results are also included in Table I.

Weak Base Metabolite—The isolated weak base fraction from 29 rats was extracted with 70 ml. of hot ethanol, the solution filtered, and the residue separated. Although a small amount of radioactivity was taken up in the extract, the majority of the material in this solution consisted of nonradioactive creatine and creatinine (as determined by chromatographic and spectroscopic means). The residue was then extracted with methanol, and isopropyl alcohol was added to the point of saturation. Concentration of the solution yielded three crops of material which gave a single biguanide-positive spot after paper chromatographic separation. These spots corresponded directly to the radioactive area.

Table I—Percentage Distribution of Excreted Radioactive Metabolites

	Total	Strong Base	Weak Base
Urine	56	28	28
Feces	45	35	Undetermined

In order to further purify the radioactive metabolite, 60 mg. obtained from the first three crops was placed on a column of pressure packed Whatman No. 1 powdered cellulose in *n*-butanol saturated with water. The column was eluted with 1.5 vol. of saturated butanol followed by a saturated butanol–acetic acid (3:1) solution. The fractions were collected in 10-ml. aliquots. The radioactivity came off the column in fractions 21–29. The main fraction was extracted with ether and the aqueous solution was then stripped to dryness to give 29 mg. of purified material.

Acid Hydrolysis of the Weak Base Metabolite—A solution of 3 mg. of the purified metabolite in 0.3 ml. of (1*N*) hydrochloric acid was heated for 2 hr. at 100°. At the end of the heating period 0.06 ml. was tested with barium chloride and the negative result indicated the lack of "ethereal sulfate" in the metabolite. A small portion (0.03 ml.) of the hydrolysate was tested for the presence of reducing sugar by the method described by Nelson (7). This test was strongly positive. A similar portion (0.03 ml.) was tested for the presence of phenol by the Folin-Ciocalteu method (8).

A comparison of the results obtained after hydrolysis with a blank run on the unhydrolyzed compound showed that approximately 1 mole of reducing sugar (using glucuronic acid for a standard curve) was released per mole of phenolic group obtained (using phenol for a standard curve).

Incubation with β-Glucuronidase—Incubation of the purified metabolite (5.2 mg.) with β-glucuronidase (5.7 mg., Sigma Chemical Co.) in 5 ml. of sodium acetate-acetic acid buffer (pH 5.8) was carried out for 18 hr. at 37° (9). After this time the protein was denatured with 1 ml. of 5% trichloroacetic acid, and the residue filtered off. The filtered material was washed with 0.2 ml. of water and the combined filtrates extracted with four 2-ml. portions of ether in order to remove excess trichloroacetic acid. The aqueous layer was aerated and then added to a volumetric flask and diluted to 10 ml. When the hydrolysate was assayed for phenol (8) and reducing sugar (7), the ratio was found to be approximately 1:1 (using the standard curves described above).

Strong Base Metabolite—The strong base fraction from 22 rats (335 mg.) was extracted with methanol. Almost the entire residue dissolved. The material was crystallized by means of concentration of the methanol solution and subsequent addition of isopropyl alcohol. These extracts contained the majority of the radioactivity present. The extracts were evaporated to dryness and the solid taken up in water to be used for chromatography.

Synthesis of p-Hydroxy-β-phenethylbiguanide Hydrochloride—Tyramine hydrochloride (2.5 g., 0.014 mole) was added to cyanoguanidine (1.8 g., 0.014 mole) in a 10-ml. conical flask. The flask

was heated in an oil bath to the fusion point (oil bath 175°) and then the bath temperature was raised to 190° for 2 hr. Upon cooling the mixture solidified. The solid glass-like material was dissolved in methanol and the solution concentrated until a precipitate was obtained upon cooling. The precipitate contained considerable unreacted starting material. One-half of the filtrate was added to a solution of cupric chloride dihydrate in 10 ml. of water and the pH adjusted to 5.6. The precipitated copper biguanide complex, along with any copper hydroxide formed, was centrifuged and washed with two 10-ml. portions of water. The solid material was slurried in 20 ml. of water and hydrogen sulfide gas was passed through the slurry for 1 hr. When the formation of copper sulfide was complete, the material was filtered and the solution lyophilized.

The grayish solid was extracted with methanol and the insoluble copper sulfide residue filtered off. The solution was evaporated to dryness and taken up in a minimum of hot ethanol. Upon cooling, 115 mg. of white crystals were obtained, m.p. 181–186°. Recrystallization from acetonitrile gave white crystals, m.p. 180–183°.[1] The NMR spectrum of this compound in trifluoroacetic acid confirms the structure as *p*-hydroxy-β-phenethylbiguanide. The symmetric aromatic quartet [$\delta = -7.21$ p.p.m.][2] is characteristic of *p*-substituted aromatic rings. The nitrogen protons of the protonated biguanide are observed slightly downfield of the aromatic protons. The methylene protons exhibit peaks at [$\delta = -3.13$ p.p.m.] and [$\delta = -3.92$ p.p.m.].[3]

The ultraviolet spectrum in water shows the absorption ($\lambda_{max.}$ 227 mμ, ε 15.8 × 10³) characteristic of the biguanide conjugated system (11). The infrared spectrum was consistent with the proposed structure [*e.g.*, NH peaks 3,320 cm.$^{-1}$, 1,653 cm.$^{-1}$ (12); aromatic 1,4-disubstitution peaks 1,620 cm.$^{-1}$, 832 cm.$^{-1}$] (13).

Chromatographic Identification of the Metabolite—The hydrolyzed weak base metabolite, the purified strong base metabolite, and synthetic *p*-hydroxy-β-phenethylbiguanide were chromatographed in acidic, neutral, and basic solvent systems. The results of these chromatograms are given in Table II. In all three systems the strong base metabolite, the weak base hydrolysate, and the synthetic *p*-hydroxy-β-phenethylbiguanide show the same R_f values, indicating that the three are identical.

Spectroscopic Identification of the Metabolites—The ultraviolet absorption spectra of synthetic *p*-hydroxy-β-phenethylbiguanide hydrochloride in neutral and basic solution were compared to the spectra obtained with the weak base hydrolysate, and the strong base metabolite in identical solutions. In all cases these spectra were identical, thus confirming that the metabolite was *p*-hydroxy-β-phenethylbiguanide hydrochloride.

The oxidation of aromatic rings in the process of metabolism is a well documented process (1). The observation that β-phenethylbiguanide is hydroxylated *in vivo* may have important implications as to its mode of action. Work on the physiological activity of this metabolite is currently under way.

[1] Analytically pure *p*-hydroxy-β-phenethylbiguanide hydrochloride subsequently supplied by U. S. Vitamin and Pharmaceutical Corp., New York, N. Y., was found to have identical physical characteristics as this material.

[2] Relative to external tetramethylsilane.

[3] The analysis of the structure and NMR spectra of protonated biguanides have been reported elsewhere (10). The readers are referred to the MS thesis of P. J. Murphy for the original spectra.

TABLE II—R_f VALUES OF URINARY METABOLITES AND CONTROLS[a]

Compound	R_f Value in Solvent System[b] A	B	C
Weak base (conj.)	0.25	0.20	—
Weak base (hydrol.)	0.17[c]	0.35[c]	0.65[c]
Strong base	0.17[d]	0.35[d]	0.65[d]
p-Hydroxy-β-phenethylbiguanide	0.17	0.35	0.65
β-Phenethylbiguanide	0.50	0.67	0.74

[a] Ascending technique at room temperature. [b] Solvent systems; A, *n*-butanol, saturated with water; B, *n*-butanol–formic acid–water (63:17:20); C, methanol–pyridine–water (80:2:20). [c] In each system the weak base hydrolysate gave a radioactive spot lower than the main spot. This spot is attributed to incomplete hydrolysis. [d] The reported spot is the major guanidine-positive spot, however a much weaker positive area was observed closer to the origin on all chromatograms. This spot is not presently explainable.

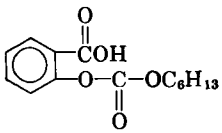
Pharmacology of the Hexylcarbonate of Salicylic Acid

By A. MISHER, H. J. ADAMS, J. J. FISHLER, and R. G. JONES

Gastric absorption of aspirin, salicylate, or acetic acid can result in increased mucosal permeability to H^+ ions leading to gastric bleeding. The pharmacology of the hexylcarbonate derivative of salicylic acid was investigated because its physical-chemical properties are such as could reduce the compound's availability to the gastric mucosa. It was found that the compound possesses antipyretic, analgesic, and anti-inflammatory activity qualitatively identical to those of aspirin. Its acute toxicity is less than that of aspirin in rats and mice and its gastric irritation potential is markedly lower in rats and dogs.

IT HAS BEEN SHOWN that the gastric absorption of aspirin, salicylate, or acetic acid can result in damage to the mucosa, making it more permeable to small ions including H^+ ions, and that the absorption of moderate quantities of H^+ ions through the insulted mucosa leads to gastric bleeding (1, 2).

The fact that aspirin administration is often associated with gastric irritation and hemorrhage is well documented in the literature (3). The authors' studies with carbonate derivatives of various drugs (4) suggested that salicylic acid might lend itself to prodrug formation, with retention of the antipyretic, analgesic, and anti-inflammatory activities, but with altered physical-chemical properties. Of the derivatives prepared, the *n*-hexyl-*O*-carboxyphenylcarbonate (SK&F 26070) (I) showed the most favorable profile being about only one-twentieth as soluble as aspirin in 0.1 *N* HCl at 37°, not producing acetic acid on hydrolysis, and having a much altered oil/water solubility coefficient (5). Changes such as these could reduce the compound's availability to the gastric mucosa.



I

These studies were conducted in order to determine the impact of these changes on the pharmacological profile of this compound and its potential to cause gastric irritation.

EXPERIMENTAL

Acute Oral Toxicity in Mice and Rats—Male Carworth Farms (CF_1-S) mice, weighing 18–24 Gm., and male Charles River rats, weighing 100–159 Gm., were randomly divided into groups of 10 and dosed orally with suspensions of aspirin or SK&F 26070. The maximum dose volume was 20 ml./Kg. Control animals received either 0.5% tragacanth or 1% methylcellulose (400 cps.) at corresponding dose volumes. Daily observations were made until no deaths had occurred for 2 consecutive days following the fifth day. Food and water were available *ad libitum*.

Gastric Irritation in Rats—Male Charles River rats, weighing 144–213 Gm., were fasted 18 hr. prior to use. They were then randomly divided into groups of 10 and dosed orally with aspirin or SK&F 26070 suspended in 1% methylcellulose (400 cps.). Drug concentrations were adjusted so that each animal received a dose volume of 10 ml./Kg.; 20 control animals received an equal dose volume of the vehicle. Two hours postdrug, the animals were sacrified with ether. The stomachs were excised, opened along the greater curvature, and gently rinsed with warm water. They were then examined under low magnification with a binocular microscope and rated positive or negative for hemorrhage and for ulceration, these evaluations were done on a "blind" basis.

Gastric Irritation in Dogs—Mongrel dogs of either sex, weighing 10–15 Kg., were randomly assigned identification numbers and divided into groups of four. Each group received one of the following treatments: aspirin, 25 mg./Kg.; aspirin, 75 mg./Kg.; SK&F 26070, 25 mg./Kg.; SK&F 26070, 75 mg./Kg.; empty gelatin capsules (control group). Each animal received six consecutive oral doses, spaced 12 hr. apart. The animals were sacrificed 4–5 hr. after the last dose. The stomachs were removed, opened, and the degree of irritation graded on a "blind" basis.

Antipyretic Activity in Rats—Eighty male Charles River rats were randomly divided into six drug groups of 10 and a control group of 20 animals. Immediately after a control rectal temperature had been taken, each animal received subcutaneously in the nape of the neck 1 ml./Kg. of a freshly prepared 20% suspension of brewer's yeast in isotonic saline. Rectal temperatures were taken 5 hr. later, and each animal then received a dose of drug or an equivalent dose volume of vehicle. Both aspirin and SK&F 26070 were administered orally at 50, 100, and 200 mg./Kg., suspended in 0.5% tragacanth, at a dose volume of 20 ml./Kg. Rectal temperatures were taken again 2 hr. postdrug. Food was withheld throughout the test period, but water was available *ad libitum*.

The results were evaluated quantitatively: if the final rectal temperature of an animal was at least 1° below the mean of the control group, the animal's

Accepted for publication March 1, 1968.

response was negative. ED_{50}'s for the antipyretic activity of the two compounds were calculated by the Logit chi-square method of Berkson (6).

Analgesic Activity in Rats—The inflamed paw method of Randall and Selitto, which has been shown to be sensitive enough to detect the mild nonnarcotic analgesics (7), was used for this study. Male and female Dierolf Farms rats, weighing 80–110 Gm., were fasted 16 hr. before use. Inflammation was produced by the injection of 0.1 ml. of a freshly prepared 20% suspension of brewer's yeast into the plantar surface of the rat's left hind foot. Two and one-half hours after the yeast injection, pain threshold determinations (predrug control values) were made on the inflamed paw. Animals were then randomly divided into groups of five and dosed orally. Drugs were prepared as suspensions in 0.5% tragacanth, and concentrations were adjusted so that each animal received a dose volume of 20 ml./Kg.; 10 control animals received 20 ml./Kg. of vehicle. Threshold determinations were made at 30, 60, 120, 180, and 240 min. postdrug.

To determine pain thresholds, pressure was applied to the plantar surface of the inflamed paw at a constant rate of 20 mm. Hg/sec. by means of a Plexiglas cone attached to the plunger of a 10-ml. syringe; the syringe was connected to a pressure gauge, control valves, and a source of air pressure. The pain threshold is expressed as the pressure (in mm. Hg) required to induce struggle in the animal. Analgesic activity is expressed as the difference (Δ mm. Hg) between the pressure required to induce this behavior after drug administration as compared to the measurement before drug administration.

Anti-inflammatory Activity—Anti-inflammatory activity was tested in the rat in which polyarthritis was induced by the intradermal injection of adjuvant; the method used was similar to that described by Ward and Cloud (8) and by Glenn (9). Paw volumes were recorded by means of a modification of the method described by Winter and Nuss (10).

On the morning of Day 1, the plantar surface of the right hind paw of male Carworth Farms rats (initial weight 145–213 Gm.) was injected intradermally with adjuvant (0.1 ml. of a 2.5 mg./ml. suspension of *Mycobacterium butyricum*[1] in mineral oil). Immediately after the injection, animals were randomly divided into groups of 10, and the volume of each injected paw was measured by immersing the paw to the level of the lateral malleolus in a mercury bath which was connected through a closed, fluid-filled tube to the Microcord 44[2] recorder. Volumes could be measured accurately with reliability to the hundredth of a milliliter.

The drugs were administered immediately after this initial paw volume measurement, and again 3 hr. later. The doses of aspirin were 100 and 200 mg./Kg., b.i.d., the doses of SK&F 26070 were 148 and 293 mg./Kg., b.i.d. and were equimolar to those of aspirin. The drugs were suspended in 0.5% methylcellulose (4,000 cps.) and administered orally, b.i.d., at a dose volume of 10 ml./Kg. for 19 days.

From Day 2 through Day 19 the second dose was administered approximately 5 hr. after the first dose. One adjuvant control group received 0.5% methylcellulose (4,000 cps.) orally, b.i.d., at a dose volume of 10 ml./Kg. for 19 days. To provide "normal" values for the parameters measured, a group of 10 rats that received neither adjuvant nor treatment was used.

On Day 20, plasma inflammation units were determined according to the method outlined by Glenn and Kooyers (11). The animals were anesthetized with ether, and blood was obtained in heparinized syringes by cardiac puncture. The blood samples were placed into heparinized glass centrifuge tubes and centrifuged at about 1500 r.p.m. for 30 min. Plasma samples were withdrawn, and inflammation units were determined after diluting the plasma 1:200 with sterile physiological saline.

The initial turbidity readings of the diluted solutions were determined in a Coleman No. 9 nephelometer, set at full sensitivity, against the nephalos standard, $N = 19$. The diluted solutions were subsequently placed in a water bath at 56° for 30 min., cooled to room temperature, and turbidity again determined. The differences between initial and final nephelometric readings are expressed as "corrected inflammation units."

RESULTS

Acute Oral Toxicity in Mice and Rats—As shown in Tables I and II, milligram for milligram, aspirin is about twice as toxic orally in both mice and rats as SK&F 26070; on a molar basis, aspirin is significantly more toxic ($p = 0.05$) than SK&F 26070. With both drugs, most or all deaths occurred within 24 hr. postdrug.

TABLE III—GASTRIC IRRITATION IN RATS

Drug	Dose, mg./Kg., p.o. (10 Animals/Group)	Incidence of Gastric Hemorrhage, %	Incidence of Gastric Erosions %
SK&F 26070	84.4	30	0
	148	20	0
	259	30	0
Aspirin	57	70	20
	100	100	30
	175	100	90
1% Methylcellulose	10 ml./Kg.	0	0

Gastric Irritation in Rats—At equimolar dose levels, the incidence of hemorrhagic stomachs in rats that received SK&F 26070 was markedly lower than in rats that received aspirin (Table III). Even at the highest dose tested (259 mg./Kg.), SK&F 26070 produced no gastric erosions; the molar equivalent dose of aspirin, on the other hand, caused gastric erosions in 90% of the animals.

Gastric Irritation in Dogs—In dogs, the effects of the drugs were studied after repeated administration—six doses spaced 12 hr. apart—rather than after a single administration as in rats. The results are even more pronounced than in rats. The stomachs of all eight dogs that received SK&F 26070 were normal in appearance and indistinguishable from those of control animals. All four dogs that received the 25 mg./Kg. dose of aspirin and one of those that received the 75 mg./Kg. dose showed localized superficial mucosal irritation or inflammation; the other three dogs at the high dose showed mucosal irritation and isolated hemorrhage. On a molar basis, the high dose of SK&F 26070, which produced no gastric irritation, is about twice that of the low dose of aspirin, which caused gastric irritation in all four animals.

Antipyretic Activity in Yeast-Fevered Rats—At each dose level, the percent of animals tested that exhibited an antipyretic response to the drugs was identical for both SK&F 26070 and aspirin: 50 mg./Kg.—60%; 100 mg./Kg.—80%; 200 mg./Kg.—100%. Therefore, the two compounds appear equipotent, on a mg. for mg. basis, in antipyretic activity in this test procedure.

Analgesic Activity in Rats—At 200 mg./Kg., aspirin and SK&F 26070 caused a maximum increase in the pain threshold of the inflamed paw of 31 mm. Hg and 34 mm. Hg, respectively; at 400 mg./Kg., aspirin produced a maximum increase of 87 mm. Hg and SK&F 26070 effected a 72 mm. Hg increase. These data indicate that SK&F 26070 exhibits analgesic activity comparable to that of aspirin.

Anti-inflammatory Activity: Paw Volume Change—The onset of the polyarthritis was indicated by an increase in volume of the injected paw after an initial inflammatory phase of about 10 days in which the volume first increased and then decreased. In the vehicle control group, the onset of polyarthritis occurred between Days 9 and 11 (see Table IV). Statistical analysis of the data seems to indicate that the onset of drug activity occurred earlier with SK&F 26070 than with aspirin.

On Days 15–19, both dose levels of SK&F 26070 and of aspirin elicited similar degrees of inhibition of paw volume increase. On Days 17 and 19, the inhibition of paw volume increase by the high dose

	200	20.3		
0.5% Methocel, 4,000 cps.	10 ml./Kg.	57.2	—	—
Nonarthritic control	No treatment	5.1	—	—

[a] Limits could not be calculated.

of both drugs was significantly greater ($p = 0.05$) than elicited by the low dose of the two drugs. ED_{50}'s for inhibition of paw volume increase (doses that decreased by 50% the difference in paw volumes between the vehicle control and nonarthritic control groups) were calculated from the data of Day 19. The mean paw volumes for each day and the ED_{50}'s for Day 19 are listed in Table IV.

The mean paw volume of the nonarthritic control group remained relatively constant during the 19 days of this study. Apparently the extremeties do not increase in size in proportion with the weight gain of the rat during this interval of growth.

Plasma Inflammation Units—The mean "corrected plasma inflammation units," determined on Day 20, are shown in Table V. The "corrected plasma inflammation units" for the low dose of SK&F 26070 and aspirin are not significantly different from the vehicle control group. The mean "corrected inflammation units" for the high dose for both compounds were similar and statistically significantly different from that of the vehicle control group. ED_{50}'s were calculated and are shown in Table V.

DISCUSSION

Orally in the mouse and rat, SK&F 26070 is less toxic, both on a milligram for milligram and on a molar basis, than aspirin. It is also significantly less irritating to the gastric mucosa of the rat and dog, even when administered repeatedly as was done with dogs. Although one might conclude that the lower toxicity and reduced gastric irritation are due to an incomplete or a slower rate of absorption, a previous study showed that SK&F 26070 is absorbed as rapidly and completely as aspirin following oral administration to dogs (5).

SK&F 26070 exhibits antipyretic, analgesic, and anti-inflammatory activities, and its pharmacological profile is, therefore, qualitatively similar to that of aspirin. One can infer from this and from the *in vitro* studies of hydrolysis of the compound (5) that the prodrug is cleaved after oral administration (and possibly after absorption) and that the pharmacological activities are due to the resultant salicylate formation. SK&F 26070's reduced gastric liability may be due to a reduced availability of the compound to the gastric mucosa because of the physical properties previously discussed.

Although SK&F 26070's acute toxicity and gastric irritation potential are less than those of aspirin, it appears, on a molar basis, as potent as aspirin in reducing both paw volume and plasma inflammation units in the chronic study of adjuvant-induced arthritis in rats.

SUMMARY

SK&F 26070, the hexylcarbonate of salicylic acid, possesses antipyretic, analgesic, and anti-inflammatory activities qualitatively identical to those of aspirin.

Its acute toxicity is less than that of aspirin, and its gastric irritation potential is markedly lower. Upon chronic administration, SK&F 26070 is as potent as aspirin in reducing both paw volume and plasma inflammation units in rats with adjuvant-induced arthritis.

Study of the Sympathomimetic Action of Cyclohexylamine, a Possible Metabolite of Cyclamate

By H. I. YAMAMURA, I. P. LEE, and R. L. DIXON

The pharmacological actions of cyclohexylamine on the autonomic nervous system were tested using the cat's blood pressure and nictitating membrane responses. Although cyclohexylamine had no effect upon the adrenergic, cholinergic, or histaminic responses as shown by epinephrine, norepinephrine, acetylcholine, or histamine, it was demonstrated to possess a pressor action, and this pressor activity could be blocked by phenoxybenzamine. The results indicated that cyclohexylamine may act by releasing the neural humoral transmitter substance norepinephrine because prior pretreatment with reserpine, which depletes the catecholamine stores, abolished the pressor effect. Upon subsequent administration of norepinephrine the pressor response returned. It was shown that there was no potentiation between cyclohexylamine and a monoamine oxidase inhibitor, but potentiation did occur between tyramine and the monoamine oxidase inhibitor.

CYCLAMATE AND saccharin are extensively used as noncaloric sweetening agents for various beverages and foods. Ingestion of cyclamate in excess of 5 Gm. per day is not an unreasonable amount considering its widespread use. Recently, Kojima and Ichibagase (1) and Leahy *et al.* (2) have indicated the possibility that a small portion of administered sodium cyclamate may be metabolized to cyclohexylamine. The possibility also exists that cyclohexylamine may be ingested either as impurity or due to spontaneous breakdown in various food products. These findings prompted this investigtion of cyclohexylamine in order to: (*a*) investigate the action of cyclohexylamine on the vascular system, (*b*) study the effect of cyclohexylamine on the action of various endogenous transmitter substances, and (*c*) consider the possible interaction between cyclohexylamine and monoamine oxidase inhibitors.

METHODS

Twenty-five cats of either sex, weighing between 2.5–3.5 Kg., were anesthetized with sodium pentobarbital (30 mg./Kg.) administered intraperitoneally (i.p.). Blood pressure was recorded from the cannulated left femoral artery using a physiograph "Four" recorder, E & M Pressure Transducer (model P-1000) and E & M Myograph (type B). The contractions of the nictitating membrane were determined after placing it under an initial tension of 5 Gm. A tracheal cannula was routinely inserted and artificial respiration was administered when necessary.

Drugs—The following drugs were used: *l*-epinephrine bitartrate (Sigma Chemical Co.); *l*-norepinephrine bitartrate (City Chemical Co.); tyramine HCl (Mann Research Laboratories); acetylcholine chloride (NBC); histamine phosphate (Burroughs Wellcome & Co.); cyclohexylamine HCl (K & K Laboratories, Inc.); reserpine (Ciba Pharmaceutical Co.); pargyline HCl (Abbott Laboratories); phenoxybenzamine HCl (Smith Kline and French Laboratories); and propranolol (Ayerst Laboratories). The concentrations of drugs used in all experiments were expressed on the basis of their salts, except for epinephrine and norepinephrine, which were expressed on the basis of their base forms.

RESULTS

General Action of Cyclohexylamine—Figure 1 shows a record taken from an experiment performed using an anesthetized cat. It can be seen that injections of 10 mcg./Kg. each of epinephrine and norepinephrine, 3 mcg./Kg. of acetylcholine, and 5 mcg./Kg. of histamine resulted in the characteristic responses of each drug. Cyclohexylamine (5 mg./Kg.) was then administered intravenously and a pressor response was noted. Subsequent administration of epinephrine, norepinephrine, acetylcholine, and histamine still produced their characteristic responses indicating that cyclohexylamine was not an adrenergic, cholinergic, or a histaminic blocker, but that it was capable of exerting a pressor action.

Reversal of Cyclohexylamine Response by Phenoxybenzamine—To determine if cyclohexylamine was a sympathomimetic amine, phenoxy-

benzamine (10 mg./Kg.), an α-adrenergic blocking agent, was administered intravenously. These results are presented in Fig. 2. After the adrenergic blockade was established, which required approximately 30 min., a second dose of cyclohexylamine (5 mg./Kg.) was given. The usual pressor response to cyclohexylamine was no longer noticed; rather a depressor response was now observed. Propranolol (0.5 mg./Kg.), a β-blocking agent, was then given to determine whether the depressor response could be blocked. Partial blockage of the depressor response was noted as seen in Fig. 2.

Effect of Cyclohexylamine After Pretreatment with Reserpine—Figure 3 demonstrates that an injection of 500 mcg./Kg. of tyramine, an indirect acting amine, caused a rise in blood pressure and produced a contraction of the nictitating membrane in a normal anesthetized cat. An injection of 5 mg./Kg. of cyclohexylamine also caused a large rise in blood pressure and a large and prolonged contraction of the nictitating membrane. In a subsequent study (Fig. 4), the successive injections of tyramine and cyclohexylamine were administered to a cat pretreated approximately 24 hr. with reserpine (1 mg./Kg. i.p.) in order to deplete the catecholamine stores. The effects of tyramine and cyclohexylamine, both on the blood pressure and nictitating membrane response, were diminished by the reserpine treatment. Norepinephrine (0.6 mg./Kg.) was then administered slowly into the femoral vein. This injection of norepinephrine caused a large rise in blood pressure and contraction of the nictitating membrane (Fig. 4). After the injection of norepinephrine, the blood pressure and contraction of the nictitating membrane returned to their initial level. An injection of tyramine (500 mcg./Kg.) followed by cyclohexylamine (5 mg./Kg.) was made again as shown in Fig. 4. The increase in the blood pressure was equal to that of control values and there was a noticeable contraction of the nictitating membrane which was absent after pretreatment with reserpine. The events shown in Fig. 4 were observed in each of three experiments. After the pressor action of tyramine and cyclohexylamine had been restored by administration of norepinephrine, the repeated injections of either tyramine or cyclohexylamine had a diminished effect. However, another injection of norepinephrine once again restored the pressor action.

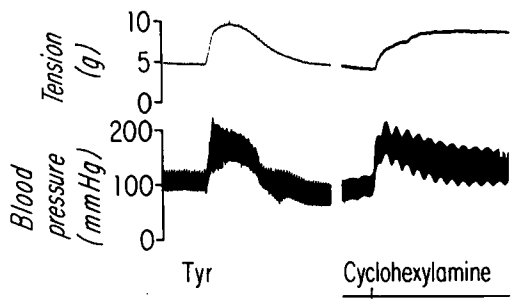

Fig. 3—The cat's pressor and nictitating membrane responses to tyramine (500 mcg./Kg.) and cyclohexylamine (5 mg./Kg.) in a normal anesthetized cat.

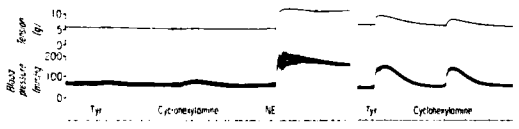

Fig. 4—The effect of slow administration of norepinephrine (0.6 mg./Kg.) on the cat's pressor and nictitating membrane responses to tyramine (500 mcg./Kg.) and cyclohexylamine (5 mg./Kg.) in a reserpinized (1 mg./Kg. i.p.) cat.

Effect of Cyclohexylamine After Pretreatment with Pargyline—These experiments were undertaken to determine if potentiation of the action of cyclohexylamine would be observed following animal pretreatment with a monoamine oxidase inhibitor. It should be recalled that pretreatment of patients with monoamine oxidase inhibitors resulted in a hypertensive crisis when these patients ingested the sympathomimetic agent, tyramine, contained in various foods (3, 4).

Therefore, pargyline (25 mg./Kg.), a monoamine oxidase inhibitor, was administered i.p. to cats 24 hr. prior to the start of the experiments. As can be seen in Fig. 5, pargyline pretreatment had no effect on the action of cyclohexylamine on either blood pressure or nictitating membrane response. However, in contrast, pretreatment with the monoamine oxidase inhibitor potentiated the responses seen after tyramine (500 mcg./Kg.). It can be seen that after tyramine there was a potentiation in both the pressor and in the nictitating membrane responses when compared to control values. Data obtained from all experimental animals are presented in Table I. Thus, there did not appear to be any significant interaction between this monoamine oxidase inhibitor and cyclohexylamine. This is most likely due to the fact that cyclohexylamine, in contrast to tyramine, is only a very weak substrate for MAO (5).

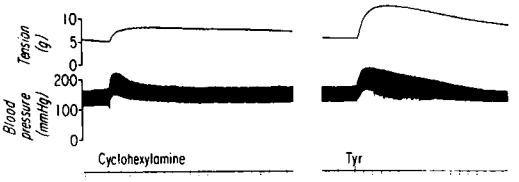

Fig. 5—The effect of cyclohexylamine (5 mg./Kg.) and tyramine (500 mcg./Kg.) on the pressor and nictitating membrane responses of a 24 hr. pargyline (25 mg./Kg. i.p.) pretreated cat.

TABLE I—CHANGE IN BLOOD PRESSURE[a] AND TENSION OF THE NICTITATING MEMBRANE IN CONTROL AND PARGYLINE-PRETREATED CATS

Experiment	Cyclohexylamine (5.0 mg./Kg.) Blood Pressure (mm. Hg)	Cyclohexylamine (5.0 mg./Kg.) Nictitating Membrane (Gm.)	Tyramine (500 mcg./Kg.) Blood Pressure (mm. Hg)	Tyramine (500 mcg./Kg.) Nictitating Membrane (Gm.)
Control	82 ± 8.2[b] (5)[c]	5.2 ± 0.62 (5)	64 ± 4.8 (7)	3.5 ± 0.71 (7)

DISCUSSION

The data presented in this paper demonstrate that cyclohexylamine, a possible metabolite of cyclamate, possessed pressor activity and caused contraction of the nictitating membrane of the anesthetized cat. Cyclohexylamine had no effect upon the adrenergic, cholinergic, or histaminic responses elicited by epinephrine, norepinephrine, histamine, or acetylcholine.

The pressor activity of cyclohexylamine was shown to be due to the action of cyclohexylamine on the sympathetic nervous system. Prior administration of phenoxybenzamine, an irreversible competitive α-adrenergic receptor blocker, reversed the pressor response of cyclohexylamine and resulted in a depressor response which in turn was slightly blocked by the β-receptor blocking agent, propranolol.

Cyclohexylamine appeared to be an indirect acting sympathomimetic amine. After reserpine depletion of transmitter substance, cyclohexylamine was unable to produce its characteristic increase in blood pressure. The same result was seen with tyramine, which is a known indirect acting sympathomimetic amine. The responses to both tyramine and cyclohexylamine could be restored by slow administration of norepinephrine which has been shown to restore the depleted transmitter levels after reserpine pretreatment (6). Further evidence to indicate the indirect nature of cyclohexylamine was obtained by injecting cats repeatedly with the amine. After the first injection, the subsequent responses became progressively less until cyclohexylamine had only minimal effect. The same decrease in response has been demonstrated for tyramine.

Cyclohexylamine appeared to be like tyramine in many ways: (*a*) both produced hypertension in cats after i.v. injection, (*b*) both appeared to act indirectly by release of catecholamines, and (*c*) both were effective only after relatively high doses were administered. Recently, it was demonstrated that clinically useful monoamine oxidase inhibitors could potentiate or change the action of several other drugs and even certain foods (3, 4). For example, tyramine evoked, augmented, and prolonged hypertensive effects in animals and patients treated with inhibitors of monoamine oxidase. Usually innocuous amounts of tyramine present in certain food, including cheese caused hypertensive reactions in patients treated with the enzyme inhibitor.

Because cyclohexylamine produced a pressor response which closely resembled the pressor action of tyramine, and cyclohexylamine may possibly be ingested in many diets or produced from ingested substrate, its interaction with monoamine oxidase inhibitors was investigated. The action of cyclohexylamine was not potentiated in animals treated before with a monoamine oxidase inhibitor. This finding was in contrast to that demonstrated when tyramine was administered to animals pretreated with a monoamine oxidase inhibitor. After inhibition of this enzyme system the response to tyramine was potentiated and prolonged. The explanation for this dichotomy most likely is the fact that cyclohexylamine is not a substrate for monoamine oxidase; in fact, cyclohexylamine has been shown to be a weak inhibitor of the enzyme (5).

The possible clinical implications of these findings must wait until the metabolism and possible spontaneous breakdown of cyclamate are better understood. If an enzyme system is responsible for the hydrolysis of the artificial sweetening agent, then the possible substrate-induction of the enzyme must be considered. This, of course, could increase tremendously the amount of cyclohexylamine produced in the body and therefore also increase the possible toxicologic implications of the metabolite. Other pharmacological aspects concerning the interaction of the artificial sweetening agents and their metabolites are presently under investigation.

Absorption and Elimination Profile of Isoproterenol III

The Metabolic Fate of *dl*-Isoproterenol-7-^{3}H in the Dog

By W. D. CONWAY*, H. MINATOYA, A. M. LANDS, and J. M. SHEKOSKY

Intravenous injection of isoproterenol-7-^{3}H in dogs, in doses ranging from 0.4 to 1.6 mcg./kg. body weight, immediately induced tachycardia which declined with a half-life of about 1 min. The resulting levels of radioactivity in blood declined with a significantly longer half-life of 3–4 min. Unchanged isoproterenol accounted for less than 1 percent of the total radioactivity in plasma after intravenous medication. After oral administration of 15 mg. of isoproterenol-7-^{3}H hydrochloride to dogs, a biphasic time course was observed for both heart rate and radioactivity in blood with maxima occurring at 0.5 and 1–2 hr. after medication. The metabolic fate of isoproterenol was determined by the route of medication, the intravenous and intraportal route giving rise mainly to 3-*O*-methylisoproterenol, while oral medication was converted mainly to a sulfuric acid ester which was formed either by the intestinal flora or during passage through the intestinal wall. The rapid decrease in tachycardia after intravenous medication is consistent with the rapid conversion of the drug to inactive metabolites while the more prolonged tachycardia induced by oral medication results from slow absorption.

THE EFFICACY of the sympathomimetic amine, isoproterenol hydrochloride,[1] [1-(3,4-dihydroxyphenyl)-2-isopropylaminoethanol] in the treatment of bronchial asthma and other bronchopulmonary diseases as well as heart block, when administered by various routes of medication, prompted recent studies of the absorption profile of the drug in dogs (1, 2). The drug was found to be poorly absorbed from the stomach but well absorbed from the small intestine, proximal colon, rectum, and from the mucous membrane of the trachea as measured indirectly by the resulting tachycardia. The rapid disappearance of chronotropic activity observed after intravenous administration in contrast to the prolonged activity following oral medication and the relatively greater efficiency in producing tachycardia by infusion of the drug into the femoral vein in contrast to the gastroepiploic vein, prompted the biochemical studies of the metabolic fate of isoproterenol after various routes of administration. The tachycardia is believed to reflect only the concentration of free isoproterenol in plasma and it was hoped that this could be confirmed by direct measurement.

EXPERIMENTAL

Materials—*dl*-Isoproterenol-7-^{3}H hydrochloride with a specific activity of 287 μc./mg. base was used for the intravenous injection studies. This was diluted with nonradioactive carrier to prepare medication with specific activities ranging from 4 to 66 μc./mg. base for the oral and intravenous infusion studies. The drug was dissolved in 5% dextrose solution containing sodium bisulfite (1:100,000) and ethylenediaminetetraacetic acid disodium salt (1:10,000). All doses are expressed in terms of isoproterenol base.

Animal Preparations—The heart rate was monitored by means of an electrocardiograph (Viso-Cardiette, Sanborn) using the Lead I attachments. Food was withheld 17–18 hr. prior to medication. Dogs of either sex, weighing between 8 and 17 kg., were anesthetized with sodium pentobarbital (30 mg./kg., i.v.). Both femoral veins were exposed, one for drug injection and the other for drawing blood *via* an implanted catheter. Urine samples were obtained periodically by rinsing the bladder with two 20-ml. portions of distilled water through an indwelling catheter. Ethylenediaminetetraacetic acid (100 p.p.m.) and α-thioglycerol (10 p.p.m.) were added to urine and blood samples as preservatives. All samples were kept frozen until analyzed. Where collection of bile was desired, the cystic duct was ligated and a polyethylene catheter was implanted in the common bile duct.

Conscious dogs of either sex, which weighed from 12 to 18 kg., were placed in sling-stand frames designed to keep the animal still but with a minimum of restraint. Blood was withdrawn periodically from the saphenous and radial veins. Urine was obtained periodically as described above.

Analytical Methods—Duplicate samples of blood (0.5 ml.) were dried and prepared for counting by a modification of the oxygen-flask combustion technique (3). Samples of urine were dissolved in a water-miscible scintillator for counting (4). Plasma samples (0.1 ml.) were digested with 1 *N* NaOH at 60° for 1 hr., neutralized with 0.5 ml. of oleic

acid, diluted with 1 ml. of water, and added to 15 ml. of the water-miscible scintillator. All samples were counted for 10 min. in a Packard Tricarb model 3324 liquid scintillation spectrometer operated at 2° and were corrected for quenching by an internal standard technique. The sensitivity of the assays was determined by the specific activity of the drug used in the particular experiment. Concentrations indicated as not significant in the text were based on net count rates less than 7 c.p.m.; corresponding to a standard error in the net count of ±20%.

Approximately 0.5 mg. each of authentic samples of isoproterenol (I), 3-*O*-methylisoproterenol (OMI), normetanephrine (NM), and norepinephrine (NE) were added to aliquots (1–2 ml.) of urine or plasma which contained 100,000–200,000 d.p.m. of tritium in the form of radiochemically labeled isoproterenol and its metabolites, after which the samples were adjusted to pH 8. Metabolites were then separated by ion-exchange chromatography on 1 × 3-cm. columns of Bio-Rex 70 resin (approx. 10 g., 200–325 mesh, Biorad Laboratories, Richmond, Calif.) developed with ammonium phosphate buffer (0.05 *M*, pH 8.0) containing 0.001 *M* thioglycerol as an antioxidant. The elution volumes of the compounds added to the sample were determined by continuous monitoring of the absorption of UV light (254 mμ) by the effluent. The effluent stream was also split to provide aliquots for monitoring the elution of radioactivity. The presence of conjugates was established by the shift in the elution pattern of metabolites brought about by enzymatic hydrolysis of samples prior to chromatography.

Paper electrophoresis was conducted using phosphate buffer (0.05 *M*, pH 8.0) and a voltage gradient of 900 v./56 cm. Authentic compounds, added as carriers, were located by spraying with iodoplatinate reagent. Mobilities, as cm., migrated toward the cathode in 1 hr., were: I, 11; OMI and NE, 12; NM, 13. Electrically neutral material migrated 3.5 cm. as a result of electroosmosis. The distribution of radioactivity was determined by cutting the electrophoregrams into 1-cm. strips which were soaked for 2 hr. in counting vials with 2 ml. of water, then mixed with 15 ml. of dioxane scintillator (4).

Conjugates of metabolites with glucuronic and sulfuric acids were hydrolyzed by adding 0.1 ml. of glucuronidase[2] mixture A to 2.0 ml. of plasma or urine (adjusted to pH 5.5 with acetate buffer) and incubating for 18 hr. at 37° in a closed vessel containing a nitrogen atmosphere and a drop of chloroform. This assay indicated that such an incubation mixture contained 77 arbitrary units of glucuronidase/ml. and 560 arbitrary units of sulfatase/ml. One arbitrary unit is defined as the quantity of enzyme required in 1 ml. of the reaction mixture to hydrolyze 1 μmole of substrate per hr. at 37°, pH 5.5, substrate concentration 0.0025 *M* in the presence of bovine serum albumin, 0.25 mg./ml. Substrates used in the assay were potassium *p*-nitrophenyl sulfate and *p*-nitrophenylglucosiduronic acid.

RESULTS

Chromatographic Analyses—The typical pattern for elution of metabolites from the weak cation exchanger is shown in Fig. 1. Neutral, acidic, and conjugated metabolites are not retained by the resin and the elution volume for these metabolites (approximately 8 ml.) represents the hold-up volume of the column. The authentic compounds, OMI, I, NM, and NE, were eluted in that order as indicated by the lower curve. The upper curves present the distribution of radioactivity in the column effluent from samples of a urine before and after hydrolysis with glucuronidase mixture A, a potent source of the enzymes β-glucuronidase and sulfatase. The radioactivity eluted in a particular peak before hydrolysis represents the free compound and that eluted after hydrolysis represents the total (free + conjugated) amount of the metabolite.

It is apparent from the shift of the pattern after glucuronidase treatment that the major metabolite in the particular urine sample illustrated is conjugated isoproterenol. From the difference in the radioactivity contained in each peak before and after enzymatic hydrolysis, the composition of this particular urine (as % of radioactivity in urine) can be calculated as I (free 0%; conjugate, 67.5%), OMI (free 6.7%; conjugate, 7.3%), NM (free 0.8%; conjugate, 0.0%), neutral and acidic materials (17.5%), NE (0%). NE was not detected as a metabolite in any urine or plasma sample. The presence of 0.8% NM in the sample illustrated is of borderline significance. Failure of the numbers to total 100% may result from rounding off errors or from elution of small amounts of radioactivity in areas not represented by discrete peaks. The results of many such analyses are presented later in the text and figures, usually calculated as a percentage of the administered dose. Where the concentrations of metabolites or conjugates are expressed as mcg./l., the figures refer to concentrations of molecularly equivalent solutions of isoproterenol.

Blood Levels After Intravenous Administration—Rapid intravenous injection of 0.4, 0.8, and 1.6 mcg./kg. of isoproterenol-^{3}H increased the heart rate of anesthetized dogs by 70, 105, and 120 b.p.m. within 30 sec. The tachycardia regressed with a

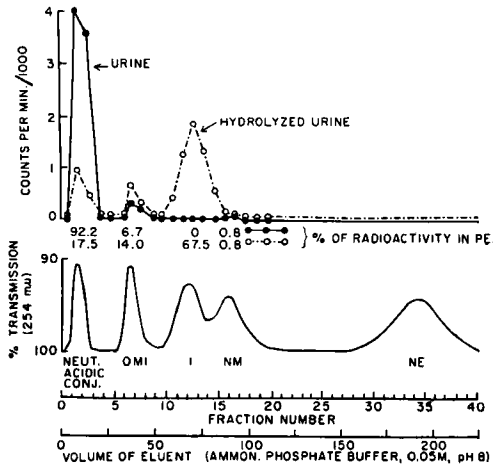

Fig. 1—Fractionation of metabolites on weak cation-exchange resin.

[2] Glusulase, Endo Products Inc., Richmond Hill, N. Y.

half-life ranging from 0.9 to 1.3 min. during the first 3 min. after medication (Fig. 2) and returned to the premedication rate within 5–7 min. On the other hand, the concentration of radioactivity in whole blood declined with a much longer half-life which ranged from 3.0 to 4.1 min. The heart rate is believed to reflect only the concentration of unchanged isoproterenol, whereas the tritium concentration represents the sum of all radioactive compounds in the blood.

In order to obtain a plasma level of radioactivity sufficiently high to enable estimation of the circulating metabolites, a dose of 131 mcg. isoproterenol-7-^{3}H/kg. (specific activity 287 μc./mg. base) in 1 ml. of aqueous solution was given by rapid injection into the femoral vein of one anesthetized dog. The tritium declined in two phases, a rapid phase with a half-life of about 5 min. and after 30 min. a second slower decline with a half-life of about 4 hr.

One minute after injection, ion-exchange chromatography indicated that the major metabolite in the plasma was OMI which accounted for 63% of the radioactivity. Isoproterenol amounted to less than 1% of the total radioactivity and, in fact, could not be detected. The NM content was also less than 1%. Neutral, acidic, and conjugated metabolites, which were not further resolved, made up 35% of the total. Electrophoretic analysis of the 3-min. plasma gave similar results, 65% OMI and 35% electrically neutral material; isoproterenol and acidic materials were not detectable.

Urinary Excretion—The rate of excretion of radioactivity in urine was similar for the four dogs given intravenous medication. After 6 hr. the amounts excreted were 84, 82, 70, and 83% following doses of 0.4, 0.8, 1.6, and 131 mcg./kg., respectively. The urine from the dog given the highest dose was examined in detail by ion-exchange chromatography and these results are summarized in Fig. 3, where the cumulative excretion of both total radioactivity and individual metabolites are shown. Free isoproterenol was found only in the early urine, 0.4% of the dose in the first 20 min., and another 0.2% in the next 10 min. Conjugated I was detected throughout the 6-hr. period although a major portion had been excreted within the first hour. NM and its conjugates accounted for only 3% of the dose. The metabolite excreted in largest amount at all times was OMI which, in the free form, accounted for 43% of the administered dose over the 6-hr. period. Another 10% was excreted in conjugated form. Neutral and acidic metabolites accounted for about 20% of the dose. The exact nature of this fraction has not yet been determined, but preliminary results involving fractionation on an anion-exchange resin indicate that less than 2% of the dose can be accounted for as 3-methoxy-4-hydroxymandelic acid.

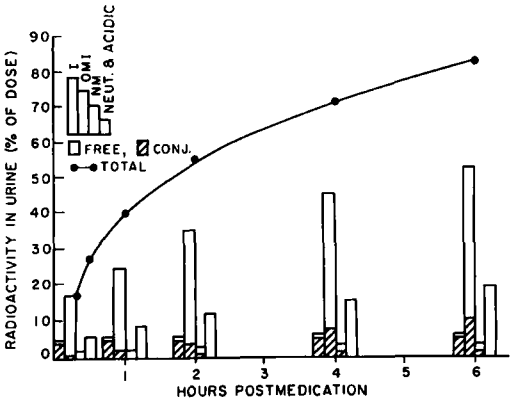

Fig. 3—Cumulative excretion of metabolites in the urine of dog No. 12 following rapid injection of 0.13 mg./kg. of isoproterenol-^{3}H into the femoral vein.

Blood Levels After Oral Administration—A dose of isoproterenol-7-^{3}H hydrochloride equivalent to about 0.8 mg./kg. was dissolved in 2 ml. of water and administered orally to four conscious dogs. The dose was delivered from a syringe at the back of the tongue and was followed immediately by a rinse with 5 ml. of water. The time course of the resulting tritium concentration in whole blood (Fig. 4) shows a distinct double peak in three of the four dogs. This double peak was also reflected in the heart rate.

The mean maximal increase in heart rate (173%) was obtained in 10 min. following medication, and the duration of action was approximately 3 hr. In comparison with the intravenous half-life of 1–2 min., this longer duration of heart-rate activity

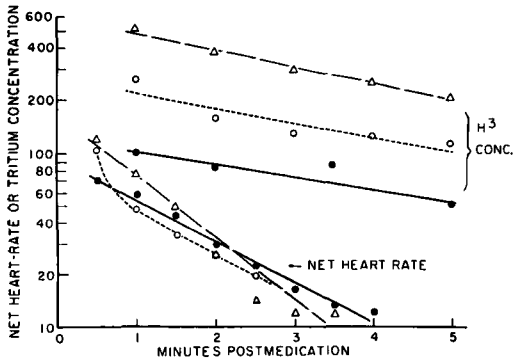

Fig. 2—Net heart rate (b.p.m. above premedication level) and tritium concentration (as 100 × the equivalent level of isoproterenol-^{3}H in mcg./l.) in whole blood following rapid intravenous injection of isoproterenol-^{3}H in dogs. Key (dose in mcg./kg.): ●, 0.4; ○ 0.8; △, 1.6.

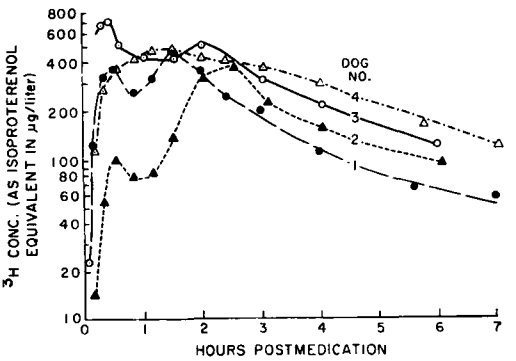

Fig. 4—Blood level of radioactivity following oral administration of isoproterenol-^{3}H to dogs as a solution of the hydrochloride salt. Key (dose, mg. base/kg.): ●, 0.78; ▲, 0.65; ○, 1.08; △, 0.82.

following oral medication indicated that the absorption from the intestinal tract was slow and prolonged. Slow absorption of oral medication was reflected also in the blood tritium level, which decreased at a considerably slower rate after oral than that after intravenous administration. At the third hour, when most of the cardiac effect had been terminated, the total blood tritium was still at a relatively high level of 270 mcg./l., reflecting mostly the total metabolites rather than active isoproterenol. In one experiment (dog No. 3) the plasma was analyzed by ion-exchange chromatography. Twenty minutes after medication, 5% of the radioactivity was in the form of OMI and 94% in the form of either neutral, acidic, or conjugated metabolites. Paper electrophoresis confirmed this and further indicated the presence of less than 5% in the form of acidic metabolites. Neither I nor NM was detected by either method. Estimation for tritiated water content of plasma indicated the conversion of 3% of the dose in 4 hr.

Urinary Excretion—The amount of radioactivity excreted in the urine of dogs within 6 hr. was 64, 45, 74, and 57%, respectively, of the administered dose. Chromatographic analysis of the urine from dog No. 3 (Fig. 5) indicated that less than 0.1% of the total dose was excreted as unchanged I. The major metabolite was conjugated I which accounted for 50% of the dose. Free OMI accounted for 5.8% of the dose and its conjugate accounted for another 6.2%. Less than 1% of either free or conjugated NM was found, and neutral and acidic metabolites, which have not been further identified, accounted for only 10% of the dose.

Plasma Levels After Intraduodenal Administration—The levels of radioactivity observed in three anesthetized dogs following direct injection of isoproterenol-^{3}H hydrochloride (in 2 ml. of water) into the duodenum are presented in Fig. 6. In contrast to the orally dosed dogs, only a single peak was observed. Chromatographic analysis of plasma samples indicated that the major metabolite at all times was conjugated I which, in one experiment, measured 70 mcg./l. at 10 min. and a maximum of 152 mcg./l. after 3 hr. Free drug levels ranging from 1 to 2.4 mcg./l. were measured in the

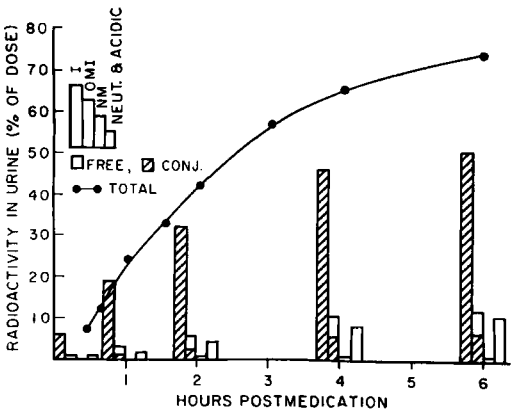

Fig. 5—Cumulative excretion of metabolites in the urine of dog No. 3 following oral administration of 1.08 mg./kg. of isoproterenol-^{3}H as the hydrochloride salt in solution.

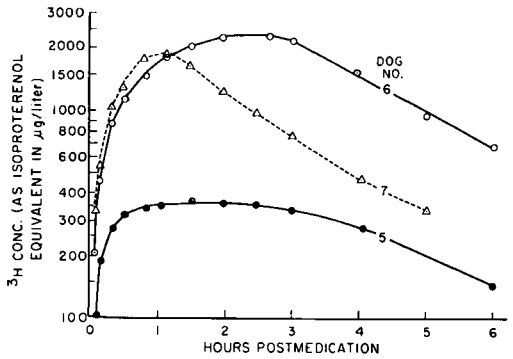

Fig. 6—Plasma level of radioactivity following intraduodenal administration of isoproterenol-^{3}H to anesthetized dogs. Key (mg. base/kg.): ●, 0.80; ○, 1.06; △, 1.07.

3-hr. period following medication, but these levels are so low as to be of doubtful significance. They do serve, however, to place an upper limit on the level of free drug to be expected under these conditions. From a level of 42 mcg./l. at 10 min., a maximum level of 66 mcg./l. of OMI was reached 30 min. after medication while its conjugates, which were labile to glucuronidase mixture A, attained a maximum of only 13 mcg./l. after 4 hr. NM was never present at a concentration above 2.4 mcg./l., but its conjugates were present at a concentration of 35 mcg./l. after 10 min. and a maximum concentration of 67 mcg./l. after 3 hr.

Urinary and Biliary Excretion—The excretion of radioactivity in the urine after intraduodenal administration ranged from 59 to 65% of the dose in 5–6 hr. after medication. However, biliary excretion was less than 2.6% of the dose. The drug was well absorbed under these conditions and after 5–6 hr. only 0.4–1.2% of the administered radioactivity remained unabsorbed from the small intestine.

Intraportal Infusion—In order to ascertain the fate of the drug after direct introduction into the portal system, isoproterenol-7-^{3}H in saline solution was infused into a branch of the mesenteric vein of dog No. 8 at a rate of 7.26 mcg. base/kg./min. for a period of 1 hr. (total dose 0.44 mg. base/kg.) in one experiment. This rate was felt to approximate that of absorption after oral medication.

The time course of radioactivity in plasma during and following the 1-hr. intraportal infusion of isoproterenol-7-^{3}H is given in Fig. 7. The effect on the heart rate is illustrated in Fig. 8. Although the level of radioactivity in the blood rose sixfold during the period of infusion, the heart rate, after the first 10 min., was found to be very constant at about 160 b.p.m. On cessation of the infusion, the heart rate returned to its preinfusion level within 10 min.

The cardiac effect during the steady state was relatively small considering the dose infused, indicating appreciable metabolic conversion of the drug on its passage through the liver. This was confirmed by estimation, using ion-exchange chromatography, of the plasma levels of free isoproterenol which were found to range from about 2–20 mcg./l. during the infusion. These levels were close to the limit of detection and should be regarded only as an order of magnitude. Only

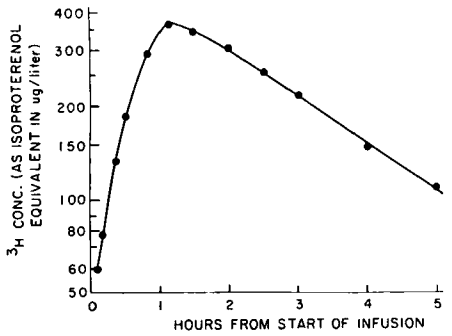

Fig. 7—Plasma level of radioactivity during and following infusion of isoproterenol-^{3}H into the mesenteric vein for 1 hr. at a rate of 0.44 mg. base/kg. body wt./hr. (dog No. 8).

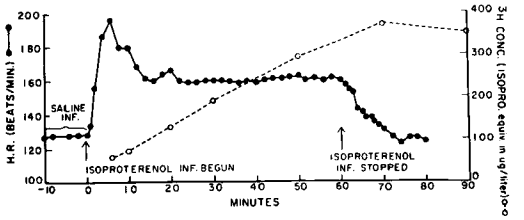

Fig. 8—Heart rate and plasma level of radioactivity during intraportal infusion of isoproterenol-^{3}H in anesthetized dog No. 8.

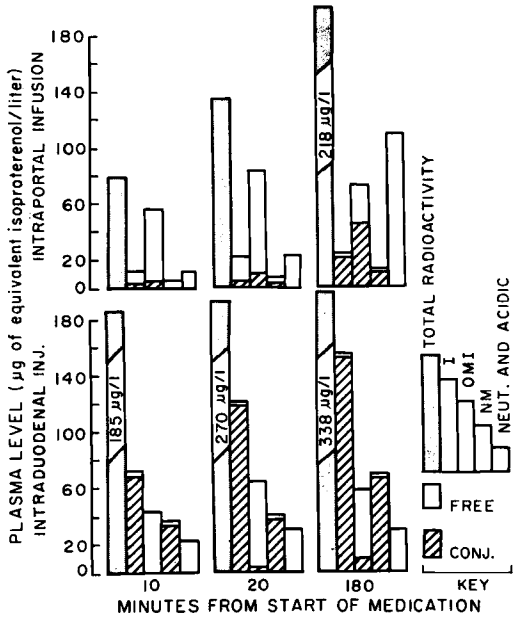

Fig. 9—Metabolites in plasma after intraduodenal administration (dog No. 5) and after the start of a 1-hr. intraportal infusion (dog No. 8).

slightly higher amounts of conjugated I were present ranging from 3 mcg./l. at 6 min. to 24 mcg./l. at 50 min. The levels of conjugated NM were also low each ranging from less than 3 mcg./l. at 6 min. to less than 11 mcg./l. at 50 min. The major metabolite present at all times was free OMI which rose from 36 mcg./l. at 6 min. to 108

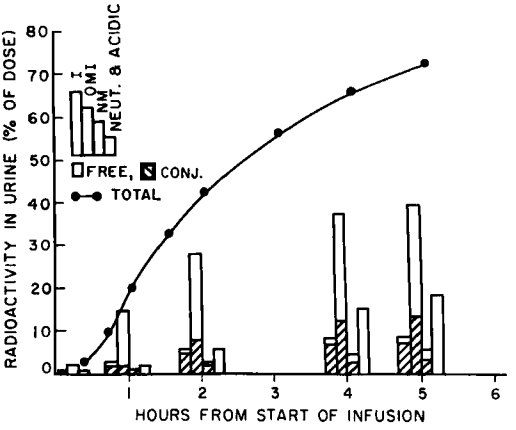

Fig. 10—Cumulative excretion of metabolites in the urine of dog No. 8 during and after infusion of isoproterenol-^{3}H into the mesenteric vein for 1 hr. at a rate of 0.073 mg. base/kg./min.

mcg./l. at 50 min. The level of conjugated OMI rose from 0 at 6 min. to 11 mcg./l. at 30 min. to 58 mcg./l. at 50 min. Unidentified neutral and acidic metabolites rose from 14 mcg./l. at 6 min. to 67 mcg./l. at 50 min.

A graphic comparison of the metabolites in plasma at 10, 20, and 180 min. after intraduodenal administration (dog No. 5) and after the start of the 1-hr. portal infusion (dog No. 8) of isoproterenol into the mesenteric vein is given in Fig. 9. It is readily apparent that the major metabolite in plasma at early times after intraduodenal administration was conjugated isoproterenol while after intraportal administration it was OMI.

Urinary and Biliary Excretion—Over a 5-hr. period from the start of portal infusion, 72% of the dose was excreted in the urine (Fig. 10). An additional 2.3% was excreted in bile. The major metabolites excreted in urine were OMI and its conjugates which together accounted for 40% of the dose. A comparison of the metabolites excreted in urine during the 0–4 hr. postmedication period with those excreted following oral administration and injection into the femoral vein is given in Fig. 11. It emphasizes the similarity of the excretion

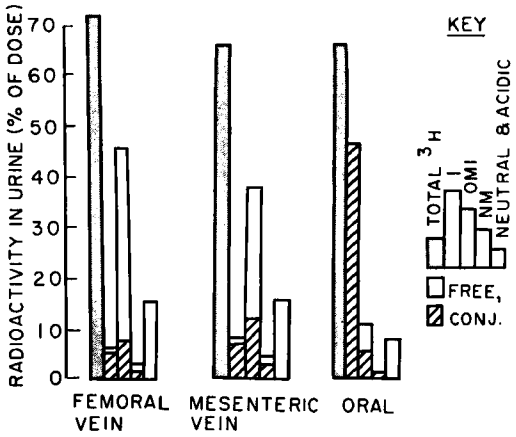

Fig. 11—Comparison of metabolites of isoproterenol-^{3}H excreted in the 0–4 hr. postmedication period after various routes of administration.

pattern after administration *via* either the femoral or mesenteric vein where OMI is the major metabolite and contrasts this with the pattern obtained after oral administration where mainly conjugated isoproterenol is excreted.

Nature of Conjugated Isoproterenol—As described under *Methods*, the various samples of urine and plasmas were hydrolyzed with glucuronidase mixture A, which contains both β-glucuronidase and sulfatase, in order to determine the relative amounts of free and conjugated material.

Hydrolysis of all urine samples from dog No. 3 with glucuronidase mixture B,[3] which contains glucuronidase, released no isoproterenol, indicating that the conjugate was a sulfuric acid ester. But since glucuronidase mixture B is a much less potent source of glucuronidase than is glucuronidase mixture A, the 30–60 min. urine sample from dog No. 3 was hydrolyzed with various sources of glucuronidase as summarized in Table I. In addition to glucuronidase mixture B, a liver glucuronidase preparation did not hydrolyze the conjugate, nor did glucuronidase mixture A in the presence of 0.5 *M* phosphate buffer, which inhibits 98% of the sulfatase activity while depressing glucuronidase by only half. Glucuronidase mixture A in the acetate buffer was the only effective agent, indicating that the conjugate is a sulfate.

Gastric Emptying Time—Enterohepatic recirculation was ruled out as the explanation of the double peaks observed in the blood level *versus* time curves after oral medication (Fig. 4), because it was found that only a small percent of the dose was excreted in bile (dogs No. 5–8). Preliminary studies have been carried out in three additional experiments to determine the location of the unabsorbed drug in the gastrointestinal tract at various times after oral medication. In two of the animals, which were sacrificed 1 hr. after medication, 55 and 29% of the administered radioactivity was still retained in the stomach. The stomach of the third dog sacrificed 2 hr. after medication contained only 1% of the administered radioactivity. In all cases less than 14% of the dose was found in the small intestine, indicating that the drug is readily absorbed from this area when it is released from the stomach.

DISCUSSION

The absorption and elimination profile of isoproterenol in dogs has been studied previously using the increase in heart rate as an indirect measure of the plasma level (1, 2). Only two other studies (5, 6) on the metabolic fate of the drug have been reported. However, pertinent metabolic studies have been carried out on the related drugs *dl*-nordefrin[4] and 4-(2-methyl-aminoethyl)pyrocatechol,[5] and several studies on epinephrine have been reported and will be reviewed in the following discussion.

Sjoerdsma (5) has reported that, when intravenously administered, the *d*-isomer of isoproterenol is converted to its 3-*O*-methyl derivative and has utilized this reaction to measure catechol *O*-methylating activity in man. No other metabolic studies in humans have been reported.

After intravenous administration of approximately 23 mcg. of isoproterenol-^3H/kg. to rats, Hertting (6) found that one-half of the administered radioactivity was excreted in urine over an 8-hr. period and 77% within 24 hr. The remainder was accounted for in the bile in a form which was not readily absorbed from the intestine. In addition to 10% of the dose in unchanged form, he found the urine to contain 18% as isoproterenol glucuronide, 14% as the *O*-methyl derivative, and 35% as the glucuronide conjugate of OMI. He was unable to detect any deaminated metabolites and concluded that the drug was metabolized exclusively by *O*-methylation and conjugation.

These results show that while isoproterenol given intravenously to dogs is metabolized largely by *O*-methylation, the orally administered drug is converted mainly to a sulfuric acid ester. Only traces of unchanged drug were excreted after i.v. administration and none after oral medication. The excretion of 10–20% of the dose as unidentified neutral and acidic products and up to 3% as normetanephrine or its conjugates indicates that monoamine oxidase plays a secondary role in the metabolism of the drug by the dog.

Haggendal (16) found that conjugation did not play a significant role in the metabolism of epinephrine and norepinephrine by humans when the plasma levels of these hormones were increased either by insulin administration or performance of muscular work. His conclusion was based on the fact that there was no concomitant increase in the levels of their conjugates. In contrast, after oral administration of epinephrine he found conjugation to be the predominant metabolic pathway. Since previous workers had proposed that circulating catecholamines are metabolized by *O*-methylation, primarily in liver tissue (17, 18), Haggendal suggested that the oral medication may be con-

[3] Ketodase, Warner-Chilcott, Morris Plains, N. J.

[4] Corbasil.

[5] Epinine.

jugated by the intestinal flora or in the intestinal mucosa.

Oral doses of epinephrine administered to humans have been reported to be inactivated by formation of the sulfuric acid conjugate (7–9) and after oral administration to rabbits by formation of the glucuronic acid conjugate (10, 11). Likewise more than half of the 50-mg. oral doses of the related drugs *dl*-nordefrin, $3,4\text{-}(OH)_2C_6H_3CHOHCH(NH_2)CH_3$, and 4-(2-methyl-aminoethyl)pyrocatechol, $3,4\text{-}(OH)_2C_6H_3CH_2CH_2HNCH_3$, were eliminated in conjugated form in the urine of humans and dogs within 9 hr. (7, 9).

In contrast, after intravenous infusion of epinephrine in humans (approximately 0.18–0.3 mcg./kg./min. for 0.5 to 1 hr.), urinary excretion of metanephrine or its conjugates was reported to account for almost half the dose while most of the remainder was excreted in the form of deaminated products (mainly 3-methoxy-4-hydroxymandelic acid). Little free or conjugated epinephrine was excreted (12, 13). In a particularly detailed study of the excretion products after intravenous injection (approximately 0.07 mcg./kg.) of epinephrine, only a small percent of the dose was excreted within 24 hr. as epinephrine or its conjugates whereas 23% was excreted as methoxyhydroxymandelic acid and 26% as the sulfuric acid conjugate of metanephrine (14).

The conclusion by Resnick (15) that *O*-methylation represented the predominant pathway in the metabolism of orally ingested epinephrine was unwarranted since he examined the metabolites only after subjecting the urine to acid hydrolysis and did not measure the amount of unconjugated metabolites prior to hydrolysis. In fact his identification of the hydrolysis products, epinephrine and metanephrine, were only qualitative and he did not determine their relative amounts.

The inactivation of orally administered isoproterenol by conjugation with sulfate is therefore consistent with the reported findings for related catecholamines. The fact that virtually identical patterns of urinary metabolites were found following either intraportal infusion of isoproterenol or injection into the femoral vein in dogs indicates that the oral medication is metabolized by conjugation to sulfate either within the intestinal tract or during its passage through the intestinal wall.

The observation of a biphasic absorption of the oral medication as indicated by the double peak in the plasma level and heart rate *versus* time curves at first suggested enterohepatic circulation of the drug. But this was ruled out by the demonstration that only a small amount was excreted in the bile. A biphasic curve was not obtained after intravenous or intraduodenal administration. Preliminary studies of the distribution of radioactivity in the gastrointestinal tract of dogs after oral medication showed a significant proportion of the dose remaining in the stomach 1 hr. after medication. This suggested that a gastric emptying cycle may be responsible for the biphasic absorption. However, the exact cause of the phenomenon is uncertain at present.

Attempts to extend these studies to the direct measurement of isoproterenol and its metabolites in plasma were only partially successful. It was possible to demonstrate that the major metabolite in plasma after intraduodenal administration was a sulfuric acid ester of isoproterenol, while after intraportal infusion the major metabolite was 3-*O*-methylisoproterenol. These results are analogous to the authors' analysis of urinary metabolites after oral and intravenous medication, respectively. Metabolism of the drug was demonstrated to be quite rapid as evidenced by the finding that the unchanged drug constituted less than 1% of the radioactivity in plasma 1 min. after an intravenous injection.

Isoproterenol disappears from the circulation with a half-life of a few minutes as indicated by the decrease in the induced tachycardia following intravenous administration of the drug. Initial disappearance of radioactivity from the blood occurs at a significantly slower rate. The initial regression of tachycardia results mainly from metabolic conversion of isoproterenol to inactive products while the slower elimination of total radioactivity reflects the slow excretion of these metabolites.

Orally administered isoproterenol is slowly absorbed and is less efficient than intravenous medication in inducing tachycardia in dogs. This lower efficiency results from inactivation of a large portion of the medication by conversion to a sulfuric acid ester either before or during absorption from the small intestine. Even that fraction of the drug which escapes this conjugation is then subjected to deactivation by conversion to the 3-*O*-methyl derivative on passage through the liver. Thus, only a very small fraction of an oral dose reaches the general circulation in an active form even on the first circuit of the blood through the body.

Blood Plasma Levels and Elimination of Salts of 2-PAM in Man After Oral Administration

By ALBERT A. KONDRITZER, PETER ZVIRBLIS, A. GOODMAN, and S. H. PAPLANUS

The absorption and elimination of pralidoxime salts after oral administration to human volunteers have been studied at a dosage of 1.5–10 g. of drug for a 70-kg. man. The biological half-life, calculated from blood plasma values and urinary excretion rates, was approximately 1.7 hr. A 10-fold increase in dosage of the pralidoxime salts increased the peak plasma level of oxime 3.5-fold. The average total amount of pralidoxime recovered in the urine was 27 percent. In subjects given the iodide salt, symptoms of iodism were observed; all other clinical tests were negative. Some observations were made on the behavior of a bis-quaternary oxime.

A NUMBER of oximes have been found to reactivate the cholinesterases that have been inactivated by organic esters of phosphoric acid derivatives (1). One quaternary oxime in particular has proved effective in combination with atropine in the treatment of poisoning by some of these toxic chemicals and in reducing their toxicity in various animal species (2). Salts of the oxime, chemically known as 2-hydroxyiminomethyl-1-methylpyridinium chloride, iodide, and methane sulfonate, are commonly referred to as 2-PAMCl, 2-PAMI, and P-2-S, respectively. Pralidoxime (3) is the generic name given to the oxime moiety.

Few studies have been carried out in man of plasma levels after oral administration of salts of 2-PAM. Sundwall (4) reported that the maximum concentration in plasma of man after oral administration of 45 mg./kg. of P-2-S, packed in gelatin capsules, was about 4 mcg./ml. and that a concentration over 3.5 mcg./ml. was maintained from 1 to 4 hr. These results may be compared with peak plasma concentrations, averaging 15 mcg./ml., which were reached 20 min. after an intramuscular injection of 30 mg./kg.

The half-life for 2-PAM iodide in the blood serum of man after its intravenous administration in a dose of 15 mg./kg. has been reported (5) to be 0.9 hr. Most of the injected oxime quickly passed into the urine and no oxime was detected in the spinal fluid 70 min. after its injection.

The present investigation was carried out to measure the concentration of oxime in plasma and urine of man after ingestion of various salts of 2-PAM in order to determine the relation of the amounts ingested to the attainable concentrations and to acquire information concerning rates of excretion.

Received February 29, 1968, from the Physiological Chemistry Branch, Medical Research Laboratory, Edgewood Arsenal, MD 21010

Accepted for publication April 11, 1968.

MATERIALS AND METHODS

Organic and inorganic salts of 2-PAM, differing in water solubility, were used in this study (6). Adult male volunteers were given aqueous solutions of the 2-PAM salts by mouth; 400 ml. of water was drunk during the hour before and 100 ml. of water each hour for 5 hr. after the ingestion of the drug to insure good hydration and urine collections.

The following information was sought; (*a*) plasma levels of oxime at various times after ingestion, (*b*) rates of disappearance of oxime from blood, (*c*) urinary excretion of oxime, and (*d*) biological half-life of the oxime, calculated from plasma and urine data. The concentrations of the oxime in plasma, urine, and feces were measured by ultraviolet spectrophotometry, based on procedures previously described (7). The oxime salts, dosage, and number of subjects are listed in Table I.

In addition to the 2-PAM salts listed in the table, the bis-quaternary oxime *N,N'*-trimethylenebis-(pyridinium-4-aldoxime) dibromide, commonly referred to as TMB-4 (8), was given to three subjects at a dose of 1 g./70 kg.

Clinical laboratory tests were carried out on the volunteers to uncover indications of any pathologic damage associated with the ingestion of the 2-PAM salts as follows. (*a*) Urinalysis, including microscopic examination, before and the day after the test. (*b*) Blood examination, including hemoglobin, total and differential white blood cells, before and the day after the test. (*c*) Liver function tests, including alkaline phosphatase and serum glutamic-pyruvic transaminase, before and on the morning after the test. (*d*) In addition to the oxime measurements red

TABLE I—SALTS OF 2-PAM AND DOSE GIVEN ORALLY

[a] Number of subjects is given in parentheses; the average weight was 72 kg. with a range of 63–84 kg.

cell and plasma cholinesterase activity measurements were made two or three times on separate days before the test, on the morning of the test, 3 and 6 hr. after ingestion of the oxime, and the morning after the test.

During the tests, the volunteers were observed closely for changes in blood pressure, pulse rate, and respiratory rate, and for development of abnormalities in their neurologic status; they were questioned repeatedly concerning their subjective reactions. At regular time intervals after ingestion of the oximes, muscular function was checked by means of a grip dynamometer and the standard step tests.

RESULTS AND DISCUSSION

Blood Plasma—Oxime was found in the blood plasma within 15 min. after oral administration. The concentration rose rapidly, approached a peak at 2–3 hr., and then declined at an approximately first-order rate. The first part of the curve results predominantly from absorption, and at the peak of the curve the rate of absorption is about equal to the rate of elimination; the latter portion of the curve results predominantly from elimination of the oxime. Average oxime absorption-elimination curves for plasma are shown in Figs. 1, 2, and 3. Absorption-elimination curves as a function of dosage of one salt, namely the iodide, are given in Fig. 1. The peak concentration of oxime in plasma increased with the increasing dosages. The time of reaching peak oxime concentration was slightly delayed with increasing dosages, from 2 hr. for the 5-g. dose to 2.5–3 hr. for the 10-g. dose. Evidently absorption of the oxime from the gut is prolonged to some degree with increasing dosage.

Figure 2 compares the rates of absorption and elimination of the lactate and dihydrogen phosphate salts after oral administration. At the dose of 2 g./70-kg. man, the peak plasma concentration obtained was higher with the lactate (6 mcg./ml. after 2 hr.). With the lactate salt a plasma concentration of mcg./ml. was reached in approximately 1.25 hr.

P-2-S and 2-PAMCl are compared in Fig. 3, which shows the plasma molar levels obtained when equimolar amounts of each of the two salts were given at two dosage levels. The results here indicate

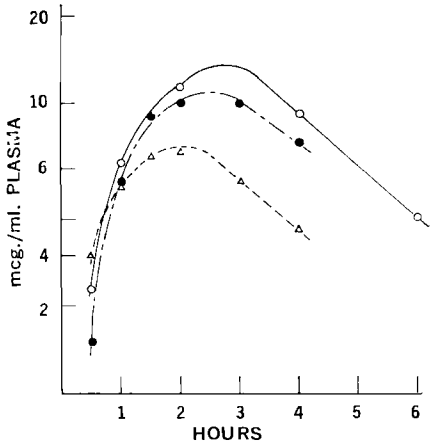

Fig. 1—Plasma concentrations of 2-PAM iodide in man after oral administration of 5, 8, and 10 g./70 kg. of body weight. Key: ●, 8 g.; ○, 10 g.; Δ, 5 g.

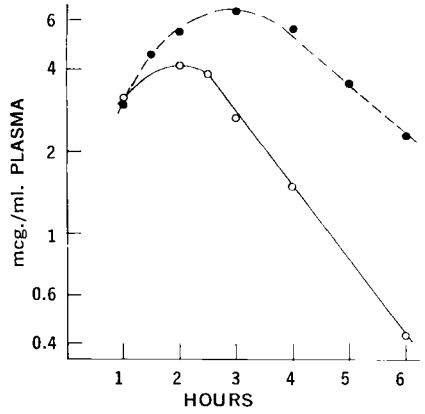

Fig. 2—Plasma concentrations of the lactate and dihydrogen phosphate salts of 2-PAM in man after oral administration. Key: ●, 2 g. lactate; ○, 2 g. phosphate.

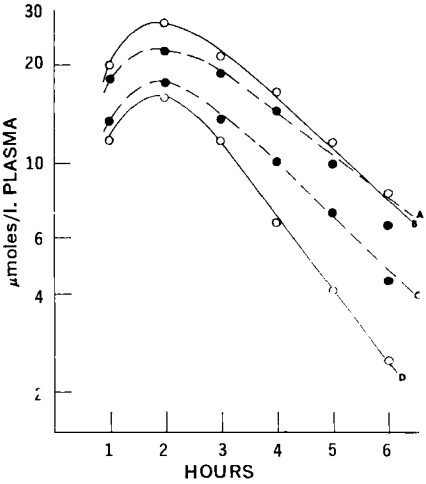

Fig. 3—Plasma concentrations of 2-PAM chloride and 2-PAM methane sulfonate (P-2-S). Key: A, 21.6 mmoles/70 kg. PAM-Cl; B, 21.6 mmoles/70 kg. P-2-S; C, 8.6 mmoles/70 kg. PAM-Cl; D, 8.6 mmoles/70 kg. P-2-S.

clearly that these salts are very similar with respect to absorption into and elimination from blood plasma.

The relationship between peak plasma levels of oxime and oral doses of the various salts may be approximated by an equation of the type

$$Y = kX^n$$

where Y is the oxime concentration in μmoles/l. of plasma, X is the dose in mmoles/70-kg. man, k is a constant, equal to Y when X is 1, n is a constant that describes the change in Y with change in X. The log form of this equation is plotted in Fig. 4. The best values of the constants were calculated by the method of least squares; the calculated value of log k is 0.79 and that of n (slope) is 0.54. Variability among individual results precludes any statement concerning statistically significant differences in peak oxime plasma levels resulting from the various 2-PAM salts. However, within the limits of this variability the estimation can be made that a 10-fold increase in dosage of any of the 2-PAM salts would increase the peak plasma level of oxime 3.5-fold.

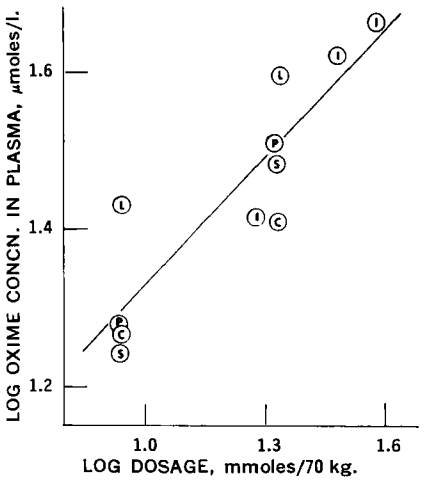

Fig. 4—Relationship between maximum oxime concentration reached in plasma and oral dosage of PAM salts. Key: C, chloride; I, iodide; L, lactate; P, dihydrogen phosphate; and S, methane sulfonate. The equation of the line is log Y = 0.79 + 0.54 log X.

Biological Half-Life—A considerable portion of the plasma concentration curve approaches or resembles the curve for a first-order process or reaction where the decrease in concentration of a reacting substance at a given time, t, is proportional to the concentration present at that time (9). Stated in logarithmic form,

$$\log C = \log C_0 - kt/2.303 \qquad \text{(Eq. 1)}$$

where C is concentration at time t, C_0 is concentration at time zero, t_0, k is the specific rate constant that characterizes the process.

A plot of log C *versus* time, t, gives a straight line; the slope of the line is equal to $-k/2.303$, from which the rate constant, k, is calculated. The time for the plasma concentration to be reduced by one-half may be defined as the biological half-life (10), and is equal to $0.693/k$. This value has been calculated from the plasma data for the 2-PAM salts; the best estimates are given in Table II.

Urinary Excretion—A valuable addition to the literature of urinary excretion equations was that which enabled a specific velocity constant, k, to be derived from the rate of urinary excretion by means of the equation

$$\log dC/dt = kt/2.303 + \log(-kC_0) \qquad \text{(Eq. 2)}$$

Table II—Biological Half-Life of 2-PAM Salts Given Orally in Man

2-PAM Salt	Mean Half-Life (hr.)[a] By Plasma	Mean Half-Life (hr.)[a] By Urine
Chloride	1.7 (7)	1.7 (7)
Lactate	1.7 (9)	1.7 (9)
Phosphate	1.3 (5)	1.5 (5)
Methane sulfonate	1.7 (10)	1.6 (10)
Iodide	2.0 (9)	2.2 (5)

[a] Figures in parentheses indicate number of subjects used.

where, after the attainment of pseudo-steady-state diffusion conditions in the body, C may be defined as the amount of unexcreted substance after a single dose, and C_0 is the apparent maximal amount of excretable substance (11). A plot of the change in C for each equal increment of t is a straight line having the same slope as a plot of Eq. 1. Application of Eq. 2 to urinary excretion data requires a measurement of the drug or substance excreted in a series of reasonably equal time intervals.

Plots illustrating the urinary excretion rates of 2-PAM salts are given in Fig. 5. In Fig. 6 a plot is shown of urinary excretion in which 2-PAMCl and P-2-S are compared; four subjects were used for each salt and all subjects were studied during the same day. The hourly points, in millimoles excreted per hour, were obtained from an average Cartesian coordinate plot for each salt. The excretion rate is approximately the same for both salts. The plateau between 2 and 3 hr. indicates the point where absorption is about equal to excretion of the oxime and agrees with the data on peak oxime levels found in plasma.

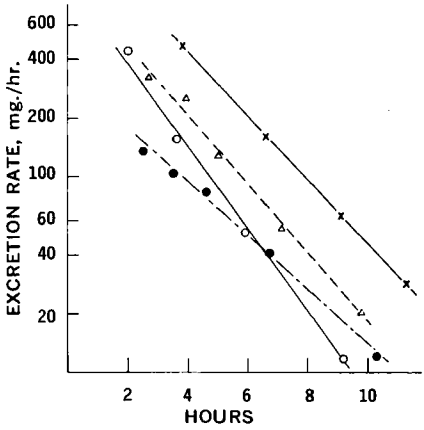

Fig. 5—Urinary excretion rate of salts of 2-PAM in man after oral administration. Key: ×, 10 g. iodide; Δ, 5 g. lactate; ○, 5 g. phosphate; ●, 2 g. P-2-S.

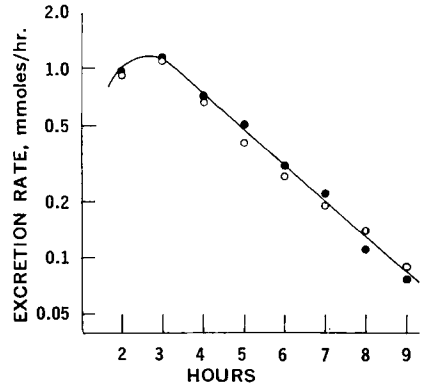

Fig. 6—Comparison of urinary excretion rates of 2-PAMCl and P-2-S following oral administration of 21.6 mmole/70 kg. Points were interpolated from Cartesian coordinate plots of the experimental data and are averages of four subjects for each salt. Key: ○, P-2-S; ●, PAM-Cl.

The concentrations of oxime in urine at various times of excretion were used to calculate the rate constant, k, and biological half-life, $t_{1/2}$ (Table II). Most of the urine samples were reasonably spaced; where the sample or urine collection spacing was too variable, values were interpolated from a smooth Cartesian coordinate plot. The procedure used, of necessity, is not a rigorously correct mathematical application of the equation. However, its use in this manner constitutes, under the conditions of the experiment, a reasonably good approximate evaluation of the total disappearance and excretion rates of the oximes.

An analysis of variance of the data revealed no significant difference at the 95% confidence limit in half-life among the various salts. The mean biological half-life of the five oxime salts was 1.7 hr. with a coefficient of variation of 24%. Statistical comparison of 35 paired replicates showed no significant difference between half-life calculated from plasma data and that calculated from urinary excretion data.

The average total amount of oxime recovered in the urine for the various 2-PAM salts was 27%; the standard deviation of individual recoveries was 9%.

Clinical Findings—With regard to the clinical laboratory tests, the following findings were made: (*a*) no changes were observed in the hematologic status of any of the subjects; liver and kidney functions were also unaffected. (*b*) A 20% drop in both RBC and plasma cholinesterase activity occurred in the men given TMB-4. No change in cholinesterase values occurred after ingestion of the other oxime salts. (*c*) No consistent changes in blood pressure, pulse, or respiratory rate occurred; no effect on either neurologic status or muscular performance was observed. (*d*) No subjective complaints were made by the volunteers, with the exception of those receiving 2-PAM iodide. These subjects had signs and symptoms of iodism: coryza, pharyngeal burning, and painful parotid glands. Two of the 10 subjects receiving 2-PAM iodide had detectable parotid enlargements, and in one subject the swelling was pronounced. These findings appeared to be unrelated to the dosage, inasmuch as the most severe case was a subject who received the lowest dose of 2-PAM iodide (5 g./70 kg.).

General Observations—The amount of oxime found in the feces among 18 subjects, taken at random, was variable, ranging from 5 to 35% of the doses administered. No correlation was observed between the amount found in the feces and either the urinary excretion or the plasma levels. No oxime could be found in the feces of one subject who had taken 2 g./70 kg. of the lactate salt. When this subject was given P-2-S and at another time the dihydrogen phosphate salt, no oxime could be found in the feces. It was later established that this individual harbored intestinal parasites. No studies were carried out to establish a correlation between these observations.

The peak plasma level achieved with the bis-quaternary oxime TMB-4 was approximately 1 mcg./ml., which caused no apparent clinical discomfort; however, all three volunteers suffered a 20–25% reduction in RBC and plasma cholinesterase. This latter result cannot be considered a conclusive characteristic since only three subjects were used.

Recovery of the bis-oxime in the urine over 24 hr. averaged less than 3% for each of three subjects, and the amount found in the feces was about 2% in two subjects. In one *in vitro* experiment 0.1 mg./ml. of 2-PAMI and of TMB-4 each were mixed with aliquots of a 1:3 suspension of a control fecal sample and allowed to remain at room temperature overnight. Recoveries from the samples were 80% for 2-PAMI and 8% for TMB-4, indicating that considerable destruction of TMB-4 may occur in the lower gut.

During the course of these trials the effect of withholding water (dehydration) from the subjects before and during the period of absorption of the oxime salt was studied in three volunteers who were given 5 g. of 2-PAM lactate. The subjects drank no fluids the night before and no water for 8 hr. after ingestion of the material. A significantly lesser amount of oxime was excreted in the urine of these volunteers compared with those subjects who were "hydrated"; no significant differences in blood plasma levels were observed.

Probenecid, which inhibits tubular secretion of substances such as penicillin and phenosulfonphthalein dye and inhibits tubular reabsorption of uric acid, was given in divided doses of 0.5 g. to three volunteers before ingestion of 2 g. of 2-PAM lactate, at the time of ingestion, and 1 hr. after ingestion. The probenecid did not increase or prolong plasma levels of the oxime and did not significantly alter its excretion in urine.

SUMMARY

1. Adult male volunteers were given, orally, aqueous solutions of each of the chloride, iodide, dihydrogen phosphate, methane sulfonate, and lactate salts of pralidoxime in varying amounts. A measurable amount of oxime was found in blood plasma within 15 min.; the concentration rose rapidly, reached a peak at 2–3 hr., and then declined at a rate that approximated a first-order process.

2. The rates of absorption into and elimination from plasma of 2-PAMCl and P-2-S were practically identical.

3. The equation, $\log Y = 0.79 + 0.54 \log X$, gives an approximate relationship between peak plasma levels of oxime (Y) and oral doses (X) of the various salts. Accordingly, a 10-fold increase in dosage of the 2-PAM salts increased the peak plasma level of oxime 3.5-fold.

4. The biological half-life in man of the 2-PAM salts given orally, calculated from blood plasma values and urinary excretion rates, was 1.7 hr., with a coefficient of variation of 24%.

5. The average total amount of 2-PAM recovered in the urine was 27%; the standard derivation of individual recoveries was 9%. Considerably less TMB-4 was excreted *via* the urine; an average of 3% was recovered during 24 hr. among three subjects.

6. Clinical changes observed were (*a*) iodism symptoms in subjects given 2-PAMI and (*b*) a 20% decrease in both RBC and plasma cholinesterase in subjects given 1 g./70 kg. of TMB-4. All other clinical tests were negative.

4-Acetamidophenyl 2,2,2-Trichloroethyl Carbonate

Particle Size Studies in Animals and Man

By LEWIS W. DITTERT*, H. JACK ADAMS†, FRED ALEXANDER, CLIFFORD W. CHONG, THEODORE ELLISON‡, and JOSEPH V. SWINTOSKY*

4-Acetamidophenyl 2,2,2-trichloroethyl carbonate (ATC) was prepared in coarse, regular, and fine particle sizes by sieving and grinding. The powders were found to dissolve in water at significantly different rates in a mechanically stirred system. When administered orally in suspensions to mice, the LD_{50}'s of the ATC powders were as follows: coarse—3340 mg./Kg.; regular—2461 mg./Kg.; and fine—1796 mg./Kg. The three ATC powders produced significantly different blood plasma concentrations of total acetaminophen in mice during the 0- to 2-hr. period after oral administration. In humans, the blood plasma concentration curves produced by oral administration of coarse and regular ATC were nearly identical. However, both had lower peaks and slower rates of decline than those produced by fine particle ATC or acetaminophen. Forty-eight-hour recovery of acetaminophen from human urine indicated that all the ATC powders were as efficiently absorbed as acetaminophen itself. It was concluded that ATC is a true prodrug of acetaminophen and that the acetaminophen blood plasma concentrations produced by orally administered ATC can be controlled to some degree by controlling its particle size.

ONE OF THE MAIN objectives of preparing prodrugs is to influence the dose–time–action profiles of drugs with known pharmacologic activities. The authors' studies with the prodrug carbonate esters of acetaminophen (1, 2) have been directed primarily toward prolonging its duration of action. This is done conveniently when the prodrug is much less soluble in water and has a slower dissolution rate in aqueous fluids than the parent drug. Under these circumstances, the appearance of the parent drug in the body is slowed by the slow dissolution of the prodrug in the gastrointestinal tract. Previous studies have indicated that the dissolution rates of the acetaminophen prodrugs, rather than their rates of hydrolysis, determine the rates at which acetaminophen is released to the tissues following their oral administration (2).

4-Acetamidophenyl 2,2,2-trichloroethyl carbonate (ATC) is much less soluble in water than acetaminophen (1). If the duration of action of ATC is indeed controlled by its dissolution rate in the gastrointestinal tract, then it would be expected that the particle size of ATC powder administered orally might have a pronounced influence on its dose–time–action profile. This paper describes the influence of particle size on oral toxicity of ATC in mice, on the blood plasma concentrations of total acetaminophen it produces in mice and in humans, and on the urinary excretion of acetaminophen after its oral administration to humans.

EXPERIMENTAL

Preparation of ATC Powders of Various Particle Sizes—ATC was prepared in coarse, regular, and

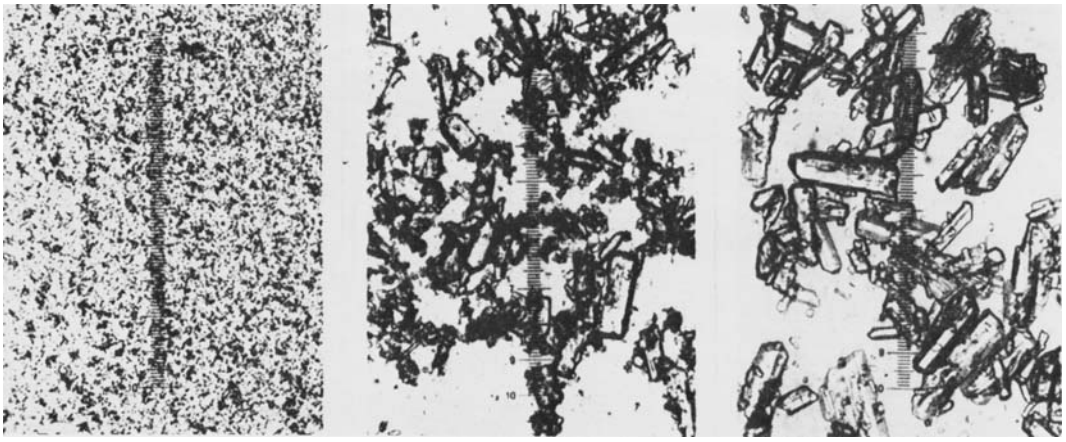

Fig. 1—Photomicrographs of the fine, regular, and coarse-particle ATC used in this study (scale = 6.03 μ/small division).

fine particle sizes by the following techniques: coarse—ATC particles which passed through a U. S. No. 140 mesh screen (hole size 150 μ) and remained on a U. S. No. 170 mesh screen (hole size 88 μ). Regular—ATC passed once through a U. S. No. 80 mesh screen in a Fitzpatrick model M comminuting mill (The W. J. Fitzpatrick Co., Chicago, Ill.) with hammers forward. Fine—ATC passed once through a fluid energy mill (Trost Jet Mill, Helme Products, Inc., Helmetta, N. J.).

Photomicrographs (125× magnification) of the powders are shown in Fig. 1. The volume surface mean diameters (d_{vs}) of the regular and fine powders were measured by air permeation using a Fisher subsieve sizer (Fisher Scientific Co.). After preparing and measuring the particle sizes of the powders, colloidal silicon dioxide[1] was added to comprise 2% by weight of the final powder to aid in dispersion.

Dissolution Rates of ATC Powders—The rate of dissolution of each of the ATC powders was determined by a method similar to that used by Parrott *et al.* (3). The apparatus consisted of a 2-L. three-neck round-bottom flask stirred by a glass impeller driven by a constant-speed electric motor (720 r.p.m.). The flask contained 1,500 ml. of 0.01% dioctyl sodium sulfosuccinate[2] solution which immediately wetted and dispersed the powders. One-hundred and fifty milligrams of the powders (about twice the amount necessary to make a saturated solution) was added through a powder funnel, and the appearance of ATC in solution was followed spectrophotometrically.

Oral Toxicity in Mice—Male Carworth Farms mice, weighing between 12 and 18 Gm., were randomly divided into groups of 10 and dosed orally with drug suspended in a 0.5% dispersion of gum tragacanth in water. Concentrations were calculated so that each animal received a dose volume of 20 ml./Kg. Control animals received 20 ml./Kg. of 0.5% tragacanth. After dosing, the animals were observed daily for 7 days; if no deaths occurred on the sixth and seventh days, the study was terminated. If deaths occurred during this 2-day period, the study was continued until no deaths occurred for two consecutive days. LD_{50}'s and potency ratios with 95% confidence limits were calculated by the Logit chi-square method of Berkson (4).

Blood Plasma Concentrations of Acetaminophen in Mice—Male Carworth Farms mice, weighing between 12 and 18 Gm., were randomly divided into groups of 10 and dosed orally with 1,000 mg./Kg. of drug suspended in a 0.5% dispersion of gum tragacanth in water. Concentrations were calculated so that each animal received a dose volume of 20 ml./Kg. At selected time intervals after dosing (0, 15, and 30 min., 1, 2, 4, and 6 hr.), heparinized blood was collected and pooled for each treatment group. The blood was centrifuged and the plasma analyzed for total acetaminophen (free + conjugated) by the method described below.

Protocols for Blood and Urine Studies in Humans—Twelve adult males were employed in a 6 × 6 crossover study with 6 subjects receiving 1 Gm. of coarse-particle ATC and 6 subjects receiving 1 Gm. of fine-particle ATC in hard gelatin capsules. Specimens of oxalated blood were collected at 0, 0.5, 1, 2, 3, 4, 7, 10, 12, and 14 hr. postdrug administration. Total urines were collected in polyethylene bottles at the following 8-hr. periods: 0, 0–8, 8–16, 16–24, 24–32, 32–40, and 40–48 hr. postdrug administration. (In this study, no changes in protocol were necessary.)

In a second study, 12 adult males (6 × 6 crossover) were given 1 Gm. of regular-particle ATC and 463 mg. of acetaminophen (molar equivalent of 1 Gm. of ATC) in hard gelatin capsules. Specimens of oxalated blood were collected at 0, 2, 4, 6, 8, 10, and 12 hr. postdrug, and total urine was collected in polyethylene bottles at 0, 2, 4, 6, 8, 10, 12, 14, 16, 24, 30, 36, and 48 hr. postdrug. (In this study, one subject was eliminated; and another, scheduled to receive acetaminophen during the second part of the crossover, was dropped.)

Analytical Method for Acetaminophen in Blood Plasma and Urine—The method employed for the determination of total acetaminophen (free + conjugated) in blood plasma and urine is similar to that used by Brodie and Axelrod (5). All samples were stored at −15° until assayed.

[1] Cab-O-Sil, Cabot Corp., Boston, Mass.
[2] Aerosol OT, American Cyanamid Co., Pearl River, N. Y.

One milliliter of the plasma or urine was transferred to a 12-ml. Pyrex graduated centrifuge tube containing 1 ml. of concentrated hydrochloric acid and diluted to 5.5 ml. with distilled water. The unstoppered tube was then placed in an autoclave at 15 lb. pressure for 1.5 hr. The tube was cooled to room temperature and the volume adjusted to 6 ml. A 5-ml. aliquot of the reaction mixture was transferred to a 40-ml. centrifuge tube containing 5 Gm. of dibasic potassium phosphate. The tube was shaken on a mechanical shaker for 5 min. (The pH of the final solution is between 7 and 8.) Twenty-five milliliters of isoamyl alcohol–ether solvent (prewashed with base, acid, and distilled water) was added, and the tube was shaken mechanically for 10 min. and then centrifuged for 10 min. to separate the phases. Twenty milliliters of the ether phase was transferred to a 40-ml. Pyrex glass-stoppered bottle containing 7 ml. of 0.01 *N* HCl, and the mixture was shaken mechanically for 5 min. and centrifuged for 5 min. Four milliliters of the aqueous phase was transferred to a colorimeter tube, and 1 ml. of a freshly prepared phenol solution (1% in water) was added and mixed. One milliliter of a freshly prepared sodium hypobromite solution (sufficient bromine water added to 1 *N* sodium carbonate solution to produce a slightly yellow color) was added, and the mixture was allowed to stand at room temperature for 20 min. The percent transmittance was read on a Coleman Junior spectrophotometer at 620 mμ against a blank consisting of 1 ml. of pretest plasma or urine treated in the same manner as the test specimens. The concentrations of acetaminophen in the specimens were determined by interpolation of a standard curve of transmittance *versus* concentration of *p*-aminophenol hydrochloride. Freshly prepared standard solutions of *p*-aminophenol hydrochloride were run through the analytical procedure along with the test and blank plasma and urine specimens.

RESULTS AND DISCUSSION

Photomicrographs of the coarse, regular, and fine ATC powders (Fig. 1) show that the coarse powder was of a relatively uniform particle size with nearly all particles falling in the 90- to 150-μ size range. The size range of this powder can be estimated from the photomicrograph in which each small division on the scale has a value of 6.03 μ. The fine powder also appears to be relatively uniform in particle size and was found by air permeation measurements to have a volume surface mean diameter (d_{vs}) of about 3.3 μ. The regular powder was not uniform in size and appears to be a mixture of relatively small particles (2–10 μ) and relatively large particles (80–100 μ). It was found to have a d_{vs} of about 22 μ. Dissolution rate experiments with the three powders showed that the solutions approached saturation at significantly different rates in the first 60 min. (see Fig. 2). Thus, significant differences in the onset and peak magnitude of the biological effects of ATC in the three particle sizes were anticipated.

Table I shows the LD_{50}'s of the three ATC powders when administered orally to mice. The LD_{50}'s and relative potencies were calculated by the Logit chi-square method of Berkson (4). The results show that both regular- and coarse-particle ATC were significantly less toxic than fine-particle ATC at the 95% confidence level. The toxicities of the regular and coarse ATC powders were not significantly different from each other at the 95% confidence level, but the actual LD_{50}'s strongly suggest that there were differences in the availabilities of these two powders for absorption in mice.

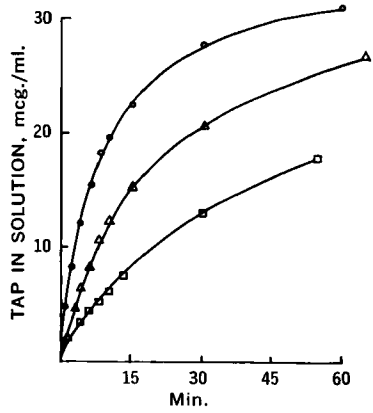

Fig. 2—Plots showing the relative rates of dissolution of fine (O-O), regular (Δ-Δ), and coarse (□-□) particle ATC powders in 0.01% dioctyl sodium sulfosuccinate solution in an apparatus similar to that used by Parrott et al. *(3). The plots illustrate different rates of* in vitro *dissolution and suggest that the powders would release ATC for absorption from the gastrointestinal tract at considerably different rates following oral administration.*

It was felt that a more sensitive test of availability, such as determination of drug plasma concentrations, might demonstrate even more unequivocally the differences in the availabilities of the three powder forms of ATC. Therefore, groups of mice were dosed orally with 1,000 mg./Kg. of the powders, and plasma concentrations of total (free + conjugated) acetaminophen were determined at various time intervals postdrug administration. The results in Fig. 3 show that, regardless of particle size, all three ATC powders produced peak plasma acetaminophen concentrations at about 1-hr. postdrug, suggesting that in each case absorption of ATC in the mouse was essentially ended after about

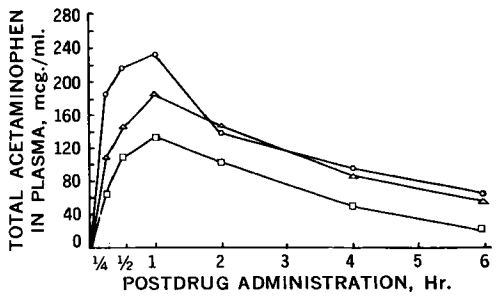

Fig. 3—Plots of plasma concentrations of total acetaminophen (free + conjugated) in mice following oral administration of 1,000 mg./Kg. of fine (O-O), regular (Δ-Δ), and coarse (□-□) particle ATC powders suspended in a 0.5% dispersion of gum tragacanth in water. The plots suggest that, in each case, the absorption of ATC was essentially ended after about 1 hr. The plasma concentrations in the 0- to 2-hr. period are dependent upon the particle sizes of the powders and, presumably, are controlled by their rates of dissolution

1 hr. However, Fig. 3 also shows that there were substantial differences in the plasma concentrations of acetaminophen produced by the powders during the first 2 hr. Thus, the fine-particle material gave rise to a substantially higher maximum plasma concentration during the first hour than the regular material; and the regular material gave rise to a substantially higher maximum plasma concentration than the coarse material.

Between 2 and 6 hr., the disappearance rates of acetaminophen from the plasma appeared to be identical for each of the three particle sizes of ATC. This supports the view that absorption of the administered doses was ended before 2 hr. The coarse-particle material gave the lowest peak and the lowest overall plasma concentrations of acetaminophen at all collection times, suggesting that the fraction of the dose absorbed was lowest from this form of ATC. The regular and fine-particle materials gave virtually superimposable plasma concentration curves between 2 and 6 hr. suggesting that the fractions of the doses absorbed were virtually identical from these two forms of ATC.

The higher plasma concentrations observed for the fine-particle ATC during the first hour suggests that absorption was fastest from this material. Also, the sudden drop in plasma concentration from Hour 1 to Hour 2 suggests that absorption-distribution equilibrium was not maintained during the first hour of absorption of fine-particle ATC. However, after absorption was ended, at about Hour 1, distribution equilibrium between the blood and other tissues was established by Hour 2; and the plasma concentrations observed thereafter were virtually the same as for the regular particle size ATC powder.

Figure 4 shows a plot of the LD_{50}'s of the three ATC powders (Table I) *versus* the peak plasma concentrations of total acetaminophen (log scale) at 1 hr. postdrug administration shown in Fig. 3. This plot shows that there was good correlation between the toxicities of the ATC powders and the peak plasma concentrations. The latter, in turn, appear to be related to the rate of absorption. In the mouse, the rate of absorption appeared to be a function of the particle size; therefore, there was excellent correlation between: (*a*) particle size and acute oral toxicity, (*b*) particle size and peak plasma concentration, and (*c*) peak plasma concentration and acute oral toxicity.

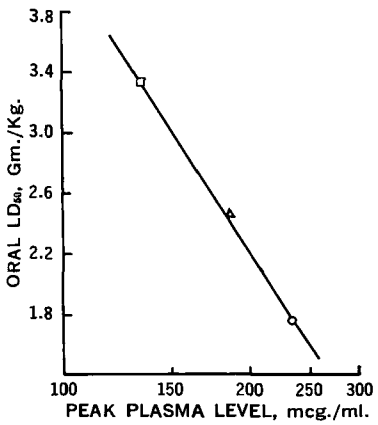

Fig. 4—Plot showing the correlation between the LD_{50}'s (Table I) and the peak plasma concentrations of total acetaminophen (log scale) at 1-hr. postdrug (Fig. 2) produced by oral administration of coarse (□), regular (Δ), and fine (○) particle ATC to mice.

TABLE I—ORAL LD_{50}'S AND POTENCY RATIOS WITH 95% CONFIDENCE LIMITS FOR COARSE, REGULAR, AND FINE-PARTICLE ATC POWDERS IN MICE[a]

LD_{50}	mg./Kg.
Coarse	3340 (1800–3710)
Regular	2461 (1820–2905)
Fine	1796 (1341–2079)
Relative Toxicities	
Coarse *vs.* regular	1.24 (0.93–1.59)[b]
Regular *vs.* fine	1.38 (1.12–1.73)[c]
Coarse *vs.* fine	1.71 (1.23–2.10)[c]

[a] Data calculated by the Logit chi-square method of Berkson (4). [b] Not significant at the 95% level. [c] Significant at the 95% level.

The results obtained with the three particle sizes of ATC in mice stirred interest to determine how particle size would affect the performance of ATC in humans. Two 6 × 6 crossover studies were carried out to compare (*a*) coarse-particle ATC with fine-particle ATC, and (*b*) regular-particle ATC with acetaminophen with respect to the plasma concentrations of acetaminophen produced in humans. Plots of the time profiles of plasma total acetaminophen in subjects administered 1 Gm. of coarse, regular, or fine-particle ATC or 436 mg. of acetaminophen (molar equivalent of 1 Gm. of ATC) orally in hard gelatin capsules are shown in Fig. 5.

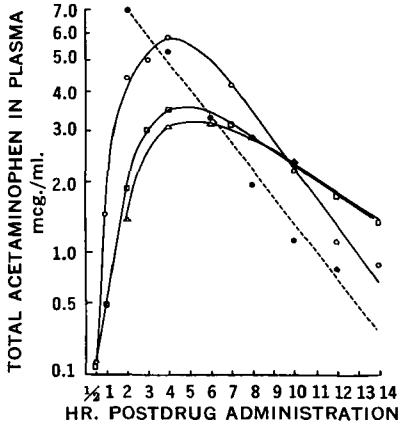

Fig. 5—Semilog plots of plasma concentrations of total acetaminophen (free + conjugated) in humans following oral administration of 1 Gm. of fine (○-○), regular (Δ-Δ), or coarse (□-□) ATC powders or 463 mg. of acetaminophen (●-●) (molar equivalent of 1 Gm. of ATC) in hard gelatin capsules. The study was carried out in two parts on 6 × 6 crossover plans. The acetaminophen and fine-particle ATC curves descend at rates corresponding to half-lives of about 3.4 and 3.2 hr., respectively, suggesting that no further absorption or conversion of ATC to acetaminophen took place after about 6 hr. following oral administration of fine-particle ATC. The regular and coarse-particle ATC curves descend at a rate corresponding to a half-life of about 6 hr. suggesting that absorption of ATC and conversion to acetaminophen was continuing well beyond 6 hr., perhaps as long as 14 hr., with these powders.

TABLE II—AVERAGE URINARY RECOVERY OF TOTAL (FREE + CONJUGATED) ACETAMINOPHEN FOLLOWING ORAL ADMINISTRATION OF COARSE, REGULAR, OR FINE-PARTICLE ATC OR ACETAMINOPHEN TO HUMANS (6 × 6 CROSSOVER)

Material Administered	Dose	Total Acetaminophen (mg./ml.) Collected per Postdrug Period (hr.) 0–8	8–16	16–24	24–32	32–40	40–48	Total	(Limits)
Acetaminophen	463 mg.	189.4 (40.9%)	70.7 (15.3%)	20.1 (4.3%)	←——7.8——→	←——(1.7%)——→		288.0 (62.2%)	(84.4–413.1) (18.2–89.3%)
Coarse ATC	1 Gm.	100.1 (21.6%)	142.3 (30.7%)	35.8 (7.7%)	23.9 (5.2%)	6.6 (1.4%)	2.2 (0.5%)	310.9 (67.1%)	(179.5–413.2) (38.8–89.2%)
Regular ATC	1 Gm.	112.3 (24.3%)	127.5 (27.6%)	41.7 (9.0%)	←——25.0——→	←——(5.4%)——→		306.5 (66.3%)	(207.4–432.1) (44.8–93.4%)
Fine ATC	1 Gm.	111.5 (24.1%)	134.6 (29.1%)	77.4 (16.7%)	10.1 (2.2%)	4.0 (0.9%)	1.9 (0.4%)	339.5 (73.3%)	(236.4–413.1) (51.1–89.2%)

The plasma concentration curves of regular and coarse-particle ATC were very similar, confirming the wide degree of overlap in the range of particle sizes in these two powders. In humans, where the gastrointestinal tract is much longer than in the mouse, proportionately smaller doses were given; and both the large and small particles in the regular-particle ATC powder were probably completely dissolved and absorbed. Since there was a relatively high proportion, on a weight basis, of coarse particles in regular-particle ATC powder (see Fig. 1), it was reasonable to expect that this powder would behave more like coarse-particle ATC in humans in which a large fraction of the administered dose is dissolved and absorbed.

Figure 5 shows that after peak drug concentrations were reached, the rates of plasma clearance with regular and coarse particle ATC were slower (half-life about 6 hr.) than that observed with acetaminophen (half-life about 3.4 hr.). Gibaldi and Schwartz (6) have shown that prolonged absorption of a prodrug of penicillin G gave a blood concentration plot of penicillin G with the appearance of prolonged excretion; that is, the half-life of the descending curve was much longer than that observed following administration of penicillin G itself. They pointed out that the apparent half-life from the "tail" of the plot was an artifact caused by absorption of the prodrug during the period in which the blood concentration curve was descending. Similarly, the slower apparent rate of clearance of acetaminophen from the blood of humans administered regular and coarse-particle ATC is probably due to prolonged or delayed absorption of the larger particles in these powders.

On the other hand, the plasma concentrations of acetaminophen produced by fine-particle ATC reached a higher, slightly earlier peak (4 hr.) than those produced by coarse or regular-particle ATC, and the rate of plasma clearance (half-life about 3.2 hr.) in the fine-particle case was the same as that observed for acetaminophen (half-life about 3.4 hr). This effect is probably due to "complete" absorption of fine-particle ATC within about 5 hr. postdrug and is indicative that ATC was completely converted to acetaminophen (and trichloroethanol) by about 5 hr. postdrug. Thus it appears that the low aqueous solubility of ATC would enable the formulator to lower the peak and extend the duration of acetaminophen (and presumably also trichloroethanol) blood levels by merely controlling the particle size of administered ATC powder.

The plasma concentration data obtained with mice suggested that coarse-particle ATC was not as completely absorbed as regular or fine-particle ATC, and it was of interest to know if this was also true in humans. Therefore, the urines of the subjects administered coarse, regular, or fine-particle ATC powder or a molar equivalent dose of acetaminophen were collected for 48 hr. following administration of the drug and analyzed for total acetaminophen content. The results shown in Table II suggest great variability in absorption efficiency from subject to subject with a given form of the drug. Also, the absorption efficiencies vary to the degree that the ranges overlap for each form of ATC and for acetaminophen. However, there is a trend toward greatest absorption efficiency for the fine form of ATC. Perhaps more importantly, these results confirm that ATC is a true prodrug of acetaminophen which releases molar equivalent amounts of acetaminophen to the tissues at a slower rate following oral administration than does acetaminophen itself. As a result, when a coarse powder form of ATC is administered to humans, acetaminophen blood levels show a profile which is suggestive of a slower, more prolonged release and absorption of this prodrug.

CONCLUSIONS

1. In mice, only a fraction of the dose of ATC appeared to be absorbed orally from the coarse powder form. The dissolution rate of the ATC powder controlled the blood plasma concentrations of acetaminophen (and presumably also trichloroethanol) during the first 2 hr. after oral dosing. The peak plasma concentration attained during this period was directly related to the LD_{50} of the powder.

2. In humans, coarse, regular, and fine-particle ATC powders appeared to be completely absorbed orally. The slow dissolution of the larger particles in the coarse and regular ATC powders caused the plasma concentrations of acetaminophen to reach lower peaks and descend at slower rates than those following oral dosing with acetaminophen or fine-particle ATC.

3. The low aqueous solubility of ATC would allow the formulator to control, to some extent, the blood levels and, presumably, the pharmacologic activity of ATC given orally. Thus, a prodrug might be employed to produce a sustained action of the parent drug in cases where the parent drug may not lend itself readily to formulation in common sustained-release dosage forms.

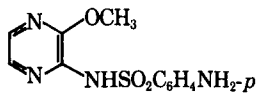
Selective Acid-Catalyzed Hydrolyses of Methoxysulfanilamidodiazines

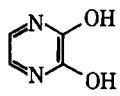
By VINCENT S. VENTURELLA*

The dilute acid hydrolysis of 3-methoxy-6-sulfanilamidopyridazine and several methoxysulfanilamidopyrimidines has been studied. Experiments show that in cases where an intermediate 2-pyrimidone is a possible postulation, further hydrolysis usually leads to the formation of sulfanilamide and the corresponding hydroxypyrimidine. A multistage route for the acidic degradation of 3-methoxy-6-sulfanilamidopyridazine, 2,4-dimethoxy-6-sulfanilamidopyrimidine, and 2-methylthio-4-methoxy-6-sulfanilamidopyrimidine is proposed.

RECENTLY, during a routine evaluation of the acidic degradation of the sulfanilamidopyrazine (I), it was found that the normally expected dilute acid cleavage to sulfanilic acid and 2-amino-3-methoxypyrazine did not occur (1), but that the products formed were sulfanilamide and 2,3-dihydroxypyrazine (II). Such a result



(I)



(II)

is in part unexpected, due to the fact that a 60% HBr solution is routinely used to effect the cleavage of difunctional methoxypyrazines (2), although there is a report (3) that 2,3-disulfanilamidopyrazine forms II under similar conditions. Since the result obtained with (I) may be due to the activation of the CH_3O position by the p-$H_2NC_6H_4SO_2NH$ group, it was desirable to test the mutual activation of these groups on the other substituent in similar sulfanilamidodiazines, such as those with the pyridazine and pyrimidine rings. The hydrolyses (except where noted) were carried out in refluxing 2 *N* HCl.

Hydrolysis of 3-methoxy-6-sulfanilamidopyridazine (III) (sulfamethoxypyridazine)[1] gave the expected sulfanilic acid, but activation of the ether position occurred forming 3-hydroxy-6-aminopyridazine. This result is surprising, even though Jacobs (4) states that the pyridazine ring is susceptible to substitution by nucleophilic reagents, because the present study has shown that a CH_3O group in the 3 position is not susceptible to nucleophilic displacement under the reaction conditions employed. In 2 *N* HCl solutions, neither 3-methoxy nor 3-methoxy-6-aminopyridazine (IV) formed more than a nominal amount of hydrolyzed material (3-hydroxypyridazine; 3-hydroxy-6-aminopyridazine, respectively) after several hours reflux followed by standing in solution for 24–72 hr. This seemingly anomalous result demands further study although a partial explanation can be made on the basis of an induced increase in the basicity of N^2 in the substituted pyridazine. The basicity increase is probably lacking or very weak in 3-methoxy- and 3-methoxy-6-aminopyridazine; a *point which*

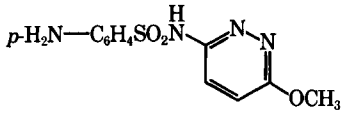
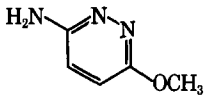
would account for the lack of acid-catalyzed aqueous nucleophilic displacement.



(III)

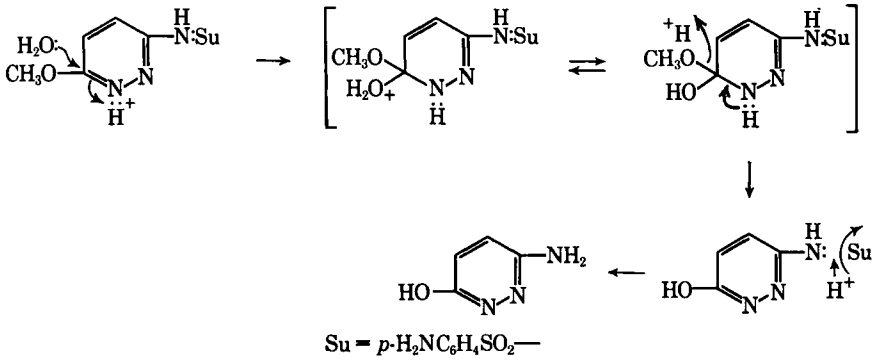


(IV)

A partial explanation which is then possible for the acid hydrolysis of III may be represented by Scheme I. In this scheme, an S_NAr attack is presumed to occur at the methoxyl position. This attack is aided by the induced electrophilic center produced by an electron migration promoted by the protonation of N^2.

hr. with 3.6 *N* HCl and 64.4% after 5.5 hr. with 3.6 *N* H_2SO_4.

Similar dilute acid hydrolysis of 4-methoxy-6-sulfanilamidopyrimidine, 4,6-dimethoxy-2-sulfanilamidopyrimidine, and 2-methylthio-4-methoxy-6-sulfanilamidopyrimidine (V) formed sulfanilic acid and the corresponding hydroxyaminopyrimidine (2-methylthio-4-hydroxy-6-aminopyrimidine with V). The 6 sulfanilamido compounds presumably hydrolyze by a nucleophilic alkoxy displacement *via* the S_NAr mechanism. This can then be followed by either normal SO_2NH bond cleavage or a second S_NAr nucleophilic displacement. In order for hydrolytic displacement of the sulfanilamido group to occur, the results of this study suggest that a 2-pyrimidone intermediate is needed, although there is no definitive proof of requirement. An incomplete hydrolysate of 4-methoxy-6-sulfanilamidopyrimidine was subjected to thin-layer



Su = *p*-$H_2NC_6H_4SO_2$—

Scheme I

Of the pyrimidines tested, 2,4-dimethoxy-6-sulfanilamidopyrimidine (sulfadimethoxine)[2] gave a novel result, yielding sulfanilamide and barbituric acid. The novelty of this result rests in the nucleophilic displacement of the sulfanilamido group, whereas one normally would expect nucleophilic displacement of the OCH_3 groups on the basis of the known S_NAr reaction which occurs at the 2,4, or 6 pyrimidyl alkoxy centers in acid solution (5, 6). By comparison with the experimental work of Daniels *et al.*, who used 2-methoxypyrimidine (7), there was a greater amount of reaction completed in a comparable period of time in the current study thereby indicating that CH_3O displacement in the hydrolysis of sulfadimethoxine is indeed accelerated by the presence of the sulfanilamido group. In the present study, essentially quantitative results were obtained after 4 to 6 hr. reflux, whereas the Daniels report (7) showed 40% completion in 1.5 chromatography (Silica Gel G, 0.5 mm., 70 Me_2CO; 30 *n*-BuOH; 30 NH_4OH) and showed an extra spot at R_f 0.52. This substance was isolated from an identical macrobatch and was shown to be 4-methoxy-5-aminopyrimidine [m.p. 148.5–150°; lit. (8), 150–151°]. The appearance of this compound thus points to the fact that when normal sulfa cleavage occurs, CH_3O^- displacement is more resistant.

However, when V was subjected to incomplete hydrolysis in 6 *N* HCl, 2-hydroxy-4-methoxy-6-sulfanilamidopyrimidine was isolated along with 2,6-dihydroxy-4-methoxypyrimidine as the intermediate hydrolytic products. This result was expected in view of the lability of 2-SR substituents of pyrimidines toward 6 *N* HCl (9). Either of the two intermediates then upon further reaction proceed along the sulfadimethoxine pathway since 2,6-dihydroxy-4-methoxypyrimidine (or its 2-pyrimidone tautomer) can be shown to be an intermediate during the sulfadimethoxine hydrolysis (Scheme II). This route is logical since the

Scheme II

2 position is more reactive in acid solution than either the 4 or 6 position in the absence of a retarding group such as the 2-methylthio group which is known to be unreactive in compounds similar to V in 2 *N* HCl (9).

Considering the results of the hydrolyses obtained with sulfadimethoxine and with V (2 *N* HCl and 6 *N* HCl) together with the established fact that a structure such as VI is favored in aqueous solution, a possible stepwise reaction for the hydrolysis of sulfadimethoxine can be represented by Scheme II. Alternately one might propose protonation of the other ring nitrogen first in the structure in Scheme II to give an incipient cross-conjugated cation. This alternative however is unlikely since neither 4-methoxy-6-sulfanilamidopyrimidine, 4,6-dimethoxy-2-sulfanilamidopyrimidine, nor V showed nucleophilic displacement of the sulfonamido group in 2 *N* HCl.

It is noteworthy that in neither of the other pyrimidines tested can an intermediate such as VI be postulated, the absence of which promotes normal SO_2NH bond cleavage and S_NAr attack at the CH_3O center (6).

In an effort to determine what normally might be expected to occur in the nonetheric sulfanilamidopyrimidines, 4-sulfanilamidopyrimidine, sulfadiazine, sulfamerazine, and sulfamethazine were subjected to similar hydrolytic experiments. In each of these four compounds the absence of a CH_3O function or the absence of a group that would yield a 2-pyrimidone (or 2-hydroxypyrimidine) function, based upon the present experimental results, would suggest that normal p-NH_2-$C_6H_4SO_2NH$ cleavage should occur. The lack of formation of sulfanilamide during the 2 *N* hydrolysis of 4-sulfanilamidopyrimidine, sulfadiazine, sulfamerazine, and sulfamethazine lends further support to the argument that the net effect of the CH_3O group is to promote the nucleophilic displacement of the p-NH_2-C_6H_4-SO_2NH group. In all the cases concerning the nonetheric sulfanilamidopyrimidines tested in this study, sulfanilic acid and the corresponding aminopyrimidine was isolated indicating the need for the CH_3O substituent in order to effect S_NAr displacement of the sulfanilamido group. It is also worthy of note that even CH_3 substitution, as in sulfamerazine and sulfamethazine, will not promote an S_NAr effect, and a CH_3O group in either the 4 or 6 position alone does not exhibit the unusual S_NAr sulfonamido displacement effect noted with sulfadimethoxine.

EXPERIMENTAL[3]

Isolated compounds were authenticated by comparison with physical constants appearing in the literature or with authentic samples (m.p., UV, IR spectra), mixture melting points, TLC comparison and/or by elemental analysis.

The procedure used for the hydrolysis of III, and the isolation of products is typical of that followed for all of the pyridazines and pyrimidines tested except V in 6 *N* HCl. The results of the hydrolytic experiments are collected in Tables I and II along with pertinent analytical data.

Hydrolysis of 3-Methoxy-6-sulfanilamidopyridazine (III)—Twenty grams (0.071 mole) of III was dissolved in 125 ml. of 2 *N* hydrochloric acid and was heated to reflux for 4 hr. The mixture was cooled and filtered, the solid washed with 50 ml. of cold 2 *N* hydrochloric acid, and suction dried to give a light yellow solid which crystallized from boiling water as white plates, m.p. 280–285° (decomposition); m.p. undepressed on admixture with sulfanilic

[3] All melting points were taken on a Thomas-Hoover apparatus and are corrected. UV spectra were obtained by use of the B. and L. Spectronic 505 or Cary model 15 (courtesy of George Irwin, SKF Laboratories). IR spectra were recorded on Perkin-Elmer model 137 spectrometer.

		2-Amino-4,6-dimethylpyrimidine	3.8 Gm., 87%	149–151°	Lit. (19) reports m.p. 152–154°; analysis for $C_6H_9N_3$: C, 58.40; H, 7.31; N, 34.18. Found: C, 58.10; H, 7.22; N, 33.97

[a] As the dihydrate. [b] Reported $\lambda_{max.}$ 257 mμ (pH 3.0); log ε 4.04 (*Ref. 12*). [c] An additional 2.1 Gm. (19%) of impure product was obtained from the recrystallization liquor. [d] Undepressed when admixed with authentic sulfanilamide (Distillation Products Industries, Rochester, N. Y.). [e] Identical to that obtained from the hydrolysis of 3-methoxy-6-sulfanilamidopyridazine (Table I). [f] Lit. (14) reports m.p. 263–264°. [g] 3.1 Gm. of 4-methoxy-6-sulfanilamidopyrimidine recovered. [h] Lit. (8) reports m.p. 150–151°. [i] Aldrich Chem. Co., Milwaukee, Wisc. [j] Lit. (15) reports m.p. 260–263° (dec.). [k] Prepared according to Baker *et al.* (15); reported m.p. 125–128°. [l] 2,6-Dichloro analog, m.p. 51–53° prepared according to Baddiley and Topham (16) (see experimental part). [m] Lit. (17) reports m.p. 150–151°. [n] Lit. (14) reports $\lambda_{max.}$ 232 mμ (ε 11,300) and 265 mμ (ε 3780). [o] The rust colored solid was extensively hydrated as isolated giving a higher melting product than reported. Confirmation of the product was obtained by drying for 10 hr. at 85° *in vacuo* over P_2O_5 yielding a product which melted at 205–208° (dec.); m.p. 173–175° (dec.) when admixed with authentic 2-hydroxypyrimidine.HCl.

acid.[4] The weight of crude material was 11.4 Gm. (93%), calculated as sulfanilic acid.

The filtrate after isolation was carefully neutralized with solid potassium carbonate, cooled in an ice bath, and filtered to give a 91.5% yield of the bland colored 3-hydroxy-6-aminopyridazine (7.2 Gm.), m.p. 243–244.5° (decomposition) after recrystallization from ethanol–water [lit. (11), m.p. 245–246°].

3-Methoxypyridazine—Twenty-five grams (0.17 mole) of 3,6-dichloropyridazine was treated with 1.05 equivalents of sodium methoxide in methanol according to the procedure described by Druey (21) and gave 11.6 Gm. (0.08 mole; 47%) of 3-methoxy-6-chloropyridazine (from boiling hexane, m.p. 87.9–89°; reported 90°). The product was dissolved in 120 ml. of anhydrous methanol and hydrogenated over 0.8 Gm. of Pd/C (22) for 4.5 hr., the dark reaction solution filtered, the filtrate evaporated under reduced pressure to a moist residue, the mixture neutralized with a saturated solution of potassium carbonate, and extracted with 380 ml. of methylene chloride. The extract was dried over

[4] Distillation Products Industries, Rochester, N. Y.

anhydrous magnesium sulfate, the solvent was removed *in vacuo*, and the product distilled to give 4.1 Gm. (0.037 mole) (46%) of a light yellow oil, b.p.$_8$ 76–79° (Druey reports 86–87°, 13 mm.).

4-Chloro-6-sulfanilamidopyrimidine—Twenty-five grams (0.168 mole) of 4,6-dichloropyrimidine,[5] 68.5 Gm. of sodium sulfanilamide, and 68.5 Gm. of acetamide were heated in the absence of solvent and the mixture worked up to yield 14.3 Gm. (0.05 mole; 29.5%) of product as the hydrochloride, m.p. 330–334° (decomposition), in the manner described by Shepherd (23), by acidifying the final solution to pH 3 rather than pH 4, followed by overnight refrigeration.

4-Sulfanilamidopyrimidine—Fourteen grams (0.047 mole) of 4-chloro-6-sulfanilamidopyrimidine was hydrogenated at 3 atm. in 82 ml. of 1.7 *N* sodium hydroxide for 75 min. (H_2 uptake complete) over 2.45 Gm. of 10% Pd/C catalyst (23). The filtered solution was neutralized with 1 *N* hydrochloric acid, refrigerated overnight, and filtered. The yellow solid was crystallized from hot acetonitrile to give 6.8 Gm. (0.031 mole; 63.5%) of 4-sulfanilamidopyrimidine as white microcrystals, vacuum dried at 55°, m.p. 225–227° [lit. (23), m.p. 232–232.5°].

4,6-Dimethoxy-2-sulfanilamidopyrimidine—The general methods described by Braker *et al.* (24) were used with some modifications in the preparation of this compound in 21% overall yield.

Fifty grams (0.392 mole) of 4,6-dihydroxy-2-aminopyrimidine was treated with 200 ml. of phosphorus oxychloride, added all at once, the mixture diluted with 20 ml. of dimethylaniline, stirred mechanically, and refluxed for 3 hr. The mixture was cooled in an ice bath and poured slowly onto 800 Gm. of cracked ice moistened with 50 ml. of ether. After all the ice had melted, the mixture was brought to pH 6 with concentrated ammonia and extracted continuously with ether for 36 hr. The ether extract was washed with saturated sodium chloride solution, dried over anhydrous magnesium sulfate, and evaporated to dryness, *in vacuo*. The solid was crystallized from a 1:1 ether–hexane mixture and recrystallized from the same solvent to give 34.2 Gm. (0.21 mole; 53%) of 4,6-dichloro-2-aminopyrimidine, m.p. 220–223° (reported by Braker as 223–225°).

The purified dichloro compound (0.20 mole; 32.8 Gm.) was suspended and stirred in 250 ml. of absolute methanol and treated with 3.5 molar equivalents (37.1 Gm.) of solid sodium methoxide and the mixture refluxed for 10 hr. The suspension was cooled to 5°, filtered, the filtrate evaporated to dryness, and the residue triturated with 50 ml. of water. The solid was filtered, washed with three 10-ml. portions of cold water, and vacuum dried at 45° over calcium chloride to yield 30.1 Gm. (0.19 mole; 97%) of 4,6-dimethoxy-2-aminopyrimidine, m.p. 95–97° [lit. (24) m.p. 94–95°] after recrystallization from hot hexane.

The purified dimethoxy compound (29.5 Gm., 0.18 mole) was mixed with 65 ml. of pyridine and 20 ml. of cyclohexane. The mixture was cooled in an ice salt bath, stirred, and treated portionwise with 52.4 Gm. (0.22 mole) of acetylsulfanilylchloride. The mixture was stirred for 3 hr. at room temperature after an initial 30-min. reaction time at 0°. The solvent was evaporated *in vacuo*, the residue treated with 150 ml. of water, the water evaporated under vacuum to give a solid which was crystallized from hot acetone. The yield of 2-(N^1-acetylsulfanilamido)-4,6-dimethoxypyrimidine was 58.2 Gm. (0.16 mole; 91%); m.p. 242–244° (decomposition) [lit. (24) m.p. 240–241° (decomposition)]. The *N*-acetyl sulfonamide was boiled with 180 ml. of 10% aqueous sodium hydroxide solution for 2 hr., the mixture cooled, and acidified with acetic acid to pH 4. The resulting suspension was refrigerated at 5° for 48 hr., filtered, the precipitate washed with 150 ml. of ice water, and suction dried. The white solid obtained was recrystallized from hot methanol–water and vacuum dried at 45° for 12 hr. to give 23.6 Gm. (0.076 mole; 47%) of 4,6-dimethoxy-2-sulfanilamidopyrimidine, m.p. 177–178° (*Reference 24* reports the same m.p.) as white microcrystals.

2-Methylthio-4-methoxy-6-sulfanilamidopyrimidine (V)—This compound was prepared in a manner substantially similar to that reported by Budesinsky *et al.* (25). Twenty-five grams (0.143 mole) of 2-methylthio-4-chloro-6-aminopyrimidine was suspended in 200 ml. of methanol containing 8.65 Gm. (0.16 mole) of sodium methoxide, and the mixture refluxed for 12 hr. The hazy solution was cooled to −10°, the mixture was filtered, the filtrate evaporated to dryness under reduced pressure, the solid suspended, and macerated with 250 ml. of water. The solid was removed by suction filtration and dried in air overnight to give 18.3 Gm. (0.107 mole) (74.8%) of the white microcrystalline 2-methylthio-4-methoxy-6-aminopyrimidine which melted at 106.2–108° after recrystallization from 50% aqueous methanol [lit. (16), m.p. 110°].

Anal.—Calcd. for $C_6H_9N_3OS$: C, 42.08; H, 5.29; N, 24.54. Found: C, 41.77; H, 5.06; N, 24.81.

Reaction of the isolated methoxy compound with acetylsulfanilylchloride in pyridine (24) followed by alkaline hydrolysis gave 23.1 Gm. (66.2%) of V, m.p. 171.5–173°, after recrystallization from ethanol–water [lit. (23), m.p. 171°].

Anal.—Calcd. for $C_{12}H_{14}N_4O_3S_2$: C, 44.15; H, 4.32; N, 17.16. Found: C, 44.70; H, 4.12; N, 17.45.

2,6-Dichloro-4-methoxypyrimidine—One-hundred sixty mg. (0.0011 mole) of 2,6-dihydroxy-4-methoxypyrimidine (isolated from the incomplete 6 *N* hydrochloric acid hydrolysis of 2-methylthio-4-methoxy-6-sulfanilamidopyrimidine) and 1.5 ml. of phosphorus oxychloride were diluted with 2 ml. of dimethylaniline and the mixture refluxed for 1.5 hr. The cooled mixture was poured onto 25 Gm. of cracked ice and extracted with seven 10-ml. portions of ether. The ether extracts were washed with saturated sodium bicarbonate solution, dried over anhydrous sodium sulfate, and distilled under reduced pressure to give 110 mg. (0.00062 mole) (56%) of the 2,6-dichloro derivative, b.p.$_5$ 132–135°. The oil solidified on standing and was crystallized from hot methanol, m.p. 51–53° [reported (26) to melt at 51°].

Crystal and Molecular Structure of 6-Thiopurine Riboside

By ELI SHEFTER

The molecular structure of 6-thiopurine riboside (commonly known as 6-mercaptopurine riboside) has been determined by X-ray crystallographic analysis. The material crystallizes from water as orthorhombic needles (space group $P2_12_12_1$) with unit cell dimensions of $a = 8.622$ Å., $b = 13.624$ Å., and $c = 20.262$ Å. There are two unique molecules in the asymmetric unit of the cell. The structure was solved by the heavy atom technique and refined by block diagonal least squares. The final R index is 0.067. In general, the bond lengths and angles agree with those found in other nucleoside structures. The C6-S distances of the two molecules (average 1.669 ± 0.002 Å.) together with the presence of a hydrogen on each of the N1 atoms indicates that the molecules are in the thiolactam configuration rather than the mercapto form. The glycosidic torsion angles (ϕ_{CN}) are +135° and +144° for the two molecules. The *syn* conformation about each of the CN bonds is stabilized by O5′-H...N3 intramolecular hydrogen bonds. The furanose rings are puckered; C2′ being displaced *endo* in both molecules. Each of the unique sulfurs is involved in a C-H...S interaction, while one is also participating in an O-H...S hydrogen bond.

6-Thiopurine (commonly known as 6-mercaptopurine) has been well established as an effective antineoplastic agent. It has been postulated that the compound exerts its effect at an enzymatic level., *i.e.*, through the purine metabolic pathway (1). In order to act as an inhibitor, it must first be converted to its active form, the ribonucleotide. In the hope of providing information on the electronic and steric configuration of this active species, the crystal and molecular structure of the riboside has been investigated.

The author is indebted to the Computing Center at this University for a generous gift of computing time, and to Mrs. Phyllis Sackman for her technical assistance.

EXPERIMENTAL

The compound was obtained from Sigma Chemical Co. (St. Louis, Missouri) and crystallized from water. Orthorhombic needles so derived have the following data:

$a = 8.622 \pm 0.002$ Å. $D_M = 1.589 \pm 0.005$ Gm./-cm.^{3} (by flotation)

$b = 13.624 \pm 0.002$ Å. $D_{calcd.} = 1.586$ for $Z = 8$

$c = 20.262 \pm 0.004$ Å. Space group $P2_12_12_1$

[a] Temperature factors in the form; exp = $(b_{11}h^2 + b_{22}k^2 + b_{33}l^2 + b_{12}hk + b_{13}hl + b_{23}kl)$.

The cell dimensions and the subsequent intensity measurements were carried out at 22 ± 4°, with Ni filtered Cu Kα radiation.

The intensities were measured by the stationary crystal-stationary counter technique using balanced Ni-Co filters. A General Electric XRD-6 diffractometer was utilized for this purpose. In the range of measurement (0 to 150° in 2 Θ), 2,729 unique reflections out of a possible number of 2,799 had intensities significantly greater than their background counts. These data were corrected for Lorentz and polarization factors and $\alpha_1 - \alpha_2$ splitting. An adjustment for the anisotropy of transmission of X-rays as a function of the angle ϕ was made as a means of correcting for absorption. The crystal used to collect the data was approximately 0.5 mm. along a (which in turn was parallel to the ϕ axis) and approximately 0.1 mm. in diameter. The structure factors were put on an absolute scale by a Wilson plot (2).

A three-dimensional Patterson synthesis calculated with only the $|F_0^2|$ terms having a value of $\sin \Theta/\lambda$ greater than 0.5 enabled the positions of the two unique sulfurs to be found. The coordinates of the 36 other nonhydrogen atoms were located in subsequent electron density Fourier syntheses. The positional and isotropic thermal parameters of these atoms were refined by least squares using a block diagonal approximation to the normal equations. A modified version of ACA program No. 317 of Gantzel, Sparks, and Trueblood (unpublished) was used for this purpose. Anisotropic temperature factors were introduced after the R value ($\Sigma||F_0| - |F_0||/\Sigma|F_0|$) was less than 0.2. After two cycles of least squares, a difference electron density map was calculated and 18 of the 24 hydrogens were easily located. The least squares was continued, including these atoms with isotropic temperature factors, until the shifts were less than $^1/_3$ of their estimated standard deviations (*SD*'s). A final difference map was then calculated and the positions of the four other hydrogens were obtained. The weighting scheme utilized in the final cycles of refinement was $W^{-1} = [(|F_0| - 15)/10]^2 + 1$, such that $\langle W\Delta^2 \rangle$ was constant throughout the range of $|F_0|$ (16). The unobserved data were given zero weight. The final R value for the observed data is 0.067.[1]

Throughout the above calculations, the atomic form factors utilized were those of Cromer and Waber (3) with the exception of hydrogen for which those in the International Tables of Crystallography (4) were used.

A listing of the fractional coordinates and temperature factors for the various atoms may be found in Tables I and II. Since the absolute configuration

[1] A list of the observed and calculated structure factors has been deposited in the Health Sciences Library, State University of New York at Buffalo, under the title of this publication.

[a] The use of the scattering curve for the free hydrogen atom usually results in anomalously low values for *B* [Jensen, L. H., and Sundaralingham, M., *Science*, **145**, 1185(1964)]. [b] These were found in the final difference electron density synthesis.

was not determined, the positional parameters were set so that they adhere to the usual convention for D-ribosides. The prefix number on each atom denotes to which of the two unique molecules the atom belongs. The estimated *SD*'s in these tables were calculated from the inverses of the full normal equation blocks. The estimated *SD*'s in the positional parameters of the nonhydrogen atoms, except for the sulfurs, are approximately 0.006 Å. and for the sulfurs 0.002 Å. These *SD*'s correspond to an uncertainty of about 0.009 Å. and 0.4° in bond lengths and angles involving the C, N, and O atoms and in the case of the C—S bonds, 0.006 Å. The errors in the hydrogen positions are at least ten times as great as those for the atoms to which they are attached, *i.e.*, average bond length error of 0.09 Å.

The intramolecular bond distances and angles for the compound are shown in Figs. 1 and 2. The angles involving the hydrogens are not presented in these figures, and only those relevant to the discussion will be presented because of their estimated *SD*'s. They are, however, in good agreement with their expected values. In general, the bond distances and angles in the two unique purine moieties are considered to be similar, *i.e.*, using the levels of significance suggested by Cruickshank and Robertson (6), the comparative differences are not highly significant.

DISCUSSION

The bond distances of both purine residues together with the placement of a hydrogen on each of

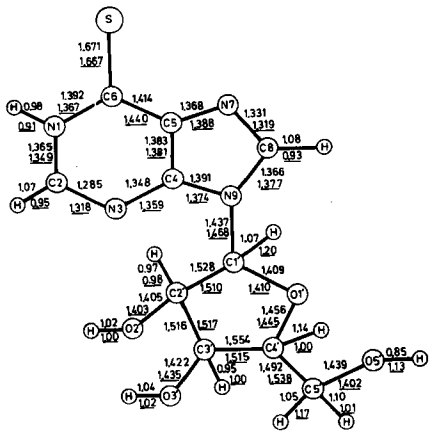

Fig. 1—Schematic drawing of molecule showing bond lengths. The distances for molecule 2 are underlined.

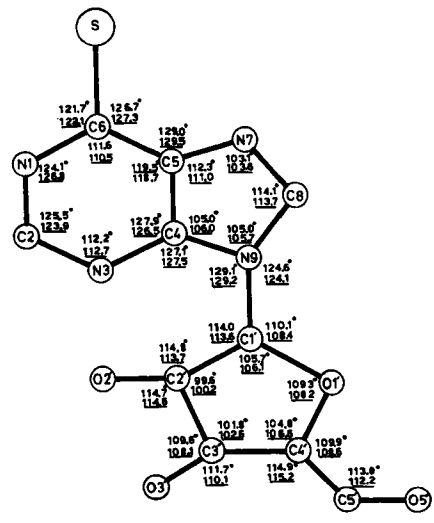

Fig. 2—Bond angles. Those obtained for molecule 2 are underlined.

[a] Calculated by the method of Schomaker, V., Waser, J., Marsh, R. E., and Bergman, G., *Acta Cryst.*, **12**, 600(1959).

the N(1) atoms, indicate that at least in the solid state the molecule exists in the thiolactam form rather than the mercapto form. This configuration has also been observed in the crystal structures of 6-mercaptopurine (5) and 2,4-dithiouracil (17). The C—S bond length in each of the two unique nucleoside molecules agrees well with the corresponding distance in the former structure; 1.673 ± 0.003 Å. Based on the compilation of structural data of sulfur compounds by Abrahams (13), the 1.67-Å. length corresponds to approximately 20% single bond character. It thus appears that though the thione configuration, (—NH—C(=S)—), is the predominant valence state, the zwitterionic amidic form, (—+NH = C(—S⁻)—), makes a substantial contribution to the overall resonance.

With the exception of the imidazole portion of the purine residue, the bond lengths and angles are in quite good agreement with those found for 6-mercaptopurine. The disparity observed between the imidazole rings of the two structures is expected as the free base is protonated at N7 rather than at N9.

The least-squares planes calculated through the purine residues (see Table III) show that the atoms comprising the two rings are essentially coplanar. Both C1′ and S are significantly displaced from these least-squares planes. In molecule 1, they are displaced on opposite sides while in molecule 2, they are on the same side of the plane. It is not uncommon in nucleoside structures to find exocyclic atoms significantly out of the base plane. The equations of the least-squares planes are as follows:

$$\text{purine 1}(-0.8208X + 0.1171Y + 0.5591Z = 4.5373 \text{ Å.})$$

$$\text{purine 2}(-0.8044X + 0.0714Y + 0.5898Z = 0.4884 \text{ Å.})$$

X, Y, and Z are the coordinates measured in Å. along a, b, and c, respectively.

The torsion angles (ϕ_{CN}) about the glycosidic bonds (7, 8) in molecules 1 and 2 are +135° and +144°, respectively. The *syn* conformations in the two molecules are stabilized by 05′-H...N3 intramolecular hydrogen bonds. Though the majority of X-ray structural analyses on purine nucleosides show a preference for the *anti* conformation in the solid state, there have been three other nucleosidic compounds reported in the *syn* configuration; formycin, an antibiotic (18), adenosine 3′-5′-cyclic phosphate (19), and deoxyguanosine in the hydrogen bonded complex with 5-bromodeoxycytidine (14).

TABLE IV—CONFORMATIONAL ANGLES

Angle	Molecule 1	Molecule 2	Deoxyquanosine
$\phi C_1' \rightarrow C_2'$	39.3	41.2	30.61
$\phi C_2' \rightarrow C_3'$	−40.6	−36.9	−30.9
$\phi C_3' \rightarrow C_4'$	27.8	23.3	20.2
$\phi C_4' \rightarrow O_1'$	−2.1	1.3	−2.1
$\phi O_1' \rightarrow C_1'$	−24.6	−25.8	−17.6
ϕ_{0c}	55.4	56.7	42.8
ϕ_{00}	62.5	62.7	70.7

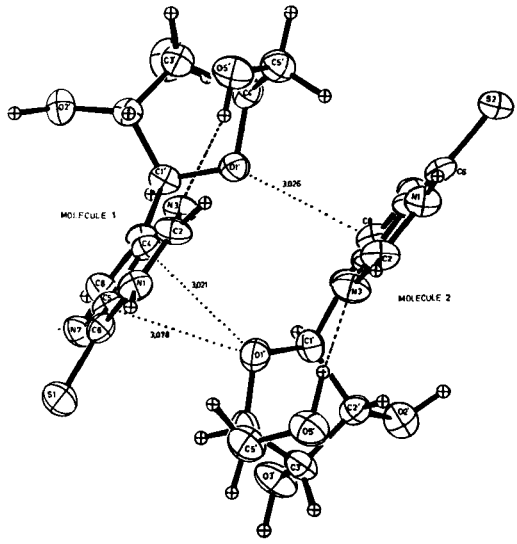

Fig. 3—View of the two unique molecules as seen down the b *axis. The thermal ellipsoids enclose a probability density of 0.50 for the nonhydrogen atoms (15).*

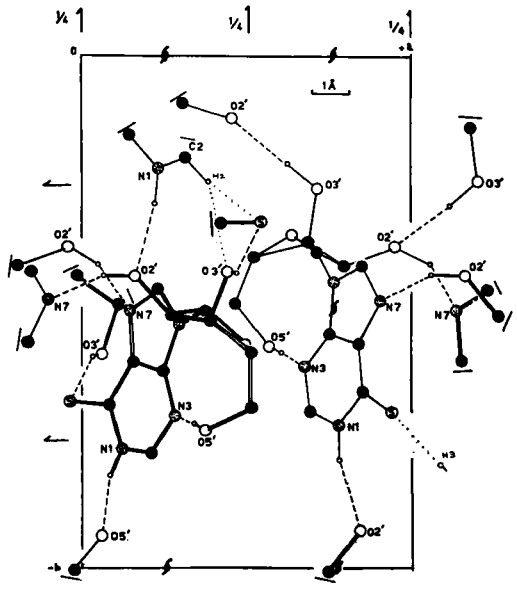

Fig. 4—Hydrogen bonding scheme about the two unique molecules as viewed down the c *axis. Dashed lines represent proposed hydrogen bonding scheme, while dotted lines are short contacts of the C-H variety. Key:* ●, *carbon;* ⊛, *nitrogen;* ○, *oxygen;* —, *molecule 1;* =, *molecule 2.*

The former two have chemical features not typical of the natural nucleosides and -tides and, therefore, a comparison with these will not be offered. The latter compound exhibits a similar intramolecular hydrogen bond. It has been shown (7, 9) using molecular models that purine nucleosides have very little restriction to rotation about the glycosidic bond, in contrast to pyrimidine nucleosides.

Although the glycosidic bond lengths fall within the usual range for nucleosidic compounds, they do appear to be significantly different (at 95% confidence level) from each other. This may be the result of the variation in the rotation angles about the glycosidic bonds and the adjacent furanose bonds. It has been shown that rotation about single bonds involving hetero-atoms having unshared pairs of electrons can influence neighboring bond lengths and angles (10).

The puckering of the furanose rings is such that C2′ is displaced on the same side of the five-member rings as C5′. *Endo* puckering of C2′ was also observed in the *syn* structure of deoxyguanosine (14). Since the usual sugar distortion in nucleotides and -sides involves C2′ and/or C3′, it can be described as a twist about the C2′—C3′ bond relative to the plane of the other three ring atoms (8). In these terms, molecule 1 shows a C2′ (*endo*)—C3′ (*exo*) conformation, while the other has a C2′ (*endo*)—C3′ (*endo*) conformation (*cf.* Table III). The overall configuration of the sugar residues can best be described in terms of torsional angles about each of the ring bonds. These twist angles, as defined by Brown and Levy (11) and Sundaralingam (10) are given in Table IV, for the two unique riboses with those for the furanose moiety in deoxyguanosine. The agreement of these angles among the three sugars is excellent. These angles probably reflect the most stable sugar configuration for the *syn* conformer.

The orientation of the exocyclic C5′-05′ bond with reference to furanose ring is usually described by its projected angle down C4′-C5′ with respect to 01′ and C3′ (12). These angles are referred to as ϕ_{00} and ϕ_{0c}, respectively. The intramolecular 05′-H... N3 interactions constrain the values of these angles to be in the vicinity of 60° (*i.e.*, gauche).

Distortions from tetrahedral symmetry of the ribose carbons are commonly found in the crystal structures of nucleosides and -tides. These deformations are possibly the result of intermolecular associations and the nonbonding interactions within the ribose structure. These reasons may also be re-

TABLE V—SHORT INTERMOLECULAR CONTACTS

Hydrogen Bonds		Pertinent Distances and Angles	
Acceptor	Donor[a]

[a] The value in parentheses following the donor atom name denotes its equivalent position in fractional coordinates, as follows: (1) $^1/_2 + x, ^1/_2 - y, -z$, (2) $^1/_2 + x, ^3/_2 - y, -z$, (3) $1 + x, y, z$, (4) $^1/_2 - x, 1 - y, z - ^1/_2$, (5) $1 - x, y - ^1/_2, ^1/_2 - z$, (6) $x - 1, y, z$, (7) $x - ^1/_2, ^1/_2 - y, -z$, (8) $x - ^1/_2, ^3/_2 - y, -z$, (9) $1 - x, ^1/_2 + y, ^1/_2 - z$, (10) $2 - y - ^1/_2, ^1/_2 - z$.

sponsible for the differences in the bond lengths and angles between the two unique sugars. The two ribose moieties have bond lengths and angles which closely resemble those found in other nucleosidic structures.

The two unique molecules in the asymmetric unit (as shown in Fig. 3) appear to be approximately related by a noncrystallographic twofold axis nearly parallel to the *b* axis. The only short contacts between the two molecules shown in Fig. 3 are those involving 1O1′...2C8, 2O1′...1C4 and 2O1′...1C5, which have distances of 3.026 Å., 3.021 Å., and 3.078 Å., respectively. These are slightly less than the sum of the van der Waals radii of the respective atoms (3.1 Å.).

The arrangement of the hydrogen bonds around the two unique nucleosides are shown in Fig. 4. The pertinent distances and angles associated with the various hydrogen bridges are given in Table V. An interesting facet of the proposed intermolecular bonding scheme is the presence of a 2O3′-H...2S hydrogen interaction. The 2O3′ proton is considerably displaced from the plane of the purine nucleus and the C6-S...H angle also deviates considerably from linearity (116°). These distortions may possibly result from the valence state of the sulfur. The O3′-H...S distance of 3.133 Å. is much shorter than the O-H...S length reported in the structure of 6-mercaptopurine hydrate (3.374 Å.). There is also a very short contact between the 1C2 hydrogen (H2) and 2S, which is suggestive of a C-H...S interaction (20). The other sulfur (1S) appears to be only participating in a C-H type interaction and by virtue of its length (H3...1S 2.47 Å.) is a relatively strong hydrogen bond.

There are two N1-H...O hydrogen bonds. The 2N1-H...1O5′ length is 2.722 Å., while the 1N1-H...2O2′ interaction is 2.902 Å. The difference in the strengths of these two hydrogen bonds appears to be attributable to differences about N1 in the two unique residues. The N1-C6 bond length of molecule 2 is 0.025 Å. shorter than the same bond in molecule 1, and the C6-N1-C2 angle 2.7° greater than in molecule 1. Though these differences are only significant at the 95% confidence level, they are consistent with the marked inequality of the hydrogen bond lengths, *i.e.*, the proton on 2N1 is more acidic in character than the one on 1N1.

Each of the O2′ atoms is participating in the hydrogen bonding scheme as both a donor and acceptor, while the O3′ atoms only appear to be acting as donors. The other short intermolecular contacts are listed in Table V. Although some of these H contacts are slightly shorter than normal van der Waals contacts, only two are felt to be of a significant nature (mentioned above).

Structural Studies on Complexes II

Crystal and Molecular Structure of a 1:1 Caffeine and 5-Chlorosalicyclic Acid Complex

By ELI SHEFTER

Crystals of a 1:1 complex of caffeine and 5-chlorosalicylic acid are orthorhombic with space group P *bcn*. The unit cell parameters are a = 7.952 Å., b = 16.303 Å., and c = 25.491 Å. The structure was solved by a symbolic addition procedure. The positional and thermal parameters were refined by least squares to an R value of 0.077. The caffeine molecule shows significant deviations from planarity. The molecules are held together in the lattice by O—H...N and C—H...O intermolecular hydrogen bonds. Polarization bonding also seems to play a dominant role in the stacking of the molecules in the lattice.

THE ABILITY of xanthine and purine derivatives to form association complexes with a wide variety of biologically important molecules is well documented in the literature. It has been shown that caffeine, through its complexing behavior, can influence the rates of hydrolysis of various molecules (1, 2) and also inhibit salivary amylase (3). To date there appears to be very little information reported as to the exact mode of the interaction in these "complexes." Recent structural studies on complexes of tetramethyluric acid with a variety of aromatic hydrocarbons (4–6) have indicated that polarization bonding is of primary importance. The structure analysis of the 1:1 complex of caffeine and 5-chlorosalicylic acid was undertaken as part of a continuing study to gain further insight into the nature of the forces that are responsible for intermolecular complexes between xanthines and purines with substituted aromatic compounds of biological and pharmaceutical importance.

EXPERIMENTAL

Orthorhombic prisms of the complex were obtained from an aqueous solution saturated with the two respective molecules. The following crystallographic data were measured for these crystals:

a = 7.952 ± 0.003 Å. $\alpha = \beta = \gamma = 90.0°$
b = 16.303 ± 0.003 Space group $P\ bcn$ (uniquely defined)
c = 25.491 ± 0.004 ρ measured = 1.47 ± 0.01 Gm./cm.^{3}
ρ calcd. (assuming 8 molecules of a 1:1 complex) = 1.462 Gm./cm.^{3}

The density was determined in a mixture of chloroform and methylene chloride. The unit-cell parameters were established by means of least-squares refinement of 30 general *hkl* reflections measured on a GE XRD-6 diffractometer. The temperature during these measurements and the subsequent intensity collection was approximately 22 ± 4°.

The intensity data were measured by the stationary crystal-stationary counter technique with balanced nickel and cobalt filters. The size of the crystal utilized was approximately 0.9 mm. × 0.3 mm. × 0.2 mm. These data were converted to structure factor amplitudes, $|F|$s, by applying α_1-α_2 splitting corrections, Lorentz-polarization factors, and an absorption factor based on the anisotropy of transmission of the X-rays as a function of the angle ϕ. The $|F|$'s were put on an absolute scale by use of Wilson's statistics (7), and then converted to their respective normalized structure factors, $|E|$'s. In the sphere of the data collection (0°–125° in 2 θ) 2519 reflections out of a possible number of 2,646 had values greater than twice the standard deviation of their measurement.

A trial structure was obtained using the symbolic addition procedure. The phases of 180 normalized structure factors, all having values of $|E|$ greater than 1.75, were determined using the Sayre equation (8), which is the same as the Σ_2 formula of Hauptman and Karle (9). A program written by Long was utilized for this purpose (10). Three linearly independent reflections (2.1.4, 2.2.1, 1.1.14) each having a large number of interactions were assigned positive signs in order to specify the origin. Aside from the origin-determining planes four other structure factors having large $|E|$ values (4.1.8, 1.2.10, 3.1.6, and 3.1.10) were allowed to take up each of the 16 possible phase combinations. The program in an interactive manner generated the phases for the other 173 reflections for the 16 sets of phases. A consistency index, C,

$$C = \frac{\langle |E_A \Sigma_{A=B+C} E_B E_C| \rangle}{\langle |E_A| \Sigma_{A=B+C} |E_B|\,|E_C| \rangle}$$

Received January 12, 1968, from the Department of Pharmaceutics, School of Pharmacy, State University of New York at Buffalo, Buffalo, NY 14121

Accepted for publication February 19, 1968.

Presented to Basic Pharmaceutics Section, APhA Academy of Pharmaceutical Sciences, Miami Beach meeting, May 1968.

This investigation was supported by grants CA-10104 and A-3909 from the Public Health Service, and also in part by the National Science Foundation (G202-07 and GB-2029).

The author is indebted to the SUNY/B Computing Center for a generous gift of computing time, to Dr. K. N. Trueblood of the Chemistry Department at U.C.L.A. for his interest and programs, and to Mrs. Phyllis Sackman for her technical assistance.

A list of the calculated and observed structure factors has been deposited in the Health Sciences Laboratory at the State University of New York at Buffalo.

where the sums are overall pairs of reflections B and C for which $B + C = A$. $\langle\rangle$ means the average overall values of A. A high value for this index usually indicates a consistent set of phases. A E-Fourier map was calculated from the solution with the highest C value (0.70). The whole molecule was not recognizable from this map, but the xanthine moiety clearly stood out. The positions of these atoms were then utilized to calculate an electron-density Fourier synthesis from which the positions of all the nonhydrogen atoms were located. The reason for the ambiguous nature of the E-map was due to the fact that a number of the phases were incorrectly assigned by the program.

The positional and thermal parameters were refined by least squares using a block-diagonal approximation to the normal equations. A modified version of the ACA program 317 (Gantzel, Sparks, and Trueblood, unpublished) was utilized. After anisotropic temperature factors were introduced and the usual reliability index (R value) was 0.10, the positions of the hydrogen atoms were found from a three-dimensional Fourier difference synthesis. These atoms were included in the final cycles of least squares with fixed isotropic B's of 5.0 Å.^{2}. The refinement was concluded when the parameter shifts were less than a third of their calculated e.s.d.'s (estimated standard deviations). In the last stages of least squares the weighing scheme utilized was $1/w = [(|F_0| - 15)/30]^2 + 1$, such that $\langle w\Delta^2\rangle$ was constant over the whole range of $|F_0|$s. The unobserved data were given zero weight in the last cycles. The final R index for the observed reflections is 0.077 and the goodness of fit, $(\Sigma w|F_0 - F_0^2|/m - n)$, is 1.23.

The nonhydrogen atomic parameters and their e.s.d.'s are given in Table I, and those for the hydrogen atoms in Table II. The e.s.d.'s were calculated from the inverses of the full normal equation blocks.

Throughout the above calculations the atomic scattering factors used were those of Cromer and Waber (11), except for hydrogen which was taken from the *International Tables for X-ray Crystallography* (12).

H15	−160(6)	− 25(3)	36(2)

[a] E.s.d.'s of the hydrogens × 10^3 in parentheses. Isotropic temperature factors (B's) were fixed at 5.0 Å.^{2}.

The results of a rigid body analysis of the temperature factors for the two residues of the complex are shown in Table III. The method of Schomaker and Trueblood (13, 14) was utilized to calculate the librational and translational tensors. The root mean-square difference between the observed and calculated Uij's were 0.0033 and 0.0041 for the caffeine and 5-chlorosalicylic acid molecules, respectively. The caffeine has a substantially smaller thermal motion than the salicylic acid moiety, which is consistent with the intermolecular bonding in the lattice (see below). Neither the librational nor the translational motions of the two molecules are significantly anisotropic.

DISCUSSION OF RESULTS

The intramolecular bond distances and angles of the two residues composing the complex are shown

in Figs. 1 and 2. These distances and angles were corrected for the effects of molecular libration by the method of Cruickshank (15). The distances and angles for the nonhydrogen atoms have average e.s.d.'s of 0.007 Å. and 0.3°. The distances and angles for the hydrogens have an average uncertainty of approximately 0.07 Å. and 2°. These e.s.d.'s include an assumed e.s.d. of 0.002 Å. for the uncertainty in intramolecular bond distances and angles corrected for librational motion.

In general the bond distances and angles of the caffeine moiety of the complex agree fairly well with

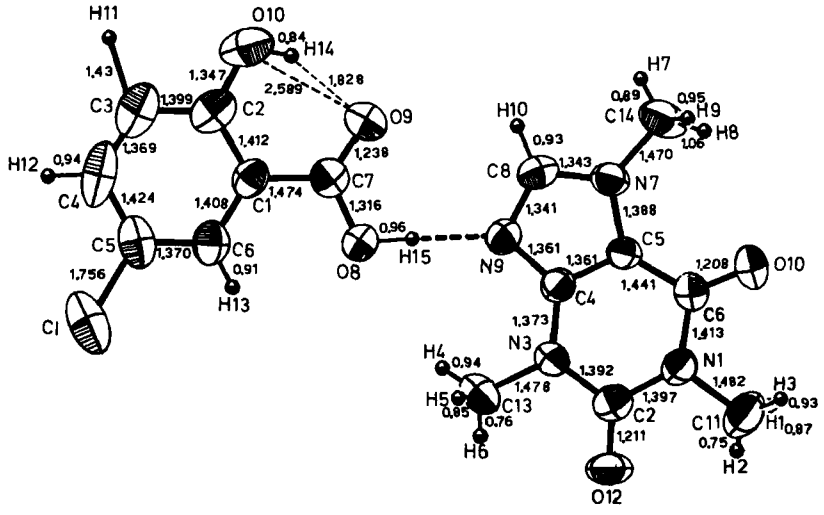

Fig. 1—Thermally corrected intramolecular distances. The thermal ellipsoids in this figure, and the others, enclose a probability density of 0.50 (30), for the nonhydrogen atoms.

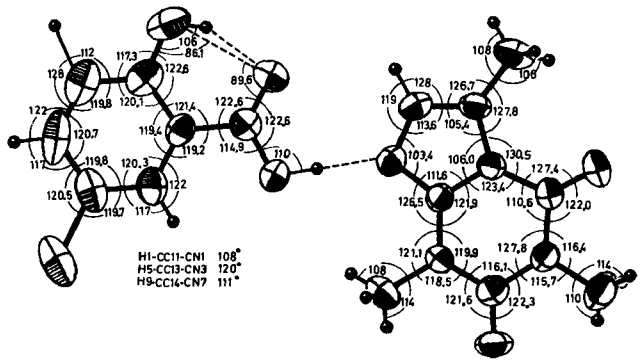

Fig. 2—Thermally corrected intramolecular angles.

those found in the structure of caffeine hydrate (16). There are however some differences worth noting; these are between the C6—O10, C6—N1, N3—C4, C4—N9,and C4—C5 bonds, whose values were found to be 1.26 Å., 1.36 Å., 1.42 Å., 1.31 Å., and 1.32 Å., respectively, in the caffeine structure. These discrepancies may reflect the higher uncertainty in the X-ray study of Sutor (av. e.s.d. ~ 0.02 Å. in bond lengths), or possibly the effect of intermolecular polarization bonding. The former of these reasons appears to be the more likely as the size of the differences in the intramolecular xanthine bonds are much smaller when these results are compared to the theophylline structure (17); *i.e.*, they all fall within 2.5 times the e.s.d.'s of that structure.

The atoms comprising the purine ring show a significant degree of puckering (see Table IV). These deviations most likely reflect the contribution of some sp^3 character to valence state of the nitrogens. This finding is not unusual as a variety of pyrimidine and purine structures have been observed to be significantly nonplanar (19).

There is a remarkably good similarity between the precise structure determination of salicylic acid (20) and the 5-chloro derivative in this complex. Only two bond lengths, the C5—C4 and C1—C7, differ by more than 2 e.s.d.'s The values for these bonds are 1.384 Å. and 1.457 Å., respectively, in the salicylic acid structure. The substitution of the electronegative chlorine atom in the five position of the ring, undoubtedly is a major factor for these observed differences. As already pointed out by Cochran (21) and Sundaralingam and Jensen (20), there appears to be a substantial contribution of the quinoid structure to the possible valence states of the molecule.

[a] Calculated by the method of Schomaker *et al.* (18).

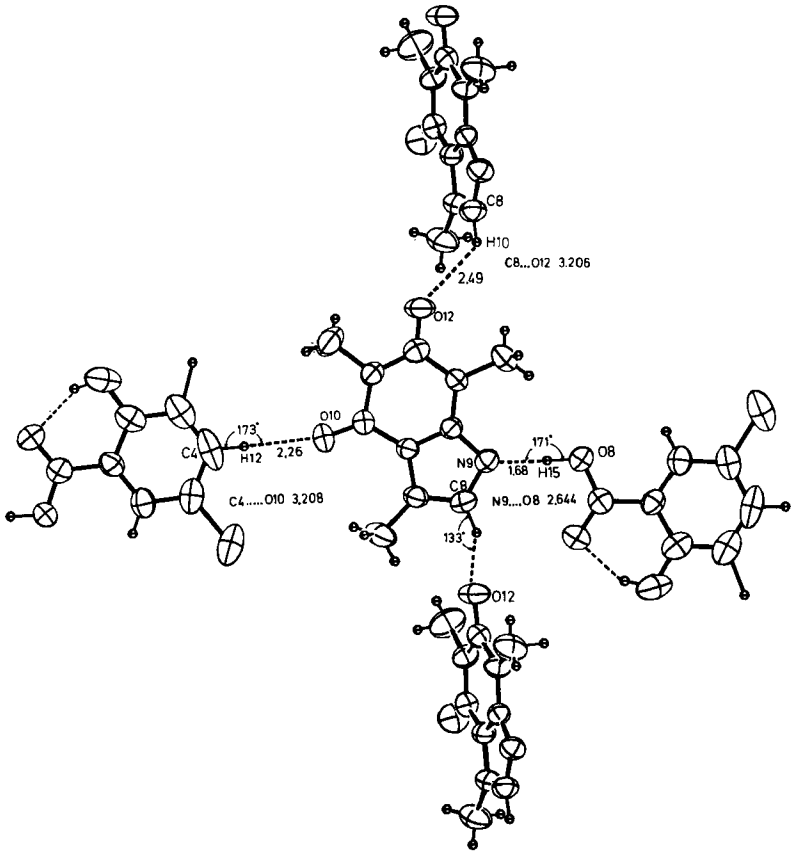

Fig. 3—A general view of the packing, showing the short intermolecular contacts.

The phenyl ring atoms are coplanar (see Table IV), within experimental error. The equation for this plane is $-0.8358\ X - 0.0142\ Y + 0.5488\ Z = 1.7274$ Å., where X, Y, and Z are in Å. measured along a, b, and c. The chlorine atom and the carboxyl group displacements from this plane are significant. In regard to the chlorine atom, it is most interesting to note that the displacement of the hydrogen in the five position of the salicylic acid structure is also significantly displaced from the ring. In the present instance the chlorine does not appear to have any short intermolecular contacts to it which might cause this distortion. The displacement of the carboxyl group from the least-squares plane is not unreasonable, as in both the structures of salicylic acid and 2-amino-3-methyl benzoic acid (22) a similar effect is observed.

The most dominant intermolecular bond observed in the complex is the N9...H—O8 interaction (see Fig. 3). The 2.644 Å. N...O length together with the 1.68 Å. H...N9 distance indicate this to be a relatively strong interaction. In general O—H...N bonds found in structures where the dominating proton comes from an acidic group, the hydrogen bond lengths are usually low. In the structures of nicotinic acid (23), hydroxy-L-proline (24), and 1,4-piperazine-α,α^1-dibutyric acid (25) the N...H—O lengths are 2.66, 2.67, and 2.60 Å., respectively. In most other types of O—H...N bridges the lengths are considerably longer as evidenced by the average value of 2.80 ± 0.09 Å. tabulated by Pimental and McClellan (26).

There are two other short intermolecular interactions that appear to be joining the molecules in chains throughout the crystal lattice (see Fig. 3). These are between SC4—H...O10 and CC8—H...O12. The hydrogen to oxygen distance in these two bridges are 2.26 and 2.49 Å., respectively, which are much less than the sum of the van der Waals radii of the atoms involved (2.6 Å.). There are numerous examples of this type of bonding in the recent literature. In the structures of both caffeine hydrate and theophylline hydrate the C8 hydrogen was also found (27) to be participating in a hydrogen bond with a carbonyl oxygen. The resonance in the purine system is probably responsible for the acidic nature of this proton. The acidic character of the SC4 hydrogen possibly results from the inductive effect of the chlorine atom. It is of interest to point out while on the subject of C—H hydrogen bonds, that spectroscopic evidence shows that C—H...O=C bonding plays a significant role in the stability of polypeptides (28).

The general features of the stacking of the molecules are shown in Fig. 4. Some of the distances between the stacked planes are listed in Table V. Though none of these lengths are shorter than the sum of the van der Waals radii of the atoms concerned, the general arrangement of the stacked molecules tends to indicate polarization bonding between layers. This idea has been discussed in a previous communication on this structure (29). The greatest degree of stacking overlap occurs between the salicylic acid moiety at $-x, -y, -z$ (drawn with the thickest bonds in Fig. 4) and the caffeine at x, y, z. Only the carboxyl group overlaps the caffeine on the underside, *i.e.*, at $1 - x, -y, -z$ (thinnest lines in Fig. 4). Similar observations have been reported by Damiani *et al.* (4–6) in the complexes of tetramethyluric acid and some aromatic hydrocarbons. The perpendicular separations between planes in the latter structures were 3.45 Å.

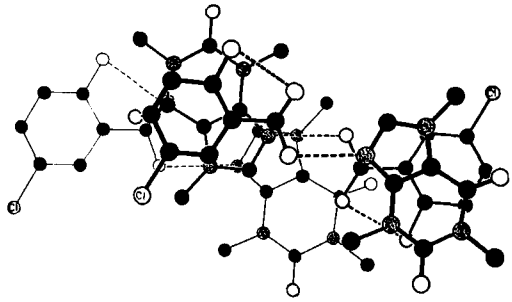

Fig. 4—The stacking arrangement viewed in the direction perpendicular to the molecular plane of caffeine. Broadest bonds indicate molecules at −x, −y, −z, *next broadest bonds indicate molecules at* x, y, z, *and the thinnest represents the molecules at* 1 − x, −y, −z. *Key:* ●, *C;* ⊛, *N;* ○, *O.*

TABLE V—INTERMOLECULAR DISTANCES LESS THAN 3.45 Å.[a]

Comparative Study of a New Fluorometric Assay Mestranol Ether in Tablets with GLC and Colorimetric Assays

By ROBERT J. TEMPLETON, WILLIAM A. ARNETT, and IVAN M. JAKOVLJEVIC

Mestranol (17α-ethinylestradiol-3-methyl ether) has been found to react with methanol–sulfuric acid mixture of a critical composition to give a stable fluorophor of high intensity. This fluorescence permits the analysis of mestranol in the submicrogram range. The use of varying proportions of methanol and sulfuric acid enables the analyst to measure the fluorescence at several different wavelengths. The analyst can choose the reagent which gives him the selectivity necessary for his analytical problems. Colorimetric, GLC, and TLC methods for the determination of mestranol are also discussed and compared with the fluorometric method. The described method is satisfactory for both control and stability measurements of mestranol.

THE ANALYTICAL DETERMINATION of the estrogenic component of oral contraceptive tablets is of the utmost interest to the pharmaceutical industry. Control of manufacturing processes, quality control of the finished product, and stability measurements of the active ingredients require accurate and sensitive methods of analysis. The amounts of estrogen formulated into these tablets require analytical methods which are highly sensitive and selective in the microgram range. Other applications, such as the analysis of biological fluids, may require sensitivity in the submicrogram range.

Mestranol and ethinyl estradiol have been determined by colorimetric measurements for many years. Ganshirt and Polderman (1) developed a chromophor with mestranol using an aqueous sulfuric acid reagent. Shroff and Huettemann (2) used a phenol–sulfuric acid reagent to measure mestranol. The colorimetric determination of ethinyl estradiol by Tsilifonis and Chafetz (3) made use of a methanol–sulfuric acid reagent, which has been used in the determination of mestranol in this laboratory for several years.

The determination of mestranol by UV was described by Bastow (4). Shroff and Grodsky compared UV and GLC procedures (5), and an assay which was a combination of UV and TLC was compared to a GLC procedure by Schulz (6). France and Knox (7) assayed ethinyl estradiol by GLC without derivative formation, and Umbreit and Wisniewski (8) reported that mestranol could be assayed by GLC without thermal degradation.

Mestranol was determined fluorometrically by Hüttenrauch and Keiner (9) with antimony trichloride in glacial acetic acid. Bates and Cohen (10) heated steroids with aqueous sulfuric acid to develop fluorescence. Phosphoric acid was used by Boscott (11) to develop specific colors and fluorescence with several steroids. Comer *et al.* (12) and Cali and Khoury (13) have reported automated methods for mestranol.

The fluorometric procedure described by the authors is quite simple. The reagent develops a fluorophor at room temperature, which is highly intense and stable for at least 30 min. This

paper will compare the newly developed fluorometric procedure with the authors' versions of the colorimetric and GLC assays. The ability of these methods to measure stability will also be discussed. TLC has been used to detect degradation products as well as to demonstrate and confirm the quantitative results of the other procedures, and a brief discussion is included. Because of the simplicity and sensitivity of this method, it will find application in biological analysis, trace analysis, and contamination control.

EXPERIMENTAL

General Procedure for Tablet Extraction

The tablets used for assay evaluation in this paper were labeled to contain 80 mcg. mestranol per tablet. The bulk of the tablet excipient material is sodium bicarbonate.

One tablet was weighed accurately and placed in a 50-ml. volumetric flask. Three drops of a 20% aqueous solution of sodium hydroxide and 2 ml. of water were added to the flask. The tablet was then dissolved by placing the flask in an ultrasonic cleaner for about 5 min. Approximately 25 ml. of chloroform was added to the flask, which was then shaken for 30 min. on a wrist-action shaker. Sufficient chloroform was added to raise all of the aqueous layer into the neck of the flask. The aqueous layer was aspirated and discarded, and the chloroform was transferred to a 100-ml. volumetric flask through anhydrous sodium sulfate. The content of the flask was diluted to volume with chloroform. This is the sample solution containing approximately 0.8 mcg. mestranol per ml. which is used in each of the described assays.

Fluorescence Assay Procedure

Apparatus—An Aminco-Bowman spectrophotofluorometer equipped with a xenon lamp, a IP21 photomultiplier tube, and silica cells was used to check all activation and emission wavelengths. A Turner model 110 filter fluorometer equipped with a G.E. F4T4 lamp and matched borosilicate cells was employed for all quantitative fluorometric measurements. Kodak Wratten filter 47B which has peak transmission at 430 mμ was used as the primary filter, and Corning filter 3385 which cuts off below 480 mμ as the secondary filter.

Reagent—To develop fluorescence, a 50% v/v mixture of absolute methanol and concentrated sulfuric acid (50% reagent) was used. To prevent heat build-up, the 50% reagent was prepared in an ice bath by adding sulfuric acid dropwise to a chilled flask of methanol.

Tablet Assay Procedure—Two milliliters of the sample solution containing about 1.6 mcg. of mestranol was pipeted into a test tube (18 × 120 mm.) and carefully evaporated to dryness using air and mild heat. The sample was redissolved with 0.1 ml. of methanol and then 5 ml. of the 50% reagent was added to the test tube. After shaking to mix thoroughly, the tube was allowed to stand at room temperature for 1 hr. to obtain maximum fluorescence development. The solution was then transferred to a Turner cell and the fluorescence measured against a reagent blank. To obtain on-scale readings with solutions in the concentration range of 0.1–0.4 mcg. per ml., a 1× aperture setting was used and a 10% transmittance density filter was combined with the secondary filter.

Colorimetric Assay Procedure

Apparatus—A Beckman model DU spectrophotometer with 1-cm. cells was used.

Reagent—The reagent used to develop the chromophor was 30% v/v mixture of methanol in concentrated sulfuric acid (30% reagent). The reagent was prepared in the same manner as the 50% reagent.

Tablet Assay Procedure—A 20-ml. aliquot of the sample solution, corresponding to 16 mcg. of mestranol, was pipeted into a 25-ml. volumetric flask. This solution was evaporated to dryness under a current of air and with gentle warming. Four drops of methanol, from a 1-ml. pipet, was added to redissolve the residue, and then 10 ml. of 30% reagent was pipeted into the flask. The contents were mixed well and the absorbance was read after 10 min. at 545 mμ against a reagent blank. A mestranol standard of about the same concentration was treated in the same way.

Gas-Liquid Chromatographic Procedure

Apparatus—F and M model 402 equipped with dual hydrogen flame detectors was used.

Column—A U-shaped glass column, 61 cm. (2 ft.) × 4 mm. i.d. was used. The column was cleaned with chromic acid cleaning solution and silanized before packing.

Liquid Phase—A silicone gum rubber, W-98 (F and M Scientific Corp., cat. No. LP-166).

Inert Support—Diatoport S, 80/100 mesh (a diatomaceous earth specially treated and silanized by F and M Scientific Corp.). The glass wool used to plug the ends of the column was also silanized.

Preparation of Column Packing—A 1% solution of W-98 in toluene was prepared by dissolving 3.0 Gm. of W-98 in 300 ml. of toluene with constant stirring on a steam bath. Fifty grams of 80/100 mesh Diatoport S was added to the W-98 solution in a liter filter flask. Vacuum was applied to degas the solution and it was allowed to stand for 5 min. The support was then separated from the solution by vacuum filtration. The support was spread and air dried for 24 hr. To remove the last traces of toluene, the support was heated at 100° for 1–2 hr.

Column Conditioning—The column was "no-flow" conditioned for 1 hr. at 325°. After cooling to room temperature, the carrier gas flow was started and the column was conditioned at 275° for 24 hr.

Instrumental Parameters—The instrument was operated isothermally at a column temperature of 205°. The injection port temperature was set at 230° and the detector temperature at 260°. Helium was used as carrier gas with the flow rate at 60–70 ml./min. Oxygen was used for operating the hydrogen flame detector. The range setting was at 10, and the attenuation at 16×.

Preparation of Mestranol Standard Solution—An accurately weighed and diluted solution of pure mestranol in chloroform containing 10 mcg./ml. was used in most cases.

Internal Standard—Cholestane (5α-cholestane

TLC homogeneous, Mann Research Laboratories, Inc.) was selected as the internal standard because of the stability, solubility, and retention time relative to mestranol. A cholestane solution at a concentration of 25 mcg./ml. of chloroform was used.

Preparation of Standard Curve—Internal standard solution in the amount of 2.0 ml., corresponding to 50 mcg. of cholestane, was pipeted into each of five 100-ml. beakers. Then 1.0, 2.0, 3.0, 4.0, and 5.0-ml. aliquots of 10 mcg./ml. of mestranol standard solution were pipeted into each beaker, respectively. Each solution was mixed and evaporated to dryness under a stream of air and mild temperature. The residue was redissolved with 1.0 ml. of chloroform, and approximately 5 μl. of the solution was injected into the gas chromatograph. The peak heights of mestranol and cholestane were measured to the nearest 0.5 mm. from the top of the peak to the corrected base line. The standard ratio of the mestranol peak height to the cholestane peak height was calculated.

Tablet Assay Procedure—Two milliliters of the 25 mcg./ml. cholestane solution was pipeted into a 100-ml. beaker. Then 50 ml. of the sample solution was pipeted into the same beaker. This mixture was then carefully evaporated to dryness under a stream of air and with gentle warming. One milliliter of chloroform was added to the dried residue to redissolve the sample, and 5 μl. of this solution was injected into the gas chromatograph. The sample ratio was calculated in the same way that the standard ratios were calculated and was used to determine the tablet strength.

Thin-Layer Chromatography

Up to 100 mcg. of material was applied to a 250-μ Silica Gel F_{254} plate supplied by Brinkmann Instruments Inc. The plate was developed in a saturated chamber containing chloroform–ethanol, 29:1. The solvent front was allowed to travel 15 cm. To visualize the spots the plate was sprayed with 30% reagent, heated at 110° for 10 min., and then viewed under long-wavelength UV light.

RESULTS AND DISCUSSION

Reagent Composition and Fluorescence Formation—Table I summarizes the characteristics of fluorescence formed by reacting mestranol with reagents of varying methanol–sulfuric acid concentration. It was found that two and possibly three distinct fluorophors are formed by mestranol. Using other reagent proportions than those described here, no other fluorophor was found. When the fluorophor formed with 40% reagent was examined, the spectra indicated that a mixture of the fluorophors of 30 and 50% reagents had been formed. The fluorophor of 60% reagent was the same as that of 50% reagent, but was less intense.

Table I—Color and Fluorescence Characteristics of Mestranol

	Color	Fluorescence, mμ Max. Activ.	Max. Emiss.
Sulfuric acid, concentrated	Orange-red	525	555
30% Reagent	Pink	545	565
50% Reagent	None	468	498

The activation and emission curves of these fluorophors were plotted using an Aminco-Bowman spectrophotofluorometer. In order to compare the intensity of fluorophors, instrument settings, and sample concentrations were the same for all of the spectra (0.2 mcg./ml.). The spectra of mestranol in concentrated sulfuric acid, in 30 and 50% reagents are shown in Fig. 1. These spectra are not energy corrected. The formation of two different and highly intense fluorophors, may allow the analyst to selectively eliminate fluorescence interferences due to other steroids by making a choice of either 30 or 50% reagent. Work is in progress on application of these reagents to the analysis of other steroids.

Detection of Mestranol by Fluorescence—To determine the lowest detection limits of mestranol by this procedure, aliquots of a 0.01 mcg./ml. solution of mestranol were evaporated and treated with 50% reagent. With the aperture set at 10 and no density filter, a solution of 0.001 mcg. (1 nanogram) mestranol per ml. of 50% reagent gave a reading of 22 galvanometer units. The linearity of the measurements at different concentrations in the nanogram range is shown in Fig. 2. Since the tablet assay method described here is in the microgram range, the instrument sensitivity had to be decreased. This was done by using an aperture of 1× and a 10% transmittance density filter in conjunction with the secondary filter. It was found to be more convenient to do this, than to make additional sample dilutions. The linearity of the measurements up to 2 mcg. is shown in Fig. 2. To improve

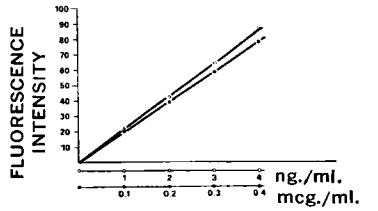

Fig. 2—Linearity of measurements of mestranol by fluorescence.

the reproducibility of the assay it was necessary to dissolve the residue of mestranol in a small volume (0.1 ml.) of methanol before adding the 50% reagent. Insufficient heat was evolved to require cooling, and the reagent properties were not adversely affected by additional methanol. The calculation of precision on a series of five standards assayed by this technique gave a relative standard deviation of ±0.63%.

Fluorescence Development—The reaction of the 50% reagent and mestranol to form the fluorophor does not go to completion at once. At room temperature, the intensity of the fluorescence increased until it reached maximum intensity about 50 min. after addition of the reagent to the sample. The maximum fluorescence was maintained from 50 to 90 min., when it began to decrease slowly as seen in Fig. 3. Based on these findings, it was decided to read all samples about 1 hr. after the addition of the reagent.

Colorimetric Determination—Colorimetric analysis with the 30% reagent has been the standard method in these laboratories for several years. It has been used along with various extraction techniques for both control and stability assays. The assay requires a sample concentration of about 2.0 mcg./ml. of 30% reagent. The calculation of precision on a series of five standards assayed by this technique gave a relative standard deviation of ±0.30%.

Gas Chromatographic Determination—Gas chromatography is a more specific technique for measuring mestranol, because it is a separation technique as well as a quantitation technique. Using the conditions described here, mestranol was chromatographed with no evidence of decomposition on the column. This was done without resorting to derivative formation, which would complicate the procedure. No problems were experienced due to interference from tablet excipients. They were apparently eliminated in the extraction procedure or during the chromatography. A typical chromatogram of mestranol and cholestane is shown in Fig. 4. Since only 0.25 mcg. of mestranol was injected on column in this procedure, the sensitivity of detection should make the procedure applicable in cases where much less sample is available to the analyst. An aliquot of the sample solution containing 40–50 mcg. of mestranol was usually taken for the assay. The procedure proved to be linear in response from 10 to 50 mcg. The precision of measurement by GLC was determined by calculating the standard ratios of 10 sample injections from the same solution, and gave a relative standard deviation of ±0.63%.

Measurement of Stability—In order to evaluate the application of these methods for stability measurement, tablets were artificially degraded with heat and humidity. Several tablets were placed in an area of high humidity at a temperature of about 65° for 14 days (Group I tablets). Another group of tablets was placed in an oven at 105° for 3 days (Group II tablets). These tablets were then

[a] Results in mcg./Gm. [b] Individual tablets "within" analysts.

assayed by the three procedures described here and the results were compared as shown in Table II. Group I tablets retained only about 55% of their original strength, while in Group II tablets only trace amounts of mestranol remain. These observations were confirmed by the use of TLC.

By the GLC technique all known breakdown products of mestranol are separated from the parent compound. Because of this specificity the GLC assay is a positive measure of stability. Since the fluorometric and colorimetric results correlate very closely to the GLC results, all three methods are considered to be satisfactory stability assays.

Thin-Layer Chromatography—This technique was used as a qualitative assay to confirm the results by the other methods. The tablets were extracted in the same way as for the GLC measurements, then the desired portion of the tablet extract was applied to the plate. As is shown in Fig. 5, degradation of mestranol is observed in the tablets of Groups I and II. The figure also shows the result of exposing a methanol solution of mestranol raw material to irradiation by UV lamp. By this artificial means of accelerating decomposition, it was possible to form at least five decomposition products of mestranol, none of which corresponded to the related steroids chromatographed in lanes 5 and 6. However, the extract from the heated tablets, as seen in lane 4, contains components identifiable by this procedure as estrone methyl ether and 17α-ethinylestradiol. These results are not in agreement with the conclusions of Shroff and Grodsky (5) who state that "mestranol does not undergo any decomposition when stored under various conditions."

Comparison of Assay Methods—In order to evaluate the tablet assay procedures described in this paper, a study was run to compare the three different methods of measurement. The assays were performed by three different analysts. All samples were taken from a single lot of tablets. Each analyst extracted six single-tablet samples and then used aliquots of the extract for the different measurement procedures. The results were reported in mcg. of mestranol per Gm. to e'iminate the effect of tablet weight differences. The results are summarized in Table III. The means of six determinations by each analyst are shown.

An analysis of variance suggested that the variation of individual determinations within each of the three methods appeared to be consistent and that no significant difference among assay methods was shown. The grand mean of the experiment (n = 48) was not significantly different from the theory of 705.3 mcg. mestranol per Gm.

Assay of Ethinyl Estradiol—Ethinyl estradiol is the other estrogen besides mestranol which is widely used in oral contraceptive tablets. All three of the procedures applied to mestranol in this paper are applicable to the assay of ethinyl estradiol. The fluorescence spectrum of ethinyl estradiol is almost identical with that of mestranol in 50% reagent. Ethinyl estradiol forms a pink color with 30% reagent that has an absorbance maximum at 538 mμ instead of the 545 mμ of mestranol. It may also be assayed by GLC with the same operating parameters described for mestranol. It can be chromatographed without derivative formation and is eluted approximately 30 sec. after mestranol under the stated instrumental conditions.

Fenfluramine Metabolism

By ROBERT B. BRUCE and WILLIAM R. MAYNARD, JR.

The metabolism of fenfluramine in man results in the excretion of unchanged fenfluramine, deethylated fenfluramine, and *m*-trifluoromethylhippuric acid. Methods are described for the determinations of these three compounds and the total metabolites in urine by GLC. The *m*-trifluoromethylhippuric acid accounts for 66 to 93 percent of the dose and 79 to 100 percent of the dose may be accounted for as these three metabolites.

FENFLURAMINE [*N*-ethyl-α-methyl-*m*-(trifluoromethyl)-phenethylamine hydrochloride] is an effective anorexigenic agent showing little or no CNS stimulant properties (1). Structurally, this compound is similar to the amphetamines.

Duhault and Fenard (2) have reported a study of the excretion, distribution, and metabolism of fenfluramine using methyl orange complex for its determination. They found that fenfluramine persists in the animal body for considerably longer than amphetamine. The total excretion following oral doses in man and in dogs was 27 to 38% of the dose over a 5- to 6-day period. Relatively large amounts were found in fatty tissues of the dog. These authors found that the drug is deethylated but could find little or no evidence for hydroxylation, as occurs with amphetamine. Beckett and Brookes (3), using gas chromatographic methods, have studied the dependence of the rate of excretion on urinary pH. They found that some 50% of fenfluramine was excreted unchanged or deethylated under acidic urinary conditions, but could account for only 6 to 23% with uncontrolled acidity of the urine.

The relatively low recoveries of the amines, which has been confirmed in these laboratories, led the authors to investigate the fate of the remainder of the drug in the animal body. Extensive use of gas chromatography in these studies was made to determine the amounts of unchanged drug and its metabolities in biological materials. Blood levels in man and the dog have been determined by GLC. The results given below indicate that the major portion of an oral dose of fenfluramine in man is excreted as *m*-trifluoromethylhippuric acid (Scheme I).

EXPERIMENTAL

Human Study—Two normal, healthy males were given a 60-mg. tablet of fenfluramine as a single dose, and urine was collected at intervals for 72 hr. Ammonium chloride was administered the previous day and throughout the period of urine collection, in an attempt to maintain an acidic urine. All urine samples were kept in the refrigerator until analysis. The pH of each sample was determined with a pH meter immediately upon receipt. Blood samples of 20 ml. were collected at intervals during the first 8 hr. for analysis.

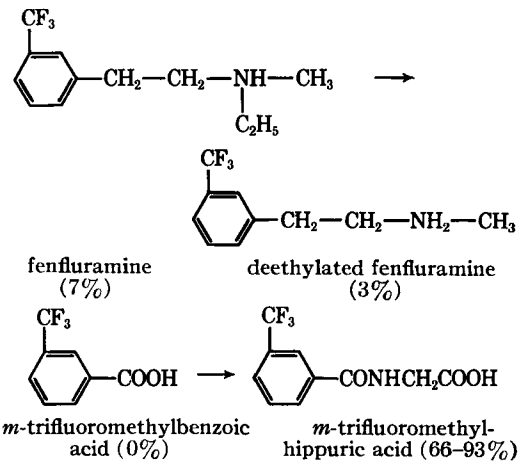
Dog Study—A mongrel male dog weighing 11.7 kg. was given a divided oral dose of 117 mg. of fenfluramine, and urine was collected for 5 days and stored under refrigeration.

Materials—*m*-Trifluoromethylbenzoic acid was purchased from J. T. Baker Chemical Co.

m-Trifluoromethylhippuric acid was prepared by reaction of *m*-trifluoromethylbenzoic acid with thionyl chloride to give *m*-trifluoromethylbenzoyl chloride. The acid chloride was then reacted with glycine to give the hippuric acid.

METHODS OF ANALYSIS

Fenfluramine and Norfenfluramine—These compounds were determined by gas-liquid chromatography according to a modification of a method described by Beckett and Rowland (4). An aliquot of 20.0 ml. of urine or 15.0 ml. of blood was made alkaline with 2 ml. of 2 *N* NaOH and extracted three times with 10-ml. portions of ethyl ether, centrifuging to separate the phases. The combined ether extracts were dried over anhydrous sodium sulfate and evaporated to 0.10 ml. under a gentle stream of nitrogen. Aliquots of 1 to 3 μl. were injected into the gas chromatograph under the follow-



Scheme I—Excretion of fenfluramine and metabolites by man

Received February 27, 1968, from the Research Laboratories, A. H. Robins Company, Inc., Richmond, VA 23220
Accepted for publication April 8, 1968.

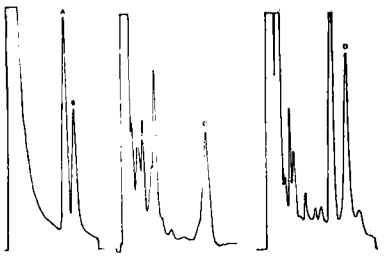


Fig. 1—Gas chromatograms obtained from the analysis of urine samples (Subject A) showing (a) fenfluramine, (b) deethylated fenfluramine, (c) the methyl ester of m-trifluoromethylhippuric acid, and (d) the methyl ester of m-trifluoromethylbenzoic acid. The large peak immediately preceding (d) is the ester of benzoic acid. See text for conditions.

ing conditions, and the peak heights compared with those of a standard.

Detector–flame ionization; column—10% polyethylene glycol[1] 20 M and 5% KOH on HMDS treated Chromosorb W, 2.1 m. × 0.31 cm. (7 ft. × 1/8 in.); column temperature—120°.

The retention times of fenfluramine and norfenfluramine under these conditions were 4 and 4.5 min., respectively. The peaks were sharp and well separated (Fig. 1). No interference has been found from control urine samples carried through the procedures. Recoveries varied from 98 to 102% and peak height was proportional to concentration over the range of 10 to 200 ng. (Standard deviation = ±2.2 at the 100-ng. level.)

Total Fenfluramine Metabolities—The following procedure was designed to determine fenfluramine and all metabolities that might be formed. However, any metabolite in which the benzene ring was altered would not be determined.

An aliquot of 2.0 ml. of urine was oxidized with 10 ml. of saturated potassium permanganate and 0.5 ml. of 2 *N* sodium hydroxide by heating for 1 hr. in the steam bath. The cooled solution was then extracted with a total of 20 ml. of ether in three portions and the acids repartitioned into 10 ml. of sodium bicarbonate. The sodium bicarbonate was acidified and the acids returned to ether by extracting three times with a total of 15 ml. The ether solution was treated with diazomethane, washed with 3 × 5-ml. portions of water, dried over anhydrous sodium sulfate, and concentrated to 0.10 ml. An aliquot of 2 μl. was injected into the gas chromatograph.

The major interference that was expected in this determination was benzoic acid, which was formed during the oxidation in relatively large amounts. The methyl esters of benzoic acid and trifluoromethylbenzoic acid are easily separated by GLC under the following conditions:

Column—10% 20 polyethylene glycol M on Gas Chrom Q, 1.2 m. × 0.31 cm. (4 ft. × 1/8 in.) at 75°; flow rate—25 ml./min.; injection port temperature —250°; detector–flame ionization.

The retention time for methyl trifluoromethylbenzoate is 5 min. and that of methyl benzoate is 4 min. (Fig. 1).

m-Trifluoromethylbenzoic Acid—Acidified urine was extracted with ether and carried through the procedure used for total metabolites, omitting the oxidation steps.

m-Trifluoromethylhippuric Acid—The hippuric acid derivative could not easily be extracted from urine without extracting interfering materials. It could be separated from these materials by the use of an ion-exchange column. A column,[2] (200-400 mesh) 12 × 500 mm., was prepared in 95% ethanol. A sample of 4.0 ml. of urine was placed on the column and the column was washed with 330 ml. of 95% ethanol. The trifluoromethylhippuric acid was then eluted with 70 ml. of 0.1 *N* hydrochloric acid in 95% ethanol. The ethanol solution was evaporated to dryness, the residue taken up in 10 ml. of ether, and methylated with diazomethane. After washing with water, the ether solution was evaporated to 0.10 ml. and 2 μl. were injected into the gas chromatograph. Conditions: Column—10% polyethylene glycol 20 M on Gas Chrom Q, 1.2 m. × 1.2 cm. at 190°; flow rate—30 ml./min.; injection port temperature—300°. Both hippuric and trifluoromethylhippuric acids are eluted from the ion-exchange column under these conditions but they are easily separated by GLC. The retention time of methyl trifluoromethylhippurate is 10 min. and that of the methyl hippurate is 14 min. (Fig. 1).

IDENTIFICATION OF METABOLITES

The correspondence of retention times found by GLC was an indication that the metabolites from urine were the same as those of authentic compounds. Beckett and Brookes established the presence of fenfluramine and norfenfluramine.

In addition, the following information as to identity of the other metabolites was found.

m-Trifluoromethylbenzoic Acid—A sample of acidified dog urine was continuously extracted with ethyl ether and the acids were separated from phenols by sodium bicarbonate partitioning. The resulting bicarbonate solution was acidified and the acids reextracted into ether. An aliquot of the ether was concentrated and used for thin-layer chromatography on silica gel. Using a solvent system consisting of benzene, methanol, and acetic acid (90:10:4) two spots were found that corresponded to *m*-trifluoromethylbenzoic acid and its glycine conjugate.

In order to separate a larger quantity of the *m*-trifluoromethylbenzoic acid, a partition column of 0.1 *N* sulfuric acid on silicic acid was prepared. A portion of the ether extract was added to the column and it was eluted with skellysolve B. Fractions were collected and monitored by UV and TLC. Those fractions corresponding to the *m*-trifluoromethylbenzoic acid were combined and evaporated to dryness. The infrared spectrum of the isolated material was identical with that of an authentic sample of *m*-trifluoromethylbenzoic acid. A melting point following sublimation was 101–102°, and a mixed melting point 100–101°.

Anal.—Calcd: C, 50.33; H, 2.64. Found: C, 50.56; H, 2.71.

m-Trifluoromethylhippuric Acid—Although this acid could not be separated in sufficient quantity and purity from urine for infrared identification and elemental analysis, the GLC and TLC results are good evidence for its identification.

Time After Dose, hr.	Fenfluramine, mcg./100 ml. of Blood Subject A	Subject B
Control	0	0
1	2.3	0.9
2	2.6	2.3
3	2.9	2.9
4	1.2	1.5
6	1.2	1.2
8	0.6	0.9

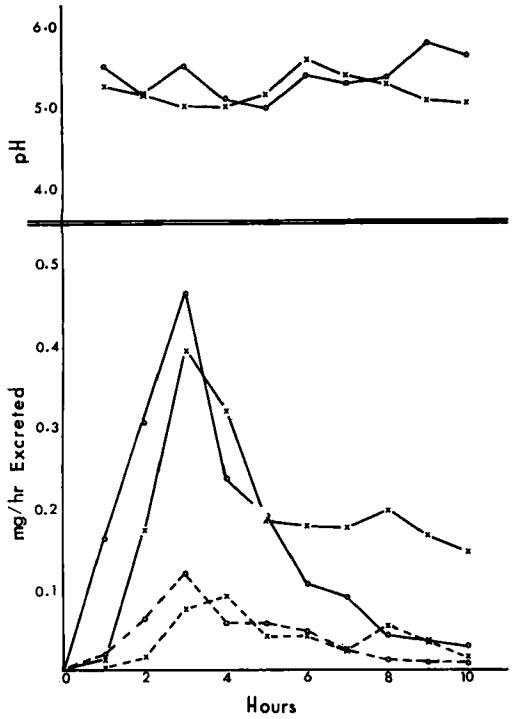

Fig. 2—The urine pH and rates of excretion of fenfluramine (solid line) and deethylated fenfluramine (dashed line) in two normal males.

Hydroxylation—The procedure as described by Axelrod (5) was used to determine whether a hydroxylated product might occur in the urine. No reaction was obtained with 1-nitroso-2-naphthol using either hydrolyzed or unhydrolyzed urine.

RESULTS AND DISCUSSION

The results of the blood level study in man are shown in Table I. These results indicate that fenfluramine is readily absorbed and persists for some time in the blood stream. Even in the final sample 8 hr. after the dose, measurable concentrations are still present. The maximum concentration appears at about the third hour. The persistence of fenfluramine in the body is in agreement with previous studies by Duhault and Fenard (2).

Determination of blood levels in dogs, that received 2 mg./kg. of fenfluramine, showed that both fenfluramine and norfenfluramine were present. However, no norfenfluramine has been found in blood during any of the studies on humans.

Typical results of the urinary excretion of fenfluramine and norfenfluramine are shown in Fig. 2. Although it was attempted to maintain an acidic urine, the pH did not reach levels below 5, as did those reported by Beckett and Brookes. The maximum excretion rate occurred at around 3 hr. which was at the same time as the maximum blood levels. Urine was continued to be collected from these subjects for 72 hr. Determinations of the acidic metabolic products were carried out on samples of urine pooled for 1–10 hr., 10–24 hr., 24–48 hr., and 48–72 hr. These results are shown in Table II. The excellent agreement found between the sum of individual metabolites and the total by oxidation indicates the accuracy of the methods and also that the oxidation procedure results give the desired results.

Although free trifluoromethylbenzoic acid was found in dog urine, none could be detected in human urine. It can be seen from these results that the main excretory product of fenfluramine in man is the trifluoromethylhippuric acid. These two subjects excreted approximately 10% of the dose as fenfluramine and its deethylated metabolite, which corresponds closely with that amount found by others with uncontrolled pH (5). In one subject (A), 93% of the dose was excreted as *m*-trifluoromethylhippuric acid and in the other, 66% was excreted in the 72-hr. period.

Amphetamine and methamphetamine also un-

dergo side-chain oxidations. Oxidation occurs through the stages of benzyl methyl ketone and 1-phenyl-propane-2-ol to the acid. A corresponding mechanism would be expected to occur with fenfluramine. The amphetamines also undergo ring oxidation to give the phenol. The presence of the trifluoromethyl group on the benzene ring of fenfluramine appears to prevent such oxidation. The phenolic derivative of fenfluramine was not available to determine whether the reaction given by Axelrod would take place, but the recovery of 77 to 100% of the administered drug as fenfluramine and its two metabolites suggests that if such oxidation does occur, it can be only to a very small extent.

Previous observations (2, 5) have indicated that fenfluramine is rapidly absorbed into the tissues and is then slowly released into the extracellular fluid. This is also indicated by the present studies. The two amines continue to be excreted over at least a 72-hr. period and during the first 48 hr. *m*-trifluoromethylhippuric acid is excreted at an almost continuous rate.

Structure-Activity Relations in an Imidazoline Series Prepared for Their Analgesic Properties

By W. BROCK NEELY*, H. C. WHITE†, and A. RUDZIK‡

A specific pharmacological property of a series of substituted imidazolines was examined in an effort to determine the structure-activity relationships that might be present. The best measure of the chemical reactivity was based on a charge-transfer complex between the drug and the receptor site. Using the molecular orbital technique for measuring this reactivity index, and combining with the partition coefficient in the manner described by Hansch 94.4 percent correlation was found for the biological activity.

STRUCTURE-ACTIVITY relationships have been an intriguing subject for organic and biological chemists for many years. At the same time, it is an area that has seen many frustrations and disappointments. The reasons for the failures are readily appreciated when the complexity of the biological system is taken into consideration. In attempting any type of rigid structure-activity study all of the the biological parameters such as active and passive transport, metabolism to a more or less active agent, nonspecific binding to proteins, and finally the reaction at the receptor site, must be taken into account. Obviously, the system is much too complicated and too little understood for a detailed analysis. As a starting point, a simple model is required. In such a case, if the model works, *i.e.*, can predict the data, it may give new insights into the mechanism of action. Conversely, if the model fails, then one must look for the reasons; this in itself could provide new concepts in the area under investigation.

The model used in this study is the one that has been developed by Hansch and his co-workers (1) and used extensively in a number of different biological applications (1–5). In effect, the model assumes that the amount of drug found at the receptor site is related to a single substituent constant which is derived from octanol–water partition-coefficient measurements. The reaction of the chemical at the receptor site is related to the rate constant. The model is illustrated by Eq. 1.

$$\log \text{B.R.} = -\alpha\pi^2 + b\pi + c \log k_x + d \qquad \text{(Eq. 1)}$$

Structure-Activity Relations in an Imidazoline Series Prepared for Their Analgesic Properties

By W. BROCK NEELY*, H. C. WHITE†, and A. RUDZIK‡

A specific pharmacological property of a series of substituted imidazolines was examined in an effort to determine the structure-activity relationships that might be present. The best measure of the chemical reactivity was based on a charge-transfer complex between the drug and the receptor site. Using the molecular orbital technique for measuring this reactivity index, and combining with the partition coefficient in the manner described by Hansch 94.4 percent correlation was found for the biological activity.

STRUCTURE-ACTIVITY relationships have been an intriguing subject for organic and biological chemists for many years. At the same time, it is an area that has seen many frustrations and disappointments. The reasons for the failures are readily appreciated when the complexity of the biological system is taken into consideration. In attempting any type of rigid structure-activity study all of the the biological parameters such as active and passive transport, metabolism to a more or less active agent, nonspecific binding to proteins, and finally the reaction at the receptor site, must be taken into account. Obviously, the system is much too complicated and too little understood for a detailed analysis. As a starting point, a simple model is required. In such a case, if the model works, *i.e.*, can predict the data, it may give new insights into the mechanism of action. Conversely, if the model fails, then one must look for the reasons; this in itself could provide new concepts in the area under investigation.

The model used in this study is the one that has been developed by Hansch and his co-workers (1) and used extensively in a number of different biological applications (1–5). In effect, the model assumes that the amount of drug found at the receptor site is related to a single substituent constant which is derived from octanol–water partition-coefficient measurements. The reaction of the chemical at the receptor site is related to the rate constant. The model is illustrated by Eq. 1.

$$\log \text{B.R.} = -\alpha\pi^2 + b\pi + c \log k_x + d \qquad \text{(Eq. 1)}$$

where B.R. = biological response; π = log

(P_x/P_h); P_x, P_h = partition coefficient of substituted compound P_x and parent compound P_h; k_x = rate constant; a, b, c, d = equation constants.

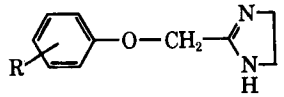
In attempting to arrive at some measure of the reactivity of a drug with a receptor site it is desirable to have some idea of what the mechanism might be. For example, in interpreting the insecticidal data of organophosphates, it is assumed that those phosphates which are most susceptible to nucleophilic attack will be the insecticidal agents. Consequently, a measure of the reactivity is the rate of hydrolysis of the phosphate by hydroxide ion. There are many papers that deal with this subject, but only a few are cited (6–8).

In the present case, the authors do not have a mechanism for the pharmacological activity (which in this case is assumed to be analgesic action); consequently, there is a problem of deciding on an appropriate reactivity index for the imidazoline compounds, I. What is required is a technique for estimating different electronic parameters and attempting to deduce which index correlates with the biological response. This requirement is met by the use of the simple Hückel molecular orbital (MO) technique. The theory and applications of MO to problems in biochemistry have been described by many authors (9–12). In using these electronic parameters as a measure of the rate constant in Eq. 1 the following assumption must be remembered. The rate constant k is related to the energy of activation E by means of the Arrhenius Eq. 2. The assumption

$$k = Ae^{-\Delta E/RT} \quad \text{(Eq. 2)}$$
$$\text{or } \log k = A - B\Delta E$$

where A and B are constants, is that the various indexes calculated from MO theory are linearly related to ΔE and hence may be substituted for $\log k$ in the regression equation, Eq. 1.

This paper reports the results in using the Hansch approach to correlate the pharmacologic activity, derived from an analgesic test, with the structure of a series of imidazoline derivatives, I.



I

MATERIALS AND METHODS

Synthesis of Aryloxyacetonitrile—A mixture of 0.10 mole of the appropriate phenol, 0.10 mole of anhydrous K_2CO_3, 0.11 mole of chloroacetonitrile, and 100 ml. of dimethyl sulfoxide was stirred at 75° for 3 hr. The reaction mixture was poured into 100 g. of ice and the product extracted with methylene chloride. The product was then isolated by vacuum distillation through a 40-cm. Vigreux column. The identification was made with a Varian A-60 nuclear magnetic resonance spectrometer with a 10% $CDCl_3$ solution. The physical properties and yields are listed in Table I.

TABLE I—ARYLOXYACETONITRILE

R	Yield, %	B.p., 2 mm., °C.	M.p., °C.[a]
2,6-di Cl	66	114–118	39–40[b]

[d] Clark *et al.* (17) report m.p. 94–95° by a different method of synthesis. The authors' material showed no sign of crystallization even at 0°. The NMR spectrum of this material confirmed unambiguously the structure assigned.

Synthesis of the Imidazolines—A mixture of 0.10 mole of the aryloxyacetonitrile, 0.10 mole of 1,2-ethylenediamine monotosylate, and 100 ml. of *o*-dichlorobenzene was heated with stirring under a nitrogen blanket until ammonia evolution ceased. This usually required 1–2 hr. at 170–180°. The reaction mixture was poured into water, one equivalent of NaOH added, and the imidazoline extracted into methylene chloride. After the solvent was removed under vacuum, the residue was dissolved in isopropyl alcohol and a slight excess of anhydrous HCl in isopropyl alcohol added. The resulting imidazoline hydrochloride was then collected by filtration and recrystallized from isopropyl alcohol. Identification was by chloride equivalent and NMR. The spectra in D_2O in all cases were consistent with the expected substitutions in the aromatic regions, as well as the methylene bridge and the ethylene portion of the imidazoline ring. The properties of the imidazolines studied in this investigation are shown in Table II.

18–22 g. were used in these tests. Relative potency was measured by the ability of these compounds to antagonize the HCl-induced writhing response. Writhing was induced by the intraperitoneal injection of 10 ml./kg. of a 0.1 *N* HCl solution. The compounds to be tested were administered orally 30 min. prior to the HCl. The results are expressed as the dose that will effectively prevent 50% of the animals from exhibiting the characteristic writhing. This test has been used as a measure of a drug's ability to cause analgesia (13). The ED_{50} values are given in Table II.

Reactivity Index—Calculated Value—The simple MO calculations were carried out as described by the Pullmans (9). There are many indexes that may be deduced from this type of procedure. The one that appeared to have the most significance for measuring the biological activity of the imidazolines was the energy of the highest occupied molecular orbital (HOMO). This index is a relative measure of the ability of an electron to be transferred to an acceptor molecule.

The calculations were performed on the substituted phenol present in the imidazoline structure. This simplification was made since it could be assumed that any perturbation caused by the imidazole would be insulated from the rest of the molecule by the methylene group. The parameters used for the heteroatoms in this study are listed in previous publications (6, 9).

Experimental Value—The oxidation potentials of the phenols, corresponding to the imidazoline derivatives, were determined with a Leeds and Northrup Electron chromograph type E instrument. This was equipped with 0.6 cm. (1/4 in.) graphite (ultrapure spectroscopic electrodes from Ultra Carbon Corp.) and a calomel reference electrode. The electrolyte was a 1 *M* acetic acid and 1 *M* sodium acetate buffer. The procedure was as follows: the phenol was made 0.001 *M* in methanol, 5 ml. was diluted to 10 ml. with the electrolyte, the solution was placed in the cell, and the potential was scanned from 0 to 1 v. The oxidation potential was recorded as the midpoint of the resulting curve.

Partition Coefficient—The substituent constant π was calculated from the values given by Hansch (5).

Calculations—The MO calculations and the regression analyses were performed by the Computation Laboratory, The Dow Chemical Company, using a Burroughs B5500 computer.

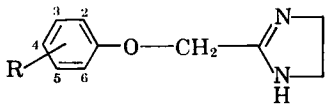
RESULTS

The data collected for this series are shown in Table III. In order to ensure that the calculated value for the energy of the highest occupied molecular orbital was relevant, the oxidation potential was determined for the various phenols. The correlation between the experimental and the calculated values are shown in Fig. 1.

Using the Hansch procedure (1) the biological data in Table III were regressed against the two parameters, π and HOMO. The analysis generated Eqs. 3–5 where

$$\log ED_{50} = -0.445\pi + 1.015 \qquad r = 0.640 \quad r^2 = 0.406 \quad \text{(Eq. 3)}$$

TABLE III—BIOLOGICAL AND CHEMICAL PARAMETERS FOR A SERIES OF IMIDAZOLINE DERIVATIVES



Substituent (R)	ED_{50}[a]	π[b]	HOMO[c]	Oxidation[d] Potential, v.
2,6-diCH_3	0.6	1.36	0.716	0.469
2-Br, 6-Cl	2.0	1.34	0.802	0.642
2,6-di Br	3.2	1.50	0.797	0.634
2,6-di Cl	3.3	1.18	0.808	0.659
2,6-diCl, 3-CH_3	5.4[e]	1.69	0.789	0.625
2,6-di OCH_3	25	−0.66	0.618	0.363

[a] Oral dose in mg./kg. (HCl induced rat writhing test for analgesics). [b] Determined from Hansch's values (5). [c] Energy of the highest occupied molecular orbital of the substituted phenol. The smaller the value, the greater the ease of electron donation. [d] Oxidation potential of substituted phenol determined by means of a Leeds and Northrup Electro chromograph type E. [e] Estimated value derived from the value for a subcutaneous dose of this derivative compared to a similar type of injection of the other derivatives.

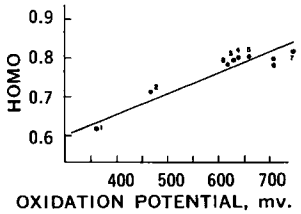


Fig. 1—Plot of HOMO against the oxidation potential (mv.) of a series of phenols. Key: 1, 2,6-di OCH_3; 2, 2,6-di CH_3; 3, 2,6-di Br; 4, 2,-Br, 6-Cl; 5, 2,6-di Cl; 6, phenol; 7, 3,4-di Cl; 8, 2,6-di Cl, 3-CH_3. The values of HOMO and the oxidation potential in mv. for the two phenols not listed in Table III are: phenol (0.711 and 705 mv.), 3,4-diCl (0-811 and 765 mv.).

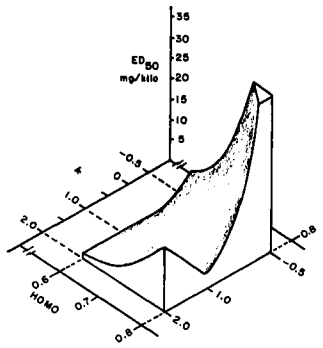

Fig. 2—Structure-activity surface generated by Eq. 5. The most potent analgesic has the smallest ED_{50}. The data for this figure are listed in Table III.

$$\log ED_{50} = +0.655\pi^2 - 1.00\pi + 0.455 \qquad 0.728 \quad 0.531 \quad \text{(Eq. 4)}$$

$$\log ED_{50} = 0.945\pi^2 - 1.850\pi + 7.90\,(\text{HOMO}) - 5.117 \qquad 0.975 \quad 0.944 \quad \text{(Eq. 5)}$$

r is the correlation coefficient. The good correlation

shown by r is indicated by r^2 (*i.e.*, 94.4% of the variance is "explained" by Eq. 5). An F test indicated that the inclusion of the HOMO term in Eq. 5 is significant at the 5% level, whereas Eqs. 3 and 4 were considerably less than 95% significant. There was no correlation when the biological response was regressed using the HOMO parameter by itself (Fig. 2).

DISCUSSION

One of the important items to emerge from this study is the role played by the substituent constant π. As Eq. 4 indicates 50% of the activity may be correlated with π. Consequently, the balance between the hydrophobicity and hydrophilicity of a chemical (as expressed by π) would seem to be critical. One interpretation of these data is that the partition coefficient has a strong influence on the actual amount of drug found on the receptor site. This occurs through a "random walk" process in the organism and finally association with the site itself. The recent work of Hansch (4) dealing with the influence of π on the binding of small molecules to bovine serum albumin helps to substantiate this hypothesis. As the drug builds up a concentration on the receptor site the intrinsic reactivity takes over and through the formation of a charge-transfer complex elicits the observed response. Green and Malrieu (11) made use of the concept of charge-transfer complex in study of a series of indole derivatives. In essence this type of complex may be formed when a compound capable of donating electrons is mixed with a receptor possessing the capacity to accept electrons.

In a recent review article on the molecular basis of drug action, Mautner (14) raised the question as to the molecular significance of the Hansch-type of correlation. The authors agree that the correlation does not predict a specific mechanism where the reactivity of the actual functional groups is implicated. The phosphorylation of the esteratic site in cholinesterase, as a mechanism for inhibition, is an example of a molecular description (6, 7). On the other hand, these correlations do provide a working model for speculating on the mode of action. In the present case, the interpretation of the results suggests a model which can be tested by further experimentation. The model that emerges consists of a receptor site which has the ability to accept electrons from an electron-donating drug. The association is probably similar to a Michaelis-Menten-type situation, hence the biological activity would have a short half-life relative to a drug that forms an actual C—C covalent linkage. The ability of the two parameters, π and HOMO, to correlate with the biological response would also indicate a type of drug that was not very selective in its action. While this model does not give a molecular mechanism, it may provide insight as to how this particular series of chemicals elicit their analgesic-like activity.

Identification of Sugars from Rates of Oxime Formation

By THOMAS J. MIKKELSON and JOSEPH R. ROBINSON

The concept of using precise kinetic measurements to aid in the characterization of organic compounds has been applied to sugars. Hydroxylamine reacts with sugars to form oximes; the rate of the reaction can be conveniently followed spectrophotometrically. At pH 6.5 and with an excess of hydroxylamine the rate of oxime formation follows apparent first-order kinetics and is sufficiently discriminating to allow identification of many sugars. Kinetic evidence obtained in this study indicates that the reaction of ketoses and aldoses with hydroxylamine proceeds through a carbinolamine addition compound intermediate, analogous to that proposed for other aldehydes and ketones.

IDENTIFICATION OF an unknown organic compound is usually carried out by a combination of qualitative elemental analysis, determination of the functional groups present in the molecule by chemical or spectroscopic means, determination of constants such as melting point, density, refractive index, *etc.*, and ultimately preparation of a derivative. In many cases a clear distinction between possible choices cannot be made on the basis of the classical approach (and the full range of possible spectroscopic methods is not always available), and therefore a further criterion for identification is desirable. An earlier publication (1) has introduced the concept of using precise kinetic measurements as an additional aid in the characterization of organic compounds. It is the purpose of the present report to extend the concept to another class of organic compounds, namely, carbohydrates.

Sugars represent a class of organic compounds that are difficult to characterize, due partly to their great water solubility, and also to the large number of functional groups in the molecules. Numerous methods have been proposed (2–6) for the identification of sugars, the most common being chromatographic techniques. These procedures usually involve the preparation and purification of a derivative; this is at best difficult, and in addition it may not be very discriminating and may be limited to a small number of compounds.

Phenylhydrazine, semicarbazide, and similar nitrogenous bases react with sugars to form compounds that, because of their low water solubility, can be used as derivatives for identification purposes. The rate of this reaction has been used for many years as a qualitative test for identifying sugars, *e.g.*, the rate of osazone formation using phenylhydrazine as the base. Since qualitative kinetic differences exist with this reaction, it was expected that reactions with other more water-soluble bases, such as hydroxylamine, would also show kinetic differences. Appreciable water solubility of the reactants and products is essential for a study such as this in order to have homogeneous reaction conditions and also to encompass as many members of the carbohydrate class as possible.

Gladding and Purves (7) utilized the reaction of hydroxylamine and sugars to determine quantitatively the purity of various starch and cellulose derivatives. The study indicated that the rate of oxime formation of sugars did follow apparent first-order kinetics, but was nondiscriminating in that sugars could be grouped into only two categories, fast and slow reactants. This last observation is to be expected in view of the reaction conditions used and the currently accepted mechanism for oxime formation (8).

Reactions between hydroxylamine and various aldehydes and ketones have been studied extensively (8), although to the authors' knowledge the reaction between hydroxylamine and sugars has not yet been reported. It is the aim of this study to investigate the feasibility of using the reaction between hydroxylamine and sugars as a method to distinguish between various sugars, and, in addition, to compare the mechanism of this reaction with the proposed mechanism for other aldehydes and ketones.

EXPERIMENTAL

Reagents and Apparatus—Hydroxylamine hydrochloride (Baker reagent grade) was used without further purification. Sugars were obtained from customary commercial sources, and their decomposition points were the sole criteria of purity (9). Representative sugars were repeatedly recrystallized to establish that impurities normally present in sugars had no effect on the rate of oxime formation. Water was glass-distilled from alkaline permanganate. All other chemicals employed were either analytical or reagent grade purity.

Received February 26, 1968, from the School of Pharmacy, University of Wisconsin, Madison, WI 53706

Accepted for publication April 22, 1968.

This research was supported by a grant from the Research Committee of the University of Wisconsin.

This paper is Part II in the series "Precise Kinetic Measurements Applied to the Identification of Organic Compounds," for the first paper see *Reference 1.*

pH measurements and adjustments were made on a Corning model 12 pH meter with an expanded scale using a Beckman-type E-3 wide range glass electrode. The pH meter-electrode system was standardized against a phosphate buffer as described by Bates (10).

Water-bath temperatures were maintained to ±0.1° with Sargent Thermonitor electronic relays.

Kinetic Procedure for Spectrophotometric Determinations—The standard buffer solution employed in all runs was prepared by weighing 0.1 mole (6.950 g.) of hydroxylamine hydrochloride and dissolving to a volume of approximately 95 ml. with water. This solution was titrated to a pH of 6.50 with a saturated sodium hydroxide solution, and brought to a precise volume of 100 ml. with water. The solution was equilibrated to 25 ± 0.1° and brought to a final pH of 6.50 with the addition of one or two drops of concentrated NaOH or HCl solution.

Six milliliters of buffer solution were introduced into a 2-cm. absorption cell (or 3 ml. of buffer into a 1-cm. cell) together with 50 μl. of a 1 *M* aqueous solution of sugar. Mixing of the solutions was accomplished by shaking the absorbance cell prior to placement into the cell compartment. Absorbance changes were measured on a Cary model 15 recording spectrophotometer with thermostated cell compartments. The appearance of all the sugar oximes was followed at 245 mμ with pure buffer as a blank.

By following the experimental conditions as specified a large excess of the free base, hydroxylamine, is present and pseudo first-order kinetics ensue. From semilogarithmic plots of $(A_\infty - A_t)$ (absorbance at time infinity minus absorbance at time t) against time or by the Guggenheim method (11), pseudo first-order rate constants were obtained.

The convenience of the relatively rapid rates of aldose-oxime formation enabled these reactions to be followed by a direct recording method on the instrument. Because of the slower rates of oxime formation for the ketoses (L-sorbose and D-fructose), a nonrecording technique was employed by measuring absorbance at 1,800-sec. intervals with the absorbance cells kept at 25 ± 0.1° in a constant-temperature bath between measurements.

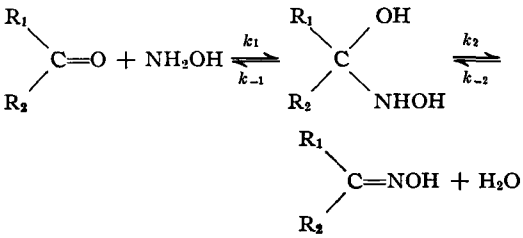
The procedure was altered slightly for some of the polysaccharides. The buffer solution was used as described above but 100 μl. of the sugar solution (cellobiose 0.5 *M*, lactose 0.5 *M*, and raffinose 0.25 *M*) was employed. This change in procedure was required by the decreased molar solubility of these di- and trisaccharides.

Formation and Characterization of Sugar Oximes—Mannose oxime was prepared by the method of Wolfrom and Thompson (12). The melting point of the oxime was found to be 174–176° [lit. m.p. 175–177° (12)]. Elemental analysis yielded N = 7.15%, calculated N = 7.175%. The molar absorptivity of mannose oxime was ϵ_{245} = 38.8.

Attempts to prepare fructose oxime by the method of Wohl (13) were considered unsuccessful. Repeated recrystallization of the product yielded a crystalline material, m.p. 120–122° [lit. m.p. 118° (13)]. However, elemental analysis for nitrogen content was more than two and a half times the calculated amount, and, in addition, the molar absorptivity was more than two and a half times the expected value. The authors assume that degradation of the fructose occurred during the reaction due to the rather harsh reaction conditions, and a species other than fructose oxime is formed.

KINETIC RESULTS AND DISCUSSION

Jencks (8), as well as others (14–16), has suggested that hydroxylamine, semicarbazide, and other similar nitrogeneous bases react with carbonyl functional groups to form additional compound intermediates which subsequently break down to product. The general reaction scheme for oxime formation can be written as:



It was also suggested that the characteristic bell-shaped pH profile obtained for reactions such as this was due to a change in rate-limiting step, which is attributed to two opposing effects. At pH values below the rate maximum there is a decrease in the concentration of the attacking free nitrogen base, and the formation of the carbinolamine addition compound is rate-determining. At pH values above the rate maximum general acid-catalyzed dehydration of the carbinolamine intermediate leading to the oxime is rate-determining (8). The pH-rate maximum is the result of a transition between these two opposing effects.

The partial pH profiles for formation of the oxime from an aldose and ketose exhibit the characteristic pH-rate maximum as shown in Fig. 1. No attempt was made to determine rates beyond the buffer capacity of hydroxylamine (below pH 4 and above pH 8), and the pH dependence is assumed to follow the profile reported for other carbonyl compounds.

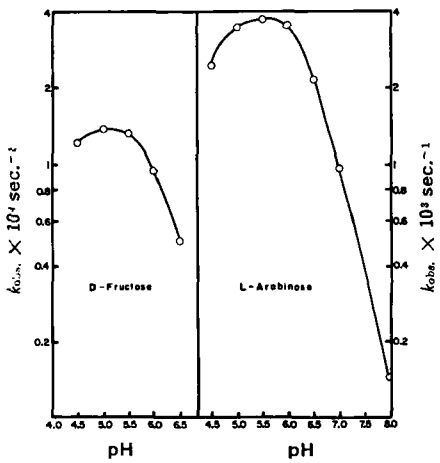


Fig. 1—Partial pH profiles for the formation of a keto- and an aldo-sugar oxime from the reaction of hydroxylamine and the respective sugar at 25° in aqueous solution.

Jencks (8) has found that the first-order rate constants for the reaction of hydroxylamine with ketones or aldehydes increase with the concentrations of free base and hydrogen ions so that the overall reaction is third order. However, at higher concentration of base the rate at a given pH becomes independent of the concentration of free base and approaches first-order kinetics; this was determined to be the case for the reaction between sugars and hydroxylamine (the terminal portions above pH 6, of the pH profiles shown in Fig. 1, have slopes that approach one). At acid pH (low concentration of nitrogen base) the first-order rate constants were found to increase with increasing free hydroxylamine, indicating that the reaction is second order with respect to hydroxylamine in this region, which is in agreement with published work.

Elemental analysis of mannose oxime indicates that only 1 mole of hydroxylamine is consumed per mole of oxime formed, unlike the reactions between sugars and other nitrogenous bases such as phenylhydrazine, which results in the addition of 2 moles of the base to 1 mole of sugar. The oxime reaction is second order with respect to hydroxylamine, but this is because the reaction is general acid-catalyzed and the second mole of hydroxylamine is serving as a general acid. From the above data the authors conclude that keto and aldo sugars react with hydroxylamine to form oximes *via* the same mechanism that is proposed for other aldehydes and ketones.

There is the possibility with aldo and keto sugars that tautomeric conversion from the cyclic ring structure to the open chain analog prior to reaction with hydroxylamine could be rate-limiting in this sequence (17). However, the rate of mutarotation for many of the sugars does not parallel the rate of oxime formation; *e.g.*, fructose shows the slowest rate of oxime formation, but is reported (7) to have a relatively fast rate of mutarotation. Although sugars in the solid state as well as in solution exist mainly in the cyclic ring structure, it is assumed, based on the above, that conversion to the open chain is not rate-determining in the reaction sequence.

Quantitative conversion of the aldo sugar to oxime occurred in the reaction, as calculated *via* the molar absorptivity of mannose oxime. The keto sugar oximes (fructose and sorbose) have molar absorptivities that are three times greater than the aldo sugars, as observed from the spectrophotometric data. It is assumed that the keto sugars are also quantitatively converted to oximes.

ANALYTICAL RESULTS

Figure 2 shows typical ultraviolet spectra of the formation of a sugar oxime at various time intervals. This time course absorbance profile demonstrates that the reaction can conveniently be followed at 245 mμ. Because of the absence of any appreciable absorbance by sugars in the concentrations employed and at a wavelength of measurement, the observed absorbance change was due solely to formation of the sugar oxime.

Choice of reaction conditions is always important in a study of this type. In this study reaction conditions are even more critical than usual in that the variables pH and hydroxylamine concentration affect not only the rate but also the order of the reaction. At pH values below the maximum, pseudo first-order conditions are approached but not rigorously adhered to because of the decreased concentration of the attacking free nitrogen base. At the pH maximum, spectral interference due to overlap of the reaction sequence is observed. At pH values above the maximum, pseudo first-order conditions rigorously hold. The choice of pH 6.50 for the kinetic determinations was based on two factors. First, pseudo first-order conditions exist. Second, the rates of oxime formation are sufficiently rapid at this pH so that the procedure is not self-prohibitive with respect to time.

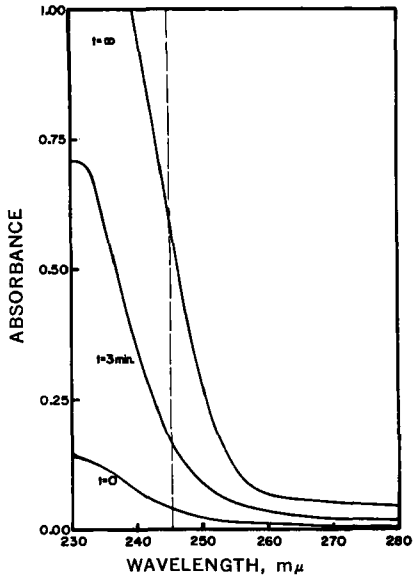

Fig. 2—Absorbance spectra of D-*arabinose-oxime ormation in 1* M *hydroxylamine buffer at pH = 6.50, 25°. Dashed line (245 mμ) indicates the wavelength at which the rates of oxime formation were followed.*

Table I lists the observed first-order rate con-

TABLE I—FIRST-ORDER RATE CONSTANTS FOR THE FORMATION OF OXIMES FROM THE REACTIONS OF VARIOUS SUGARS AND HYDROXYLAMINE IN AQUEOUS SOLUTION

Sugar	Decomposition Point	$k_{obs.} \times 10^3$ (sec.$^{-1}$)[a]	SD[b]	No. of Determinations

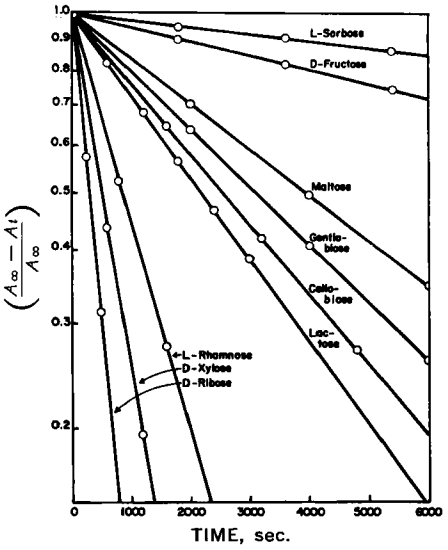

Fig. 3—Normalized representation of some sugar-oxime formations. The reactions were carried out in 1 M hydroxylamine, pH = 6.5 at 25°.

stants for sugar-oxime formations as well as sugar decomposition points. It should be noted that no rate constant for sucrose appears; sucrose does not form an oxime. Glyceraldehyde and ascorbic acid were also investigated, but the reactions did not appear to follow apparent first-order kinetics.

Figure 3 illustrates a normalized graphical representation of some sugar-oxime formations. This displays the approximate 125-fold difference in rate observed between the fastest and slowest oxime formations.

Variation of the ionic strength from 1.0 to 3.0 had a negligible effect on the rate. For this type of reaction only a secondary salt effect would be expected.

DISCUSSION

Utilizing kinetic measurements as an aid in the identification of the sugars as described above gives one the important advantage of a rapid and precise method without the necessity of a common derivative of the sugar. It is apparent from Table I that, with a combination of decomposition point and rate constant of oxime formation, it is possible to differentiate any sugar listed in the table.

The more than 10-fold difference in rate between the keto and aldo sugars is unexpected on the basis of steric and inductive effects. The structural difference between the ketoses and aldoses reported here is the presence of a hydroxymethyl group alpha to the carbonyl group in the ketoses and a hydrogen in the aldoses. Although the authors would predict a small steric effect for dehydration of the tetrahedral intermediate, this effect together with inductive effect cannot explain the difference in rate.

The procedure suggested here for identifying sugars is a relatively sensitive method. For example, a typical experiment with any of the aldoses included in this study would require approximately 5×10^{-5} mole of sugar, while the ketoses would require approximately 1.7×10^{-5} mole of sugar. Naturally this sensitivity could be increased 10-fold by using the expanded scale on the spectrophotometer. Many times only a limited amount of unknown sugar is available for identification, and therefore a sensitive characterization procedure is desirable.

Spectroscopic techniques (NMR, IR, *etc.*) are limited in differentiating among members of this class of compounds. The procedure suggested here for identifying sugars is rapid, sensitive, and quite discriminating. As with most solution kinetic measurements the limiting factor in reproducibility lies in the pH measurements.

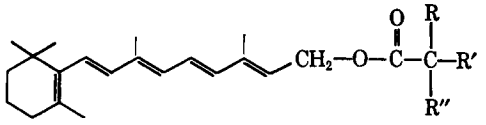
Preparation and Stability of a New Series of Sterically Hindered Esters of Vitamin A. I

By A. J. FORLANO*, C. I. JAROWSKI, and H. F. HAMMER

A series of α,α-dialkyl substituted aliphatic esters of vitamin A was prepared. The stability of these compounds was compared with vitamin A palmitate in hydroalcoholic acidic media, alkaline media, and under oxidative conditions. In all cases steric hindrance on the α-carbon of the fatty acid group increased the stability of the esters in solution. Under oxidative conditions it appeared that a long aliphatic chain was necessary for maximal stability. These results indicate that an ester such as vitamin A α,α-dimethylpalmitate could demonstrate optimal stability under all the conditions examined.

FORLANO AND HARRIS (1) demonstrated that the introduction of an electronegative group in the α-position of the acid portion of vitamin A esters increased stability toward acid-catalyzed elimination in anhydrous ethanol. The rate of anhydrovitamin A formation in anhydrous acidic media was slower for the α-chloropropionate than it was for either the palmitate or acetate. However, the resultant polarization of the ester linkage in the α-chloropropionate also rendered the ester more susceptible to solvent-catalyzed elimination in the hydroalcoholic media. These results suggested that vitamin A esters should be prepared from acids containing electropositive groups in the α-position to provide greater stability toward solvent-catalyzed degradation.

Vitamin A trimethylacetate (I) (R,R′, R″ = CH_3) was the first ester prepared using electropositive groups in the acid portion of the ester.



I, R, R′ and R″ = CH_3 or larger alkyl groups

This ester was more resistant toward solvolysis in an alcoholic medium but it also proved to be more stable than the acetate or palmitate toward acid-catalyzed elimination. Since this ester possessed greater stability in both media, it became obvious that steric and electromeric effects were both important considerations in the stability of vitamin A esters. The steric hindrance exerts an "umbrella-type" blocking effect which mechanically prevents reactive reagents from attacking the carbonyl group of the ester. The data obtained in this study showed that there was a direct relation between acidic and basic solution stability and the size of the groups in the α position of the ester. α,α-Disubstituted fatty acid esters were considerably more stable than the palmitate in anhydrous ethanolic 0.01 *N* HCl, 95% and 70% aqueous ethanolic 0.1 *N* HCl, 70% aqueous ethanol, and in alcoholic base. This suggested that reactions which involve either hydrolysis of the ester linkage or lysis of the alkyl-oxygen bond as the initiating step of the degradation, can be diminished appreciably by introducing steric hindrance on the carbon atom adjacent to the carbonyl group.

Oxidation studies of the sterically hindered esters were not very promising when compared with the palmitate in a vegetable oil (Wesson oil). These tests were run at a level of 1,000,000 units of vitamin A ester per gram of solution with and without antioxidants. Only the α,α-methylethylcaproate of the sterically hindered series of esters exhibited any appreciable resistance to oxidation, but it was not as resistant as the palmitate. When the pure compounds used in this study were subjected to oxidation tests, the crystalline pivalate (trimethylacetate) appeared to be the most stable ester. Since the pivalate is a solid and the others are liquid, it was not unreasonable to assume that its apparent stability was due to reduced surface area or to a coating of oxidized material on the surface which prevented the uniform penetration of oxygen through the crystal. This produced results that were misleading as far as the rate of oxidation under use conditions were concerned; consequently, all the oxidation tests were performed in Wesson oil at a level of 10^6 units of vitamin A per gram of solution. This procedure eliminated the variables of physical form and molecular concentration, since these solutions were all of the same molarity. The results of this test indicated that good oxidative stability in vitamin A esters required a high degree of liposolubility and a long aliphatic chain. Molecular models of the palmitate showed that it is possible for the aliphatic portion of the molecule to orient itself alongside the vitamin A

Received February 2, 1968, from Chas. Pfizer & Co., Inc., Laboratories, Brooklyn, NY 10017
Accepted for publication March 5, 1968.
* Present Address: School of Pharmacy, Ferris State College, Big Rapids, MI 49307

chain and thus afford a mechanical barrier against attack by oxygen. The relationship between acid chain length and resistance to oxidation clearly showed that chain length was a critical factor. On the basis of resistance to acid degradation, alkaline hydrolysis, solvent-catalyzed degradation, and oxidation, the α,α-methylethylcaproate was found to be most stable of the sterically hindered esters. The major disadvantage of this compound was its inability to resist oxidation to the same extent as the palmitate. Based on the observed results it was theorized that a vitamin A ester of maximal stability should have (*a*) steric hindrance in the α-position of the acid group, and (*b*) a long aliphatic chain. An ester that could fulfill these requirements would be vitamin A α,α-dimethylpalmitate. The study of the preparation and properties of this ester will be discussed in a future publication.

The balance of this paper deals with the methods of preparation, determination of degradation rates, and comparisons of the stability of these esters. Vitamin A β-cyclopentylpropionate and tetrahydrophthalate were also included in this study. While they are not classical aliphatic-type fatty acid esters, it was desirable to observe the effect of other types of steric hindrance.

EXPERIMENTAL

Preparation of the Esters

The esters were prepared and purified using the method described by Forlano and Harris (1). Essentially, vitamin A alcohol dissolved in a methylene chloride–pyridine mixture was treated with the respective acid chloride or anhydride. The acids or anhydrides were obtained from K & K Laboratories, Jamaica, N. Y. The reaction mixtures were purified by alumina column chromatography, and the esters were isolated as viscous yellow oils after evaporating the solvent. The pivalate crystallized from ethanol upon refrigeration as a yellow solid (m.p. 52–55°), and the monotetrahydrophthalate was crystallized from warm petroleum ether (30–60°) and had an m.p. 94–97°. The esters were identified by their IR and UV spectra which are typical for vitamin A esters along with the absorptivity (*a*) 327 mμ, which is a specific identification factor for each ester. The *a* and the wavelength of maximum absorption for each of the esters are presented in Table I. Vitamin A alcohol and acetate are also included in this table for comparison purposes. They were not prepared in this study.

TABLE I—OBSERVED *a* AND $\lambda_{max.}$ IN ISOPROPANOL FOR THE VITAMIN A COMPOUNDS USED IN THIS STUDY

Compd.	m$\mu_{max.}$	*a*
Trimethylacetate	327	130.8
Triethylacetate	327	115.0
α,α-Dimethylvalerate	328	120.9
α,α-Methylethylcaproate	327	118.1
β-Cyclopentylpropionate	326	122.0
Monotetrahydrophthalate	327	118.9
Palmitate	326	93.6
Alcohol	325	183.5[a]
Acetate	326	155.0[a]

[a] These values were obtained from "Merck Index," 7th ed., (1960).

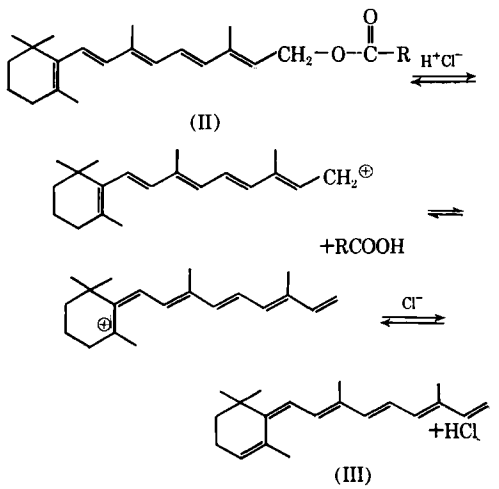
Stability Testing

In order to compare the stability of the hindered esters to that of the palmitate, they were subjected to the tests described below. Since vitamin A palmitate is the most stable ester commercially available, it was chosen as the standard with which to evaluate the new esters. The commercial material, however, was not suitable for these comparative tests, since it contained small quantities of antioxidants. Consequently, the standard used in these experiments was made by the same method used for the other esters.

Stability of Vitamin A Esters in Anhydrous Ethanolic 0.01 *N* HCl—*Part I*—A sufficient quantity of vitamin A ester was added to anhydrous ethanolic 0.01 *N* HCl, such that the initial UV absorbance at the maximum for vitamin A esters (327 mμ) was 0.700. The solutions were maintained at a constant temperature of 22 ± 1°, and changes in UV absorbance at 327 and 391 mμ were measured every 30 min. Anhydrovitamin A, one of the major degradation products under the conditions of this experiment, has a maximum absorbance at 391 mμ and an absorbance at 327 mμ, the maximum for vitamin A, equal to 0.2 the absorbance at 391 mμ. Since vitamin A has a negligible absorption at 391 mμ, the following correction factor for the absorbance for vitamin A at 327 mμ was determined:

$$A_{327\ m\mu\ (corr.)} = \left[A_{327\ m\mu\ (obs.)} - (0.2\ A_{391\ m\mu\ (obs.)})\right]$$

A is the UV absorbance at the specific wavelength. A plot of log $A_{327\ m\mu(corr.)}$, a measure of the concentration of vitamin A in solution, *versus* time was linear; consequently, the first-order rate constants were determined from the slope of this line. Under these conditions, the principal degradation pathway proceeds from the ester (II) to anhydrovitamin A (III), as shown below.



In the following tables, the "stability factor" represents the ratio of the rate constant of the specified ester compared to the rate constant of vitamin A palmitate. The first-order degradation rates are given in Table II.

Stability of Vitamin A Esters in 95% Ethanolic 0.1*N* HCl—*Part II*—The testing procedure used in this case was similar to that used in Part I, except that the solvent here was 0.1 *N* HCl in 95% ethanol. The results are presented in Table III.

Stability of Vitamin A Esters in 70% Ethanolic 0.1 *N* HCl—*Part III*—The testing procedure used in this section is outlined under Part I, except that the solvent here was 0.1 *N* HCl in 70% aqueous ethanol, and the results are presented in Table IV.

Stability of Vitamin A Esters in 70% Ethanol—*Part IV*—Since the degradation rate at 22° was too slow to be measured satisfactorily, the procedure used in this section was similar to that used under Part I, except that the reaction was run at 42 ± 1°, and the solvent here is 70% aqueous ethanol. The results are given in Table V.

Alkaline Hydrolysis of Vitamin A Esters—*Part V*—The method used to determine the resistance to alkaline hydrolysis was a modification of the procedure of Isler *et al.* (2) where 2.0 mmoles of ester was dissolved in 50 ml. of *n*-butanol and 50 ml. of 90% aqueous ethanol containing 2.0 mmoles of NaOH. The solutions were maintained in a constant temperature bath at 42 ± 1° and 10-ml. samples were removed for assay at 45, 80, 170, 235, 285, 330, and 375 min. The quantity of base consumed, a measure of the rate of hydrolysis, was determined by titrating the samples with 0.008 *N* HCl using thymol blue indicator. Since a plot of log concentration *versus* time was linear, it appeared that the reaction followed first-order kinetics. The rates of hydrolysis were determined from the slope of the line and the results are presented in Table VI.

Oxidation Studies—*Part VI*—The first test involved direct exposure of 0.2 ± 0.05 Gm. of accurately weighed pure compound to air at 37°, evenly spread over the surface of a 20-ml. opened Wheaton vial. The rate of oxidation, however, was too rapid to measure accurately; consequently, the experiment was performed at 22°. The amount of vitamin A remaining at any time was determined by dissolving the entire sample in isopropyl alcohol and measuring UV absorbance at 310, 325, and 334 mμ. Since the degradation products of these esters interfered with the direct measurement of vitamin A from the absorbance at 325 mμ, a correction factor (3) was applied to determine the portion of the absorbance at 325 mμ due to vitamin A.

The correction factor used in this experiment to determine the *a* 325 mμ for a 1:25,000 dilution of the sample, is shown below:

$$a_{(\text{corr.})\ (325\ \text{m}\mu)} = \frac{7A_{325(\text{obs.})} - 2.625A_{310(\text{obs.})} - 4.375A_{334(\text{obs.})}}{\text{weight of sample in Gm.}} \times 25$$

A plot of log *a* (corr.) *versus* time was a straight line; consequently, the first-order rate constants were calculated from the slope of the line. The results are shown in Table VII. There did not

appear to be any induction period in this study, however, this is not surprising since no antioxidant was present.

Subsequently, the oxidative stability of these esters was determined under use conditions in Wesson oil solutions with butylated hydroxyanisole (BHA) and butylated hydroxytoluene (BHT) as antioxidants. The esters were dissolved in commercial Wesson oil at a level of 1,000,000 units per gram of solution and the antioxidants at a level normally used in commercial preparations were added. Accurately weighed samples of 0.5 Gm. were placed into 20-ml. Wheaton vials and transferred to a 37° oven with free access to air. Since plots of log concentration of vitamin A *versus.* time in this case were not linear, the length of the "induction period" was considered the criterion of stability. This period represents the time lag before oxidation begins after the sample is exposed to air. Following the induction period, oxidation and destruction of the vitamin A molecule proceeds rapidly. The cyclopentylpropionate and monotetrahydrophthalate were not included in the solution experiments because of their insolubility in Wesson oil at the level of 10^6 units per gram. The lengths of these periods are given in Table VIII.

The oxidation tests in Wesson oil solutions were repeated without antioxidants and at a lower temperature (22°). The same conditions were used as in the previous section, except that the antioxidants were not included. Under these conditions it appeared that esters having the longer chain lengths in the acid portion have a measurable induction period which is not true of the short chain esters. The results are presented in Table IX.

TABLE VIII—INDUCTION PERIODS FOR VITAMIN A ESTER SOLUTIONS IN VEGETABLE OIL WITH ANTIOXIDANTS AT 37° (10^6 UNITS OF VITAMIN A PER GRAM)

Vitamin A Ester	Induction Period, hr.

Palmitate	53
α-Methyl-α-ethylcaproate	41
α,α-Dimethylvalerate	0
Pivalate	0
Triethylacetate	0

SUMMARY AND CONCLUSIONS

The results of the stability testing of the new esters when compared to vitamin A palmitate indicate the following:

1. Steric hindrance in the α-position of the acid portion of vitamin A esters confers stability with respect to acidic or alkaline degradation.

2. Vitamin A α,α-dimethylvalerate (DMV), α-methyl-α-ethylcaproate (MEC), and triethylacetate (TEA), were four to eight times more stable than the palmitate in anhydrous and hydroalcoholic acidic solutions.

3. The DMV, MEC, and TEA esters were five times more stable than the palmitate in 70% aqueous ethanol.

4. The DMV, MEC, and TEA esters were approximately 20 times more stable than the palmitate in alkaline hydrolysis studies.

5. The α,α-methylethylcaproate was found to be the most stable sterically hindered ester of the series because of its superior stability in solution relative to the palmitate, and its ability to compare somewhat favorably with the latter ester when subjected to air oxidation studies.

6. Since the palmitate and α,α-methylethylcaproate both showed stability, it can be considered that a long aliphatic chain (C_6—C_{16}) in the fatty acid portion is necessary for resistance toward oxidation. A future publication will deal with a sterically hindered ester, having a long aliphatic chain such as vitamin A α,α-dimethylpalmitate.

7. The β-cyclopentylpropionate and monotetrahydrophthalate were not as stable as the sterically hindered aliphatic esters under any of the conditions examined.

Preferred Conformation of Serotonin and a Postulate on the Nature of its Receptor from Molecular Orbital Calculations

By LEMONT B. KIER

Using extended Hückel molecular orbital theory, the preferred conformation of serotonin (5-hydroxytryptamine) I has been calculated. The internitrogen distance was calculated to be 5.84 Å. and the quaternary nitrogen to oxygen distance was calculated to be 6.96 Å. The complementary features of the serotonin receptor are predicted and the relationship of serotonin in its preferred conformation to the serotonin antagonist, LSD, is noted as an explanation of LSD's antagonism.

OVER THE past decade, an enormous amount of information has accumulated on serotonin (5-hydroxytryptamine) (I). A recent book on this subject by Garattini and Valzelli brings together much of this material (1). Of considerable interest to many scientists is the nature of the biological receptor interacting with the molecule. Gaddum and his group concluded, after a series of investigations, that the effect of serotonin on smooth muscle is specific and is not related to the effect of acetylcholine or histamine (2–5). The term "tryptamine receptors" was proposed to classify the receptors of the smooth muscle sensitive to serotonin. In reporting a study of antagonists, Barlow suggests that tryptamine and serotonin receptors may not be identical (6). This concept of the specific effect of serotonin is supported by results from numerous studies of known chemical mediators on serotonin-induced smooth-muscle stimulation (1).

A further elaboration of the serotonin-receptor concept was proposed by Gaddum, who offered evidence for two types of serotonin receptors, M and D (4). The M receptors were those blocked by morphine and the D receptors those blocked by dibenzyline. He found that the D receptors, located in the plain muscle fibers, were also blocked by LSD, gramine, or dihydroergotamine, while the M receptors, not accurately localized, were not easily blocked by these drugs (7–8).

Other authors have explained the dual-receptor-type effects by suggesting that serotonin stimulates organs containing smooth muscle by a direct action on the smooth muscle fiber, and by an indirect action on the nervous tissue (9–12).

The question of whether serotonin interacts with two different types of receptors or functions both as a direct and indirect acting agent has not been resolved. The two-receptor concept is reminiscent of that proposed for the action of acetylcholine while the direct-indirect action is typified by ephedrine. In connection with the acetylcholine dual-receptor concept, Martin-Smith, Smail, and Stenlake have recently proposed that acetylcholine acts at both receptors (muscarinic and nicotinic) by being able to assume two different conformations (13).

Recently, this problem of the muscarinic and nicotinic actions has been considered by the author in studies on the preferred conformations of acetylcholine, muscarine, muscarone, and nicotine (14, 15). By performing quantum mechanical calculations using extended Hückel theory, the total energy of each molecule was minimized as a function of geometry and calculated preferred conformations were obtained. In the case of acetylcholine, the author reported that the molecule exhibited some degree of conformational flexibility and could exhibit a preferred conformation over a range of one bond-angle variation. At one point in this variable energy minimum, the acetylcholine conformation corresponded to the preferred conformations of muscarine and muscarone. The heteroatoms in each molecule bore a similar relationship to each other and were similarly related to the other muscarinics. From this it was possible to deduce the nature of the muscarinic receptor and to deduce the muscarinic conformation of acetylcholine (14).

It was also found that acetylcholine in a preferred conformation different from its muscarinic conformation placed key atoms in a relationship nearly identical to that of comparable key atoms found for nicotine in its calculated preferred conformation (15).

These studies supported the idea of dual conformers functioning at two different receptors. Further support for this theory was found in the most recent study on histamine (16). In this case, it was found from these calculations that histamine exists in two different preferred conformations, and it was possible to relate one

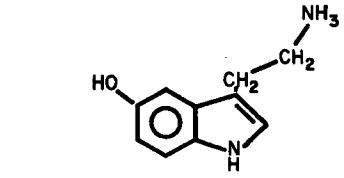
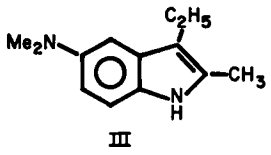
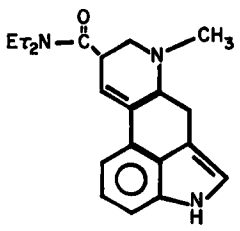
Accepted for publication March 21, 1968.



I



III



II

preferred conformation to a postulated receptor associated with one histamine action. The second preferred conformation was inferred to be complementary to a second histamine receptor.

From these studies it is possible to propose a theory concerning dual-receptor involvement that provides a rationale for considering the serotonin molecule by quantum mechanical methods. Essentially, it was postulated that *an observed dual action of a molecule may be explained by the presence of two preferred conformers of the molecule in equilibrium.* As a corollary, it can be stated that *if a molecule can exist in two nearly equally preferred conformations, an observed dual action of that molecule can be explained by the interaction of these different conformers with different receptors.*

If these postulates are assumed to be valid, it is readily apparent that quantum-mechanical calculations of the preferred conformation of the serotonin molecule may well lead to some understanding of its activity.

CALCULATIONS

The calculations used in this work have been described in detail elsewhere (14, 17). Briefly, the expansion of a molecular orbital as a linear combination of atomic orbitals yields

$$\Psi_i = \sum C_{ij}\phi_j$$

upon minimizing the total energy, a set of Hückel equations,

$$\sum_{i=j}^{n}[H_{ij} - ES_{ij}]C_{ij} = 0 \qquad j = 1,2 \ldots . n$$

where Ψ is the molecular orbital wave function, H the Hamiltonian operator, E the energy, S the overlap integral, and C the orbital coefficient. The calculations are performed for the valence electrons in s and p orbitals, using Slater orbitals as a basis set. The input parameters consist of the Slater exponent and the Coulomb integral, approximated by the ionization potential. All overlap integrals are considered. The resonance integrals are approximated by the equation

$$H_{ij} = 0.5\,K\,(H_{ii} + H_{jj})S_{ij}$$

with K set at 1.75. The total electronic energy is computed to be the sum of doubly occupied molecular orbitals,

$$\epsilon = 2\sum E_i$$

The total molecular energies can be written as

$$E = 2\sum E_i + \sum_{n,n'} Enn' - \sum_{e,e'} Eee'$$

where Enn' and Eee' are nuclear-nuclear and electron-electron repulsion energies. The success of the calculations in predicting preferred conformations from minimum energies lies in the fact that the method of selecting the H_{ij} values must simulate, within the calculated electronic energies, the contribution of nuclear repulsions to the total energy (17, 18). Thus, the nuclear-nuclear and electron-electron repulsion energies cancel approximately, and the simple sum of one-electron energies behaves similarly to the true molecular energy (19). A characteristic of the extended Hückel theory is the frequently correct prediction of equilibrium conformation with an exaggeration of barrier heights due to overestimation of nonbonded interactions.

For the calculations in this study, it was necessary to input precise three-dimensional coordinates for each atom. This otherwise very difficult task was expedited by a computer program that was obtained from the Indiana University Quantum Chemistry Program Exchange. The program performs a series of vector summations with previously determined planes of atoms as references. The program can be keyed to output the atom coordinates on punched cards in the fields required for the extended Hückel program. The bond angles and lengths used in the coordinates program were derived from standard values proposed by Pople and Gordon (20). Bond lengths were assumed not to vary in the different conformational models. To simulate the molecule in an *in vivo* environment, the author considered the amino-alkyl group as being protonated.

RESULTS

Calculations made every 45° for rotation of the bond joining the side chain to the ring through 180° revealed an energy minimum at $\theta_{ring-C} = 90°$ (Fig. 1). At this angle, the C—C bond of the side chain projects directly away from the plane of the ring system. Throughout this rotational pattern, the side chain is held in an all-*trans* conformation. The energy drop is not severe as the bond is rotated away from the all-planar conformation depicted in 1. An energy difference of 0.1 ev. exists between $\theta_{ring-C} = 45°$ and $\theta_{ring-C} = 90°$ (see Fig. 1). As the side chain rotates past the 90° minimum toward the benzene side of the ring system, the energy rises steeply, with a 1.5-ev. difference between $\theta_{ring-C} = 90°$ and $\theta_{ring-C} = 180°$. As has been pointed out, the energy barriers are exaggerated in these calculations; nevertheless, the values calculated must still be regarded as being considerable, based upon com-

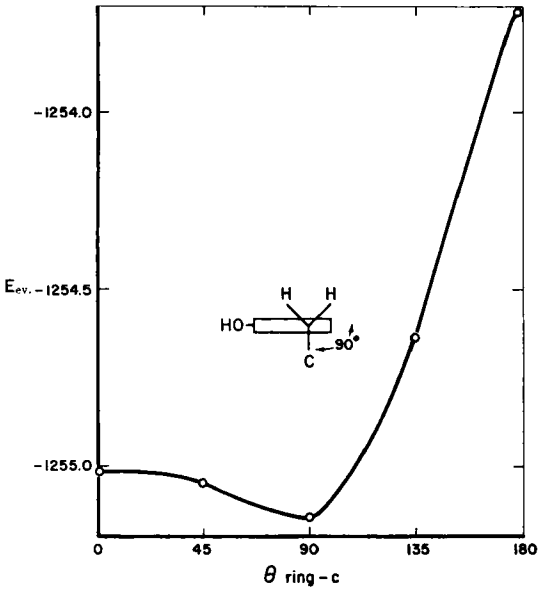


Fig. 1—Angle of rotation of ring to side chain bond vs. *energy.*

parisons of calculated with experimental values (17).

A further search for the energy minimum was conducted by varying the C—C bond of the side chain through 360°. This was done for the $\theta_{ring-C} = 90°$ and the $\theta_{ring-C} = 45°$ conformations. It was felt prudent to consider the latter conformation since the energy difference between the two was not so great as to exclude the 45° conformation as being part of a preferred conformation. The C—C rotation *versus* energy is depicted in Fig. 2. The minimum energy for this rotational model occurred for $\theta_{C-C} = 180°$, or on all-*trans* side chain. This minimum was found for both the $\theta_{ring-C} = 90°$ and the $\theta_{ring-C} = 45°$ conformations, although the former conformation had a substantially lower energy.

At the energy minimum, $\theta_{ring-C} = 90°$, $\theta_{C-C} = 180°$, the internitrogen distance was calculated to be 5.84 Å. The (*tetetete*)N-to-0 distance was calculated to be 6.96 Å. while the ($tr^2trtr\pi$)N-to-0 distance was 5.61 Å. The charge densities are displayed in Fig. 3, in which the values are for ($\sigma + \pi$) electrons. Note that the nitrogen atom of the quaternary group is negatively charged. The author has previously commented on this finding (16). The net charge of the quaternary group (including the α and β atoms) is +1.018.

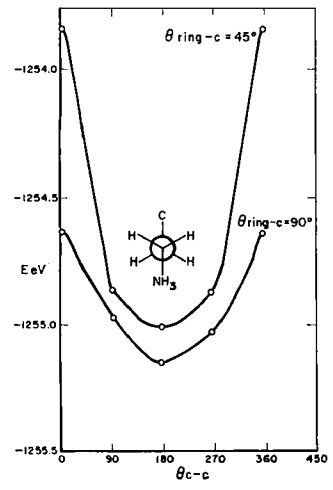

Fig. 2—Angle of rotation of side chain carbon to carbon bond vs. *energy.*

DISCUSSION

From these calculations it was found that serotonin exists in the single-energy preferred conformation shown in Fig. 4. From the energy *versus* angle profiles, it is evident that the molecule has a fair degree of rigidity in this conformation. Thus, a pattern of heteroatoms may be presented to a receptor, as shown in Fig. 5. The choice of these three atoms as being the essential ones for activity is speculative but reasonable. The inclusion of the oxygen in this category is based on the knowledge that, although tryptamine will produce some serotonin effects in the gut, its activity is feeble (2). In addition, as previously noted, antagonist actions suggest that serotonin and tryptamine receptors are different (6).

Because serotonin has only one preferred conformation, as indicated by these calculations, its

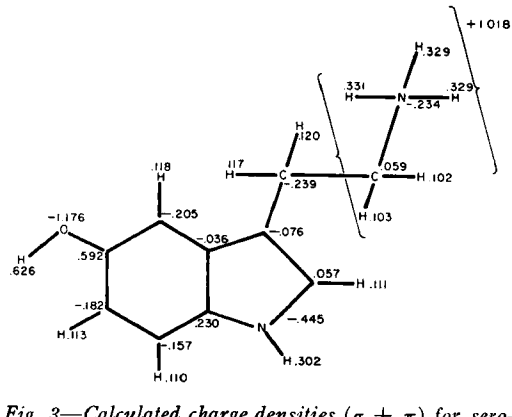

Fig. 3—Calculated charge densities ($\sigma + \pi$) for serotonin.

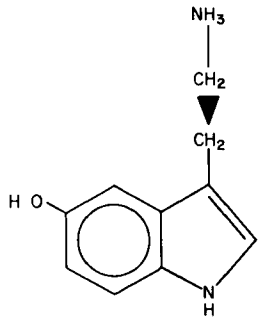

Fig. 4—Calculated preferred conformation of serotonin.

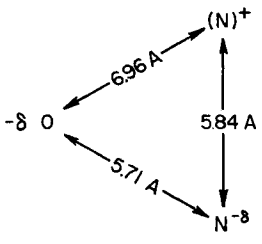

Fig. 5—Structural features proposed as being complementary to the serotonin receptor.

activity cannot be explained by the dual-conformation concept. However, the calculated inability of serotonin to exist in more than one preferred conformation does not completely exclude the possibility that the molecule could interact with two different receptors. There is the remote possibility that this could occur if the molecule presented alternate faces to each of two approximately mirror-image receptor patterns. Thus, each receptor would have its own set of stereospecific requirements for an agonist and each face of the serotonin molecule would satisfy these requirements. It remains to be conclusively demonstrated whether there are two receptors for serotonin. An explanation for the accommodation of serotonin to each is possible from this work. This possibility is considered remote since the quaternary N projects well above the plane of the rings, hence only one side of the molecule presents a planar aspect to a receptor. The alternate side of the molecule does not permit a close approach of the quaternary N if the other nitrogen and the oxygen atoms are anchored to a receptor. The alternative hypothesis of both direct and indirect effects is easier to explain since, as in the case of indirect-acting adrenergic agents, lower stereospecific requirements are present. Thus, only two of the three serotonin heteroatoms may be involved in an indirect action.

A comparison of the calculations reported here with previous calculations on the histamine molecule reveals that the two molecules in their preferred conformations do not have their heteroatoms separated by a similar distance (16). This suggests that the two molecules are not involved with the same receptor.

It is instructive to compare the results of these calculations with the dimensions of the more rigid, potent serotonin antagonists. The most prominent of these compounds is lysergic acid diethylamide (LSD) (II). It is known to be an antagonist for virtually all actions of serotonin (1). Because it is such an effective antagonist, it is reasonable to assume that the molecule successfully binds with enough of the serotonin receptor to exclude serotonin although it does not have the full complement of structural features necessary to produce an efficacious complex. Measurements on accurate scale models of LSD indicate a distance between the amino and the pyrrole nitrogen atoms to be 6.0 ± 0.2 Å. At physiological pH, the *N*-methyl group would be protonated. Therefore, it is evident that these two nitrogen atoms could interact with portions of the serotonin receptor complementary to the quaternary and pyrrole nitrogens of serotonin, based upon their positions in the calculated preferred conformation. Derivatives of lysergic acid would also present these same atoms to the serotonin receptor, which accounts for the prominence of antagonism in this class of compounds.

A second antagonist molecule from which one can readily derive values of interatomic distances is 2-methyl-3-ethyl-5-dimethylaminoindole (medmain) (III) (21). The internitrogen distance in this molecule, estimated from a scale model, is about 5.75 Å. This closely approximates the 5.61 Å. distance calculated to separate the oxygen from the pyrrole nitrogen of serotonin.

From these calculations on the serotonin molecule, it can be concluded that there is a single preferred conformation and that the relative preference is fairly high. In this preferred conformation, the molecule presents three heteroatoms to a receptor in a predictable manner, hence a complementary pattern of forces on the receptor can be deduced. The antagonism of LSD and other inhibitor molecules can now be explained in terms of this postulated receptor, since comparable interatomic distances are found in these antagonist molecules. This finding also tends to verify speculation on the serotonin receptor (Fig. 5).

Acceleration of Peritoneal Dialysis by Surface-Active Agents

By S. C. PENZOTTI and A. M. MATTOCKS

Peritoneal dialysis is an effective method of removing endogenous poisons, but it is a slow process. In a search for agents to accelerate dialysis across the peritoneum, a number of wetting agents were tested and used in the peritoneal fluid. Dialysis tests were run on rabbits with radioactive urea and rate constants were calculated from dialysate and blood curves. The anionic and cationic wetting agents had significant effects, while the nonionic wetting agents were much weaker. On the basis of effectiveness and gross toxicity dioctyl sodium sulfosuccinate 0.01 percent was chosen as the most promising accelerator. It was evaluated in more detail and found to accelerate the dialysis of urea to about four times the rate of controls. When tested with radioactive creatinine the acceleration was two to threefold. It was concluded that dioctyl sodium sulfosuccinate is worthy of the further work required to bring it to the stage of clinical trial.

PERITONEAL DIALYSIS is an effective means for removal of endogenous poisons (1). It has the advantage over the artificial kidney of requiring no special equipment or facilities and being a relatively simple technique which might be performed in any physician's office. It has the serious disadvantage of being slow to clear the body of toxic agents, requiring up to 72 hr. in treatment of kidney failure and being so slow in removal of drugs as to have questionable value in suicidal or accidental drug poisonings (2, 3). If the process could be accelerated this would be of utmost importance, making possible the treatment of a larger number of uremic patients in a given institution and offering an effective treatment for drug poisoning in any locality.

In a search for substances which might accelerate diffusion across the peritoneal membrane, wetting agents were among the first type of compound to be considered. It is conceivable that incomplete wetting of the membrane by the dialysis fluid might occur with the common solutions, possibly due to fatty material on the membrane surface or on other tissues where penetration of the fluid to the membrane might be blocked. Also, diffusion acceleration of unknown nature has been observed in laboratory experiments with cellophane membranes when certain wetting agents were added (4). In this laboratory it was found that tris-hydroxymethyl aminomethane (THAM), a substance with weak surface-active properties, accelerated peritoneal dialysis by an unknown mechanism (5).

A group of common wetting agents was selected for test in peritoneal dialysis, including some anionic, cationic, and nonionic compounds. Experiments were planned to observe dialysis rates of urea and gross toxic effects with one to three animals as a screening test, then to select optimum concentrations of any found to be effective, finally to run a series of tests with the selected concentration of the best agents found. Since creatinine as well as urea is used as an indicator of the progress of peritoneal dialysis, it was planned to test the most promising of the agents for its effect on the dialysis of creatinine also.

As was pointed out in a previous paper (5), the effectiveness of peritoneal dialysis is best evaluated by means of a rate constant, since the amount dialyzed in a given time is dependent on the blood-dialysate gradient at each instant of time throughout the period, while the blood level is affected by urinary excretion and metabolism as well as diffusion into dialysate. Thus, experiments were set up to measure both blood level and dialysate level over the period of experiment, allowing the rate constant to be calculated from suitable equations.

MATERIALS AND METHODS

Healthy, mature male albino rabbits were selected as the experimental animal. No general anesthesia was used, but 50 mg. of chlorpromazine hydrochloride was administered intramuscularly 20 min. prior to the beginning of the experiment. A urinary catheter was inserted and 1 Gm. of ^{14}C-tagged urea (200 mg./ml.) was injected intravenously. Twenty to 30 min. was allowed for distribution of the drug throughout the body fluids before beginning dialysis, then 150 ml. of dialysis fluid was introduced into the peritoneum by means of a pediatric-size peritoneal catheter. Blood samples were taken from the marginal ear vein. Dialysate samples were withdrawn through the peritoneal catheter, taking care to return contents of the outlet tubing and catheter after removal of the sample. Samples of blood and dialysate were removed at 10–15 min. intervals over periods up to 200 min. Urine

samples were taken but are not used in this analysis and are not presented here. With creatinine dialysis the same procedure was used except that 0.5 Gm. of ^{14}C-tagged creatinine (50 mg./ml.) was injected and the beginning of dialysis was delayed until about 1 hr. after injection in most cases.

The urea injection was prepared by dissolving an amount of radioactive urea equivalent to about 70 microcuries and sufficient stable urea to make 10 Gm. total urea in bacteriostatic water for injection (0.9% benzyl alcohol) to make 50 ml. This was sterilized by filtration and stored in the refrigerator.

Creatinine injection was prepared by dissolving an amount of creatinine-1-^{14}C equivalent to about 70 microcuries and sufficient stable creatinine to make a total of 5 Gm. in water for injection, then adding 0.2 ml. of 0.2 *N* hydrochloric acid and sufficient water for injection to make 100 ml. The solution was filtered, sealed in multidose injection vials, and autoclaved. The acid and heat were used to insure that any traces of creatine would be converted to creatinine.

The dialysate solution used for control was a commercial formula, Inpersol No. 46244—Abbott containing dextrose 1.5%, sodium lactate 0.5%, sodium chloride 0.56%, calcium chloride USP 0.026%, and magnesium chloride hexahydrate 0.015%. The surface-active agents were merely dissolved in this fluid to prepare the test solutions, except where concentrations of wetting agents were high enough to alter significantly the osmolality. In such cases the same formula was used except that sufficient dextrose or dextrose and sodum chloride was deleted from the formula to balance the number of moles of added substance. The only fluids of this type of the data tables of this paper are those containing THAM.

The wetting agents used, their grade and source were: sodium desoxychlorate, purified, (Fisher); polysorbate 60 and polysorbate 85,[1] pharmaceutical grade; trishydroxymethyl aminomethane (THAM), primary standard (Fisher); sodium lauryl sulfate USP (Amend); benzalkonium chloride[2] 17% solution; dioctyl sodium sulfosuccinate (DSS), solid, (Fisher); cetyl trimethyl ammonium bromide (CTAB), technical, (Matheson); and cetyl trimethyl ammonium chloride (CTAC), practical, (Fisher).

Measurements of concentrations in blood and dialysate were made by standard radioactive counting methods. For blood, a 0.2-ml. sample of whole blood or serum was added to 1 ml. of 6% trichloroacetic acid in a centrifuge tube and immediately shaken vigorously, then centrifuged. A 0.5-ml. aliquot of the clear supernatant was added to 10 ml. of dioxane phosphor solution and counted. For dialysate, 0.5 ml. of the solution was transferred to the counting vial containing 10 ml. of phosphor solution for counting. An accurate dilution of the injection used served as a standard which was counted with each set of samples. The dioxane phosphor solution contained 0.7% PPO, 0.005% POPOP, and 5% reagent naphthalene in spectro quality dioxane. All samples were counted with 1% error or better in a Packard 314-X Tri-Carb liquid scintillation counter and corrected for quenching by channels ratio.

RESULTS AND TREATMENT OF THE DATA

The dialysis rate constant describing the diffusion from blood to dialysis fluid is depicted as k_1 in the following equation:

$$\begin{array}{c} \overset{k_1}{\rightleftarrows} \\ \mathrm{B} \rightleftarrows \mathrm{D} \\ k_3 \downarrow \quad k_2 \\ \mathrm{U} + (\mathrm{M}) \end{array} \qquad \text{(Eq. 1)}$$

where B represents the compound, urea or creatinine, in blood, D, in dialysate, and U and M represent urinary excretion and metabolism, respectively. Values of k_1 were calculated from the equations of Rescigno and Segre (6) as previously described (5) using an analog computer. These rate constants are tabulated in Table I. Figures 1 and 2 illustrate curves obtained with controls and effective accelerating agents, respectively.

DISCUSSION AND CONCLUSIONS

In the design of these experiments, it was planned to run each test solution on a minimum number of animals as a screening test, then to run repeated tests with more animals where comparisons of rate constants with controls were desired. Thus, only in the cases where the agents showed promise as accelerators were more than two tests run. Substances were judged to be promising if no gross toxicity was evident and the rate constants were two to three times those of controls.

From the data it is seen that polysorbate 60, a nonionic wetting agent, appeared to have a weak effect at relatively high concentration. The low concentration of polysorbate, 0.01%, was run to determine whether this solution, with surface tension almost as low as the 1.8% solution, might give an equal effect. Since it did not, it appears, with this limited experience, that the polysorbate effect was not due simply to lowered surface tension. Polysorbate plus THAM was run to obtain an indication as to whether the two compounds affect dialysis by the same mechanism. Since the results showed a higher rate than either had alone, the indication, based on limited data, is that the two mechanisms are not the same.

In general, results show that both anionic and cationic wetting agents increase the rate of dialysis of urea across the peritoneal membrane and that the effect reaches a maximum, with higher concentrations yielding no appreciable increase in dialysis rate. The cationic agents, CTAB, CTAC, and benzalkonium chloride were all effective with the maximum in each case being at about 0.02%. With these agents, however, toxic effects and deaths were detected at concentrations 2–3 times as high as the most effective level. With benzalkonium chloride, deaths resulted with 0.02%. All deaths observed were similar, respiratory in nature, accompanied by fall in blood pressure, convulsions, appearance of a deep orange to red color in urine and dialysis fluid, and occasionally appreciable hemolysis as seen in the hematocrit. Because of the toxic manifestations observed at levels close to the effective concentrations, attention was focused on the less toxic anionic wetting agents.

TABLE I—DIALYSIS RATE CONSTANTS, k_1, FOR UREA AND CREATININE DIALYSIS WITH VARIOUS PERITONEAL FLUIDS

[a] Animal died shortly after last sample taken. [b] Controls taken from earlier data (5).

The difference in effect of CTAB and CTAC is unexpected, but since both are mixtures rather than pure compounds, it is presumed that certain effective components are present in greater proportions in one mixture than the other. The bromide ion would be undesirable in dialysis fluid since bromism might result. It was for this reason that the chloride was tested.

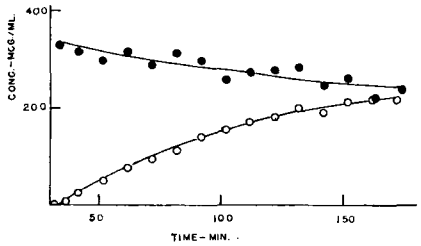

Fig. 1—Dialysis with control fluid, animal no. 54. Key: ●, blood; ○, dialysate.

Among the anionic agents tested, sodium lauryl sulfate, DSS, and sodium desoxycholate, DSS was the most effective. No gross toxicity was observed

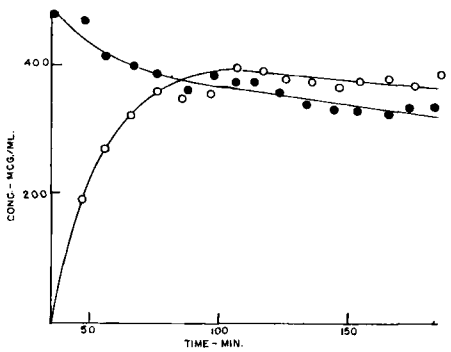

Fig. 2—Dialysis with an effective wetting agent, 0.01% DSS, animal no. 16. Key: ●, blood; ○, dialysate.

at levels five times the concentration of maximum activity, 0.01%. Sodium lauryl sulfate required a concentration of 0.2% to yield dialysis rate roughly equivalent to those with 0.01% DDS. Higher concentrations of sodium lauryl sulfate were not tested, since the 0.2% caused irritation in the abdomen evidenced by squirming and discomfort of the animal when the solution was introduced. It did not show any evidence of permanent damage, however. The rates obtained with sodium lauryl sulfate varied more than with any other agents used.

From these experiments it was concluded that DSS was the most promising of the wetting agents, accelerating the dialysis rate for urea to about four times that of the controls. This would constitute a significant improvement in the dialysis process.

Since DSS appeared to be the most promising agent it was also tested for its effects on the dialysis of creatinine. As seen in Table I, it also accelerates the removal of the compound, rates being about three times the controls.

The experiments with sodium desoxycholate were quite surprising. Death resulted with concentrations as low as 0.01%, and when lower concentrations were tested the effect on dialysis rate decreased as toxicity appeared to decrease. At nontoxic levels no acceleration of dialysis was observed.

The results of this work indicate that DSS may be a useful accelerator of peritoneal dialysis and is deserving of further work. The compound accelerates the dialysis of urea and creatinine, but whether it also accelerates the removal of the multitude of other substances, some known, some unknown, which accumulate in uremia must be determined by experiments which assess the effect of general uremic symptoms and long-term treatment of the diseased condition. Before DSS can be evaluated in man, of course, a measure of its absorption and accumulation in the body must be made and correlated with possible toxic effects which might result. It seems possible that once a given level of DSS is established in the system that the concentration in the dialysis fluid might be reduced without loss of effect. These are problems which must be faced in further work leading toward clinical trials.

This work also suggests the possibility of using DSS or other wetting agents in the removal of drugs such as salicylates and barbiturates which are commonly encountered in poisonings. This study is being conducted in this laboratory.

equilibrium uptake of the four cinchona alkaloid bases by the same resins in hydrogen form from six aliphatic alcohols at room temperature (~30°).

EXPERIMENTAL

Resins (1, 2)—Styrene divinylbenzene copolymer based sulfonic acid cation-exchange resins of degree of crosslinking (% nominal divinylbenzene content) as 2, 4, and 8 (further referred to as resins X2, X4, and X8)[1] of −20, +50; −50, +100; and −50, +100 mesh size, respectively. The resins were conditioned, regenerated, air dried, and moisture content and capacity were estimated (3, 4). The percent moisture and the capacity in meq. per oven-dry Gm. were: X2, 20.4, 5.20; X4, 24.0, 5.12; and X8, 27.0, 5.09. The different ionic forms of the resins were obtained by passing excess of the salt or hydroxide solution through the resin bed. The resins were then washed, filtered, air dried, moisture content determined, and capacity of the air-dry resin calculated from the oven-dry capacity in the hydrogen form.

Resin IR-200[2] of −10, +60 mesh size, which is presumably styrene divinylbenzene copolymer based sulfonic acid cation-exchange resin of relative degree of crosslinking of about 20 but has an expanded structure. The resin was conditioned, regenerated, air dried, and percent moisture content and capacity in meq. per oven-dry Gm. were 25.5 and 4.78.

Chemicals and Solvents (5)—Quinine sulfate (Government quinine factory, Madras), quinidine sulfate (P. B. Howard, London), cinchonine sulfate (B. D. H. London), and cinchonidine sulfate (Fluka, A.G., Switzerland) were crystallized several times from hot water and stored in well-stoppered colored bottles. The composition was $Q_2H_2SO_4 \cdot nH_2O$ where Q denotes the alkaloid base. This was established from estimation of water content by drying in an oven (100 ± 3°), sulfate estimation as barium sulfate gravimetrically and estimation of the precipitated alkaloid base by weighing and by ultraviolet absorption in alcoholic solution.

For the preparation of the cinchona alkaloid bases about 0.5 *N* sodium hydroxide solution was added to alkaloid sulfate solution in slight excess, heated to about 80°, filtered hot, washed free of alkali, recrystallized (quinine from 40% v/v aqueous ethyl alcohol, quinidine from 80% aqueous ethyl alcohol, and cinchonine and cinchonidine from distilled ethyl alcohol), dried at 100 ± 2°, and stored.

The alcohols were of C.P. grade. Absolute ethyl alcohol was prepared by refluxing distilled ethyl alcohol in the presence of anhydrous calcium oxide for 6 hr. and then distilling it.

Procedure—The alkaloid sulfate (1 mole equal to two equivalents) solutions were prepared by dissolving weighed amounts of the respective alkaloid sulfates (1) in distilled water in volumetric flasks. The concentration of the solutions was rechecked gravimetrically by sulfate estimation as barium sulfate and by ultraviolet absorption (5). The alkaloid base (1 mole equal to one equivalent) solutions were prepared by dissolving the weighed amount of the alkaloid bases in the respective alcohols in the volumetric flasks. The concentration of the solutions was rechecked by ultraviolet absorption. To study the equilibrium of alkaloid sulfates and bases with the resins, weighed amounts of air-dried resins were contacted with the aqueous sulfate solutions or the solutions of the bases in the alcohols of known concentration in well-stoppered flasks with frequent shaking at room temperature (~30°). Preliminary work was carried out to find the approximate time within which equilibrium was attained. After sufficiently more time than this (about 4–40 days depending on X), the solutions were analyzed for alkaloid concentration by ultraviolet absorption. The ultraviolet absorption measurements were made with a Beckman model DU spectrophotometer using 10-mm. matched quartz cells. Preliminary work also indicated that for small changes in temperature the value of P_R did not change significantly.

RESULTS AND DISCUSSION

Effect of the Ionic Form of the Resin—The synthetic organic ion-exchange resins (6, 7) consist of an irregular, three-dimensional network of hydrocarbon chains, to which ionogenic groups are attached and the surplus electric charge is balanced by mobile counter ions. The hydrocarbon network is hydrophobic but the ionogenic groups are hydrophilic, and hence when the resin particle is placed in water, it sorbs water and swells to a limited extent. The amount of water sorbed and the extent of swelling would depend on the degree of crosslinking and the counter ions.

The equilibrium exchange of the four cinchona alkaloid sulfates in aqueous solution with resins X2, X4, and X8 in lithium, sodium, potassium, magnesium, and aluminum forms was studied and the calculated values of P_R were practically constant when P_A was varied. Table I gives an illustration of the type of results obtained, and the values of P_R obtained from such data are given in Table II.

It is suggested that the value of the equilibrium

constant for the exchange of the cation QH^+ is large and the equilibrium

$$\overline{M^{+y}} + y\overline{QH^+} \rightleftharpoons M^{+y} + y\overline{QH^+}$$

($\overline{M^{+y}}$ and $\overline{QH^+}$ denote the cations in the resin phase and M^{+y} and QH^+ denote the cations in the solution phase; y denotes the valence of M) is shifted very much to the right; however, all the replaceable ions in the resin phase are not accessible for exchange or the available capacity is only a fraction of the total capacity, probably due to the size of the organic counter ions. It is likely that the marked shift of the equilibrium to the right is aided by nonexchange interactions (1, 3).

For resins X2, X4, and X8 in lithium, sodium, and potassium forms, the values of P_R for the four cinchona alkaloid sulfates are in the order Li > Na > K which is also the order of the values of water content of the swollen resins (6, 7). For resins in the ionic forms of ions of different valence (sodium, magnesium, and aluminum), the order of the P_R values is monovalent > divalent > trivalent. The value of P_R decreases as the degree of crosslinking of the resin increases. This may be attributed to the decrease in the swollen volume of the resin as the degree of crosslinking increases and hence the number of accessible exchange sites for the organic cations in the interior of the resin decreases.

In general, the results (Table II) indicate that the P_R values for the optical isomers (quinine, quinidine cinchonine, and cinchonidine) are not substantially different. But the values of P_R for quinine and quinidine sulfates are lower than those for cinchonine and cinchonidine sulfates for the resin in the same ionic form. A possible reason for this should be the difference in the size of quinine or quinidine as compared to that of cinchonine or cinchonidine.

Effect of Added Sulfuric Acid—The equilibrium exchange of the four cinchona alkaloid sulfates with the hydrogen form of the resins X9, X8, and IR-200 with added sulfuric acid (1 N and 0.1N) was studied at room temperature. Table III gives the effect of added sulfuric acid on the equilibrium exchange of quinidine sulfate and cinchonine sulfate. The results for quinidine sulfate and cinchonine sulfate were practically the same as those for quinine sulfate and cinchonidine sulfate.

The values of P_R either decrease to a small extent or are constant with increase in P_A. The nonexchange interactions would tend to increase the extent of exchange with increase in $[A]_e$. This may be feasible to some extent by further expansion of and/or further separation between the segments in the swollen or expanded resin network and should depend on the degree of crosslinking and the extent to which the exchange has already occurred. If the further expansion and/or segment separation is sufficient to accommodate some more organic cations by exchange, P_R should increase with increase in $[A]_e$ or decrease in P_R. On the other hand, if the further expansion and/or segment separation is too small to accommodate some more organic cations by exchange, P_R should remain practically constant with increase in $[A]_e$ or decrease in P_A. The difference in the values of P_R of quinine sulfate and quinidine sulfate and those of cinchonine sulfate and cinchonidine sulfate is either relatively small or practically nil when the concentration of the added sulfuric acid is relatively large (0.1 N to 1 N). The difference in the values of P_R in the presence and absence of added sulfuric acid may possibly be due to the regenerative effect of H^+ ions and the deswelling of the resin particles for the gel-type resins (X4 and X8) and mainly due to the former for expanded structure resin IR-200.

Table IV—Equilibrium Uptake of Quinine from *n*-Propyl Alcohol by Resin IR-200 in Hydrogen Form

$[\bar{H}]_i$	$[A]_i$	$[\bar{A}]_e$	P_A	P_R
11.9	14.4	2.73	19.0	23.0
20.2	14.4	4.68	32.5	23.2
25.2	14.4	5.95	41.3	23.6
27.4	14.4	6.40	44.4	23.4
31.6	14.4	7.42	51.5	23.5
37.7	14.4	8.97	62.3	23.8

Effect of Solvent Medium (Aliphatic Alcohols)—The equilibrium uptake of the four alkaloid bases, quinine, quinidine, cinchonine, and cinchonidine, from dilute solution in six aliphatic alcohols (methyl alcohol, absolute ethyl alcohol, *n*-propyl alcohol, *n*-butyl alcohol, *t*-amyl alcohol, and *n*-hexyl alcohol) by resins X2, X4, X8, and IR-200 in hydrogen form was studied at room temperature. The value of P_R was practically independent of P_A. Table IV gives an illustration of the type of results obtained. The values of P_R obtained from such data are summarized in Table V; it also includes the values of P_R obtained for *n*-amyl alcohol by plotting P_R against the number of straight chain carbon atoms in the *n*-alcohol molecule for each resin.

The values of P_R for the optical isomers were not significantly different. The values of P_R for quinine or quinidine are different from those for cinchonine or cinchonidine in methyl alcohol. In ethyl alcohol (absolute) and *n*-propyl alcohol the values of P_R for the four bases are fairly close for each resin.

TABLE V—VALUES OF P_R FOR THE UPTAKE OF CINCHONA ALKALOID BASES FROM ALIPHATIC ALCOHOLS BY SULFONIC ACID CATION-EXCHANGE RESINS IN HYDROGEN FORM

Alkaloid → / Resin → / Alcohol	Quinine or Quinidine				Cinchonine or Cinchonidine			
	X2	X4	X8	IR-200	X2	X4	X8	IR-200
Methyl	42	33	23	30	67	38	26	34
Ethyl (abs.)	34	26	16	30	—	25	17	33
n-Propyl	23	16	09	27	24	18	11	31
n-Butyl	24	15	07	28	32	20	09	33
n-Amyl	29	14	07	30	44	25	10	33
tert-Amyl	18	11	08	28	25	23	13	37
n-Hexyl	37	14	08	32	63	29	11	39

With further increase in the chain length of the alcohol molecule (*n*-butyl and *n*-hexyl alcohols), the difference in the P_R values of quinine and quinidine and those of cinchonine or cinchonidine again becomes significant. A possible reason for this type of behavior should be the size of the organic counter ions relative to the swollen volume of the resin particle in the different alcohols. The value of P_R decreases with increase in the value of X for the gel-type resins X2, X4, and X8 due to the decrease in the swollen volume of the resin with increase in X. With increase in the chain length of the alcohol molecule, for resin of lower X, X2, the value of P_R for the four bases first decreases and then increases. With increase in the value of X, that is for resins X4 and X8, with increase in the chain length of the alcohol molecule, the value of P_R first decreases and then remains almost unchanged. With resin IR-200 which has expanded structure, the value of P_R first decreases and then increases with increase in the chain length of the alcohol molecule. The comparison of the values of P_R for *t*-amyl alcohol and the calculated values of P_R for *n*-amyl alcohol indicates that for resin of lower degree of crosslinking, X2, the value for *n*-amyl alcohol is higher than that for *t*-amyl alcohol. For resins of higher degree of crosslinking, X4 and X8 and for resin IR-200, the values of P_R for *n*- and *t*-amyl alcohols are fairly close. The variation in the values of P_R for the series of alcohols should be attributed to the variation in the swollen volume of the resin in the alcohols.

Nomenclature—

$[A]_i$ = initial concentration of the alkaloid sulfate or base solution in meq./l.

$[\bar{A}]_e$ = the meq. of alkaloid in the resin phase per liter of solution, at equilibrium.

$[A]_e$ = the meq. of alkaloid sulfate or base in the solution outside the resin phase, per liter of solution, at equilibrium.

$[\bar{M}]_i$ = the meq. of resin per liter of the solution in the M form, initially.

P_A = $100[\bar{A}]_e/[A]_i$ = the % exchange of alkaloid sulfate or base at equilibrium.

P_R = $100[\bar{A}]_e/[\bar{M}]_i$ = the % resin capacity exchanged at equilibrium.

X = the relative degree of crosslinking (% nominal divinylbenzene content).

Effect of pH and Dye Concentration on the Extraction of a Thiamine Dye Salt by an Organic Solvent

By V. DAS GUPTA*, DONALD E. CADWALLADER, HARVEY B. HERMAN†, and IRWIN L. HONIGBERG

The effect of pH and dye concentration on the extraction of thiamine dye salt by an organic solvent has been studied. An equation which expresses the dependence of the thiamine dye salt extracted with changes in pH was derived. The theoretical and experimental data were found to be in good agreement.

In a previous report (1) concerning an acid dye assay method for thiamine using bromothymol blue, it was observed that the amount of thiamine dye salt extracted by chloroform varied with pH and dye concentration. The variation in the amount of salt extracted from an aqueous solution by an organic solvent with changes in pH and dye concentration is well documented (2). Schill (3, 4) has recently reported the effect of various experimental conditions on the extraction of bromothymol blue amine salts. The purpose of this study was to derive an equation that expresses the dependence of the thiamine dye salt extracted with changes in pH and dye concentration, and to prove the validity of this equation by comparing theoretical and experimental data.

THEORETICAL

With the use of a thermodynamic argument Divatia and Biles (5) showed that the alkyl amine salts of tropaeolin 00 in the organic phase were in equilibrium with the ionic forms of amine and dye in the aqueous phase. In their studies they called the equilibrium constant for such a phenomenon the apparent partition coefficient and expressed it as

$$K = \frac{S}{A^+ \times D^-}$$

where S = concentration of salt in the organic phase; A^+ = concentration of dissociated amine in the aqueous phase; and D^- = concentration of dissociated dye in the aqueous phase.

In the authors' studies an equivalent equation was expressed as follows:

$$K = \frac{S}{[HI^-]_a[Th^+]_a} \qquad \text{(Eq. 1)}$$

where S = concentration of thiamine dye salt in the organic phase; $[Th^+]_a$ = concentration of thiamine in the aqueous phase (thiamine has one positive charge); $[HI^-]_a$ = concentration of dissociated dye in water.

The term equilibrium constant was preferred over the apparent partition coefficient because the latter gave the impression that the equilibrium was between the concentrations of the thiamine dye salt in two phases.

An equation relating the amount of thiamine dye salt extracted in a single portion of chloroform (when the volumes of immiscible solvents are equal) to changes in pH was derived using the following symbols:

S = Concentration of thiamine dye salt in the organic phase in moles/L. This also represents the concentration of dye or thiamine in the thiamine dye salt (Eq. 1).

$[C_{H_2I}]$ = Total concentration of the dye in both phases in moles/l.

$[C_{H_2I}]_a$ = Total concentration of the dye in aqueous phase in moles/l.

$[H_2I]_{ua}$ = Concentration of the undissociated dye in aqueous phase in moles/l.

$[H_2I]_c$ = Concentration of free dye in chloroform in moles/l.

$[HI^-]_a$ = Concentration of dissociated dye in water in moles/l.

A_0 = $[H^+]^2/([H^+]^2 + K_1[H^+] + K_1K_2)$ = fraction of $[H_2I]_{ua}$ at a given pH (6).

A_1 = $K_1[H^+]/([H^+]^2 + K_1[H^+] + K_1K_2)$ = fraction of $[HI^-]_a$ at a given pH (6).

K_1 = First acid dissociation constant of bromothymol blue.

K_2 = Second acid dissociation constant of bromothymol blue.

D = Distribution coefficient of the dye.

$[C_{Th}]$ = Total concentration of thiamine in both phases in moles/l.

$[C_{Th}]_a$ = Total concentration of thiamine in aqueous phase in moles/l.

$[TH^+]_a$ = Concentration of undissociated thiamine in aqueous phase in moles/l.

$[TH]_c$ = Concentration of free thiamine in chloroform phase in moles/l.

K_3 = Acid dissociation constant of thiamine.

K = Equilibrium constant (Eq. 1).

The equilibrium expression for the thiamine salt of bromothymol blue in chloroform and water is given by Eq. 1 which may be rearranged to give:

$$K[HI^-]_a[TH^+]_a - S = 0 \qquad \text{(Eq. 2)}$$

Accepted for publication March 4, 1968.

Presented to the Drug Standards, Analysis and Control Section, APhA Academy of Pharmaceutical Sciences, Miami Beach meeting, May 1968.

Abstracted in part from a thesis submitted by V. Das Gupta to the Graduate School of the University of Georgia in partial fulfillment of the requirements for the degree of Doctor of Philosophy.

Adapted from the manuscript by V. Das Gupta which received the 1967 Lunsford Richardson Pharmacy Award.

* Present Address: College of Pharmacy, University of Houston, Houston, TX 77004

† Department of Chemistry, University of Georgia.

To solve for $[HI^-]_a$ in terms of $[H^+]$, K_1, K_2, and $[C_{H_2I}]$ let

$$[C_{H_2I}] = [C_{H_2I}]_a + S + [H_2I]_c \quad \text{(Eq. 3)}$$

and

$$[H_2I]_c = D[H_2I]_{ua} \quad \text{(Eq. 4)}$$

The expression for determining $[H_2I]_{ua}$ in an aqueous phase is

$$[H_2I]_{ua} = [C_{H_2I}]_a A_0 \quad \text{(Eq. 5)}$$

therefore, Eq. 4 can be expressed as

$$[H_2I]_c = D[C_{H_2I}]_a A_0 \quad \text{(Eq. 6)}$$

The expression for determining $[HI^-]_a$ in an aqueous phase is

$$[HI^-]_a = [C_{H_2I}]_a A_1 \quad \text{or} \quad [C_{H_2I}]_a = \frac{[HI^-]_a}{A_1} \quad \text{(Eq. 7)}$$

Substituting Eq. 6 and 7 in Eq. 3 and rearranging gives

$$[C_{H_2I}] - S = \frac{[HI^-]_a}{A_1} + D[HI^-]_a \frac{A_0}{A_1}$$

or

$$[C_{H_2I}] - S = [HI^-]_a \left[\frac{1}{A_1} + D\frac{A_0}{A_1}\right]$$

or

$$[C_{H_2I}] - S = [HI^-]_a \left[\frac{1}{A_1} + D\frac{[H^+]}{K_1}\right]$$

therefore,

$$[HI^-]_a = [[C_{H_2I}] - S] \frac{A_1 K_1}{K_1 + A_1 D[H^+]} \quad \text{(Eq. 8)}$$

To solve for $[Th^+]_a$ in terms of $[H^+]$, K_3 and $[C_{Th}]$ let $[C_{Th}] = [C_{Th}]_a + [Th]_c + S$. Since $[Th]_c$ is very small (Table IV), the equation becomes

$$[C_{Th}] = [C_{Th}]_a + S \quad \text{(Eq. 9)}$$

The expression for determining $[Th^+]_a$ in an aqueous solution is

$$[Th^+]_a = [C_{Th}]_a \frac{K_3}{[H^+] + K_3}$$

or

$$[C_{Th}]_a = [Th^+]_a \frac{[H^+] + K_3}{K_3} \quad \text{(Eq. 10)}$$

Substituting Eq. 10 in 9 we obtain $[C_{Th}] - S = [Th^+]_a [[H^+] + K_3/K_3]$ or

$$[[C_{Th}] - S] \frac{K_3}{[H^+] + K_3} = [Th^+]_a \quad \text{(Eq. 11)}$$

Substituting the values of $[HI^-]_a$ and $[Th^+]_a$ from Eqs. 8 and 11 into Eq. 2 we obtain the following final equation:

$$K \left\{[(C_{H_2I}) - S] \frac{A_1 K_1}{K_1 + A_1 D[H^+]} \times [(C_{Th}) - S] \frac{K_3}{[H^+] + K_3}\right\} - S = 0 \quad \text{(Eq. 12)}$$

To prove the validity of Eq. 12 known values were substituted for the various terms and the equation solved for S with the aid of an IBM 7094 computer.[1]

[1] Computer Center, University of Georgia, Athens, Ga.

The values used were as follows: $K = 3.0 \times 10^5$ l./mole (Table II). $[C_{H_2I}] = 2 \times 10^{-4}$, 1×10^{-4}, and 0.5×10^{-4} moles/l. (same as the experimental concentrations). $[C_{Th}] = 1.186 \times 10^{-5}$ moles/l. (usual concentration used for the assay). D = Distribution coefficient of the dye (Table III). $K_1 = 1$. Bromothymol blue is a strong acid dye and should have more than one pKa value. It was found that bromothymol blue undergoes a color change from deep red to deep yellow between theoretical pH values of -1 and 1, therefore, the first pKa value was estimated to be approximately zero.

$K_2 = 1.0 \times 10^{-7}$ (*Reference 7*)

$K_3 = 1.58 \times 10^{-5}$ (*Reference 8*)

$[H^+]$-different values ranging from 1×10^{-1} to 1×10^{-11}. Results are presented in Table I and Fig. 1.

DISCUSSION

Several factors strongly influenced the extractability of thiamine dye salt in the organic phase. A change in dye concentration affects the amount of

TABLE I—EFFECT OF pH AND DYE CONCENTRATION ON THE CONCENTRATION OF THIAMINE DYE SALT EXTRACTED IN CHLOROFORM (ACCORDING TO EQUATION 12)[a] WHEN THIAMINE CONCENTRATION IS 1.186×10^{-5} MOLE/l.

[a] Similar results were obtained when solved quadratically.

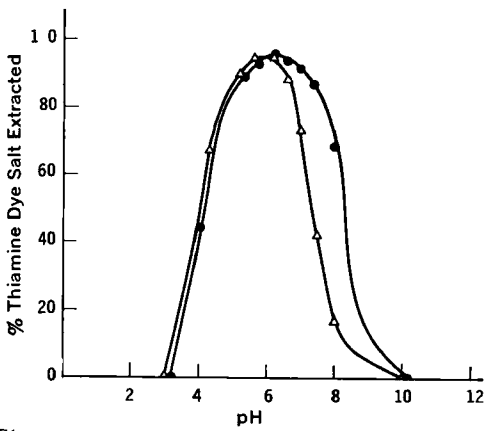

Fig. 1—Effect of pH on the extraction of thiamine dye salt when dye concentration is 1×10^{-4} mole/l. Key: ●, theoretical; Δ, experimental. Data taken from Table II, Reference 1.

salt extracted by the first 10-ml. portion of chloroform (1). This can be explained by Eq. 1.

$$K = \frac{S}{[HI^-]_a\,[Th^+]_a}$$

From this equation it can be seen that if $[HI^-]_a$ decreases S will decrease to keep K constant.

The change in the amount of thiamine dye salt extracted by the first 10-ml. portion of chloroform with a change in pH (1) can also be explained by Eq. 1. Since K is constant it is apparent that a change in the concentration of either $[HI^-]_a$ or $[Th^+]_a$ will change the value of S.

Using Eq. 1, a theoretical equation (Eq. 12) was derived (*viz. Theoretical*) to determine the changes in the amount of thiamine dye salt extracted with changes in pH. This equation was programmed for an IBM 7094 computer, and when solved within the pH range of 1–11, the amount of thiamine dye salt predicted was in excellent agreement with the experimental data (Fig. 1). Between the pH range of 7.0 to 8.0, the theoretical values were higher than the experimental values probably due to an error introduced by using the reported value for K_2 (10^{-7}). A K_2 value of 10^{-6} for bromothymol blue gave better theoretical results. The K_1 value of bromothymol blue was not in good agreement with the value reported by Schill (9), however, changes in K_1 values on either side of the approximated value did not affect the results.

The experimental and theoretical data indicate that the extraction of thiamine dye salt with a single 10-ml. portion of chloroform, between the pH range of 5.2–6.6 is greater than 88.4% (Fig. 1). This pH range appears to be the best since three 10-ml. portions of chloroform will extract more than 99.8% of thiamine dye salt.

Although the above equation was derived specifically for a thiamine-bromothymol blue system, no such limitations are placed on this mathematical expression. Therefore, it is suggested that [Th] can be any base and $[H_2I]$ can be any acidic dye. This would provide a theoretical foundation for the well-documented empirical observations of the dependence of the concentration of salt extracted on pH.

The site of reaction in thiamine may be either the amino group of the pyrimidine moiety or the quaternary nitrogen of the thiazole moiety. The amino group may be reacting with the sulfonic acid group of the dye since it is possible to form the salt by directly adding thiamine mononitrate and bromothymol blue in chloroform. On the other hand Eq. 1 predicts the possibility of reaction between the quaternary nitrogen and the sulfonic acid group as follows:

$$HI^- + TH^+ = [HI^-\,TH^+]$$

EXPERIMENTAL

Reagents—All chemicals and reagents used were either USP, NF, or ACS grade. Bromothymol blue was purchased from Fisher Scientific Company and was used without further purification.

Solutions—Various solutions were prepared using procedures as reported earlier (1). The ionic strength of the solutions was not adjusted but solutions were prepared in 0.05 M phosphate buffer.

Analytical Procedures—Procedures for determination of thiamine dye salt in organic phase, determination of dye in aqueous and organic phases, and determination of thiamine in aqueous and organic phases have been described (1).

Determination of Equilibrium Constant—The equilibrium constant was determined at three different pH values (5.6, 6.0, and 6.5). To run these experiments solutions containing 10 mcg./ml. of thiamine mononitrate were prepared in various buffer solutions and the thiamine dye salt determined according to *Procedure B* of a previous report (1). Thiamine in the aqueous phase was determined by the USP method (10) and the dye in the aqueous phase was determined by the method described earlier (1).

To determine the equilibrium constant the thiamine mononitrate present in the aqueous phase was assumed to be completely undissociated since the pKa of thiamine mononitrate is 4.8. The concentration of the dissociated dye $(HI^-)_a$ in the aqueous phase was calculated using Eq. 7. Results of the experiments are presented in Table II.

Determination of Distribution Coefficients—To determine the distribution coefficient (D) for bromothymol blue, 10.0 ml. of buffer solution of appropriate pH was vigorously shaken with 10.0 ml. of dye in chloroform solution ($6.7 \times 10^{-5} M$) in a 125-ml. separator for 1 min. The phases were allowed to separate and the dye content in both phases was determined using previously described methods (1). To determine the distribution coefficient the concentration of the undissociated dye in the aqueous phase was calculated using Eq. 5. Results are presented in Table III.

TABLE II—DISTRIBUTION OF THIAMINE AND DYE BETWEEN CHLOROFORM AND WATER (AT VARIOUS pH VALUES) FOR THE DETERMINATION OF EQUILIBRIUM CONSTANT[a]

Structure and Activity Relationships in Molluscicides

By I. NABIH* and M. T. ELWASIMI

Noninfected snails of the *Biomphalari* and *Bulinus* types (intermediate hosts for *Schistosoma mansoni* and *Schistosoma hematobium*, respectively) can oxidize instantly and intensively *p*-phenylenediamine dihydrochloride and its derivatives to the corresponding colored trivalent nitrogen-free radicals. This reaction fails to occur with snails infected with miracedia of *Schistosomes*. The reaction is inhibited through inhibitors specific for enzymes of the protoporphyrin type, also through the potent molluscicide (bayluscide). Studies revealed the enzyme involved in the reaction is the peroxidase, along with the catalase. Both enzymes were found to be present in both types of snails.

BILHARZIASIS is a world health problem; it infects millions of people all over the world and causes a tremendous loss in economy and manpower.

To bring the disease under control different aspects would be encountered, mainly the irradication of snails, the intermediate vector of the parasite, through the application of molluscicides. The chemotherapy of the disease is still inadequate particularly in the areas where infection is widely distributed, due to the serious side effects the available agents exhibit when given either orally or by injection.

In the development and search for new molluscicides, extensive work that included investigations of thousands of compounds (mostly of phenolic type) was carried out (1–3). These investigations showed that activity of these phenolic compounds depends upon the nature of substituents on the aromatic ring. The most active were pentachlorophenol and 2,4-dinitro-6-

cyclohexylphenol, whereas those bearing bulky groups on the ring were inactive, *e.g.*, 2,6-di-*t*-butylphenol. Also compounds of the quinoid structure such as benzoquinone and naphthoquinone showed significant activity. Of the aminophenols, 4-aminophenol was active while 2- and 3-aminophenols were inactive. The sample of 4-aminophenol used by the investigators was described to be colored, thus suggesting the transformation to quinoimine or benzoquinone. It had also been suggested that it may be worthwhile to consider the possibility of the conversion of those active phenols within the snails' body to quinoid-type substances with the toxic effect due to that type (3).

Chemically, many phenols can be oxidized to form a phenoxy radical, which may lead to a quinoid-type structure through dimerization or disproportionation. The transformation depends upon the nature of the substituents on the aromatic ring, *e.g.*, 4-substituted 2,6-di-*t*-butylphenoxy radical is a reasonably stable species in solution (4), also the dimerization of 2,4,6-tri-*t*-butylphenoxy radical is inhibited through the bulky *t*-butyl groups (5). This may explain the failure of those phenols bearing bulky groups to show any molluscicidal activity as the apparent biologically formed phenoxy radical, that may undergo the subsequent transformation to the quinoid structure, is prohibited by these bulky substituents on the ring.

This correlation between the molluscicidal activity of those types of phenols bearing nonbulky groups and the chemical oxidation of related types to quinones *via* free radical suggested the present work, to study the possibility of the biological formation of free radicals by snails and to detect the biological system involved in this process.

p-Phenylenediamine and its derivatives were chosen as substrates as they can be chemically oxidized to the colored trivalent nitrogen-free radicals that include the so-called "Wurster's salts." The color formation renders a possible spectrophotometric means to detect and follow the different effects on the reaction. These radicals are formed, chemically, through the oxidation of *p*-phenylenediamine derivatives, *e.g.*, with bromine (6).

Two representatives of this group, namely *p*-phenylenediamine dihydrochloride (I) and *N,N*-dimethyl-*p*-phenylenediamine dihydrochloride (II) were chosen. Both are readily soluble in water and can be prepared in a high state of purity by methods described by Nabih (7) and Michaelis (6), respectively.

Both compounds were submitted independently in appropriate dilutions to the biological action of two types of freshly collected water snails acting as the intermediate hosts for *Schistosoma mansoni* and *Schistosoma hematobium*, namely *Biomphalaria alexandrina* and *Bulinus truncatus*, respectively.

Both types can oxidize I instantly in the typical transformation pathway that usually follows when it is chemically oxidized with bromine, a transient yellow color forms, turning to green. Spectroscopic measurements showed the product to be identical with that obtained through the chemical oxidation, having absorption maxima at 462 mμ and 479 mμ (8).

Also, both types of snails were able to oxidize II to an intensive red color. Spectroscopic measurements showed the product to be identical with the corresponding free radical obtained when II was submitted to the chemical oxidation with one equivalent of bromine. It showed absorption maxima at wavelengths of 515 and 550 mμ (8).

When an excess of snails was used in the reaction, then the color of the solution faded and gradually disappeared. The same disintegration of color occurred when its solution was treated with a second equivalent of bromine to change it to the corresponding *p*-quinonediimine form (9) (Fig. 1).

When these experiments were applied on snails of the *Biomphalaria* type infected with *miracidia* of *Schistosome* using II as the substrate, the characteristic red color of the free radical either developed in a slow and faint pattern or did not at all (Fig. 2). This technique offered an easy and rapid way to differentiate between infected and noninfected snails when collected in patches from the field.

These findings suggested the presence of the enzyme peroxidase in the snail's body that may be involved in these transformation processes.

Peroxidase is an enzyme that contains a ferriprotoporphyrin hematin prosthetic group. It acts on hydrogen peroxide to cause catalytic oxi-

dation of many organic compounds of the amine type, *e.g.*, *p*-phenylenediamine (10), phenolic type (11), and hydroquinones (12, 13).

It catalyzes generally the reaction:

$$AH_2 + H_2O_2 \rightarrow 2H_2O + A$$

The proposed mechanism of action goes through a free radical intermediate (14).

The authors' studies showed that cyanide, sulfide, and azide, inhibitors specific for enzymes of the protoporphyrin type, could inhibit the foregoing reactions when applied under the same experimental conditions on solutions of II (Fig. 3).

They also tried the inhibitory effect of the potent molluscicide, 5,2′-dichloro-4-nitrosalicylanilide (bayluscide) which showed an inhibitory effect on the reaction.

Further, when freshly collected snails of both types were placed in a hydrogen peroxide solution of an appropriate dilution ($1 \times 10^{-3}M$) evolution of gaseous oxygen took place. This suggested the presence of the enzyme catalase, beside the peroxidase. Both enzymes are closely related and are referred to as hydroperoxidases as both use hydrogen peroxide as a common substrate. Snails infected with *Schistosoma mansoni* did not show the same decomposing effect on hydrogen peroxide as the noninfected snails (Fig. 4).

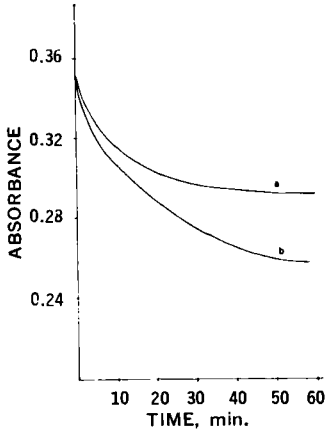

Fig. 4—Rate of decomposition of hydrogen peroxide. Key: a, *infected* Biomphalaria *snail;* b, *noninfected* Biomphalaria *snail.*

The inhibitory effect of some agents that can block the catalytic decomposition of hydrogen peroxide to its components (oxygen and water) have been investigated in connection with the snails' reaction, including cyanide, azide, sulfide, fluoride, hydroxylamine, and bayluscide.

Estimations of the rate of decomposition were made from titrimetric and spectrophotometric measurements for the residual peroxide.

These studies suggest the presence of both enzymes, peroxidase and catalase, in the snail's body, which are the specific catalysts for the foregoing reactions. The former is apparently involved in the biological oxidation of compounds of phenolic and amine types to quinones through the initial formation of free radicals within the snail's body. The quantitative assays for each in some different species of snails are now under determination and will be reported later.

MATERIALS AND METHODS

Preparation of Materials

p-Phenylenediamine Dihydrochloride (I)—Prepared in a high state of purity either by the method described in (7) or through the direct passage of dry HCl gas in absolute ethanol solution of pure *p*-phenylenediamine, then purified and recrystallized (6).

N,N-Dimethyl p-Phenylenediamine Dihydrochloride (II)—It could be obtained in a pure form by the passage of dry HCl gas in dry ether solution of

the free base, followed by purification and recrystallization (6).

The solutions of I and II used in all experiments were freshly prepared in bidistilled water solution.

All spectrophotometric measurements were run on a Unicam Sp. 500 spectrophotometer and cells with a light path of 1 cm.

The snails used were freshly collected from the field.

Oxidative Effect of Biomphalaria Snails on I

One snail of the *Biomphalaria* type (diameter 9 mm.) was immersed in 20 ml. (1×10^{-3} *M*) solution of I. The color developed instantly; after 2 min. the snail was removed and the spectroscopic measurements were run.

These measurements showed peaks of maximum absorption at 462 and 479 mμ (6).

The same peaks appeared when the measurements were run on the formed colored solution when a *Bulinus* snail (7 mm. diameter) was treated as above, with *Biomphalaria*, using I ($1 \times 10^{-3}M$) solution, as substrate.

Oxidative Effect of Biomphalaria Snails on II

One snail of the *Biomphalaria* type (diameter 7 mm.) was immersed in 20 ml. ($1 \times 10^{-3}M$) solution of II; after 2 min., the snail was removed and the absorption spectrum for the developed color was determined. Two peaks showed at 515 and 550 mμ (6).

The same peaks appeared when a snail of the *Bulinus* type (7 mm. diameter) was similarly treated as above using II in solution as substrate.

Further Oxidative Effect of Biomphalaria Snails on II—Fifty snails of nearly equal diameters (mean diameter 1 cm.) immersed in 20 ml. ($1 \times 10^{-3}M$ solution) of II. After 10 hr. the solution became colorless and spectrophotometric measurements were run (Fig. 1-*a*). Parallel, a bromine water solution was added to 10 ml. (1×10^{-3} *M* solution) of II till the red color disappeared, then spectrophotometric measurements were run (Fig. 1-*b*).

Oxidative Effect of Noninfected and Infected Biomphalaria Snails on II—A noninfected snail (8 mm. diameter) was immersed in 10 ml. ($1 \times 10^{-3}M$ solution) of II; the variation in absorbance was measured against time at wavelength 515 mμ (Fig. 2-*a*). The same was run using an infected snail (8 mm. diameter) (Fig. 2-*b*). Similar results were obtained with noninfected and infected snails of the *Bulinus* type.

The Inhibitory Effect of Some Agents on Color Development with II Using Biomphalaria Snails—The color developed by II using *Biomphalaria* snails is compared in five experiments using one snail (1 mm. diameter each) for each experiment:

a, 5 ml. of II ($1 \times 10^{-3}M$) + 5 ml. bidistilled water
b, 5 ml. of II ($1 \times 10^{-3}M$) + 5 ml. sodium azide ($1 \times 10^{-2}M$)
c, 5 ml. of II ($1 \times 10^{-3}M$) + 5 ml. *bayluscide* ($1 \times 10^{-3}M$)
d, 5 ml. of II ($1 \times 10^{-3}M$) + 5 ml. KCN ($1 \times 10^{-4}M$)
e, 5 ml. of II ($1 \times 10^{-3}M$) + 5 ml. Na_2S ($2 \times 10^{-4}M$)

Spectrophotometric measurements were run every 10 min. (Fig. 3) at a wavelength of 515 mμ.

Decomposing Effect of Noninfected and Infected Snails of Biomphalaria Type on H_2O_2 Solution—A noninfected snail (8 mm. diameter) was immersed in 10 ml. ($1 \times 10^{-3}M$ solution) of H_2O_2. An infected snail (8 mm. diameter) was immersed in 10 ml. ($1 \times 10^{-3}M$ solution) of H_2O_2. Spectrophotometric measurements, at a wavelength of 240 mμ, were carried out every 5 min. for both solutions. The results show that the rate of decomposition with the infected snail is slower than with the noninfected one (Fig. 4).

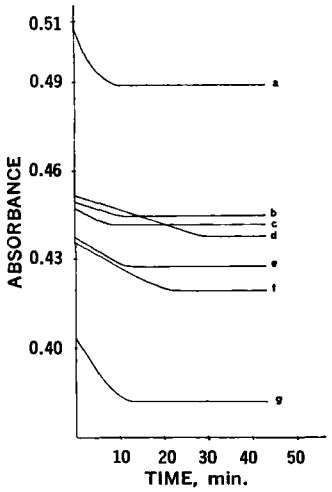

Fig. 5—Rate of decomposition of hydrogen peroxide by Biomphalaria *snails in presence of different inhibitors. Key:* a, *sulfide;* b, *azide;* c, *bayluscide;* d, *fluoride;* e, *hydroxylamine;* f, *cyanide;* g, *without.*

Rate of Decomposition of Hydrogen Peroxide by Fresh Snails and its Inhibition by Different Inhibitors—Decomposition was spectrophotometrically measured through changes in the absorbance at 240 mμ, using for each measurement one snail of *Biomphalaria* type (8 mm. diameter) + 5 ml. H_2O_2 ($1 \times 10^{-2}M$) + 5 ml. of the inhibitor of the following concentrations (Fig. 5):

a, Na_2S ($2 \times 10^{-5}M$)
b, Sodium azide ($2 \times 10^{-3}M$)
c, Bayluscide ($2 \times 10^{-4}M$)
d, Sodium fluoride ($2 \times 10^{-3}M$)
e, Hydroxylamine hydrochloride ($2 \times 10^{-3}M$)
f, Potassium cyanide ($2 \times 10^{-5}M$)
g, Bidistilled water as control.

The results show that the rate of decomposition of the peroxide is depressed through the presence of the inhibitors.

Salt Effects in the Spectrophotometric Examination of a Complex of *N'*-Methylnicotinamide Cation

By DANA BROOKE* and DAVID E. GUTTMAN†

The extent of complex formation, as determined spectrally, between the *N'*-methylnicotinamide cation and the electron donor, 8-chlorotheophyllinate anion, was found to vary greatly when different salts were used to adjust ionic strength. The degree of complex formation when sodium perchlorate was used was found to be much smaller than when sodium acetate was used. An examination of these salt effects indicated that the observed behavior was explicable on the basis that ion pair formation occurred between the pyridinium cation and perchlorate anion.

THE NECESSITY of maintaining a constant ionic strength in studying the behavior of ionic species in solution is widely recognized. It is not, perhaps, so widely appreciated that a so-called inert salt introduced for this purpose can exert an effect quite different from that anticipated solely on the basis of ionic strength variation. Recent studies in this laboratory involving the interaction of *N'*-methylnicotinamide cation (NMN) with 8-chlorotheophyllinate anion (CT) have demonstrated quite dramatically that neutral salts can influence observed behavior independently of their contribution to the maintenance of ionic strength. As will be seen, the extent of interaction of NMN with CT, as detected spectrally, was found to vary considerably depending on whether sodium acetate or sodium perchlorate was used to maintain a constant ionic strength. The observed behavior can be reasonably explained on the basis that extensive ion pair formation occurred between perchlorate anion and NMN.

Ion pairing of quaternary nitrogen compounds is well documented. For example, Azzari and Kraus (1) reported the formation of ion pairs between the tetrabutyl ammonium cation and such anions as iodide, bromide, and nitrate in water at 25°. Fuoss (2) showed that ionic associations could be treated by mass law considerations, and he and his co-workers (3) reported the ion pair formation constant for the tetraethyl ammonium-picrate ion pair to be 0.8 L. mole^{-1} in water. Kosower (4), in a description of charge transfer interactions, asserted that the major contributing form to the ground state complex between 1-methyl-pyridinium cation and iodide anion was the ion pair.

EXPERIMENTAL

Materials—The chloride salt of NMN was prepared by the method of Huff and Perlzweig (7). Nicotinamide was reacted with an excess of methyl iodide in alcohol to yield NMN as the iodide salt, m.p. 204° uncorrected [reported, 205.5–206.5° (7)]. The iodide salt was converted to the chloride salt by reacting the NMN iodide with an aqueous slurry of silver chloride. The resulting aqueous solution of NMN chloride was filtered and concentrated to yield white crystals of NMN chloride. The chloride salt was recrystallized from hot alcohol, and gave a m.p. of 241° uncorrected [reported, 237–238° (7)].

8-Chlorotheophylline was purchased from the Aldrich Chemical Co. and used without further puri-

Salt Effects in the Spectrophotometric Examination of a Complex of *N'*-Methylnicotinamide Cation

By DANA BROOKE* and DAVID E. GUTTMAN†

The extent of complex formation, as determined spectrally, between the *N'*-methylnicotinamide cation and the electron donor, 8-chlorotheophyllinate anion, was found to vary greatly when different salts were used to adjust ionic strength. The degree of complex formation when sodium perchlorate was used was found to be much smaller than when sodium acetate was used. An examination of these salt effects indicated that the observed behavior was explicable on the basis that ion pair formation occurred between the pyridinium cation and perchlorate anion.

THE NECESSITY of maintaining a constant ionic strength in studying the behavior of ionic species in solution is widely recognized. It is not, perhaps, so widely appreciated that a so-called inert salt introduced for this purpose can exert an effect quite different from that anticipated solely on the basis of ionic strength variation. Recent studies in this laboratory involving the interaction of *N'*-methylnicotinamide cation (NMN) with 8-chlorotheophyllinate anion (CT) have demonstrated quite dramatically that neutral salts can influence observed behavior independently of their contribution to the maintenance of ionic strength. As will be seen, the extent of interaction of NMN with CT, as detected spectrally, was found to vary considerably depending on whether sodium acetate or sodium perchlorate was used to maintain a constant ionic strength. The observed behavior can be reasonably explained on the basis that extensive ion pair formation occurred between perchlorate anion and NMN.

Ion pairing of quaternary nitrogen compounds is well documented. For example, Azzari and Kraus (1) reported the formation of ion pairs between the tetrabutyl ammonium cation and such anions as iodide, bromide, and nitrate in water at 25°. Fuoss (2) showed that ionic associations could be treated by mass law considerations, and he and his co-workers (3) reported the ion pair formation constant for the tetraethyl ammonium-picrate ion pair to be 0.8 L. mole^{-1} in water. Kosower (4), in a description of charge transfer interactions, asserted that the major contributing form to the ground state complex between 1-methyl-pyridinium cation and iodide anion was the ion pair.

EXPERIMENTAL

Materials—The chloride salt of NMN was prepared by the method of Huff and Perlzweig (7). Nicotinamide was reacted with an excess of methyl iodide in alcohol to yield NMN as the iodide salt, m.p. 204° uncorrected [reported, 205.5–206.5° (7)]. The iodide salt was converted to the chloride salt by reacting the NMN iodide with an aqueous slurry of silver chloride. The resulting aqueous solution of NMN chloride was filtered and concentrated to yield white crystals of NMN chloride. The chloride salt was recrystallized from hot alcohol, and gave a m.p. of 241° uncorrected [reported, 237–238° (7)].

8-Chlorotheophylline was purchased from the Aldrich Chemical Co. and used without further puri-

fication. Other chemicals were reagent grade and were obtained from Fisher Scientific Co.

Methods—The influence of sodium acetate and sodium perchlorate on the extent of complex formation between NMN and CT was evaluated by using either neutral salt, or a combination of the two, to adjust the ionic strength of solutions containing the interactants to a value of 1.0. These solutions were prepared by dissolving appropriate amounts of 8-chlorotheophylline, pKa 5.5 (6), and neutral salts in about 35 ml. of water, using enough sodium hydroxide to adjust the pH to a value of 8.0. These were placed in 50-ml. volumetric flasks and aliquots of a stock solution of NMN as the chloride salt were added to the flasks which were then made to volume to gain the desired concentrations. The ionic strength of the resultant solutions was taken as the sum of the concentrations of sodium acetate, sodium perchlorate, and sodium 8-chlorotheophyllinate. The concentration of NMN as the chloride was negligible compared to the concentrations of other ionic species. The resultant solutions were brought to 40° in a water bath. The extent of complex formation was measured spectrally at 40° using a Beckman, model DB, spectrophotometer equipped with a thermostated cell compartment. The large increase in absorbance at 360 mμ of solutions of CT on the addition of NMN, a species with no visible spectrum, was taken as a measure of the extent of interaction between NMN and CT. Absorbance values were corrected for the small contribution due to CT. Representative spectra are shown in Fig. 1.

RESULTS AND DISCUSSION

Spectral evidence for a postulated complex of NMN and CT is given in Fig. 1. It can be seen that the extent of complex formation was decreased by increasing the ionic strength from a value of 0.1 to a value of 1.0 with the addition of sodium acetate or sodium perchlorate. Though a decrease with increasing ionic strength was expected on a theoretical basis, the marked difference in the extent of interaction observed when the different salts were employed was unexpected. The results of a number of experiments are given in Table I, all of which illustrate the same behavior.

That the extent of interaction between NMN and CT is influenced differently by the two salts can be explained on the basis of a rather simple model which assumes that NMN forms ion pairs with perchlorate anion. As a first approximation, based on the much larger influence of sodium perchlorate, it was assumed that acetate anion was not involved in ion pair formation. The model neglects possible differences in activity coefficients, hydration, and ion size parameters of unassociated NMN and CT in the presence of the different salts, and attributes the larger influence of perchlorate to a competitive effect. The model is summarized by

$$\mathrm{NMN} + \mathrm{CT} \overset{K}{=} \mathrm{NMN{:}CT} \qquad \text{(Eq. 1)}$$

$$\mathrm{NMN} + \mathrm{ClO_4} \overset{G}{=} \mathrm{NMN{:}ClO_4} \qquad \text{(Eq. 2)}$$

where NMN:CT = 1:1 complex formed between NMN and CT, K = association constant for the formation of NMN:CT, $\mathrm{NMN{:}ClO_4}$ = 1:1 ion pair formed between NMN and perchlorate, G = ion pair formation constant for $\mathrm{NMN{:}ClO_4}$.

The absorbance, A, due to the complex, NMN:CT can be written as

$$A = \epsilon(\mathrm{NMN{:}CT}) = \epsilon K(\mathrm{NMN})(\mathrm{CT}) \qquad \text{(Eq. 3)}$$

where ϵ = molar absorptivity of the complex.

The absorbance can be stated in terms of total NMN, $(\mathrm{NMN})_t$, as

TABLE I—ABSORBANCE VALUES AT 360 mμ DUE TO COMPLEX FORMED BETWEEN NMN AND CT IN VARIOUS SOLUTIONS ADJUSTED TO AN IONIC STRENGTH OF 1.0

0.21	0.0025	0.79	0.00	0.214	0.222	−0.008

[a] Corrected for the absorbance contribution due to CT.

$$A = \frac{\epsilon K(\mathrm{NMN})_t\,(\mathrm{CT})}{1.0 + K(\mathrm{CT}) + G(\mathrm{ClO_4})} \quad \text{(Eq. 4)}$$

Equation 4 can be rewritten as

$$\frac{1}{A} = \frac{1}{\epsilon K(\mathrm{NMN})_t(\mathrm{CT})} + \frac{1}{\epsilon(\mathrm{NMN})_t} + \frac{G(\mathrm{ClO_4})}{\epsilon K(\mathrm{NMN})_t(\mathrm{CT})} \quad \text{(Eq. 5)}$$

Equation 5 is essentially the same as that derived by Merrifield and Phillips (8) for a case in which both a solvent and an electron donor interacted with an electron acceptor but the solvent-acceptor complex did not contribute to the absorbance of the system. When $(\mathrm{NMN})_t$ and (CT) are held constant, plots of $1/A$ against $(\mathrm{ClO_4})$ should be straight lines. Such plots are given in Fig. 2. The value of $G/\epsilon K$ can be calculated by multiplying the slopes of the lines by the appropriate $(\mathrm{NMN})_t(\mathrm{CT})$ product. The intercepts of the lines in Fig. 2. multiplied by the appropriate $(\mathrm{NMN})_t$, when plotted against $1/(\mathrm{CT})$ should give a straight line with intercept $1/\epsilon$ and slope $1/\epsilon K$. This plot, which corresponds to a Benesi-Hildebrand (5) plot, is given in Fig. 3. The values for ϵ, K, and G calculated in this manner are 359 L. mole^{-1} cm.$^{-1}$, 2.69 L. mole^{-1}, 0.92 L. mole^{-1}.

Treatments such as the one used here depend heavily upon a knowledge of the value $1/\epsilon$. Since this value is small, a small absolute error in the determination of $1/\epsilon$ can lead to large errors in ϵ, and in the association constants. An attempt was made to evaluate the association constants independently of a determination of ϵ. This can be done by considering two experimental points at one time. It can be shown that

$$\frac{A1}{A2} = \frac{(\mathrm{NMN1})_t(\mathrm{CT1})[1.0 + K(\mathrm{CT2}) + G(\mathrm{ClO_4}2)]}{(\mathrm{NMN2})_t(\mathrm{CT2})[1.0 + K(\mathrm{CT1}) + G(\mathrm{ClO_4}1)]} \quad \text{(Eq. 6)}$$

where 1 and 2 refer to two different experimental systems. The values for K and G were generated, according to Eq. 6, on an IBM 7044 computer. The values for K and G were found to be 2.67 L. mole^{-1}, and 0.86 L. mole^{-1}. The corresponding value of ϵ was calculated to be 355 L. mole^{-1} cm.$^{-1}$.

The calculated absorbance values given in Table I are based upon the computer generated values of K, G, and ϵ. The random distribution of the difference cited in Table I indicates that the observed differences in the effects of sodium acetate and sodium perchlorate can be reasonably explained on the basis of ion pair formation between NMN and perchlorate. The treatment presented here does not preclude the possibility of ion pairing between acetate anion and NMN but does suggest that such ion pairing is small compared with the association between NMN and perchlorate.

It is interesting to note that the definition of a particular ionic behavior may vary quantitatively depending upon the "inert" salt used for the purpose of adjusting ionic strength. In the present investigation, the apparent association constant for the NMN:CT complex in systems in which sodium perchlorate was the salt used was found to be 1.52 L. mole^{-1} by the Benesi-Hildebrand (5) treatment. When sodium acetate was the salt used the apparent association constant was found to be 2.59 L. mole^{-1}. This observation makes it clear that the effects of neutral salts cannot always be judged solely on the basis of their contribution to the maintenance of ionic stength.

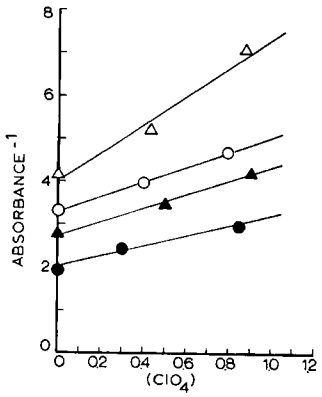

Fig. 2—Plot, based on Eq. 5, illustrating the dependence of complex formation on perchlorate concentration. Solutions contained: 0.14 M CT and 0.0025 M NMN (△), 0.21 M CT and 0.0025 M NMN (○), 0.10 M CT and 0.005 M NMN (▲), 0.15 M CT and 0.005 M NMN (●).

Aminolysis of Benzylpenicillin by Aliphatic Diamines

By MICHAEL A. SCHWARTZ

The kinetics of reaction of penicillin with a series of aliphatic diamines, $NH_2(CH_2)_nNH_2$ (n = 2–6), show terms both first order and second order in diamine. The second-order terms are basicity dependent and account for general base-catalyzed nucleophilic attack by the monoprotonated species. The first-order term includes a contribution by both monoprotonated and unprotonated diamine. An argument in favor of intramolecular general base catalysis by the latter is given and the possible relationship between this mechanism and penicillin antigen formation is discussed.

DIRECT AMINOLYSIS of penicillins by ε-amino groups of lysine residues on proteins has been shown to occur (1, 2) and may be involved in the *in vivo* formation of the penicilloyl-protein conjugate which is considered to be the principal antigenic determinant in penicillin allergy (3). Aminolysis of penicillin by primary amines is however a relatively slow reaction at neutral pH because there is usually only a small fraction of the amine present in the nucleophilic unprotonated form. Investigation of the mechanism of reaction of glycine with penicillins (4) revealed participation by two molecules of glycine anion demonstrating a requirement for general base catalysis. This result indicated that reaction of an amine with penicillin might be more rapid where a second amino group was present on the same molecule and intramolecular general base catalysis could occur. To test this hypothesis studies were conducted of the reaction of benzylpenicillin with a series of aliphatic diamines [$NH_2(CH_2)_nNH_2$ with n = 2 through 6] and the results are reported herein.

EXPERIMENTAL

Materials—Benzylpenicillin was kindly supplied by Bristol Laboratories as the potassium salt. The aliphatic diamines were obtained as, or converted to, the dihydrochloride salts and recrystallized from aqueous methanol. All other materials were reagent grade.

Rate Studies—All measurements were made at 35°. Generally the diamine solution, adjusted to the desired pH with sodium hydroxide, acted as both buffer and reactant. In some cases where the buffer capacity was too low constant pH was maintained by a radiometer TTT-1 pH-stat. Ionic strength was kept constant throughout the study by addition of KCl to the reaction mixture. Initial penicillin concentration was 1.0×10^{-3} M and the diamine concentration was always in excess (above 0.04 M).

The rate of penicillin loss was followed by one of two methods: (*a*) Samples of reaction mixture were removed at appropriate intervals and assayed for residual penicillin by the method of Brandriss *et al.* (5). (*b*) The change in optical rotation of the solution was followed at 313 mμ with the Perkin-Elmer model 141 photoelectric polarimeter with Sargent SR recorder (2.5 mv.). Opening of the β-lactam of penicillins is accompanied by a large decrease in optical rotation. In some instances where both methods were utilized excellent agreement in the results was observed.

The acid dissociation constants (pKa′) of the diamines were determined at 35° and ionic strength 0.5 by potentiometric titration, and the overlapping constants separated by the method of Noyes (6). The values are presented in Table I (see results).

RESULTS

Since the diamine concentration was in excess of penicillin first-order kinetics was observed at constant pH. The rate constants (k_{obs}) were determined either from plots of log penicillin concentration *versus* time when the assay method was employed, or Guggenheim treatment of the optical rotation data. In either case excellent linearity was observed through at least two half-lives and generally through 3–4 half-lives.

Plots of $k_{obs.}$ at constant pH as a function of diamine concentration showed an upward curvature with increasing diamine, indicating an order greater than unity in base. Linearity was observed however when $k_{obs.}/B_T$ was plotted against B_T, where B_T represents the total concentration of all species of diamine present in solution. Figure 1 shows such a plot for 1,3-propanediamine which is typical of those observed with the other diamines. It can be seen from this plot that both the slopes and intercepts vary with pH.

The intercepts, representing terms in the rate law which are first order in diamine, express the sum of rate constants for nucleophilic attack by each of the basic species in solution:

$$\text{Int.} = k_1 f_B + k_2 f_{BH^+} \qquad \text{(Eq. 1)}$$

where f_B is the fraction of the total diamine unprotonated and f_{BH^+} the fraction of monoprotonated species.

Received February 16, 1968, from the Department of Pharmaceutics, School of Pharmacy, State University of New York at Buffalo, Buffalo, NY 14214

TABLE I—SPECIFIC RATE CONSTANTS[a] FOR REACTION OF BENZYLPENICILLIN WITH $H_2N(CH_2)_nNH_2$

n	pK_1'	pK_2'	k_1[b]	k_2[b]	k_3[c]	k_4[c]
2	7.07	9.91	5.3	0.1	0.32	14
3	8.70	10.60	47	0.3	4	—
4	9.45	10.77	25	0.1	9	—
5	9.88	10.85	15	—	21	—
6	10.06	10.80	18	—	39	—

[a] $k_{obs} = k_1[B] + k_2[BH^+] + k_3[BH^+]^2 + k_4[B][BH^+]$. [b] Units are M^{-1} min.$^{-1}$. [c] Units are M^{-2} min.$^{-1}$.

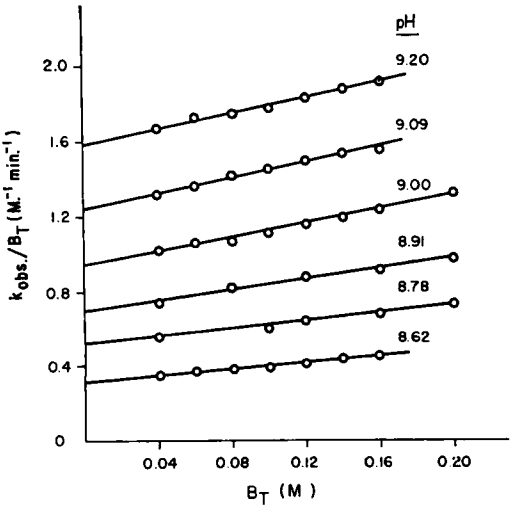

Fig. 1—Plot of k_{obs}/B_T vs. B_T for 1,3-propanediamine as a function of pH.

Dividing by f_{BH^+}:

$$\frac{\text{Int.}}{f_{BH^+}} = k_1 \frac{f_B}{f_{BH^+}} + k_2 \qquad \text{(Eq. 2)}$$

A plot of the left-hand side of Eq. 2 against f_B/f_{BH^+} should be linear with slope k_1 and intercept k_2. A plot of Eq. 2 for 1,3-propanediamine is shown in Fig. 2 and values of k_1 and k_2 were obtained from such plots for all of the diamines. These are given in Table I.

By a similar treatment it was found that the slopes (S) of the lines in Fig. 1 could be fitted by Eq. 3.

$$S = k_3(f_{BH^+})^2 + k_4(f_{BH^+})(f_B) \qquad \text{(Eq. 3)}$$

The values for k_3 and k_4 were determined from plots of $S/(f_{BH^+})^2$ *versus* f_B/f_{BH^+} All of these had zero slope (k_4 = zero) except the line for ethylenediamine where a significant value for k_4 could be determined. The values for k_3 and k_4 are also given in Table I.

Using the constants in Table I slopes and intercepts for lines of the type shown in Fig. 1 were calculated. Table II presents a comparison of these calculated values with those obtained experimentally showing generally good agreement.

DISCUSSION

The rate law for reaction of aliphatic diamines with benzylpenicillin is given in Eq. 4:

$$\text{Rate} = \{k_1[B] + k_2[BH^+] + k_3[BH^+]^2 + k_4[B][BH^+]\}(P) \qquad \text{(Eq. 4)}$$

where P denotes penicillin concentration. With the exception of the term k_2 $[BH^+]$ each of the terms may represent a general base-catalyzed nucleophilic attack by an amine. The k_2 term may denote intramolecular general acid catalysis but makes such a small contribution to the overall rate it is almost negligible. In addition there is considerable error involved in the determination of k_2 from the intercepts of plots of secondary data. The k_4 term is significant only for ethylenediamine and represents general base catalysis of nucleophilic attack by one of the species involved.

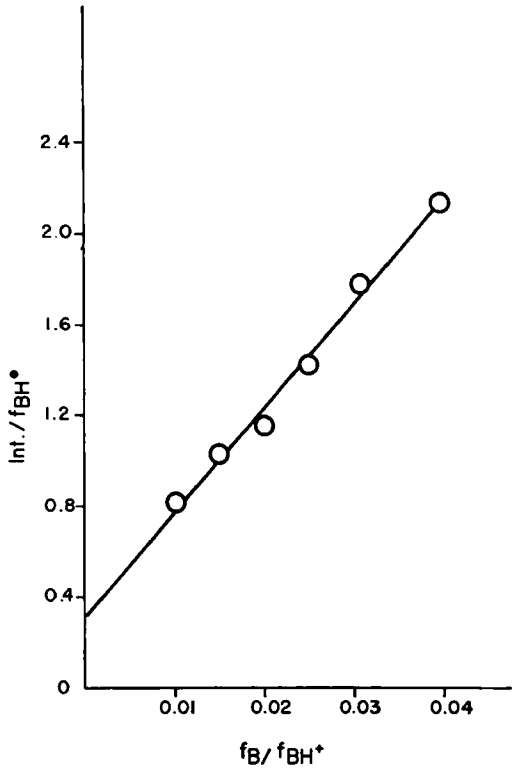

Fig. 2—Plot of equation for 1,3-propanediamine.

The values for k_3 are a function of the basicity of the amine as seen from the typical Bronsted plot in Fig. 3. Comparing the value previously obtained for glycine anion (k = 2.3, pKa = 9.10 at 50°) (4) with this data it may be seen that glycine would fall well below the line. The greater reactivity of the monoprotonated diamines probably reflects the difference in electrostatic charge of the attacking species relative to substrate. The penicillin, which exists as anion in the pH range studied, should attract the amine but tend to repel glycine anion.

There may be some controversy as to whether or not intramolecular general base catalysis does indeed occur in the reaction with the unprotonated diamine.

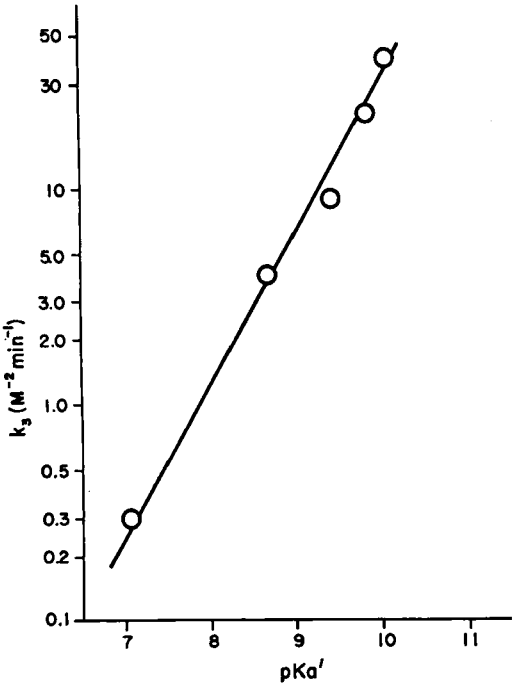

Fig. 3—Bronsted plot of k_3 *(log scale) as a function of* pK_1.

The rate law for reaction of these same diamines with phenyl acetate (7) showed only terms first order in diamine and a conclusion could not be drawn from the data as to whether or not intramolecular catalysis was taking place. On the other hand the kinetics of reactions of glycine with phenyl acetate (8) revealed terms both first and second order in amine while with penicillin as substrate only a second-order term was observed. It appears then that aminolysis of benzylpenicillin requires general base catalysis. These differences between penicillin and phenyl acetate are probably a reflection of the relative susceptibility of these two compounds to nucleophilic attack. Using rates of alkaline hydrolysis as a basis, the ester is much more susceptible, *i.e.*, k_{OH} for penicillin is 12.5 M^{-1}min.$^{-1}$ at 31.5° (9) and for phenyl acetate is 223 M^{-1}min.$^{-1}$ at 30° (10). It has been concluded from studies of aminolysis of phenyl esters that general catalysis becomes of greater significance as the leaving tendency of the phenol decreases (11). The contribution of general base catalysis is probably of more importance with those substrates less susceptible to nucleophilic attack.

It should be noted that it has previously been shown that benzyl penicillin reacts with 1,6-hexanediamine to form a penicilloamide derivative (12).

Intramolecular general base catalysis of aminolysis of penicillins by amino groups on proteins may be one route by which relatively rapid conjugation of the drug to protein may occur, forming antigen through which individuals are sensitized to the drug.

TLC Determination of Sulfanilamide as a Degradation Product in Pharmaceutical Preparations Containing Sodium Sulfacetamide

By MURRAY P. GRUBER and ROBERT W. KLEIN

Thin-layer chromatography followed by spectrophotometric analysis of eluted components was successfully employed for the separation and determination of sulfanilamide as a degradation product in sulfacetamide preparations. Significant amounts of sulfanilamide were found to be present as a contaminant in a variety of commercially available ophthalmological and dermatological pharmaceuticals containing sulfacetamide, when subjected to accelerated testing conditions and/or prolonged storage. The procedures used may be applicable to stability testing of other sulfonamides.

FOR SEVERAL DECADES, sulfonamides, especially sulfacetamide and its sodium salt, have been widely and successfully employed in the treatment of ocular and dermatological diseases (1–4). Investigators (5, 6) have observed that pharmaceutical preparations containing sulfonamides or their sodium salts undergo a color change on aging, becoming yellow to red-brown, depending on the sulfonamide(s) present.

Various recommendations (5, 6) were made to eliminate the problem of darkening, but they have not proved completely successful. The replacement of air by nitrogen in filled containers and the introduction of small percentages of antioxidants in the finished sulfacetamide products retard but do not prevent discoloration from occurring, particularly on exposure to elevated temperatures, direct sunlight, or prolonged shelf storage.

Since color changes have historically signified some form of chemical reaction ensuing in a substance, this laboratory undertook an exploratory investigation to determine if this phenomenon was indicative of decomposition.

Aqueous solutions ranging from 5 to 30% of sodium sulfacetamide were prepared. The preservative measures previously suggested were employed in an effort to prevent development of the discoloration. All precautionary measures either alone or in combination failed.

The conventional titrimetric methods of analysis as outlined by USP XVII (7) and NF XII (8) were utilized for the quantitative determination of sulfacetamide in these preparations and in each instance, employing these procedures, no decomposition was observed.

Received February 19, 1968, from the Analytical Research Department, Dermik Laboratories, Inc., Syosset, NY 11791
Accepted for publication April 2, 1968.

Although no subpotency was revealed, since the procedure used is nonspecific for sulfonamides, there appeared to be a possibility that the sulfacetamide was undergoing hydrolysis to yield sulfanilamide. In order to pursue this hypothesis, other techniques which would permit the separation of the sulfonamides prior to analysis were essential.

Chromatographic methods have met with some success in the separation of mixed sulfonamides and related materials. Shepherd, Taft, and Krazinski (9) used descending paper partition chromatography in their work on 4-sulfanilamidopyrimidines. The NF XII (8) describes a similar paper chromatrographic procedure for the separation and identification of sulfamerazine and sulfadiazine. Klein and Kho (10), using a modification of the solvent system described by Wollish, Schmall, and Hawrylyshyn (11) obtained satisfactory separations for various sulfonamides including sulfanilamide from sulfacetamide.

Accordingly, a stability evaluation of commercially available preparations was instituted using a TLC adaptation of the developing system described by Shepherd *et al.* (9). Visualization and quantitation of the developed systems was accomplished using Bratton-Marshall reagent or ultraviolet light followed by spectrophotometric determination of the eluted components.

EXPERIMENTAL

Apparatus and Reagents—Precoated 10 × 20-cm. Silica Gel GF plates, 250 and 500 μ thickness (Analtek, Inc., Wilmington, Del.) and a spectrophotometer, Beckman DU or equivalent, equipped with 1-cm. cells were used. Spray reagents, 1 *N* aqueous hydrochloric acid, 5% aqueous sodium nitrite, and *N*-(1-naphthyl)ethylenediamine dihydrochloride

0.1% in 95% ethanol (Bratton-Marshall reagent) were used. Reagents for colorimetric assay were 0.1 *N* aqueous hydrochloric acid, 2.0% aqueous ammonium sulfamate, and 0.4% aqueous sodium nitrite (freshly prepared). Chromatographic jars were equipped for ascending chromatography of sufficient internal volume for 10 × 20-cm. plates. Suitable delivery pipets for spotting purposes were used. Developing solvents system were (*a*) *n*-butanol, A.R. (*b*) ammonia 28%, A.R.

Preparation of Chromatographic Plates—All plates were activated at 40° for 30 min. and stored in a desiccator over silica gel for 1 hr. prior to use.

Standard Preparation—A 50-mg. quantity, accurately weighed, of each sulfonamide was dissolved in 30 ml. of acetone and diluted to 50 ml. with acetone. Sodium sulfacetamide was first dissolved in 1 ml. of distilled water prior to dilution with acetone.

Sample Preparation—A sample equivalent to 50 mg. of sulfacetamide or sodium sulfacetamide was dispersed in approximately 30 ml. of acetone and shaken for 15 min. The mixture was filtered (if not clear) over Whatman No. 1 paper into a 50-ml. volumetric flask and washed with acetone to volume.

Tablets were first crushed to a fine powder using a mortar and pestle and the procedure continued as above.

Sample Size—(*a*) For screening and quantitative determination of major sulfonamide; 10 μl. of sample (equivalent to 10 mcg. of labeled sulfonamide). (*b*) For quantitation of sulfonamide impurities; 50 μl. of sample applied in a band 1 cm. long for glass plates. Larger samples may be spotted if concentrations lower than 1% of sulfonamide impurities are present. Care must be taken that the applied band be as tight as possible.

Developing System—Add 90 ml. of butanol, 10 ml. of concentrated ammonium hydroxide, and 80 ml. of water to a 250-ml. separator. Shake well and allow the phases to separate. The butanol fraction is used as a developing system. Butanol–ammonium hydroxide–water (9:1:8) by volume.

Tank Preparation—All tanks were lined with Whatman No. 1 paper, filled to a depth of 1.2 cm. with developing solvent, and allowed to equilibrate overnight prior to use. The distance developed was 150 mm.

Procedures and Analysis—Samples and standards (sulfacetamide and sulfanilamide) were applied according to the appropriate procedure. After a solvent travel of 150 mm. the plates were removed and air dried. The component spots were observed under a short wavelength ultraviolet light (257 mμ) and marked.

If the screening procedure was being used, the plates were sprayed with 1 *N* hydrochloric acid followed by 5% sodium nitrite. They were then dried for 10 min. at 100°, cooled, and sprayed with 0.1% *N*-(naphthyl)ethylenediamine forming reddish-purple spots for the sulfonamides. The plates were reexamined to determine the presence of a spot produced by sulfanilamide contamination not detected under ultraviolet light.

If quantitation of the sulfacetamide present was desired, the area marked was completely scraped from the plate into a 25-ml. volumetric flask through a small funnel and the area from which the silica gel was removed carefully washed with approximately 20 ml. of 0.1 *N* hydrochloric acid into the flask. This procedure was repeated for subsequent samples, beginning with samples on the outer portion of the plate and working in. The flask and its contents were shaken for 30 min. and diluted to volume with 0.1 *N* hydrochloric acid. A 12.5-ml. aliquot of the clear supernatant was transferred to a 25-ml. flask, 0.25 ml. of freshly prepared 0.4% aqueous sodium nitrite added, and swirled intermittently for 3 min. A 0.25-ml. volume of a 2% aqueous ammonium sulfamate solution was added, the contents gently shaken for 2 min., and followed by the addition of 2.0 ml. of aqueous 0.1% *N*-(naphthyl)ethylenediamine dihydrochloride. The solution was allowed to stand with occasional shaking for 15 min. The absorbance of the solution was determined in a 1-cm. cell at 545 mμ *versus* a reagent blank prepared from a portion of the plate having the same dimensions and no sulfonamide present. The concentration was determined from an absorbance-concentration calibration curve of sodium sulfacetamide obtained using the same procedure. Results obtained from three replicates of the same sample were averaged and calculated as "% of labeled amount" of sodium sulfacetamide.

An alternate procedure involved elution from the silica gel with 4.0 ml. of 95% ethanol, centrifuging the resulting suspension, and determination of the absorbance of the clear supernatant in a 1-cm. cell at 259 mμ *versus* 95% ethanol eluate obtained from a portion of the plate having the same dimensions and no sulfonamide present. Concentration in the eluate was determined using the absorptivity of sodium sulfacetamide in 95% ethanol at 259 mμ. Calculations were carried out and reported as "% of labeled amount."

Determination of sulfanilamide as a decomposition product was carried out in a similar fashion to the determination of sodium sulfacetamide. Due to the smaller quantity of solvent involved in the direct spectrophotometric technique, this procedure in combination with 500-μ plates was preferred. Where comparatively large amounts of sulfanilamide are noted, the procedures are interchangeable. Results were reported as "% of total sulfonamide found."

RESULTS AND DISCUSSION

Analyses were performed on preparations prior to and following chromatographic separation. It was found that the use of precoated plates significantly reduced variation of the R_f values although standards were run concurrently with samples on each plate to determine the experimental range of R_f values and elution recoveries of the sulfonamides present. These figures are noted in Table I. Some varia-

F	105.6	103.0	101.7	0	1.5	2.4

tion in sensitivity and lower detection limit was observed between detection techniques. This, however, posed no particular problem in the overall study.

All of the ophthalmic and dermatologic pharmaceutical samples used in the investigation are commercially available. Stability testing was carried out at room temperature for 6 months and at 40° C. (105° F.) for 4 months. The authors felt that this elevated temperature was not unreasonable since this condition is commonly encountered during storage, particularly during the summer months and for longer duration in the southern areas of the country. With the exception of one preparation, wherein the sodium sulfacetamide was packed separately as a dry powder with instructions to the pharmacist for incorporation at the time of dispensing, none bore an expiration date (Table II).

The separately packed sodium sulfacetamide was also analyzed along with tablets containing sulfacetamide at the same temperatures and for the same durations. No deterioration was detected in any of these materials by any method used (Table III).

TABLE III—STABILITY ANALYSIS OF SULFACETAMIDE TABLETS AND POWDER[a]

Sample	Sulfacetamide (% of Labeled Amount) Initial	6 mos. at RT	4 mos. at 40°
Powder A	100.2	100.8	100.7
Powder B	99.6	100.2	99.8
Tablets A	106.2	104.6	106.1
Tablets B	101.2	102.0	101.1

[a] No sulfanilamide was found in the above preparations.

These results confirm the qualitative findings of Klein and Kho (10) who detected unlabeled sulfanilamide in suspension preparations of mixed sulfonamides containing sulfacetamide but not in tablet formulations of sulfacetamide.

Sulfanilamide was the only significant decomposition product found in sulfacetamide preparations. This was only evident after chromatographic separation. In addition, the amount of sulfanilamide present increased with length of storage. The preparation containing separately packaged dry sulfacetamide powder exhibited degradation characteristics similar to those in the same classification on prolonged storage. However, this pattern emerged only after incorporation of the sodium sulfacetamide into the vehicle and the completed preparation remained stable for the period indicated on the package insert.

SUMMARY

The customary analytical techniques as outlined in USP XVII and NF XII were demonstrated to be inadequate for purity and stability testing of pharmaceutical formulations containing sulfacetamide or its sodium salt.

Pharmaceutical suspensions and solutions containing sodium sulfacetamide were tested *via* TLC for stability under conditions of elevated temperature and prolonged storage at room temperature. All showed significant degradation to sulfanilamide. However, tablets and dry sodium sulfacetamide powder appear to be stable. Since sulfanilamide is a primary sensitizer, occurrence of sensitivity arising from prolonged use of sulfacetamide may be due to the concomitant presence of sulfanilamide as a contaminant.

This study demonstrates that ophthalmological and dermatological preparations of sulfacetamide and its sodium salt have a limited shelf life and should bear an expiration date. However, the possibility that other sulfonamides undergo similar degradation is a consideration which bears further investigation.

Methods for the quantitation of stability data for sulfacetamide are proposed which appear applicable to varied preparations of mixed sulfonamides.

The Analysis of Barium Sulfate

By EVELYN M. COCHRAN, ERVIN B. INSKIP, PERRY KING, and HOWARD W. ZIEGLER

A method suitable for compendial assay of barium sulfate USP has been developed. Barium is separated as the carbonate and precipitated as the chromate. Calcium, strontium, and silica do not interfere. The calcium and strontium content may be determined by atomic absorption or X-ray fluorescence and silica by a colorimetric procedure. An *in vitro* study of the extractability of strontium and lead from barium sulfate into simulated gastric and intestinal fluids was performed.

THE CURRENT USP XVII (1) monograph for barium sulfate does not include an assay procedure. At the suggestion of the USP Committee of Revision, an investigation was initiated and an analytical procedure for the assay of barium sulfate was developed. Norwitz has published methods for the analysis of barium compounds by homogeneous precipitation as barium chromate (2, 3). The procedures were reported to be accurate in the presence of small amounts of strontium and calcium. With some modifications, the Norwitz method has been found satisfactory for the routine assay of barium sulfate. Since the presence of calcium, strontium, and silica was expected, tests for these elements were also developed. The possibility of strontium or lead extraction from barium sulfate was investigated by an *in vitro* experiment.

BARIUM SULFATE ASSAY

Procedure—Weigh accurately between 0.58 and 0.62 g. of sample in a tared platinum crucible. Add 10 g. of anhydrous sodium carbonate and mix by rotating the crucible. Fuse over a Meker burner until a clear melt is obtained and then heat for an additional 30 min. Cool, place the crucible in a 400-ml. beaker, add 250 ml. of distilled water, stir with a glass rod, and heat to dislodge the melt. Remove the crucible from the beaker and wash thoroughly with water, collecting the washings in the beaker. Rinse the inside of the crucible with 2 ml. of 36% acetic acid and then with water, again collecting the washings in the beaker. Continue heating and stirring until the melt is disintegrated. Cool the beaker in an ice bath until the precipitate settles. Decant the clear liquid through a Whatman No. 40 filter paper, taking care to transfer as little precipitate as possible to the paper. Wash twice by decantation as follows: wash down the inside of the beaker with about 10 ml. of cold 2% (w/v) sodium carbonate solution. Swirl the contents of the beaker and allow the precipitate to settle. Decant the supernatant liquid through the same filter paper as before, transferring as little precipitate as possible. Place the beaker containing the bulk of the barium carbonate precipitate under the funnel and wash the filter paper with five 1-ml. portions of 10% hydrochloric acid. Wash the paper well with water. Dilute the solution (which may be slightly hazy) with 100 ml. of distilled water, and then add 5.0 ml. of hydrochloric acid, 10.0 ml. of 40% (w/v) ammonium acetate solution, 25 ml. of 10% (w/v) potassium dichromate solution, and 10.0 g. of urea. Cover the beaker with a watch glass (not ribbed) and digest on the steam bath, or at 80–85°, for at least 16 hr. Filter while hot through a tared *fine* porosity sintered-glass crucible. Scrub the beaker several times with a rubber policeman to insure that all the precipitate is removed from the beaker. Wash with 0.5% (w/v) potassium dichromate solution and finally with about 20 ml. of water. Dry for 2 hr. at 105°, cool, and weigh.

$$\% \ BaSO_4 = \frac{\text{wt. } BaCrO_4 \times 0.9213 \times 100}{\text{sample wt.}}$$

Results and Discussion—In the procedure initially developed, the precipitation was performed by boiling on a hot plate for 1 hr. after a precipitate first appeared. When the method was put into routine use, some difficulties were encountered. Results were not always reproducible and samples were frequently lost due to "bumping" as the precipitate that formed began to settle. The procedure was modified to that given above in which precipitation is carried out by digestion at 80–85° overnight. No difficulties have since been encountered. Replicate results on various samples are listed in Table I.

A very small amount of barium sulfate is reprecipitated with the barium carbonate. This is not dissolved by the hydrochloric acid used to dissolve the barium carbonate, and if it is transferred to the filter paper it will be lost. However, if the barium carbonate is washed by decantation, as directed, a negligible amount of barium is lost. An ignition of a filter paper from the decantation procedure showed less than 0.05% residue based on the initial sample weight. Any barium sulfate remaining in the sample solution will be filtered off and weighed as barium chromate in the final step of the procedure. It was found that the final barium chromate precipitate contains less than 0.5% barium sulfate. This has a negligible effect on the assay result be-

Received March 28, 1968, from Mallinckrodt Chemical Works, St. Louis, MO 63160
Accepted for publication April 25, 1968.

cause of the small difference in molecular weights of barium sulfate and barium chromate.

An experiment using ^{133}Ba tracer showed about 0.04% of the total barium was lost in the sodium carbonate filtrate, and about 0.06% was lost in the chromate filtrate. Atomic absorption analysis for barium in the chromate filtrate also showed less than a 0.1% loss of barium. Thus total barium losses were found to be about 0.1%.

Calcium and strontium present in barium sulfate do not interfere with the assay since they do not precipitate. Atomic absorption analysis showed that less than 0.05% of the weight of the final barium chromate precipitate is due to calcium and strontium chromates. It was suggested[1] that the ability of the method to separate calcium and strontium at high levels be evaluated. A synthetic "low assay" mixture was prepared containing 70% barium sulfate, 20% strontium sulfate, and 10% calcium sulfate. This mixture was submitted for routine assay by the procedure given above. Duplicate results obtained were 71.6% and 70.6% $BaSO_4$. The slightly high and relatively imprecise results obtained on this mixture may have been due to coprecipitation of calcium and strontium. However, this experiment did demonstrate that essentially barium content is measured.

Other Methods Investigated—As a check of the proposed method, an alternate assay method was developed. The sample was fused with sodium carbonate as in the proposed procedure above. After dissolving the barium carbonate in hydrochloric acid, a slight excess of standardized EDTA solution was added and the pH adjusted to about 10. The excess EDTA was back titrated with magnesium chloride using Eriochrome Black T indicator. In this method, calcium and strontium were also quantitatively titrated. These elements were determined by atomic absorption and the assay corrected for their content. The corrected EDTA results showed about the same precision as the chromate assays and the averages of 10 determinations by each method differed by 0.05%.

DETERMINATION OF SILICA

Procedure—Transfer 0.5 g. of sample to a platinum crucible. Add 5 g. of anhydrous sodium carbonate. Heat over a Meker burner with occasional gentle swirling until the melt is clear and continue heating for an additional 30 min. Cool, rinse the outside of the crucible, and place it in a 250-ml. plastic beaker. Add 100 ml. of water and heat on the steam bath with frequent stirring for 1 hr. Cool to room temperature. Rinse and remove the crucible. Filter through Whatman No. 42 filter paper into a plastic beaker and wash the precipitate and paper thoroughly. Prepare a blank by dissolving 5 g. of sodium carbonate in about 100 ml. of water and carry through the remainder of the procedure. Add to the filtrate 15 ml. of 6 *N* sulfuric acid. Adjust the pH to 4.5–5.0 with 6 *N* sulfuric or silica-free ammonium hydroxide if necessary. Heat on a steam bath to dispel carbon dioxide. Cool to room temperature, transfer to a 200-ml. volumetric flask, and dilute to volume with water. Determine the silica colorimetrically as the reduced silicomolybdate complex as given by Boltz (4), using a 10-ml. aliquot of the solution.

[1] Personal communication, Dr. E. F. Salim, Drug Standards Laboratory.

Results and Discussion—Fusion with sodium carbonate is the method commonly used in analyses of silica-containing materials and was found amenable to barium sulfate. However, the 30-min. fusion time is necessary to convert all of the silica to a soluble form. Samples fused only until the melt was clear gave results which were low and nonreproducible. Fusion times of more than 30 min. were not found to be necessary.

The following experiments were performed to check for losses of silica. The barium carbonate precipitate was checked for silica content on four replicates of a selected high silica sample which averaged 0.83%. The barium carbonate precipitate was dissolved in acid and tested by the colorimetric procedure. The amounts of silica found were 0.02, 0.02, 0.04, and 0.05% on the total sample basis. No silica was found on the filter paper after dissolution of the barium carbonate. This was checked by igniting the paper, fusing the residue with sodium carbonate, and testing for silica colorimetrically.

Silica in solution sometimes polymerizes and in some forms will not form the molybdate complex. Two of the solutions remaining after taking aliquots for the colorimetric determination were tested for silica gravimetrically. The results agreed with those obtained colorimetrically, indicating that all silica in the solution was in a complexable form.

DETERMINATION OF CALCIUM AND STRONTIUM

Procedure—Weigh 0.25 g. of sample into a 150-ml. beaker and add 5 ml. of 70% perchloric acid. Cover with a watch glass and heat on a hot plate until dissolved (15–30 min.). A trace of silica may remain. Cool, wash down the watch glass and sides of the beaker with a small amount of water. The barium sulfate will reprecipitate. Add 50 ml. of 0.1 *M* EDTA solution and adjust the pH to about 10 with 20% sodium hydroxide solution. Cover with a watch glass and boil to redissolve (about 30 min.). Cool, transfer quantitatively to a 100-ml. volumetric flask, and dilute to volume with water. Prepare a reagent blank and carry it through the entire procedure. Determine the calcium and strontium content of these solutions by atomic absorption spectrophotometry using the standard addition-extrapolation technique. Calculate the percent calcium sulfate and strontium sulfate in the sample.

Alternately, the samples can be compared with known mixtures of $BaSO_4$, $CaSO_4$, and $SrSO_4$ by X-ray fluorescence. The two methods were found to give equivalent results.

COMPOSITION OF BARIUM SULFATE USP

Qualitative spectrographic analysis indicated only trace contamination by other cations except sodium and potassium. It is estimated that their combined concentration is less than 0.1%. The composition of barium sulfate indicated by these analyses is summarized in Table II.

THE *IN VITRO* EXTRACTION OF STRONTIUM AND LEAD

The only potentially hazardous substances encountered in this study were strontium and lead. Tests were conducted with simulated gastric and

intestinal fluids T.S. (5) to determine to what extent these elements were extracted from barium sulfate.

Procedure—Ten-gram samples of barium sulfate were placed in 50-ml. bottles with 30 ml. of simulated gastric or intestinal fluids. The bottles were rotated at 29 r.p.m. in a 37° water bath for various periods of time. The mixtures were centrifuged and filtered. The filtrates were tested for lead and strontium by atomic absorption. Standards were prepared with the simulated fluids to provide a constant matrix.

Results—Six different samples of barium sulfate having total lead contents ranging from 15 to 70 p.p.m. were treated by the above procedure using both fluids and extraction times from 2 to 24 hr. Results on all samples showed less than 1 p.p.m. lead (calculated on $BaSO_4$ basis) extracted into the gastric or the intestinal fluids as shown in Table III. As a further check, one sample was spiked with 1,000 p.p.m. lead (on the $BaSO_4$ basis) and carried through the procedure. Again, less than 1 p.p.m. lead was found. The removal of lead from the fluids in this experiment probably is due to adsorption and precipitation since an excess of sulfate is always present in barium sulfate USP.

Fluids from five of the samples were analyzed for strontium by atomic absorption. The strontium extracted into the fluids (in p.p.m. Sr on the $BaSO_4$ basis) is listed in Table III. The extracted residues contained 0.39–0.60% strontium. These results indicate only slight dissolution of strontium in either of the simulated fluids.

SUMMARY

A procedure has been developed for the assay of barium sulfate for compendial use. Replicate analyses in our laboratory on 52 samples indicate a precision of ±0.32% for a single determination at the 95% confidence level. It is felt that the composition of barium sulfate USP has been characterized by this study. *In vitro* studies indicate that no appreciable quantitites of strontium or lead are extracted from barium sulfate by simulated gastric or intestinal fluids.

Determination of Acetylsalicylic Acid, Salicylamide, Acetaminophen, and Caffeine in Tablets or Powders by Independent Methods

By NORMAN SHANE and MARIE KOWBLANSKY

A method, suitable for automation, has been developed for the determination of four compounds commonly found in analgesic tablets. The tablet is dissolved in 85 percent methanol, filtered to remove the insoluble excipients, and three portions are taken. The first portion is analyzed for aspirin (ASA) by titration; the second portion, for acetaminophen (APAP) and salicylamide (SAL) by UV differential spectrophotometry; and the third portion for caffeine (CAF), either by a unique differential spectrophotometric operation, or by an extraction method, where the caffeine content is determined spectrophotometrically in the UV range. The average relative errors for each of the components are: 0.22% for aspirin, 0.51% for salicylamide, 0.80% for acetaminophen, 2.02% for caffeine by method I, and 1.18% for caffeine by method II.

THE ANALYSIS of a multicomponent system of analgesics usually requires many multiple separation steps or complicated UV, IR, or NMR methods, which demand solution of many simultaneous algebraic equations. Column chromatography (1) is a common procedure for the separation of phenacetin, caffeine, and acetylsalicylic acid. Solvent extraction methods for separation of components are described (2, 3). Other methods for determining the various components involve infrared spectrophotometry (4, 9), ultraviolet spectrophotometry (5, 6), titration (2), phosphorimetry (7), and nuclear magnetic resonance spectroscopy (8). Salicylic acid, acetylsalicylic acid, salicylamide, caffeine, and phenacetin in tablets or powders can be analyzed by spectrophotometric determination, requiring the solution of several algebraic expressions (10). Independent methods of analyzing for the constituents in a multicomponent system give greater accuracy, precision, and less computational problems than those which require the solution of simultaneous equations (11).

Recently, work from this laboratory has shown the power of the pH chromophoric procedure for the assay of drugs (12–14). Utilizing this concept, a method has been developed which can independently determine each of the four subject components of a tablet or powder, with no interferences from one another. It is not necessary to separate the components, except in the alternate method for caffeine, where just a simple chloroform extraction is performed. The procedures are very simple, rapid, accurate, precise, and can be easily automated.

EXPERIMENTAL

Apparatus and Reagents

Spectrophotometer—A Beckman DU spectrophotometer was used for obtaining quantitative data for SAL, APAP, and CAF. A Beckman DK 2 recording spectrophotometer was used to obtain the spectra in Figs. 5 and 6.

Standard 1-cm. square fused silica cells were employed in all cases.

Titration Apparatus—Experimental data were obtained with a Beckman model No. 1019 research pH meter set to read the millivolt scale, with a Beckman standard combination electrode filled with saturated aqueous KCl solution.

Solvents—Spectral grade, analytical reagent methanol and chloroform (Merck Co.) were used. The solvent system, 85% methanol, was prepared by volume-volume dilution of anhydrous methanol with distilled, deionized water. The titration system was 0.5 *N* alcoholic potassium hydroxide from Hartman-Leddon Co., diluted with 85% methanol and standardized with potassium acid phthalate to be 0.02 *N*.

Buffer Solutions—(*a*) pH 1.3; 250 ml. of 0.2 *M* KCl, 336 ml. of 0.2 *M* HCl, and diluted to 1,000 ml. with distilled water.

(*b*) pH 6; 250 ml. of 0.2 *M* KH_2PO_4, 28 ml. of 0.2 *M* NaOH, and diluted to 1,000 ml. with distilled water.

(*c*) pH 10; 250 ml. of 0.2 *M* H_3BO_3, 250 ml. of 0.2 *M* KCl, 220 ml. of 0.2 *M* NaOH and diluted to 1,000 ml. with distilled water. (In all cases, reagent grade materials were used.) All analgesic compounds *i.e.*, acetylsalicylic acid, USP grade; salicylamide, NF grade; acetaminophen, NF grade; caffeine, USP grade, were checked for purity by infrared spectrophotometry.

Tablets—The standard composition of the synthetic tablets which were analyzed contained 195 mg. of aspirin, 130 mg. of salicylamide, 98 mg. of acetaminophen, and 65 mg. of caffeine.

PROCEDURE

The tablet to be analyzed is crushed to a powder, quantitatively transferred to a 100-ml. volumetric flask, and approximately 4 ml. of chloroform is added (to dissolve the CAF). The solution is brought to volume with 85% methanol, shaken to dissolve all the soluble materials, and filtered to remove the insoluble excipients (Solution *A*). From Solution *A*, a 20-ml. aliquot is transferred into a 250-ml. beaker (Solution *B*), a 4-ml. aliquot is transferred into a 200-ml. volumetric flask (Solution *C*), and a 5-ml. aliquot is transferred into a 200-ml. volumetric flask (Solution *D*).

Acetylsalicylic Acid (ASA)—To determine the ASA content, 100 ml. of 85% methanol is added to Solution *B* and a magnetic stirrer is placed in the beaker. Using 0.02 *N* alcoholic KOH, which has been standardized against potassium acid phthalate, the ASA is titrated potentiometrically with a standard combination electrode filled with saturated aqueous KCl solution. As an alternate procedure, the solution could be titrated to an orange-red end point in the presence of chlorophenol red indicator. (Most tablets containing ASA also contain small quantities of salicylic acid, which are negligible when compared with the amount of ASA present. Since salicylic acid is also titratable by this procedure, the analysis cannot be carried out in the presence of appreciable amounts of salicylic acid.)

Salicylamide (SAL) and Acetaminophen (APAP)—To determine the amounts of APAP and SAL, 5 ml. of 0.5 *M* NaOH is added to Solution *C*; the solution is allowed to stand for approximately 5 min. (to ensure complete conversion of ASA to its sodium salt), and then brought to volume with distilled water. A 20-ml. aliquot of this solution is transferred into each of two beakers. To one beaker, 10 ml. of pH 6 buffer is added, and to the other, 10 ml. of pH 10 buffer is added. Using the pH 6 buffer solution as the reference, and the pH 10 solution in the sample position, absorbance readings are taken on a DU spectrophotometer at 330 mμ (for SAL) and 263.5 mμ (for APAP).

Caffeine (CAF)—*Method I*—To determine the amount of CAF in the tablet, Solution *D* is brought to volume with distilled water, and a 20-ml. aliquot of this solution is pipeted into each of two beakers. To one beaker, 10 ml. of pH 1.3 buffer are added, and to the other, 10 ml. of 1:10 concentrated HCl:H_2O solution. An absorbance measurement is made on a DU spectrophotometer at 283 mμ, with the HCl solution in the reference position.

Method II—An alternate procedure for the determination of the CAF content is to bring Solution *D* to volume with 0.01 *M* NaOH, transfer a 30-ml. aliquot of this solution into a 250-ml. separator, and extract twice with 10-ml. aliquots of spectrograde chloroform. The chloroform extract is collected in a 50-ml. volumetric flask and brought to volume with the same solvent. The absorbance of this chloroform solution is read on a DU spectrophotometer at 276 mμ with chloroform as the reference solution.

RESULTS

Acetylsalicylic Acid (ASA)—Seven synthetic tablets, which contained varied amounts of ASA in the presence of standard amounts of CAF (65 mg.), APAP (98 mg.), and SAL (130 mg.), were titrated for ASA with extremely good results.

Salicylamide (SAL)—Figure 1 depicts three curves of absorbance readings at 330 mμ of solutions containing SAL alone, SAL in the presence of varying amounts of APAP, and SAL in the presence of standard amounts of ASA, CAF, and APAP. Since the three lines representing the relationships of the points coincide, it can be concluded that the determination of SAL in the tablets or powders is independent of the concentrations of the other ingredients, and therefore, no correction term needs to be applied in the calculations. By regression analysis the absorptivity for SAL at 330 mμ has been determined to be 36.5 absorbance units/(g./l.).

Acetaminophen (APAP)—Figure 2 depicts three curves of absorbance readings at 263.5 mμ of solutions containing various concentrations of APAP alone, APAP in the presence of varying amounts of SAL, and APAP in the presence of standard amounts of ASA, CAF, and SAL. Since the three lines representing the relationships of the points coincide, it may again be concluded that the determination of APAP in the tablets is independent of the concentrations of the other ingredients. The absorptivity for APAP at 263.5 mμ, as determined by regression analysis is 38.6 absorbance units/(g./l.).

Caffeine (CAF)—*Method I (Differential Spectro-*

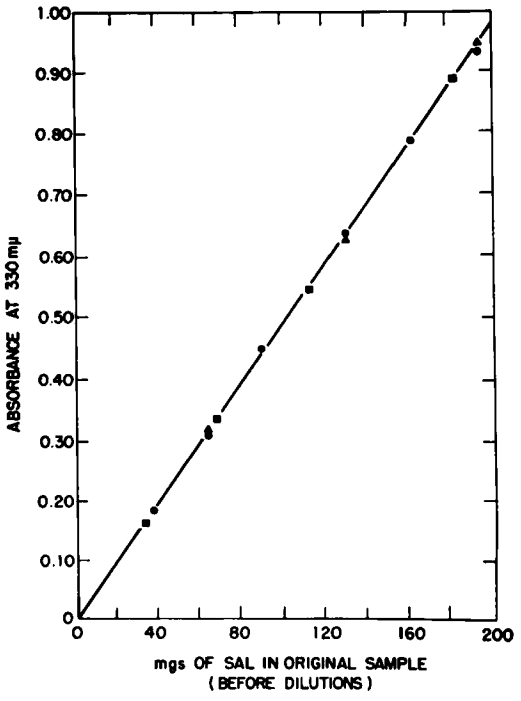

Fig. 1—Differential absorbances of various concentrations of SAL. Key: ■, SAL alone; ▲, SAL in the presence of varying amounts of APAP; ●, SAL in the presence of standard amounts of APAP, CAF, and ASA.

photometry)—Figure 3 summarizes a number of experiments that were performed to determine whether there is any interaction between any of the components in this procedure. Absorbances at 283 mμ are plotted for: (*a*) various levels of CAF alone, (*b*) CAF in the presence of SAL, (*c*) CAF in the presence of APAP, (*d*) CAF in the presence of ASA, and (*e*) CAF in the presence of all three components. As can be seen, curves 1 through 4 are linear and coincide, proving that there is no interaction. The absorbance readings for CAF in the presence of all three components are linear to the 85-mg. region (mg. in the original sample); above this quantity the plot deviates from linearity. This observation may be explained in the following manner. Direct spectrophotometry, where water is used as the reference solvent, indicates that the sample solution containing 65 mg. of CAF plus standard amounts of the other components, reads about 1.2 in absorbance. At 130 mg., the reading is approximately 2.0. At this high absorbance, the phototube response to the small amount of light transmitted through the solution becomes nonlinear. Therefore, due to the high background absorbance of the other three components, readings above 0.125 are unreliable. At 283 mμ, the absorptivity for CAF, as determined by regression analysis, is 8.98 absorbance units/(g./l.).

Method II (*Extraction*)—Figure 4 represents the following relationships: (*a*) absorbances of various concentrations of CAF in chloroform, and (*b*) absorbances of various concentrations of CAF extracted into chloroform from standard amounts of ASA, APAP, and SAL. In both cases the same

TABLE I—STATISTICAL RESULTS FOR EACH PROCEDURE

	No. Observations	No. of Analysts	Average Relative Error	Standard Deviation	95% Confidence Limits	95% Confidence Limits, mg.
ASA	7	1	0.22%	±0.30%	±0.60%	195 ± 1.15
SAL	18	4	0.51%	±0.84%	±1.68%	130 ± 2.18
APAP	18	4	0.80%	±1.00%	±2.00%	98 ± 1.96
CAF (method I)	18	4	2.02%	±2.41%	±4.82%	65 ± 3.13
CAF (method II)	24	3	1.18%	±1.43%	±2.86%	65 ± 1.86

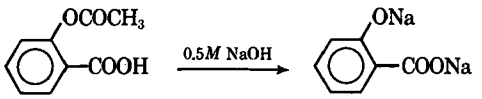
dilutions were made as described in the procedure, thus yielding the same final concentrations; however, for the sake of simplicity, the absorbances are plotted for mg. of caffeine in the original sample. By regression analysis, the absorptivity of CAF in chloroform at 276 mμ has been calculated to be 47.4 absorbance units/(g./l.), with a correction term of 0.013. The CAF concentration, therefore, is calculated using the following relationship: $(A_{276} + 0.013)/47.4$ = g. of CAF/l.

The statistical results for each of the procedures are summarized in Table I.

DISCUSSION

ASA is the only ingredient in the 85% alcoholic solution that is titratable (assuming that the amount of salicylic acid present is negligible). The excipients of the tablet or powder have no effect. For automation, spectrophotometric titration would be more workable than potentiometric titration. At the end point, a rapid color change of the dye indicator could be detected with a colorimeter or spectrophotometer.

In the SAL and APAP procedure, the ASA in the sample is converted to the disodium salt of salicylic acid with 0.5 *M* sodium hydroxide (15). See Scheme I.



Scheme I

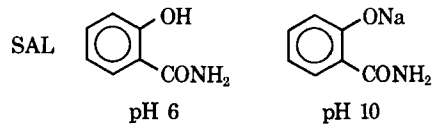
Since the pKa_1 and pKa_2 of salicylic acid are 3.0 and 13.4 (16), respectively, in buffers pH 6 and pH 10, the disodium salicylate converts to the monosodium salt (Scheme II):

Scheme II

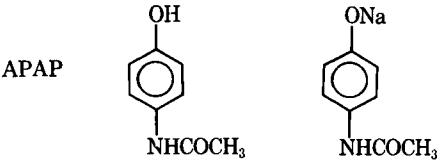
Consequently, since equal amounts of sample are contained in both buffered solutions, the absorbances of the two solutions due to ASA (which has been converted to monosodium salicylate) will exactly cancel each other, and the net absorbance will be zero.

The CAF (pKa = 13.39) (16) is in the same form at both pH's. The predominant species of APAP (pKa = 9.0) (16) and SAL (pKa = 8.4) (16) at the two different pH's are as in Schemes III and IV.

Therefore, at these two pH's each compound will exhibit different absorbance spectra. Consequently, since the pH 6 solution is in the reference position and the pH 10 solution is in the sample position, the spectra will automatically subtract in the spectrophotometer, giving new characteristic spectra for APAP and SAL.



Scheme III



Scheme IV

Figure 5 depicts the Beckman DK 2 differential spectra of samples containing various concentrations of SAL alone, APAP alone, and only CAF plus ASA. The samples were prepared by treating the individual components by the procedure described for SAL and APAP. The composition of the reference and sample solutions are as follows:

Reference pH 6	Sample pH 10	Absorbance 330 mμ	Absorbance 263.5 mμ
Monosodium salicylate (equivalent to ASA) + CAF	Monosodium salicylate (equivalent to ASA) + CAF	none	none
APAP	APAP	none	yes
SAL	SAL	yes	none

Neither CAF nor ASA (which has been converted to the monosodium salicylate) exhibit any absorbance from 255 to 340 mμ. Therefore, the SAL and APAP content of the tablets may be determined differentially at 330 mμ and 263.5 mμ, respectively, since

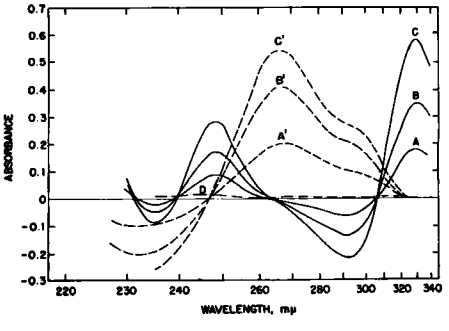


Fig. 5—Differential spectra of SAL (A, B, C), APAP (A', B', C'), and CAF + ASA (D).

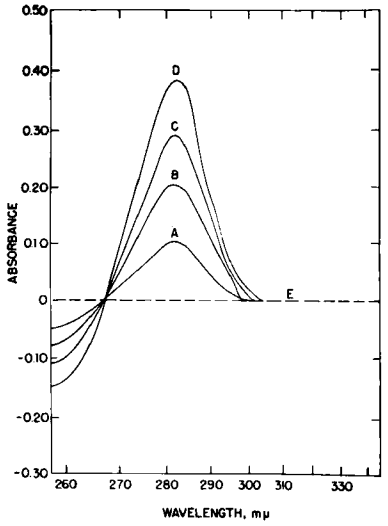

Fig. 6—Differential spectra of CAF (A, B, C, D) *and SAL + APAP + ASA* (E).

APAP shows no absorbance at 330 mμ, and SAL has an isosbestic point of zero absorbance at 263.5 mμ. A detailed explanation on the use of isosbestic point in spectrophotometry may be found (12). To ascertain that the pH 6 and pH 10 buffers cause maximum absorbance for APAP and SAL, pH 11 and pH 12 buffers were tried instead of the pH 10 buffer. As would be expected from the pK values of APAP and SAL, it was found that the pH 11 and pH 12 buffers caused an insignificant increase in absorbance over that of the pH 10 buffer.

In the differential spectrophotometric method for the determination of CAF, two buffer solutions are used—pH 1.3 and 1:10 HCl:H_2O solution. Since the pKa of the conjugated acid of caffeine is 0.61, caffeine exists predominantly as two different species at the two pH's.

Caffeine	Caffeine · H^+ (conjugated acid)
pH 1.3	1:10 HCl:H_2O

Therefore, caffeine should exhibit a differential spectrum between these pH's. Figure 6 demonstrates that CAF shows an absorbance maximum at 283 mμ. As expected from the pK values listed above, the other components exist as the unionized species in both buffers, and, therefore, exhibit no absorbance differentially. Unfortunately, the background effect is too great to permit absorbance readings to be taken in the optimum range of 0.42 absorbance units when the tablets are of standard composition. However, if tablets of different composition are analyzed (where the background absorbances are small), this procedure could prove to be very useful, since one could work at higher absorbances, with no interference from the other components.

In the caffeine extraction method, APAP, SAL, and ASA are converted to their sodium salts with sodium hydroxide and remain in the aqueous layer. The CAF, which is not affected by the sodium hydroxide can then be easily extracted from the other

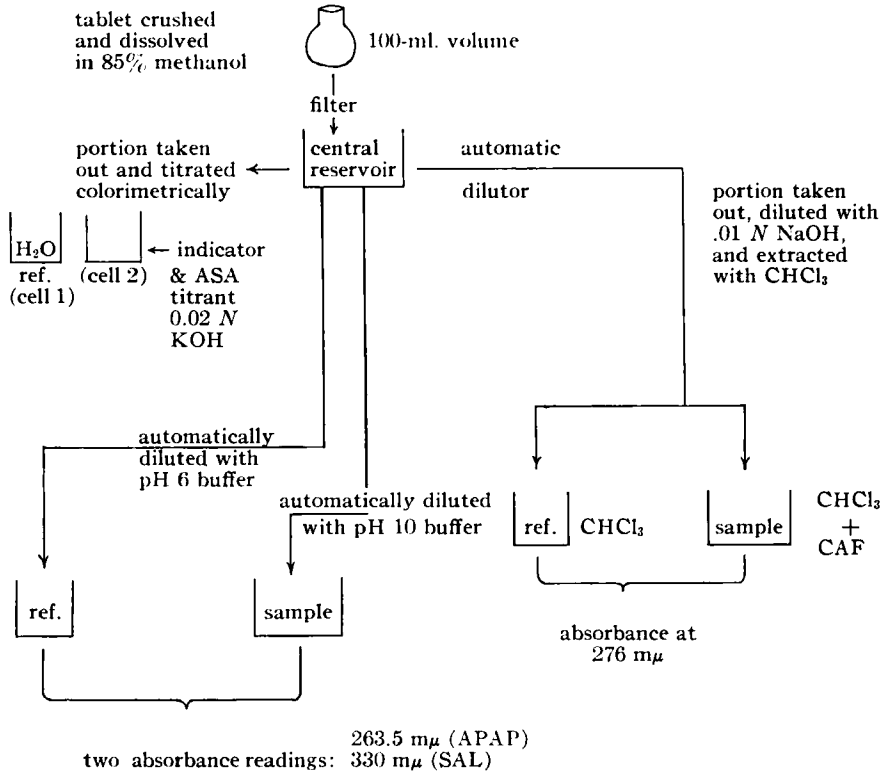

Fig. 7—Proposed schematic diagram for the automated system.

components with chloroform. However, it is imperative to use 0.01 *N* NaOH, because a stronger concentration of the base can change the CAF structure (17), and, therefore, cause erratic results.

Automation for the analysis of the four components can be performed by following the above procedures (extraction, rather than differential spectrophotometry is preferred for CAF). The results would be directly obtainable from the responses of the recorders without need of any computers or calculating devices. The proposed schematic diagram for the automated system is shown in Fig. 7.

The tablet is crushed and dissolved in 85% methanolic solution, which is filtered into a central reservoir. From this container, three portions are taken. One aliquot is colorimetrically titrated for ASA in the presence of dye indicator with 0.02 *N* KOH. A second aliquot is automatically diluted with a given quantity of 0.01 *N* sodium hydroxide, and the CAF is extracted into chloroform, which is read at 276 mμ *versus* chloroform on a spectrophotometer. A third portion is automatically diluted and separated into two segments. To one portion, a pH 6 buffer solution is added and passed through a reference flow cell located in a spectrophotometer. Simultaneously, a pH 10 buffer solution is added to the other segment of the solution and passed through a sample flow cell in the spectrophotometer. The wavelength scale is programmed rapidly to two wavelengths—263.5 and 330 mμ. The APAP and SAL are determined at 263.5 and 330 mμ, respectively.

The advantage of using these methods is that each specific procedure is independent of the concentrations of the other components, and therefore, can be used either in the presence of large quantities or in the absence of any of the other ingredients, with very good accuracy and precision.

Application of Sugar Coating to Tablets and Confections by Means of an Automated Airless Spray System I

Investigation of the Direct Coating of Tablets

By G. M. KRAUSE and T. L. IORIO*

The practicability of directly applying sugar coating to unsubcoated tablets has been studied. Initial work performed indicates that such a procedure may be feasible when used in place of current sugar-coating techniques.

THE DEVELOPMENT of automated airless-spray film-coating methods has shown signs of significant growth in recent years (1–5). Although there is considerable information pertaining to film coating by this method, particularly with coating solutions consisting of organic solvents and polymeric materials, there is little if any descriptive literature pertaining to the use of aqueous solutions of sugar or syrups as the coating medium. At the present time, sugar

coating is still the principal method used for coating tablets and also confections. Nevertheless, the time involved and the uncertain reproducibility are reflected in high costs of operation. It would seem that an investigation of the practicability of modifying the traditional sugar-coating method of tablets would be desirable.

One of the drawbacks of the traditional sugar-coating procedure has been the necessity of subcoating tablets (6). This procedure is time consuming, and in some instances, an untidy operation. Tablets and confections of odd shapes, having sharp corners and thick edges, generally require subcoating to facilitate the application of a sugar coat. Those with well-rounded edges or corners do not present too much difficulty. This discussion will deal primarily with products of standard round shapes and normal curvatures.

DESIGN AND EQUIPMENT

Hydraulic Systems—A hydraulic system was employed that was capable of developing 1400 psig, although most of the work was done at about 500 psig. The coating solutions were heated, circulated, and sprayed by an airless pump through nozzles as described by Lachman and Cooper (1).

Coating Pan—A 40.6-cm. (16-in.) diameter round stainless steel coating pan, unbaffled, was used because a reasonable quantity of tablets, about 8 kg., could be coated easily, and there was also room to accommodate the spray nozzle. Initial tumbling of the tablets was simplified by previously coating the inner surface of the pan with a thin coat of liquid latex, or syrup, and drying. The speed of the pan was 28 r.p.m. and was constant for all trials.

Ventilation and Air System—A conventional air delivery system was used capable of drying the tablets during the drying cycles. An exhaust system capable of greater air capacity than the air supply was used.

Programmer—The programmer was constructed similar to that described by Mody, Scott, and Lieberman (2), but modified to provide auxiliary controls that could be used to suspend any of the automated functions as desired. A series of neon lights was provided for the timers to indicate sequence of operation, primarily as an instructional aid. All wire connections were made to readily accessible terminal strips for any changes or modifications in circuitry.

EXPERIMENTAL

Tablets and Materials—The initial trials were conducted on ball-shaped, uncoated confections obtained from a commercial producer. They averaged 0.50 in. in diameter and weighed 1.36 g. each. The compressed tablets used during these experiments were prepared from terra alba, using the wet granulation method. They weighed 385 mg./-tablet, with a diameter and gauge of 95.4 mm. (0.375 in.) and 4.43 mm. (0.174 in.), respectively, and were compressed on a Colton 216 single rotary, using extra deep, cup-shaped punches. Approximately 1,250,000 tablets were used during this work. Coating solutions used were 4-lb. cut pharmaceutical glaze (shellac), subcoating solution according to Clarkson (6), and sugar syrup colored with 0.1% F.D. & C. Red No. 3. With the exception of batch series A and I, Table I, all batches used received two coats of glaze, and weighed 8 kg. initially. Batch series A and I received no precoat, and series C was subcoated over the shellac coat. The initial trial coating weight of series C was therefore correspondingly greater, *i.e.*, 9.27 kg. All shellac coats and subcoats were applied by the conventional pan-coating method (6). All sugar coats, with the exception of series B, Table I, were applied by the automated airless-spray method.

Four different kinds of sugar-coated commercial tablets were purchased from local pharmacies. They were in original unopened containers and were of about the same size and weight as the tablets coated by the automated method during this experiment.

Sampling Plan—Samples were removed from the coating pan at the end of 10, 20, 30, and 40 cycles, or 20, 40, 60, and 80 cycles, depending on whether the coating process was for 40 or 80 cycles. The tablets were weighed and measured for diameter and gauge increase individually. The data are seen in Figs. 1 and 2, and Tables II and III.

Coating Procedure—The ball-shaped confections received 60 applications of syrup by means of the automated airless-spray method. The average weight of sugar delivered per confection was 0.350 g., with an increase in diameter of 0.75 mm (0.030 in.), Total coating time was 90 min. The trials were repeated twice, and data are presented in Table I (series I) and in Fig. 3, which represent an average of the three batches.

Subcoated Tablets—Shellac-coated tablets were subcoated and then sugar coated by the automated method. The operation was continued through 40 cycles per batch for the series and sampled according to plan. The average cumulative gain, diameter and gauge are shown in Figs. 1 and 2. Additional data are summarized in Table I (series C).

Shellac-Coated Tablets—These were sugar coated directly by the automated process, with part of the series going through 40 cycles, and the remainder through 80 cycles. In both instances complete coverage took place after 20 cycles, and the process continued through 40 cycles and 80 cycles in order to note uniformity of coating application. Data are presented in Table I (series D, E, F, G, and H).

Uncoated Tablets—This batch series received no precoating, only the usual processing to remove any dust and loose particles. These tablets coated well, and the data are seen in Table I (series A).

Conventional Method—In order to compare the results of sugar-coating tablets by the automated-spray method with those sugar coated by the traditional pan-coating method, several batches of shellac-coated tablets were coated under conditions approximating the spray method as closely as possible. Forty coats were applied, using the same amount of sugar per coat as per cycle in the automated method. Each application was timed with a stopwatch for uniformity of conditions. With the exception of the increased drying time, all other conditions were met, and the results were almost compa-

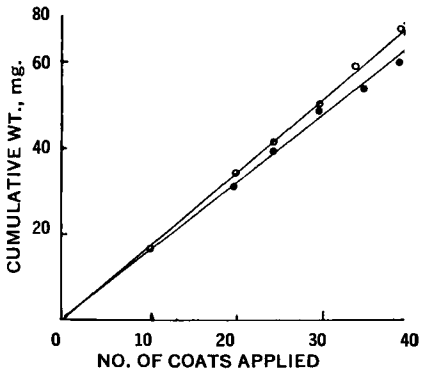

Fig. 2—Gain in weight of tablets coated by automated method and tablets coated by conventional method. Key: ○, automated; ●, conventional.

rable to those of the automated method. Data are presented in Figs. 1 and 2, and Table I (series B).

Total Operating Time—The total operating time for each batch series was dependent on (*a*) the type of tablet coated, *i.e.*, whether it was not precoated, subcoated, or shellac coated, (*b*) quantity of sugar delivered per cycle, (*c*) type of coating method employed, *i.e.*, conventional pan coating or automated airless-spray method, and (*d*) deliberate change in length of drying time increments per cycle in order to determine operating ranges for the production of a satisfactory coat. These changes are reflected in the figures for total operating times in Table I. All sugar coats entered in Table I were judged satisfactory.

Comparison of Coating Variability to Commercial Samples—Twenty tablets were chosen at random from each of four commercial samples and then individually weighed and measured. Thirty tablets each from the lots spray coated by the automated method were also selected at random and weighed and measured. The data are presented in Tables II and III.

RESULTS AND DISCUSSION

The ball-shaped confections were used as the initial samples for coating because objects of such shape roll readily in the coating pan and are rather easy to coat, since they also have no edges or corners that generally cause difficulty in coating. The settings of the programmer for sugar delivery for this ball-shaped confection could be made over a rather wide range, consistent within reasonable limits. The ease of coating experienced with ball-shaped objects would indicate that they could be used for familiarization with the operation of the automated airless-spray system. Normally, baffles are used in the coating pan to produce tumbling with the automated system. However, it was found that the application of a thin coating of liquid latex or syrup to the pan and drying it, would permit good tumbling during the initial stages when tablets generally have a

tendency to slide. Difficulty in tumbling is usually not experienced after the first or second cycle.

Each of the four samples obtained from commercial outlets represented a single production lot per sample, and the results therefore cannot be interpreted as being indicative of other lots of the same product. Variations of individual coated tablets within a single lot can be divided into three types: (*a*) those caused by inherent variations in the uncoated tablets, (*b*) those caused by the actual coating operation, and (*c*) the possibility of both *a* and *b* occurring at the same time. The standard deviation of all of the tablets coated by the automated process was equal to or less than that of the four commercial samples. These were used for comparison because they were similar in weight and dimensions to the spray-coated tablets. However, a greater standard deviation in the commercial tablets may not be objectionable if the weight variation is due only to nonmedicinal coating ingredients, and not active materials that might be included in the coats.

Tables II and III show the means, ranges, standard deviations, and coefficient of variations for tablet diameter and gauge, respectively. In all cases, tablets coated by the automated process compare favorably to those coated by the conventional method. The subcoated automated lot had less variation than any of the samples examined.

Batches of tablets weighing 8 kg. each were used because this was equivalent to about 8 l., the optimum working capacity of the 40.6 cm. (16 in.) coating pan. Standard concave-shaped tablets, particularly those with thick edges, are more of a problem than those with a curvature approaching roundness, such as the extra deep cup shape. It is well known to the arts that tablets possessing greater curvature and thin edges are coated with less difficulty than others.

During sampling, it was noted that coverage took place at about 20 cycles, as could easily be seen by examining the samples through a 7× lighted magnifier. The process was initially continued until 80 cycles, but since coverage was complete before this, and prior work indicated that additional coats could be applied readily, the operation was generally stopped at the end of 40 cycles. As was noted before, sugar was applied directly to tablets not precoated, with a reasonable degree of success. This area is being explored further.

Tablets coated by the automated process acquired a greater thickness on the edges (diameter) than on the surface (gauge). At the present time, the reason for this difference is unknown, and work is being done to determine the cause and if it can be controlled. The comparison is shown in Fig. 1.

The build-up of sugar in the coating pan ranged from about 0.08–0.13%, with a mean of 0.10%. This was found to be dependent on the weight of sugar delivered per cycle and the drying time, and could be adjusted readily. Trials were conducted with the 40.6-cm. coating pan to determine the maximum and minimum load of shellac-coated tablets that would slide or tumble in this pan when the latter was coated with latex. As little as 2.5 kg. of these tablets would tumble in the treated pan, and as much as 10–12 kg. would slide in the uncoated pan. It should be pointed out that this latex or sugar coating was used only for the initial start of tumbling of the tablets, because once there is a slight quantity or sugar on the pan walls, tumbling will generally proceed normally.

It would appear that, within specific limitations, direct application of sugar to tablets and confections, with or without precoat, shows promise. Transfering this process to an automated airless-spray system permits greater uniformity of coating and decreased costs of operation because the operator need not be particularly skilled and can control more coating pans with greater precision than one skilled in performing his work in the traditional manner.

Smooth finish coats were obtained by the usual reduction and closed pan method as described in Clarkson (6), however, this requires the removal of the spray gun from the coating pan after the last cycle. The finished tablets can be polished by any conventional means, with the usual materials.

Semiautomated Assay for the Simultaneous Determination of Propoxyphene Hydrochloride and Paramethasone Acetate in Coated Single Tablets

By C. E. STEVENSON and I. COMER

A semiautomated method for the simultaneous determination of propoxyphene hydrochloride and paramethasone acetate is described for coated tablets. A novel device for the removal and dissolution of tablet coatings is outlined. Solutions are sampled with an automatic sampler at the rate of 20/hr. and fed to two independent systems for analysis. A modified blue tetrazolium procedure is utilized for the determination of paramethasone acetate producing essentially complete color development within 5 min. at room temperature. Working concentrations of 12.5 mcg. paramethasone acetate per ml. can be assayed without resorting to range expansion. Analysis of propoxyphene hydrochloride is accomplished by the formation of a complex with bromocresol purple with subsequent extraction and color measurement in ethylene dichloride.

THE AUTOMATED analysis of single tablets has been reported by Wolski (1) as a useful tool in the concept of quality assurance. The product[1] involved in this study consists of an enteric 500-mg. acetylsalicylic acid (aspirin) core tablet coated with 32.0 mg. of the analgesic propoxyphene hydrochloride (DPH), and 0.250 mg. of the ketosteroid paramethasone acetate (PMA) (6α-fluoro-16α-methylprednisolone 21-acetate). For the quality assurance of this product, an automated single-tablet procedure for the simultaneous determination of DPH and PMA was developed using the automatic analyzer.[2]

A desirable condition involving methods for simultaneous determinations is that each component be capable of measurement in the presence of the other without significant interference. The automated method of Kuzel (2), based on the formation of a complex between tertiary amines and bromocresol purple (BCP), and the automated methods of Greely *et al.* (3) and Beyer (4), utilizing the reducing powers of the ketosteroids on blue tetrazolium (BTZ), meet this condition for the compounds in this study. Slight modifications of these procedures have been made in the development of this automated system.

EXPERIMENTAL

Reagents—*BCP*—A 2% acetic acid–98% deionized water (v/v) solution containing 0.25 mg. of bromocresol purple (5′,5″-dibromo-*o*-cresolsulfonphthalein Na salt, Eastman No. 6266) per ml.; *BTZ*—A solution containing 0.15 mg. blue tetrazolium (Fisher Certified B-410) per ml. SD-3A alcohol; *Ethylene Dichloride*—Fisher Certified E-175; TMAH—A solution of 20% tetramethylammonium hydroxide (Eastman No. 1515)–80% SD-3A alcohol (v/v); *Wash*—A solution of 50% methanol–50% deionized water (v/v); *Theory Standard*—32.0 mg. propoxyphene hydrochloride and 0.250 mg. paramethasone acetate reference standard per 20 ml. of Wash solution.

Sample Preparation—Due to the relatively low steroid concentration in the formulation, it was desirable to limit the amount of solvent used in the dissolution of the active ingredients to as low a volume as possible. Utilization of an automatic[3] module

Semiautomated Assay for the Simultaneous Determination of Propoxyphene Hydrochloride and Paramethasone Acetate in Coated Single Tablets

By C. E. STEVENSON and I. COMER

A semiautomated method for the simultaneous determination of propoxyphene hydrochloride and paramethasone acetate is described for coated tablets. A novel device for the removal and dissolution of tablet coatings is outlined. Solutions are sampled with an automatic sampler at the rate of 20/hr. and fed to two independent systems for analysis. A modified blue tetrazolium procedure is utilized for the determination of paramethasone acetate producing essentially complete color development within 5 min. at room temperature. Working concentrations of 12.5 mcg. paramethasone acetate per ml. can be assayed without resorting to range expansion. Analysis of propoxyphene hydrochloride is accomplished by the formation of a complex with bromocresol purple with subsequent extraction and color measurement in ethylene dichloride.

THE AUTOMATED analysis of single tablets has been reported by Wolski (1) as a useful tool in the concept of quality assurance. The product[1] involved in this study consists of an enteric 500-mg. acetylsalicylic acid (aspirin) core tablet coated with 32.0 mg. of the analgesic propoxyphene hydrochloride (DPH), and 0.250 mg. of the ketosteroid paramethasone acetate (PMA) (6α-fluoro-16α-methylprednisolone 21-acetate). For the quality assurance of this product, an automated single-tablet procedure for the simultaneous determination of DPH and PMA was developed using the automatic analyzer.[2]

A desirable condition involving methods for simultaneous determinations is that each component be capable of measurement in the presence of the other without significant interference. The automated method of Kuzel (2), based on the formation of a complex between tertiary amines and bromocresol purple (BCP), and the automated methods of Greely *et al.* (3) and Beyer (4), utilizing the reducing powers of the ketosteroids on blue tetrazolium (BTZ), meet this condition for the compounds in this study. Slight modifications of these procedures have been made in the development of this automated system.

EXPERIMENTAL

Reagents—*BCP*—A 2% acetic acid–98% deionized water (v/v) solution containing 0.25 mg. of bromocresol purple (5′,5″-dibromo-*o*-cresolsulfonphthalein Na salt, Eastman No. 6266) per ml.; *BTZ*—A solution containing 0.15 mg. blue tetrazolium (Fisher Certified B-410) per ml. SD-3A alcohol; *Ethylene Dichloride*—Fisher Certified E-175; TMAH—A solution of 20% tetramethylammonium hydroxide (Eastman No. 1515)–80% SD-3A alcohol (v/v); *Wash*—A solution of 50% methanol–50% deionized water (v/v); *Theory Standard*—32.0 mg. propoxyphene hydrochloride and 0.250 mg. paramethasone acetate reference standard per 20 ml. of Wash solution.

Sample Preparation—Due to the relatively low steroid concentration in the formulation, it was desirable to limit the amount of solvent used in the dissolution of the active ingredients to as low a volume as possible. Utilization of an automatic[3] module

was therefore undesirable. Since the single-tablet analysis of aspirin was not required, tablet coatings were removed using a stirring device designed by Coffy (5) and fitted with a Styrofoam block to hold twelve 25 × 100-mm. round-bottom centrifuge tubes. This apparatus is shown in Fig. 1. A 20-ml. aliquot of the Wash solution is added to each tube containing a 1.3-cm. Teflon-coated magnetic stirring bar and one tablet. The tube is then stoppered and placed in the stirring apparatus. After about 45 min. of mixing, complete removal of the tablet coatings and dissolution of the active ingredients is achieved. The tablet core and the stirring bar are then removed and the solution centrifuged to settle the undissolved particles. Two 8.5-ml. sample cups are filled with the supernatant liquid for duplicate analysis in the automatic analyzer system.

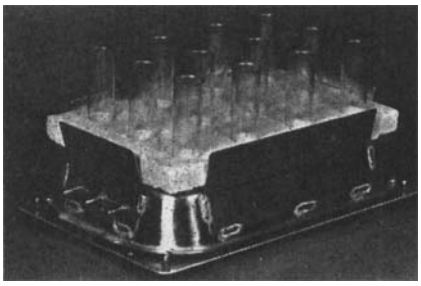

Fig. 1—Tablet dissolution apparatus.

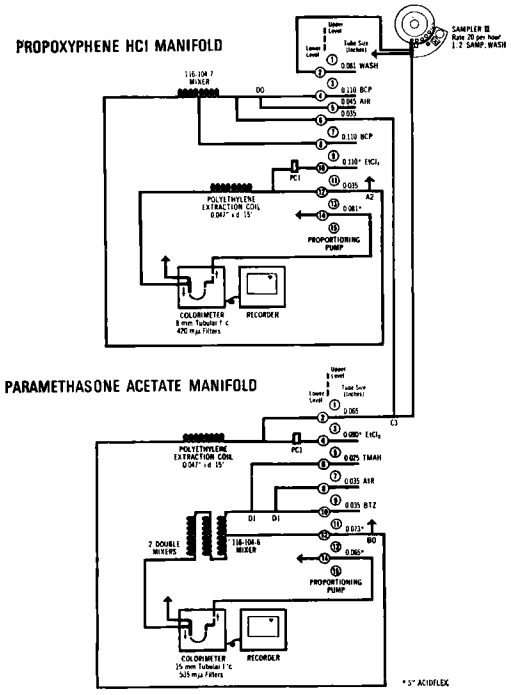

Fig. 2—Flow diagram.

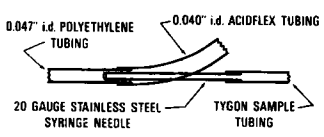

Fig. 3—Special fitting.

Procedure—The complete analytical system is outlined in the flow diagram shown in Fig. 2. The sample solution is aspirated from the liquid Sampler II and flows directly to the C3 debubbler where an unsegmented sample is taken for the PMA manifold. The remaining sample, still isolated between the air bubbles produced during sampling, flows to the DPH manifold where it is injected into an air segmented stream of BCP. This stream is further diluted with BCP and an unsegmented resample is taken at the A2 fitting. This sample is then segmented into a stream of ethylene dichloride ($EtCl_2$) by means of a fitting, previously described by Kuzel (2), and shown in Fig. 3. Extraction of the dye complex is carried out in the polyethylene mixing coil, with subsequent color measurement of the $EtCl_2$ extract after separation from the aqueous stream.

The sample taken at the PMA manifold is immediately segmented into a stream of $EtCl_2$, again using the fitting diagrammed in Fig. 3. Extraction of the PMA into the $EtCl_2$ occurs, and the unsegmented $EtCl_2$ extract is resampled from the bottom of the BO fitting. This sample is injected into an air segmented stream of BTZ and TMAH, mixed through the equivalent of five small mixing coils, and the stream debubbled before measurement in the colorimeter.

Glass wool plugs are inserted in the exit ports of both PCl pulse chambers and in the middle entrance port of the mixing coil 116-104-6 in the PMA manifold. This is done to prevent any flakes of Acidflex tubing from entering the analytical train.

In practice, five theory standards are sampled initially and the standard deviation calculated. Ten samples are then assayed in duplicate followed by standards in duplicate throughout the entire run. If the duplicate standards fall outside the range of 2 σ calculated from the first five standards, the duplicate standards are considered the appropriate values for use in the calculation of the results for the following group of samples. Normally, very little drift is experienced.

RESULTS AND DISCUSSION

The various parameters of the simultaneous methods were investigated. All concentration values listed in the figures are per 20 ml. of the Wash solution and all data were collected from combination standards of DPH and PMA unless otherwise indicated. With the exception of the BCP reagent, the brands of reagents used in this procedure were arbitrarily chosen.

Linearity of the DPH response is shown in Fig. 4 by the straight line connecting the appropriate peaks in the standard curve. All DPH data were collected on a Technicon linearized recorder. The standard curve of PMA is shown in Fig. 5. Since a normal output recorder was used in the collection of the PMA data, the pen response was charted on logarithmic paper. A plot of the absorbance values (Fig. 5) *versus* PMA concentrations results in a straight line passing through the origin. The 60-sec. sampling of the solutions in the procedure produces peak heights which are 77% of the steady state (continuous sampling response) for the PMA system and

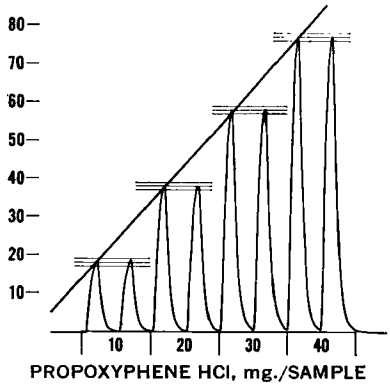

Fig. 4—Propoxyphene HCl standard curve.

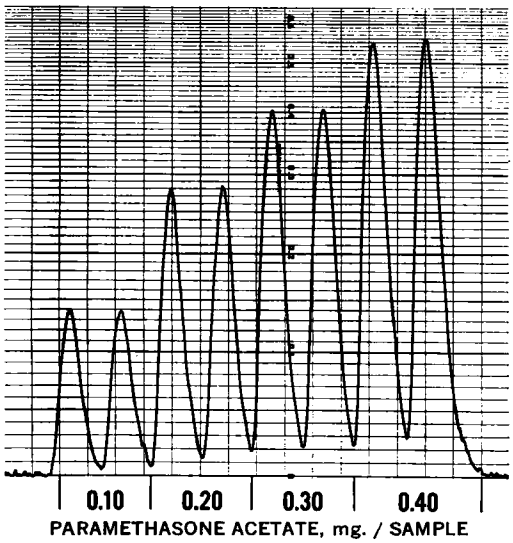

Fig. 5—Parametasone acetetate standard curve.

87% of steady state for the DPH system. Ten repetitive samplings of the Theory Standard solution demonstrated the excellent repeatability of the systems. A relative standard deviation (*RSD*) of only 0.81% was obtained from the DPH system while the PMA system produced a *RSD* of 1.11%. The effect of varying concentrations of PMA on DPH standards and of DPH on PMA standards was studied. No significant interference was observed in either system.

A placebo tablet was assayed by this procedure using 20 ml. of the Theory Standard solution to remove the tablet coating. The supernatant liquid was assayed along with the pure standard solution. An interference of minus 2% for the DPH determination and plus 2% for the PMA determination was observed.

Due to the possibility of a breakthrough of aspirin from the tablet core during coating dissolution, the effect of aspirin upon the response of DPH and PMA standards was studied. No change in DPH response to varying concentrations of aspirin was observed; however, as indicated in Fig. 6, aspirin levels somewhere between 100 mg. and 250 mg. begin to cause a decrease in the PMA response. At the level of 500

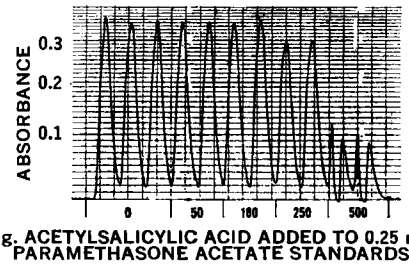

Fig. 6—Effect of acetylsalicylic acid on parametasone response.

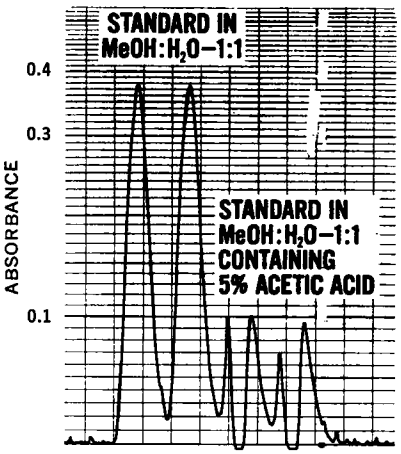

Fig. 7—Effect of acetic acid on parametasone acetate response.

mg., a peak inversion is observed. Since a basic solution is required for the BTZ reduction, it was postulated that the aspirin was producing an acidic condition which inhibited the color development. Addition of acetic acid to the standard solution as shown in Fig. 7, gave the same characteristic peak inversion obtained from the 500-mg. aspirin sample in Fig. 6.

Ten samples were taken at random from an experimental lot of tablets and assayed by the automated procedure. An average of 32.4 mg. DPH and 0.260 mg. PMA per tablet was found with a *RSD* of 5.6 and 6.5%, respectively, including tablet heterogeneity. Results obtained from this lot of tablets by a manual procedure based on a composite sample of 10 tablets were 32.3 mg. DPH and 0.253 mg. PMA per tablet.

As a result of the low PMA concentration in the formulation, the PMA manifold was designed to resample as large an amount of the $EtCl_2$ extract as possible. This in turn was injected into a minimum volume of the BTZ–TMAH reagent. Surprisingly, this resulted in a very rapid color development in the automatic analyzer system. The equivalent of only five small mixing coils was used to develop the color at room temperature. The addition of several more mixing coils before the colorimeter resulted in a relatively small increase in color intensity. Previously automated methods specify either a double holding coil (3) or a 37° heating bath (4) at this point in the flow system. In order to obtain an explanation for this accelerated color development, a study was carried out varying the percentage of

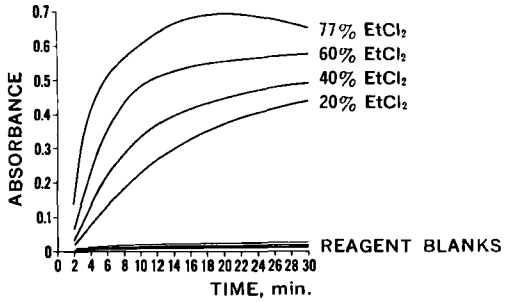

Fig. 8—BTZ–paramethasone acetate color formation.

$EtCl_2$ in the reaction mixture. The reagents used in this study were prepared as follows: 5 ml. of TMAH (10% aqueous solution) was diluted to 100 ml. with SD-3A alcohol; 25 mg. of BTZ was dissolved in 5 ml. of methanol and then diluted to 100 ml. with $EtCl_2$; 30 mg. of PMA was dissolved in 200 ml. $EtCl_2$.

Two milliliters of the PMA solution was added to four 25-ml. volumetric flasks, followed by 3 ml. of the BTZ solution; 0, 5, 10, and 15 ml. of SD-3A alcohol were pipeted into the flasks, followed by $EtCl_2$ to give a volume of about 19 ml. Five milliliters of the TMAH reagent was then added (time zero) and the solution diluted to the mark with $EtCl_2$. Reagent blanks were run substituting $EtCl_2$ for the PMA solution. The absorbance measurements used to plot Fig. 8 were obtained on a Perkin-Elmer Hitachi 139 spectrophotometer. These data show a marked acceleration of color development with increasing concentrations of $EtCl_2$. The same accelerated reaction is obtained by substituting chloroform for $EtCl_2$. Other keto-steroids (cortisone acetate, hydrocortisone acetate, prednisone, prednisolone, and flurandrenolone) assayed in both 20% and 60% $EtCl_2$, gave similar accelerated color development in the solution of greater $EtCl_2$ concentration.

Because the $EtCl_2$ concentration in the automatic analyzer system is approximately 70% and the color measured after only a 5-min. reaction time, it would seem likely from Fig. 8 that the addition of mixing coils to increase the reaction time would substantially increase the color intensity. Since this is not the case, it is speculated that the constant mixing in the automatic analyzer coils may accelerate the reaction even more than that observed by the static manual technique.

SUMMARY

An automated method for the simultaneous determination of DPH and PMA has been described. A technique for the removal of tablet coatings which may be of value in formulations of a similar nature is outlined. A further description of the construction of the stirring apparatus used in this technique was given by Comer *et al.* (6). Various parameters of the simultaneous analysis have been discussed. Due to the functional group specificity of the methods, it is probable they could be used for the simultaneous analysis of most combinations of keto-steroids and tertiary amines. It has also been demonstrated that by carrying out the steroid BTZ reduction in high concentration $EtCl_2$ solutions, an accelerated color development occurs. This knowledge, applied to the existing USP (7) and NF (8) steroid methods, could reduce the time required for these manual determinations.

Study of the Degradation of Dexamethasone in Certain Pharmaceutical Preparations

By S. K. WAHBA*, S. W. AMIN, and NAZMY ROFAEL

A chromatographic separation of the decomposition products of dexamethasone in tablet form was achieved by using thin-layer chromatography. Spectrophotometric and quantitative colorimetric analyses were run. A stable tablet formula has been suggested.

THE ANTI-INFLAMATORY corticosteroids represented by hydrocortisone and related synthetic analogs have gained an unchallenged position. The therapeutic effects of many steroids depend on their stability (1). It has been found that dexamethasone (Δ'9-fluoro-11β,17α,21-trihydroxy-16-methyl pregna-1,4-diene-3,20-dione) should be protected from light (2) and it has been proved that 50% oxidation of the α-ketol side chain occurs within 6–8 min. in the presence of a base catalyst (3). Dexamethasone has a marked oral potency in range of about 30 times that of hydrocortisone (4–7). The high oral potency is attributed to the protection from metabolic inactivation of the 17,21-dihydroxyacetone side chain by steric hindrance of 16-methyl substituents (8, 9). Identification and investigation of 16-methyl-9-fluoroprednisolone was reported to be carried out by infrared, ultraviolet spectra and triphenyltetrazolium chloride color reaction (10). It has been observed that the direct spectrophotometric analysis of a methanolic extract of dexamethasone tablets yield higher results than the triphenyltetrazolium chloride color assay on aged tablets. A study of the methods of analysis, degradation, and stability of dexamethasone tablets, leads to the finding of a stable tablet formula.

EXPERIMENTAL

Materials—(*a*) Dexamethasone (Roussel). The sample was purified by recrystallization from ether. Purity was confirmed by physicochemical means. m.p. 263°, infrared, ultraviolet absorption. (*b*) Polyvinylpyrrolidone (Kollidon-25, Badische Anilin and Soda Fabrik). (*c*) 2,3,5-Triphenyl tetrazolium chloride (Reanal-Hungary). (*d*) Talc, lactose, starch, magnesium stearate, Cellulose acetate phthalate, carboxymethylcellulose, acetone, ethyl alcohol, methyl alcohol, chloroform, sulfuric acid, Silica Gel G, all from the British Drug House and of analytical grade.

Procedure—*Thin-Layer Chromatography*—Methanolic and chloroformic extracts of dexamethasone tablets were spotted beside methanolic and chloroformic solutions of authentic sample (NF XII) of dexamethasone on 0.3 mm. thick Silica Gel G plates. The plates were developed with chloroform–methanol mixture (9:1). The plates were dried, sprayed either with triphenyltetrazolium chloride reagent (11) (Fig. 1) or sulfuric acid 50% in methanol, and then heated at 80° for 10 min. (12) (Fig. 2). The results obtained are illustrated in Figs. 1 and 2.

From Figs. 1 and 2 it is clear that the methanolic extract of the tablets showed two spots with sulfuric acid reagent; one of them is identical with the spot obtained from the chloroformic extract. On using the triphenyltetrazolium chloride reagent the methanolic extract gave only one spot which was found to be identical with that obtained by the chloroformic extract of the tablets and those of the authentic sample. Hence the lower spot proved to be nonextractable with chloroform.

Quantitative Determination of Standard Dexamethasone, Corresponding Spots, and Its Degradation Products—Dexamethasone authentic sample was assayed by direct ultraviolet absorption at 240 mμ as well as colorimetrically following the official

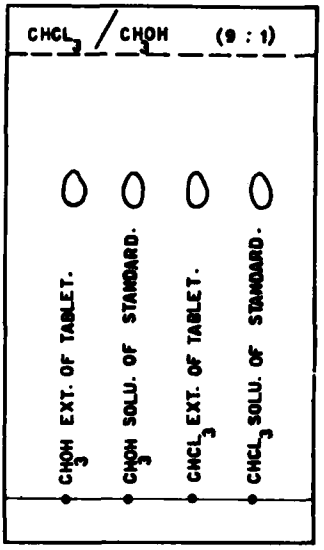

Fig. 1—Dexamethasone chromatograms sprayed with tetrazolium chloride reagent.

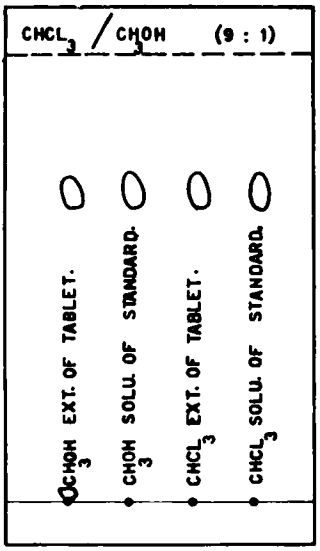

Fig. 2—Dexamethasone chromatograms sprayed with sulfuric acid reagent.

method (13). The tablets were similarly treated when the direct spectrophotometric determination for a methanolic extract gave higher results than the colorimetric method. The chloroformic extract of the same batch of tablets gave the same result as the colorimetric method when assayed spectrophotometrically. Elution of the spots corresponding to the authentic dexamethasone was effected from the plates with methanol. The methanolic eluate was assayed spectrophotometrically for its dexamethasone content. At the same time, the eluate of the lower spot was similarly assayed.

The results obtained are shown in Table I.

Stability of Dexamethasone in Tablet—Preparation of the tablets: four different samples of dexamethasone tablets of the following general formula were prepared: dexamethasone, 0.5 mg., lactose, 88 mg., starch, 15 mg., talc, 3 mg., magnesium stearate, 1.5 mg.

Sample 1: Prepared by the slugging method (14). Sample 2: Prepared by the wet granulation method (16) using 20% solution of polyvinylpyrrolidone in alcohol as a binding agent. Sample 3: Prepared by the wet granulation method using 3% solution of cellulose acetate phthalate in acetone as a binding agent. Sample 4: Prepared by the wet granulation method using 3% mucilage of carboxymethylcellulose in water as a binding agent.

An amount of lactose equivalent to the polyvinylpyrrolidone, cellulose acetate phthalate and carboxymethylcellulose used was reduced from the weight of lactose in the general formula. All tablets were compressed to give a hardness of 3 kg. using a single-punch Korsch machine.

Quantitative Analysis—The four mentioned tablets were assayed using the official colorimetric method every 20 days. Shelf storage at 25° at 60% relative humidity, temperature of 40°, 60°, and humidity of 75% and 100% at 25° temperature were chosen as different factors to compare their stability so as to choose the best tablet formula for making the most stable tablet.

TABLE I—PERCENTAGE OF DEXAMETHASONE IN DIFFERENT ELUATES

Eluate	Ultraviolet Absorption at 240 μ	Dexamethasone, %
Methanolic dexamethasone standard	1.100	100
Methanolic extract of tablets[a]	1.290	117
Methanolic extract of upper spots	0.840	76.3
Methanolic extract of lower spots	0.458	39.09

[a] Direct methanolic extract from tablets.

The results obtained are shown in Table II.

Rate of Degradation—The rates of degradation of the four tablets were found to be a pseudo first-order reaction. Figure 3 shows the relation between the log concentration of dexamethasone and time. The rate of K_{25} and the half-life (16) of the four tablets are shown in Table III.

Observations—(*a*) The high result in the total methanolic tablet extract is due to the decomposition product which absorbs heavily at that wavelength. (*b*) The summation of the absorption of the two spots is equal to the absorption of the direct methanolic extract.

RESULTS AND DISCUSSION

According to the chromatographic analysis the dexamethasone tablet, prepared either by the slugging or the wet granulation method, on aging even at room temperature (shelf) suffered from cleavage of the α-ketol side chain group. This was indicated by the fact that the lower spot was only visible with the sulfuric acid reagent and gave no color with the triphenyltetrazolium chloride reagent which is specific for this group. Hence the direct spectophotmetric determination of a methanolic extract gave higher results than the colorimetric method.

The tablets formulated with polyvinylpyrrolidone as a binding agent showed the greater stability against different humidity and temperature factors and the longest half-life time.

SUMMARY

(*a*) Tablets formulated by slugging or wet

[a] a = initial concentration %, x = degradation %, K_{2s} = integrated rate equation.

granulation method and different binding agent except with polyvinylpyrrolidone showed instability toward different humidity and temperature factors.

(*b*) The TLC analysis of the methanolic extract of the tablets showed two spots; one of them is identical with the authentic dexamethasone spot. Meanwhile the other spot could not be localized on using triphenyltetrazolium chloride reagent as a spray which indicates the cleavage of the keto side-chain group.

(*c*) Direct spectrophotometric determination of different degradation products separated by TLC or direct extraction from tablets confirmed the colorimetric assay.

Problem in the Estimation of Drugs in Biologic Tissue Recovery of Phenol Red from the GI Tract

By STUART FELDMAN and MILO GIBALDI

Recovery of phenol red from homogenates of rat intestinal tissue, using aqueous extraction procedures, was near quantitative. However, significantly poorer recovery was observed after incubation of phenol red with intact intestinal sacs. It appears likely that phenol red binds to tissue or mucosa when in intimate contact, and the bound material is relatively resistant to aqueous extraction. The relevance of this phenomenon to tissue assays is considered.

THE CLASSIC approach to the determination of drug concentration in tissue involves the extraction of the compounds from homogenates. The general principles of this approach have been set forth by Brodie *et al.* (1). Accordingly, experimental standards are based on the recoveries of known amounts of drug from tissue homogenates. The assumption is made that the extent of recovery of standard quantities from the homogenate is equivalent to the recovery from *in vivo* tissue after drug uptake. The authors have recently observed anomalies in the recovery of phenol red from the gastrointestinal tracts of intact rats, rat intestinal sacs, and tissue homogenates, which suggest that the usual assumption of equivalent recovery may lead to significant error.

EXPERIMENTAL

Materials—Phenol red, trichloroacetic acid, and sodium hydroxide were obtained from Fisher Scientific Company as certified reagent grade.

Methods—Male Sprague-Dawley descent rats (Blue Spruce Farms, Altamont, N. Y.) weighing 140–180 Gm. were fasted 24 hr. The animals were then sacrified by decapitation, and the stomach and small intestine were removed. The small intestine was divided into three segments of equal length.

Tissue Homogenates—The stomach and each intestinal segment were homogenized individually for 5 min. in an Eberbach homogenizer with a minimum quantity of distilled water (approximately 3 ml.). The homogenates were placed in Nalgene tubes and 0.5 ml. of a 70 mg. % phenol red solution was added to each tube. The tubes were then agitated slowly for 1 hr. at 37° in a gyrotory water bath shaker.

Gastric Pouch and Intestinal Sacs—Each segment was ligated at both ends and 0.5 ml. of a 70 mg. % phenol red solution was injected in the pouch or sac through the ligated end by means of a 1-ml. tuberculin syringe and blunt needle. No loss of phenol red was observed through the ligatures.

Each segment was then placed in 20 ml. of Ringer's solution in a culture tube. The tubes were agitated for 1 hr. at 37°. The sac or pouch was then removed and homogenized as described above. The serosal fluid was also retained for assay.

Assay—The assay procedure was essentially that of Reynell and Spray (2). Each tissue segment (or homogenate thereof) was homogenized for 5 min. with 1 ml. of 1 *N* sodium hydroxide and about 5 ml. of distilled water. The resulting homogenate was brought to 30 ml. volume with distilled water, centrifuged, and filtered through a Büchner funnel. A 10-ml. aliquot was taken and 1 ml. of a 30% w/v trichloroacetic acid solution was added to the aliquot to precipitate proteins. After centrifugation 5 ml. of the supernatant was removed and 1 ml. of a 1 *N* sodium hydroxide solution was added to develop the color to maximum intensity. The solution was further diluted, passed through a Millipore filter (0.45 μ pore size), and assayed with a Beckman DB-G spectrophotometer at 560 mμ.

RESULTS

Table I shows the recovery of phenol red after addition to homogenates of various gastrointestinal segments. Recovery ranged from 93% to 103% with little difference between homogenates of different segments. The average recovery of phenol

Middle	95	103
Distal	100	96

red from all segments of both rats was 97%. These findings are in agreement with those of Reynell and Spray (2) who observed quantitative recovery of phenol red from gastrointestinal tissue homogenates.

The recovery of phenol red after incubation in gastric pouches or intestinal sacs was in marked contrast to the recovery from homogenates. The data in Fig. 1, which represents *total recovery* (*i.e.*, from sac or pouch, its content, and serosal fluid) show a significant *apparent* loss of phenol red from the intestinal segments. The recovery of phenol red from the proximal intestinal segments was significantly different from the recovery from each of the other segments at the 99% confidence level. A progressive increase in recovery is observed from the first to the third intestinal segment. The average recovery of phenol red from all segments was 70%. In each case, 5–10% of the recovered phenol red represents material which permeated the sac to the serosal fluid.

A further experiment was devised to determine whether incomplete mixing of the phenol red with the tissue homogenate was responsible for the excellent recovery from these preparations compared to the recovery from the sacs. In two studies phenol red was homogenized with the intestinal segments for 5 min. to ensure intimate mixing. The homogenates were then incubated as described above for 1 hr. and assayed for phenol red. The results are shown in Table II. An average of 92% phenol red was recovered from the homogenates indicating that mixing does not account for the observed differences.

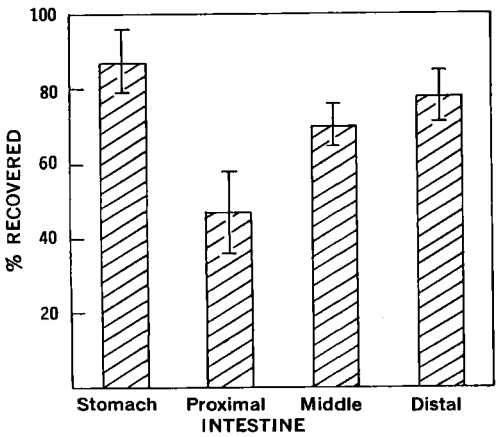

Fig. 1—Phenol red recovery from gastric pouch and intestinal sacs 1 hr. after intubation. Key: bar, average of 5 segments; vertical lines, standard deviations.

Distal	98	100

DISCUSSION

The reason for the poor recovery of phenol red from intact sacs appears to be related to mucosal or tissue binding, since the possibility of mucosal metabolism has been ruled out by the work of Levine (3). Moreover, the degree of recovery of phenol red from the sacs was site dependent with increasing recovery in the distal direction. This finding is consistent with the amount of mucosal surface available for binding in various portions of the small intestine. If similar binding sites exist throughout the small intestine, then under the conditions of this experiment the greatest amount of phenol red would be bound to the segment having the largest mucosal surface area, *viz.* the proximal portion of the small intestine.

The nature of the binding requires further investigation. However, it would appear to require the mucosa and the phenol red to be in intimate contact. Dilution with fluids or tissue mass, as in the homogenate studies, greatly minimizes the degree of binding. Although the mucosal-bound phenol red is resistant to aqueous extraction, it is unlikely that the binding is covalent since Levine has effected quantitative extraction with ethanolic solutions (3).

The difference in recovery from sac homogenates and intact sacs indicates clearly the possible error involved in assuming the recovery of drug added to homogenates reflects the ultimate efficiency of the tissue assay procedure. This is further emphasized by considering the recovery of phenol red after administration to intact rats.

The authors have recently reported an average recovery of 80% of a dose of phenol red from the gastrointestinal tract, 0.5 hr. after gastric intubation in rats (4). Levy and Jusko (5) report an average recovery of 81% after oral administration of phenol red to rats. In view of the recovery of phenol red from tissue homogenates, one might assume that 15–20% of the dose of phenol red is absorbed from the tract. This value, however, is a significant overestimate. Levine (3) has found that less than 7% of a phenol red dose is absorbed from the gastrointestinal tract. Schanker (6) and Tidball (7) have observed still poorer absorption in the range of 1–2%. On the basis of these reports one must conclude that about 15% of the dose of phenol red is bound to mucosa or tissue *in vivo* and not recovered by the aqueous extraction procedure. The results of these incubation studies with gastric pouches and intestinal sacs are qualitatively consistent with the *in vivo* binding of phenol red.

No previous reports known to the authors have considered the possibility of nonequivalent extraction efficiency after incubation of drug with homogenates or intact tissue. Hence, the extent to which this problem does exist is now known. Nevertheless,

the possibilities and ramifications are manifest. The approach of incubating the drug with intact tissue before homogenization and assay may be a useful one and should be considered even when quantitative extraction from a homogenate is obtained.

Method for Testing the Efficacy of Topical Sunscreen Preparations

By W. M. KOOYERS

A method has been developed for testing the efficacy of topical sunscreen preparations using photosensitive albino rats. The method involves pretreatment of one hind paw with a sunscreen preparation, followed by an oral dose of a photosensitizing agent and exposure to direct sunlight. The delayed reaction and resulting difference between the treated and untreated hind paw weight is an objective index of the protection afforded by the preparation tested.

INTEREST IN topical sunscreen preparations was stimulated by the successful treatment of light-sensitive patients at the University of Minnesota Hospital. Fusaro and Runge (1–3) reported clinical data supporting the hypothesis that topical treatment of the stratum corneum can reduce or minimize the harmful effect of ultraviolet radiation.

The researcher's never-ending quest for new or better means to treat human diseases has led to the development of biological systems which simulate these diseases. As the diabetic rat is used as a screen for antidiabetic drugs (4), and the adjuvant arthritic rat for testing anti-inflammatory drugs (5), this method uses a photosensitive rat to test the efficacy of topical sunscreen preparations. A sunscreen preparation (SSP) is defined as a formulation which, when applied topically, protects the treated area from sunburn.

Albino rats are not hyperphotosensitive; however, rats treated orally with 25 mg./Kg. of 8-methoxypsoralen (8-MOP) become very photosensitive (6–9). Subsequent exposure of 3–7 hr. of direct sunlight will initiate a delayed reaction that progressively worsens. The resulting erythema, edema, and blindness will incapacitate these rats after 5–7 days. Rats photosensitized with 8-MOP, which have only part of their extremities exposed to direct sunlight, will show evidence of photosensitivity on the exposed areas only (9).

This photosensitive reaction is evident 2 or 3 days after exposure and can be visually evaluated by scoring the affected extremities from 0 to 4 depending upon the severity of the erythema and edema. A more objective index is the comparison of hind paw weights of photosensitive rats and normal rats. This is a measurement of the edema caused by the reaction. This objective index is used in this method.

METHOD

Five male albino rats[1] per group, weighing 180–200 Gm., were restrained in stocks while each left hind paw was dipped into the SSP. The restraint was maintained until the treated area was completely dry. This minimized the possibility of systemic effect that could be caused by ingestion if the rats were allowed to clean the treated area.

After application of the SSP, the sunscreen groups and one control group were dosed orally with the photosensitizing agent, 8-MOP[2] at 25 mg./Kg., and were then placed in direct sunlight for 5 hr. Each group was housed in a cage designed to allow maximum exposure to the sunlight. Normal controls were exposed simultaneously.

Three to seven days after exposure, the rats were sacrificed, body weights recorded, and both hind paws were uniformly severed (10) using a suitable apparatus.[3] The weight of each hind paw was recorded. The weight difference between the untreated right hind paw and the treated left hind

Method for Testing the Efficacy of Topical Sunscreen Preparations

By W. M. KOOYERS

A method has been developed for testing the efficacy of topical sunscreen preparations using photosensitive albino rats. The method involves pretreatment of one hind paw with a sunscreen preparation, followed by an oral dose of a photosensitizing agent and exposure to direct sunlight. The delayed reaction and resulting difference between the treated and untreated hind paw weight is an objective index of the protection afforded by the preparation tested.

INTEREST IN topical sunscreen preparations was stimulated by the successful treatment of light-sensitive patients at the University of Minnesota Hospital. Fusaro and Runge (1–3) reported clinical data supporting the hypothesis that topical treatment of the stratum corneum can reduce or minimize the harmful effect of ultraviolet radiation.

The researcher's never-ending quest for new or better means to treat human diseases has led to the development of biological systems which simulate these diseases. As the diabetic rat is used as a screen for antidiabetic drugs (4), and the adjuvant arthritic rat for testing anti-inflammatory drugs (5), this method uses a photosensitive rat to test the efficacy of topical sunscreen preparations. A sunscreen preparation (SSP) is defined as a formulation which, when applied topically, protects the treated area from sunburn.

Albino rats are not hyperphotosensitive; however, rats treated orally with 25 mg./Kg. of 8-methoxypsoralen (8-MOP) become very photosensitive (6–9). Subsequent exposure of 3–7 hr. of direct sunlight will initiate a delayed reaction that progressively worsens. The resulting erythema, edema, and blindness will incapacitate these rats after 5–7 days. Rats photosensitized with 8-MOP, which have only part of their extremities exposed to direct sunlight, will show evidence of photosensitivity on the exposed areas only (9).

This photosensitive reaction is evident 2 or 3 days after exposure and can be visually evaluated by scoring the affected extremities from 0 to 4 depending upon the severity of the erythema and edema. A more objective index is the comparison of hind paw weights of photosensitive rats and normal rats. This is a measurement of the edema caused by the reaction. This objective index is used in this method.

METHOD

Five male albino rats[1] per group, weighing 180–200 Gm., were restrained in stocks while each left hind paw was dipped into the SSP. The restraint was maintained until the treated area was completely dry. This minimized the possibility of systemic effect that could be caused by ingestion if the rats were allowed to clean the treated area.

After application of the SSP, the sunscreen groups and one control group were dosed orally with the photosensitizing agent, 8-MOP[2] at 25 mg./Kg., and were then placed in direct sunlight for 5 hr. Each group was housed in a cage designed to allow maximum exposure to the sunlight. Normal controls were exposed simultaneously.

Three to seven days after exposure, the rats were sacrificed, body weights recorded, and both hind paws were uniformly severed (10) using a suitable apparatus.[3] The weight of each hind paw was recorded. The weight difference between the untreated right hind paw and the treated left hind

paw was an objective index of the protection afforded by the SSP. The statistical significance of this weight difference was evaluated by the *t* test on differences.

RESULTS AND DISCUSSIONS

Results presented in Table I are typical for this method. The body weights were routinely recorded to help identify aberrant rats. Normal and photosensitive controls are used to prove the sensitivity of this biological system. The hind paw weights within each control group are uniform; however, the photosensitive controls weigh considerably more than normal controls. This edematous condition of the photosensitive rats occurred 3–7 days after the oral dose of 8-MOP and exposure to direct sunlight.

The efficacy of the SSP is evident in Groups 3, 4, 7, and 8 of Table I. The average weight of sunscreen-treated left hind paws is similar to that of normal controls, while the untreated right hind paws are edematous like the photosensitive controls. The calculated weight difference between the untreated and treated paws of each rat is evidence of the protection afforded the treated paw by the SSP.

Using five rats per group, this weight difference is statistically significant at $p = 0.01$ when evaluated by the *t* test on differences. These statistical data are reported in Table II.

SUMMARY

A method for testing the efficacy of topical sunscreen preparations is reported. The hind paw weight difference of photosensitive rats is a statistically significant index, easily controlled, and objective.

Studies on the Mechanism of Action of Salicylates III. Effect of Vitamin A on the Wound Healing Retardation Action of Aspirin

By K. H. LEE

Vitamin A and vitamin E reverse the skin-wound healing retardation action of aspirin in rats. Vitamin A alone promotes healing and it also increases acid mucopolysaccharide synthesis in the granulation tissue. The possible mechanisms of action of vitamin A and aspirin on wound healing are discussed.

IN A PREVIOUS PAPER (1), it was shown that aspirin, like cortisone (2, 3), reduces the tensile strength of healing skin wound in rats. Lysosomal enzymes are believed to be involved in inflammation (4). Since aspirin protects lysosomal membrane (5), it was proposed that aspirin retarded healing by its anti-inflammatory action. It is well-known that vitamin A, vitamin E, and a few other fat-soluble compounds can accelerate the release of lysosomal enzymes (6–8). In the present study it was found that both vitamin A and vitamin E reversed the inhibitory action of aspirin on wound healing in rats. It was found that, in the absence of aspirin, vitamin A promoted wound healing.

Mucopolysaccharide formation in the very early phase of wound healing was noticed in many laboratories (9–12). The role of mucopolysaccharides in the formation of connective tissue or collagen has been of interest for many years (12–14). Aspirin and other anti-inflammatory agents inhibited the biosynthesis of mucopolysaccharide and sulfate uptake for chondroitin sulfate synthesis by cartilage slices (15, 16). Vitamin A, on the other hand, increased sulfate incorporation into chrondritin sulfate (17) and increased mucopolysaccharide synthesis (18, 19). In this paper the effect of vitamin A on mucopolysaccharide content of the granulation tissues in rats is reported. The possible mechanisms of action of aspirin and vitamin A on healing are discussed.

EXPERIMENTAL

Wound Procedure—The wound procedure for tensile strength study was essentially the same as described before (1). For mucopolysaccharide study, the wounding technique described by Bentley (12) was followed. Sprague-Dawley rats of either sex, weighing 200–220 Gm., were anesthetized with ethyl ether in an open mask. The hair on the back was depilitated with an electric clipper. One circular piece of skin 5 cm. (2 in.) in diameter, was removed. The wound was left undressed. On the seventh day after wounding, each rat was decapitated and the granulation tissue of the wound was carefully dissected. There were 10 rats in each group. The granulation tissue of all 10 rats of the same group was pooled together.

The body weight of each rat was taken before inflicting the wound and before sacrificing the animal.

Mucopolysaccharide Separation—The mucopolysaccharide separation method described by Bentley (14) was followed with some modification. The granulation tissue was homogenized in a Virtis homogenizer at 45,000 r.p.m. in phosphate buffer pH 8. For every gram of granulation tissue, 5 ml. of buffer was added. Three volumes of boiling acetone was added to the homogenate with stirring. After the precipitate was settled, the supernatant was carefully removed by suction. The acetone extraction was repeated two more times. The fat-free precipitate was separated by suction filtration. The precipitate was washed once with dry ether and then stored *in vacuo* over paraffin wax and phosphorus pentoxide. Three aliquots of the dried fat-free precipitate were digested separately with twice-crystallized papain as described by Antonopoulos *et al.* (20) at 65° for 8 hr. After digestion, the mixture of each sample was centrifuged separately in a Sorvall SS-1 superspeed centrifuge at 10,000× g for 30 min. Aliquot amount of the clear supernatant in each centrifuge tube was dialyzed salt-free in a cellophane tube. Mucopolysaccharide was precipitated from the clear dialysate by the addition of ethanol to a concentration of 80% together with trace amounts of sodium acetate. The precipitate was collected in a centrifuge tube by centrifugation and then redissolved in a small amount of water and reprecipitated by the addition of a small amount of cetylpyridinium chloride (CPC) (21). The CPC-mucopolysaccharide precipitate (CPC-MPS) was redissolved in 60% *n*-propanol and again precipitated by the addition of ethanol and sodium acetate. The precipitate was washed in absolute ethanol, dry ether, and dried *in vacuo* over paraffin wax and phosphorus pentoxide. The dried precipitate was weighed.

Administration of Drugs—Aspirin was administered essentially the same way as described before (1). Crystalline vitamin A acetate (Calif. Corp. Biochem. Research, Los Angeles) was dissolved in cottonseed oil so that each ml. contained 15,000 I.U. One-tenth of a milliliter of this oil containing vitamin A was injected intraperitoneally into each rat on the first, third, and fifth day after inflecting the wound. To the controls, similar amounts of cottonseed oil without vitamin A were given in the same manner. *dl*-Alpha-tocopherol NF (N.B.C., Ohio) was also dissolved in cottonseed oil, so that each milliliter contained 500 I.U. One milliliter of this oil was injected intraperitoneally into each rat on the

[a] 3,000 I.U./Kg. [b] 1,000 I.U./Kg. [c] Reported before (1).

first, third, and fifth day after wounding. One milliliter of plain cottonseed oil was injected into each of the controls. For the effect of vitamin A on the mucopolysaccharide formation in the granulation tissue studies, the experimental rats received only vitamin A (3,000 I.U./Kg.) intraperitoneally on the first, third, and fifth day after wounding. The controls received cottonseed oil. All of the rats were fed on standard rat feed prepared by Feedstuffs Processing Company, San Francisco, Calif.

Tensile Strength Measurement—The tensile strength of the healing skin wound was measured with the laboratory made centiometer as described earlier (1).

RESULTS

In Table I it is shown that rats receiving an oral dose of 150 mg./Kg. of aspirin daily, starting 1 day before wounding, have an average tensile strength of skin wound of 262 ± 8.7 Gm. on the seventh day which is about 60% of that of the control. When 1,500 I.U./rat (3,000 I.U./Kg.) of vitamin A was given intraperitoneally to rats treated under essentially the same conditions as described above, on the first, third, and fifth day after wounding, the average tensile strength was increased to 338 ± 22.7 Gm., or 77% of the control (Table I, Group III). The increase in tensile strength is significant ($p < 0.001$). When vitamin A was given on the day of wounding and also on the second, fourth, and sixth day after wounding, the average tensile strength was increased to 325.5 ± 17.6 Gm. (Group IV). The improvement was about the same as that of the rats of Group III.

When the dose of aspirin was reduced to 75 mg./Kg. the average tensile strength of the skin wound was 343 ± 21 Gm. or 78% of the control (Group VI). When vitamin A was given to rats receiving 75 mg. of aspirin daily, the average tensile strength was increased to 447 ± 14.0 Gm. (Group VII). Group VII had no significant difference from the control. However, if vitamin A alone was given to rats receiving no aspirin, the average tensile strength was increased to 490 ± 11.0 Gm. or 112% of the control.

When vitamin E (1,000 I.U./Kg.) was given to rats receiving 75 mg. of aspirin daily on the day of wounding and also on the second, fourth, and sixth day after wounding, the average tensile strength on the seventh day after wounding was 294 ± 14.8 Gm. (Group V). Vitamin A significantly reversed the retardation of wound healing action of aspirin.

The results of the studies on mucopolysaccharide formation in granulation tissue of the wound are summarized in Table II. There were 10 rats in each group and at the end of the experiment, in all cases except one, only 8 rats survived. The first 2 days after operation were critical. Rats which survived the first 2 days usually survived to the end of the experimental period. The average amount of CPS-MPS in the granulating tissue of the wound inflicted on the rats receiving vitamin A was 14.10 ± 4.3 mg./rat. The average amount of CPC-MPS of the control was 8.92 ± 1.26 mg./rat. The difference is significant. The Student test was used for evaluating significance in all cases.

TABLE II—EFFECT OF VITAMIN A ON MUCOPOLYSACCHARIDE FORMATION IN GRANULATION TISSUE

[a] Average of triplicate determinations for each group.

DISCUSSION

In a previous study (1), it was proposed that the wound healing retardation action of aspirin is due to its lysosomal membrane protection activity. This suggestion is further supported by the present study. Vitamin A and vitamin E are known to be able to release lysosomal enzymes (22). In the present study, it has been shown that vitamin A, as well as vitamin E, indeed, reversed the wound healing retardation action of aspirin.

Within 6 hr. and increasing for 4 days after wounding, mucopolysaccharide can be demonstrated in the ground substance of the regenerating tissue (23). The direct relation between mucopolysaccharide and collagen formation has been of interest for many years (24). Highberger *et al.* (25), from *in vitro* studies, have shown that a dialyzed acid solution of collagen can be made to precipitate into collagen fiber in the presence of an acid polysaccharide such as chrondroitin sulfuric acid. The collagen fiber formed looked essentially like the natural fiber under electron microscope. The soluble procollagenous substance requires mucopolysaccharide as a template to form insoluble collagen fiber (23). Collagen provides tensile strength to a wound.

Aspirin and a few other anti-inflammatory agents, which inhibited the metabolism of cartilage and other connective tissues *in vitro*, also inhibited the biosynthesis of polysaccharide sulfates by rat

rib cartilage *in vivo* (15). Aspirin (16) also decreased sulfate exchange of chondroitin sulfuric acid.

Wolf and his co-workers (18, 19) have demonstrated the role of vitamin A in the synthesis of mucopolysaccharide in rat colon segments. Recently, it was further shown (26) that a compound which appeared to be an acidic metabolite of vitamin A and vitamin acid was a component of ATP-sulfurylase (ATP: sulfate adenyltransferase, EC2.7.7.4), an enzyme involved in the first step of activation of sulfate. In the present study, it was shown that vitamin A promoted mucopolysaccharide synthesis in the granulation tissue of skin wound in rats. The effect of vitamin A and aspirin on acid mucopolysaccharide synthesis probably is another mechanism of action of these compounds on wound healing.

SUMMARY

The reversal of healing retardation action of aspirin by vitamin A and vitamin E has been demonstrated in rats. In the absence of aspirin, vitamin A promoted healing. It also increased acid mucopolysaccharide synthesis in the granulation tissue.

Inflammation and acid mucopolysaccharide synthesis are two essential features in the early stage of wound healing. Aspirin inhibited both features and vitamin A promoted both features. Two possible mechanisms of action of these two compounds are suggested.

Separation of Acetylsalicylic Acid and Salicylic Acid by Sephadex Gel Filtration

By K. H. LEE, LEON THOMPKINS*, and MICHAEL R. SPENCER

Acetylsalicylic acid and salicylic acid can be quantitatively separated by Sephadex gel filtration. A comparative study has been made by using different types of Sephadex gels.

THE AMOUNT of acetylsalicylic acid (ASA) in the biological tissues is generally determined as salicylic acid (SA) after it is hydrolyzed in the presence of the preexisted amount of SA (1). This method has large error when SA present is in great excess of ASA, a situation which often occurs in practice. A few attempts have been made to determine ASA and SA separately. Rowland and Riegelman (2) described a gas-liquid chromatography method for the determination of SA and ASA (as its silyl derivative) in plasma. Earlier, Cotty and Ederma (3) introduced a direct method for the measurement of ASA in human blood. They removed SA by reaction with ceric ammonium nitrate from salicylates mixture. These methods require two extraction procedures to remove salicylates from plasma and also require the preparation of ASA or SA derivatives. Potter and Guy (4) described a simple method for the separation of plasma protein bound SA and free SA by subjecting plasma directly to Sephadex gel filtration. This method, with modifications, can be used for the

rib cartilage *in vivo* (15). Aspirin (16) also decreased sulfate exchange of chondroitin sulfuric acid.

Wolf and his co-workers (18, 19) have demonstrated the role of vitamin A in the synthesis of mucopolysaccharide in rat colon segments. Recently, it was further shown (26) that a compound which appeared to be an acidic metabolite of vitamin A and vitamin acid was a component of ATP-sulfurylase (ATP: sulfate adenyltransferase, EC2.7.7.4), an enzyme involved in the first step of activation of sulfate. In the present study, it was shown that vitamin A promoted mucopolysaccharide synthesis in the granulation tissue of skin wound in rats. The effect of vitamin A and aspirin on acid mucopolysaccharide synthesis probably is another mechanism of action of these compounds on wound healing.

SUMMARY

The reversal of healing retardation action of aspirin by vitamin A and vitamin E has been demonstrated in rats. In the absence of aspirin, vitamin A promoted healing. It also increased acid mucopolysaccharide synthesis in the granulation tissue.

Inflammation and acid mucopolysaccharide synthesis are two essential features in the early stage of wound healing. Aspirin inhibited both features and vitamin A promoted both features. Two possible mechanisms of action of these two compounds are suggested.

Separation of Acetylsalicylic Acid and Salicylic Acid by Sephadex Gel Filtration

By K. H. LEE, LEON THOMPKINS*, and MICHAEL R. SPENCER

Acetylsalicylic acid and salicylic acid can be quantitatively separated by Sephadex gel filtration. A comparative study has been made by using different types of Sephadex gels.

THE AMOUNT of acetylsalicylic acid (ASA) in the biological tissues is generally determined as salicylic acid (SA) after it is hydrolyzed in the presence of the preexisted amount of SA (1). This method has large error when SA present is in great excess of ASA, a situation which often occurs in practice. A few attempts have been made to determine ASA and SA separately. Rowland and Riegelman (2) described a gas-liquid chromatography method for the determination of SA and ASA (as its silyl derivative) in plasma. Earlier, Cotty and Ederma (3) introduced a direct method for the measurement of ASA in human blood. They removed SA by reaction with ceric ammonium nitrate from salicylates mixture. These methods require two extraction procedures to remove salicylates from plasma and also require the preparation of ASA or SA derivatives. Potter and Guy (4) described a simple method for the separation of plasma protein bound SA and free SA by subjecting plasma directly to Sephadex gel filtration. This method, with modifications, can be used for the

quantitative separation of free ASA and free SA (5). In the present paper the method and also the results of a comparative study on the efficiency of several other types of Sephadex is reported.

EXPERIMENTAL

Chemicals and Materials—The acetylsalicylic acid, ACS grade was obtained from City Chemicals Corporation and the salicylic acid used was Baker analyzed reagent. Sephadex G-25-coarse, G-25-medium, C-25, A-25, G-15, and G-10 were prepared by Pharmacia Fine Chemicals Inc.

Preparation of Column—The column was prepared in a special needle-type Pasteur pipet, 5 mm. i.d. The length of the pipet was about 3 cm. longer than the height of the gel bed. A small amount of Pyrex glass wool was placed in the bottom of the pipet and a slurry of well-soaked Sephadex was introduced into the column. The Sephadex was allowed to settle under gravity and the height of the column was adjusted. A long stainless steel wire was used to stir the column and assist in uniform packing. A standard number 19-G hypodermic needle was then placed on the tip of the Pasteur pipet. The column was washed with phosphate buffer (0.1 *M* at pH 7.4). Every eight drops of effluent is equal to 0.1 ml.

Fractionation of ASA and SA—Two-tenth milliliter of a sample containing freshly prepared ASA (2×10^{-4} *M*) and SA (8×10^{-4} *M*) in phosphate buffer was introduced to the column from a long tip pipet. The concentration of the salicylates used are within the range present in biological fluid. As soon as the sample had disappeared from the surface of the gel bed, phosphate buffer was introduced for elution. A fraction collector (GME product) with drop counter was used to collect 16-drop (0.2-ml.) portions of the effluent. The effluent in each tube was diluted to 4 ml. and assayed in the spectrophotofluorometer (Aminco-Bowman), using an activating wavelength of 305 mμ and detecting fluoresence at 405 mμ (4). All of the samples were saved in their original tubes. Acetylsalicylate does not fluoresce, but can be measured after hydrolysis. The hydrolysis was carried out by adding one drop of concentrated ammonium hydroxide to each sample and then heating in a boiling water bath for 5 min. After cooling to room temperature, the volume in each tube was readjusted to 4 ml. before assaying again in the fluorometer. For each type of Sephadex, the 100-mm. column was usually tried first and from the result obtained the decision was made to choose columns of other lengths. For each type of Sephadex the authors filled three Pasteur pipets for each column length. The types of Sephadex studied included G-25-medium (G-25-m), G-25-coarse (G-25-c), G-15, G-10, C-25 (carboxymethyl-Sephadex), and A-25 (DEAE-Sephadex).

RESULTS AND DISCUSSION

Sephadex G-25, with 100-mm. column length, as shown in Fig. 1, can separate ASA and SA into two distinct fractions, but the fractions are too close to each other. Two fractions that are farther separated as shown in Fig. 2, are of practical importance. For example, if one uses the 200-mm. column of G-25 (Fig. 2) one may just collect the first 4 ml. (the first 20 tubes) and the next 2 ml. (next 10 tubes) of the effluent in two separate tubes, which will contain exclusively ASA or SA, for analysis, either fluorometrically or colorimetrically (6).

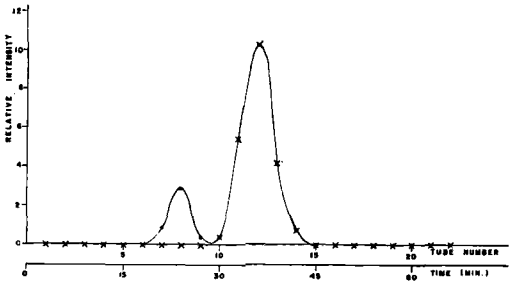

Fig. 1—Separation of ASA and SA by Sephadex G-25-m., 5 × 100 mm. Key: ×, SA before hydrolysis; O, after hydrolysis.

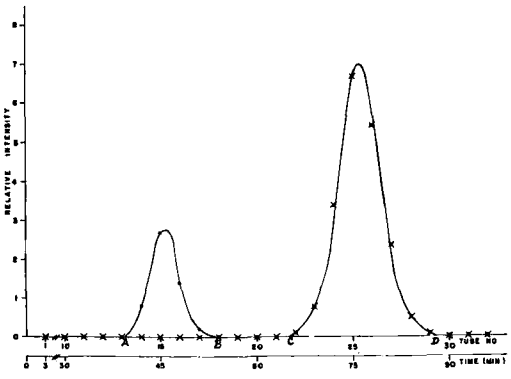

Fig. 2—Separation of ASA and SA by Sephadex G-25-m. 5 × 200 mm. Key: ×, SA before hydrolysis; O, after hydrolysis.

For the convenience of comparing resolution with all of the types of Sephadex of different column lengths studied, the results are summarized in Table I. Let A indicate the volume of effluent collected before the appearance of ASA (see Fig. 2). This volume should be much greater than the void volume (Vo) of the Sephadex bed used, if the biological fluid applied contains proteins. Plasma proteins combine with SA and they should be separated from free ASA. A small volume of effluent that comes out first, which is equivalent to the void volume, carries all of the plasma proteins, whether they are bound with drug or not. For the separation of free ASA and free SA in urine or in other nonprotein fluids, the volume of A is not important. Acetylsalicylic acid fraction is completely eluted at point B and SA begins to come out at point C and is completely eluted at point D. The difference between B and A and the difference between D and C represent the volumes of the effluent containing all of the ASA and SA, respectively. The magnitudes of (D − C) and (B − A) indicate the sizes of the fractions. The difference between C and B (C − B) should be large enough to insure the clear separation of ASA and SA fractions. Point D indicates the total volume of eluent required for the fractionation. This volume should not be too large in order

[a] See Fig. 2 or text for denotations. Each milliliter is equal to the effluent collected in five tubes.

to avoid unnecessary dilution of the drugs and prolongation of fractionation time.

Sephadex G-10 and G-15 are less porous than G-25, and will effect a better resolution of low molecular weight substances. Indeed, Sephadex G-15 of a 100-mm. column and G-10 of only 50-mm. column separated two salicylates as well as G-25 with 200-mm. column length. Sephadex C-25 (cation exchanger) behaved just like G-25-m and Sephadex A-25 (anionic exchanger, DEAE Sephadex) separated salicylates most efficiently. A 50-mm. column of A-25 was sufficient for the separation.

It is always preferable to use a shorter column. The longer column has a slower flow rate and also it is difficult to keep the bed uniform. The flow rate of different types of gel with equal column length may not be the same. The Sephadex G-25-coarse has a higher flow rate, but it has lower resolution power. Both G-10 and A-25 only need 50-mm. column. Sephadex G-10 has a higher flow rate and A-25 gives better resolution.

The recovery of drugs was complete, since there is no irreversible retention of substance on the Sephadex column. When the amounts of ASA and SA were increased, the distribution of the drugs in the effluent was not changed, but the peaks of the fractions were increased. The time required for the filtration was very short and there was no detectable hydrolysis of ASA in the column. Sephadex gel filtration method for the separation of ASA and SA is very simple and practical.

Determination of Silicon in a Commercial Hand Lotion by Atomic Absorption Spectroscopy

By ERNEST MARIO and RALPH E. GERNER

A procedure for the extraction and quantitative determination of silicon by atomic absorption spectroscopy in a commercial hand lotion is described. After the complete removal of water, benzene is used to extract the silicon derivative (dimethylpolysiloxane) from the sample. The benzene extract is then analyzed by atomic absorption spectroscopy utilizing a nitrous oxide/acetylene flame. The method was verified by the addition of known quantities of octaphenylcyclotetrasiloxane to samples of known silicon content prior to extraction. Standard curves obtained by plotting absorbance *versus* p.p.m. silicon were found to be linear in the range of 0 to 120 p.p.m. silicon.

THE RAPIDLY INCREASING utilization of silicone fluids in commercial beauty aids for skin protection has pointed up the need for a more rapid and accurate method to analyze these products for silicon content. The classical acid digestion methods (1) are rather time consuming, and high temperatures are required to convert the silicon completely to silicon dioxide. The infrared methods (2) require considerable sample clean-up and introduce the usual variables encountered with quantitative infrared determinations. This paper describes the suitability of atomic absorption spectroscopy for the determination of silicon in a commercial hand lotion containing approximately 85% water. The method offers both speed and accuracy.

EXPERIMENTAL

Apparatus—A Perkin-Elmer model 303 atomic absorption spectrophotometer was utilized with a fuel mixture of nitrous oxide and acetylene. The high temperatures achieved with this fuel mixture were necessary since silicon is a refractory element. The nitrous oxide flow rate was held at approximately seven at the flowmeter and the pressure regulated to 30 psig at the tank regulator. The acetylene flow rate was held at approximately six using the lower ball in a double ball flowmeter and the pressure regulated to 8 psig at the tank regulator. The flame was considered suitable when the red inner cone attained a height of approximately 1 in. (2.54 cm.). A hollow-cathode silicon lamp was used as the source of emission. The measurement wavelength was approximately 251 mμ (maximized) in the ultraviolet region. The instrument was operated with a slit setting of three and a meter response setting of four. These parameters are dimensionless and will therefore vary from instrument to instrument.

Materials—The commercial samples examined in this study were prepared with dimethylpolysiloxane.[1] The dimethylpolysiloxane used in the specific lot of commercial material discussed in this paper was analyzed by atomic absorption spectroscopy and found to contain 38.25% silicon. Octaphenylcyclotetrasiloxane[2] was used as the internal standard. This material is currently used by the National Bureau of Standards as a primary standard for atomic absorption studies involving silicon. The material was certified to contain 14.15% silicon. Analytical reagent grade benzene was used throughout this study.

Methods—Samples of hand lotion containing approximately 400 mg. of silicon were weighed accurately into a 250-ml. flat-bottom Pyrex flask equipped with a ground-glass neck. Several glass beads were added and a suitable glass elbow adapter affixed to the flask. The mixture was heated gently until *all* water was volatilized. The residue remaining varied in color from light amber to colorless depending on the rate of heating. The sample was allowed to cool and 100 ml. of benzene was added. The flask was stoppered and the sample extracted for 60 min. on a mechanical shaker. The extract was decanted through a cotton pledget into a 200-ml. volumetric flask. An additional extraction using 50 ml. of benzene was performed for 30 min. in the same manner. This extract was added to the 200-ml. volumetric flask as described above and the flask and cotton pledget were rinsed with sufficient benzene to obtain 200 ml. Three milliliters of this solution was pipeted into a 100-ml. volumetric flask and diluted to volume with benzene. Standards, from which a linear calibration curve was obtained, were prepared by dissolving known amounts of octaphenylcyclotetrasiloxane in benzene.

Internal recovery standards were prepared by mixing samples of hand lotion containing approximately 400 mg. of silicon with known amounts of the octaphenylcyclotetrasiloxane standard. These internal recovery standards were heated to remove all water and extracted with benzene as described above.

The samples and standards were read in an alternate manner throughout this study to verify conformance with the standard curve. The solvent (benzene) was aspirated after each test solution. Each test solution was aspirated three times and the absorbance values averaged.

RESULTS AND DISCUSSION

Table I contains the absorbance data obtained

TABLE I—CALIBRATION DATA FOR P.P.M. SILICON *versus* ABSORBANCE

TABLE II—P.P.M. SILICON IN COMMERCIAL HAND LOTION

Sample No.	p.p.m. Silicon (Theory)	p.p.m. Silicon Added	Total p.p.m. Silicon (Theory)	Total p.p.m. Silicon (Found)	
1	57.0	None	57.0	56.2	56.8
2	57.0	4.3	61.3	62.0	62.0
3	57.0	10.6	67.6	67.6	67.4
4	57.0	21.2	78.2	80.0	78.0
5	57.0	42.4	99.4	99.0	97.4

from seven samples of octaphenyltetrasiloxane in benzene containing known amounts of silicon (p.p.m.) in the range of 0 to 120 p.p.m. As can be seen in Table I, the relationship of p.p.m. silicon to absorbance is linear in the range described. This linear relationship permits the use of these data in determining the silicon content of unknown samples provided the instrument conditions remain unchanged. Table II contains the data obtained from five samples (each performed in duplicate) of the same lot of hand lotion. In all samples shown, the initial weight of hand lotion was the same. Samples 2 through 5 contain additional known quantities of silicon resulting from the addition of octaphenylcyclotetrasiloxane to the original hand lotion prior to heating and extraction with benzene.

The removal of all water from the sample prior to benzene extraction is necessary since the organic extract exhibits turbidity if water is present during extraction. This turbidity renders the benzene extracts unacceptable for aspiration and results in a ±10% variation for p.p.m. silicon. The ratio of fuel to oxidizer is critical for minimizing background signal and optimizing flame temperature. When the ratio of gases is not optimal, linearity between p.p.m. silicon and absorbance is lost above 75 p.p.m. silicon. This loss of linearity may be due to the formation of refractory oxides of silicon within the flame during aspiration.

As can be seen in Table II, the method is very reliable and accurate. The heating step to remove water (about 85% in the product examined) requires approximately 30 min. The overall procedure including standard preparations can be performed in approximately 3 hr.

SUMMARY AND CONCLUSION

A rapid, accurate method for the determination of silicon in a commercial hand lotion has been developed utilizing atomic absorption spectroscopy. In concentrations up to 120 p.p.m., silicon absorbance is linear with respect to p.p.m. Critical parameters are the flow rates of fuel and oxidizer, the appearance of the flame, the requirement of complete removal of water prior to extraction with benzene, and the need for frequent aspiration of pure solvent (benzene) to prevent instrument memory.

Mannich Bases of Vanillin Oxime

By H. V. MAULDING, Jr.*, M. A. ZOGLIO, P. TURI, and R. LA POFF

Synthesis of a group of 5-cycloalkyl- and 5-dialkylaminomethyl derivatives of vanillin oxime is reported. Results of microbiological tests are cited.

PHENOL AND CRESOLS are well-known antibacterial agents of long standing. It has previously been shown that α-dialkylamino-*o*-cresols exhibit significant activity against both bacteria and protozoa (1, 2). From these reports it was postulated that Mannich bases derived from vanillin oxime might fit the structural requirements necessary for possession of some degree of bacteriostatic effect.

Mannich bases were obtained from reaction of the oxime of vanillin with paraformaldehyde and various secondary amines.

Received February 23, 1968 from the Pharmacy Research and Development and Analytical Department, Sandoz Pharmaceuticals, Hanover, NJ 07936

Accepted for publication March 21, 1968.

* Compounds reported were prepared by H. V. M. at the University of Houston, Houston, Texas.

EXPERIMENTAL

Vanillin oxime was prepared after the general method stated by Shriner and Fuson (3) and recrystallized from ethanol–water, m.p. 115–117°. Synthesis of phenolic Mannich bases was achieved by the procedure of Burckhalter *et al.* (Procedure I) (2). The hydrochloride salts were recrystallized from solvents listed in Table I.

In the case of compound No. 4, Table I, the solid free base was obtained from the reaction mixture and recrystallized from ethanol, m.p. 181–184°. It gave a correct elemental analysis and was converted to its hydrochloride by treating an ether solution of the amine with ethanolic HCl. The other bases were oils.

pKa values were determined by differential plots of Δ pH/Δ *V versus* volume of 0.1 *N* NaOH titrant using approximately 50 mg. of the salt (4).

Antimicrobial activity was measured on *E. coli* (A.T.C.C. No. 8739) after a slight modification of the turbidimetric assay method of Eisman and coworkers (5).

From these reports it was postulated that Mannich bases derived from vanillin oxime might fit the structural requirements necessary for possession of some degree of bacteriostatic effect.

Mannich bases were obtained from reaction of the oxime of vanillin with paraformaldehyde and various secondary amines.

Received February 23, 1968 from the Pharmacy Research and Development and Analytical Department, Sandoz Pharmaceuticals, Hanover, NJ 07936

Accepted for publication March 21, 1968.

* Compounds reported were prepared by H. V. M. at the University of Houston, Houston, Texas.

EXPERIMENTAL

Vanillin oxime was prepared after the general method stated by Shriner and Fuson (3) and recrystallized from ethanol–water, m.p. 115–117°. Synthesis of phenolic Mannich bases was achieved by the procedure of Burckhalter *et al.* (Procedure I) (2). The hydrochloride salts were recrystallized from solvents listed in Table I.

In the case of compound No. 4, Table I, the solid free base was obtained from the reaction mixture and recrystallized from ethanol, m.p. 181–184°. It gave a correct elemental analysis and was converted to its hydrochloride by treating an ether solution of the amine with ethanolic HCl. The other bases were oils.

pKa values were determined by differential plots of Δ pH/Δ *V versus* volume of 0.1 *N* NaOH titrant using approximately 50 mg. of the salt (4).

Antimicrobial activity was measured on *E. coli* (A.T.C.C. No. 8739) after a slight modification of the turbidimetric assay method of Eisman and coworkers (5).

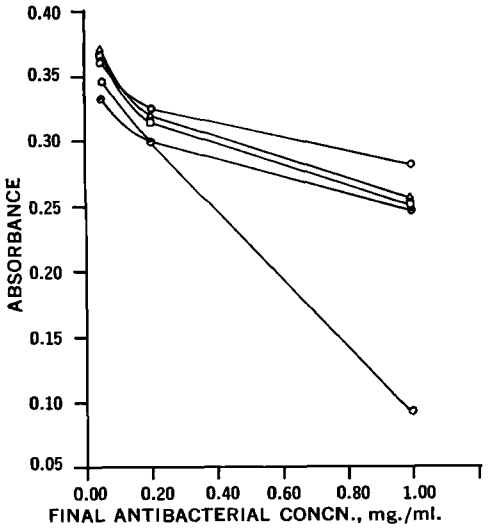

Fig. 1—Plot of absorbance of E. coli *suspension versus concentrations of antibacterial substances from Table I. Key:* ●, *compound 1;* □, *compound 2;* △, *compound 3;* ○, *compound 4;* ○, *chlorobutanol.*

A stock culture of *E. coli* was maintained on trypticase soy agar slants. The 24-hr. growth from these slants was suspended in sterile 0.9% saline and the suspension adjusted to 10–12% transmission at 580 mμ. A 1.5-ml. portion of this saline suspension was diluted with 100 ml. of trypticase soy broth.

Serial dilutions containing 4.0, 0.8, and 0.2 mg./ml. of the test compounds along with chlorobutanol were prepared in a pH 5.8 phosphate buffer (USP XVII). Aliquots of these solutions (2.5 ml.) as well as a 2.5-ml. quantity of the pH 5.8 buffer for control were mixed with 7.0-ml. portions of the inoculated broth. The tubes were incubated at 37° until the controls reached an approximate absorbance of 0.350 at 530 mμ. At this point growth was terminated by addition of 0.5 ml. of formalin in water (1:3) to all tubes and the solutions read at 530 mμ. The graph in Fig. 1 shows computed values obtained from 12 determinations.

RESULTS

The four derivatives of vanillin oxime appear to exhibit some inhibitory effect on the test organism. The slopes of the linear portions (Fig. 1) indicate this inhibition to be similar for all four compounds and they are significantly less active than chlorobutanol.

Hemolysis by Nonionic Surface-Active Agents

By TAMOTSU KONDO and MICHIKO TOMIZAWA

The hemolytic actions of polyoxyethylene glycol monododecyl ethers, $C_{12}H_{25}(C_2H_4O)_nOH$, have been studied. The amount required of these agents to produce lysis was found to be linearly related to the red cell concentration within experimental error. This was interpreted as showing the significant role of the adsorption of nonionic agent molecules onto the red cells prior to lysis. The average amount adsorbed of the agents necessary to cause lysis was estimated.

HEMOLYTIC ACTIONS of nonionic surface-active agents have been described by several authors (1–3). The mechanisms of the hemolysis, however, have not yet been well understood.

Pethica and Schulman stressed the importance of the surface effects of nonionics (4). Thus, they claimed that the nonionics used in their work lysed on attaining surface pressures of 34 dynes/cm. or above. On the other hand, the present authors suggested a significant role of the adsorption of nonionics onto the red cell membranes, because they found a proportionality between the hemolytic concentration of polyoxyethylene carboxylates and the cell count (5). The estimation of the amount adsorbed of the nonionics, however, was not possible owing to the heterogeneity of the materials.

Recently, polyoxyethylene glycol monoalkyl ethers have become available, which are homogeneous with respect to alkyl and polyoxyethylene chain length. This has now made it possible to determine the amount of nonionics adsorbed. The aim of this study has been to confirm the adsorption mechanism and to find a relation between the hemolytic activity and molecular structure of polyoxyethylene glycol monoalkyl ethers.

EXPERIMENTAL

Materials—The nonionic surface-active agents used were polyoxyethylene glycol monododecyl ethers having the general formula, $C_{12}H_{25}(C_2H_4O)_nOH$. These agents were synthesized by a successive condensation reaction between carefully fractionated dodecyl alcohol and diethylene glycol and/or triethylene glycol (6), and were generously supplied by Nihon Surfactants, Co., Ltd., Tokyo. The homogeneity of these nonionics were checked by gas or thin-layer chromatography. In Table I are listed the critical micelle concentrations and cloud points of the nonionics, which are referred to as $C_{12}E_n$ for brevity.

The red cell suspension used was prepared from dog blood as follows. Citrated blood was centrifuged and the cells were washed three times with the phosphate-buffered isotonic saline (pH 7.4). The washed, packed cells were then suspended in the above medium to yield a suspension of a desired concentration. A concentration of 1% v/v of the suspension was found in a hemocytometer to correspond to a cell count of 170–180 $\times$ 10^6/ml.

Hemolysis Techniques—The determination of the degree of hemolysis was done in the following way. Two milliliters of the cell suspension were pipeted into test tubes, into which an equal volume of various concentrations of the nonionics was added quickly by a syringe to prevent any local lysis. The mixtures were then allowed to react for an hour in a water bath controlled at 27° or 37 ± 0.1° with shaking so that the adsorption of nonionic molecules attained an equilibrium as quickly as possible. At the end of this period, the mixtures were immediately centrifuged to remove the unhemolyzed cells. The degree of hemolysis was estimated by determining spectrophotometrically the amount of hemoglobin released in the supernatant liquid.

Received March 12, 1968, from the Faculty of Pharmaceutical Sciences, Science University of Tokyo, Shinjuku, Tokyo, Japan.

Accepted for publication April 18, 1968.

The authors are indebted to Misses Naoko Fukuhara and Tomoko Yoshida for their assistance in this work.

RESULTS AND DISCUSSION

Hemolytic Activity—Effect of Polyoxyethylene Chain Length—Figure 1 shows the relation between the final percent hemolysis and the concentration of the nonionics studied at a cell concentation of 5% v/v.

All the hemolysis curves are of the similar shape and they shift toward the higher concentration region as the chain length of polyoxyethylene becomes longer. This means that the hemolytic activity of $C_{12}E_n$ decreases as the value of n increases. The same tendency was observed at all the cell concentrations studied.

Effect of Cell Concentration—In general, as the cell

TABLE II—$C_{12}E_7$ CONCENTRATIONS REQUIRED TO PRODUCE 100% HEMOLYSIS FOR 5% v/v RED CELL SUSPENSION

Run	27°C.	37°C.
1	$1.2 \times 10^{-4}M$	$0.96 \times 10^{-4}M$
2	$1.4 \times 10^{-4}M$	$1.2 \times 10^{-4}M$
3	$1.3 \times 10^{-4}M$	$1.1 \times 10^{-4}M$

concentration was raised, the hemolytic curves were shifted to higher concentrations of the nonionics without change in shape. A typical example for $C_{12}E_7$ is given in Fig. 2. This result may rule out the possibility of the surface pressure mechanism, because the hemolytic concentrations are independent of surface tension of solutions.

Effect of Temperature—The rise in temperature appeared to make the red cells more sensitive to the lyzing agents. Thus, the hemolytic concentrations of the nonionics at 37° were lower than those at 27°. Table II gives the $C_{12}E_7$ concentrations to cause 100% hemolysis at both temperatures.

In connection with these findings, it is worth noting that the release of lipids from the red cell membranes was detected after shaking the cell suspension without the presence of surface-active agent in water bath for an hour. Moreover, the amount released of the lipids was observed to increase as the temperature rose. It may be inferred, therefore, that the lipid release from the red cell membranes correlates with the adsorption of the nonionics in the hemolysis, especially at elevated temperatures.

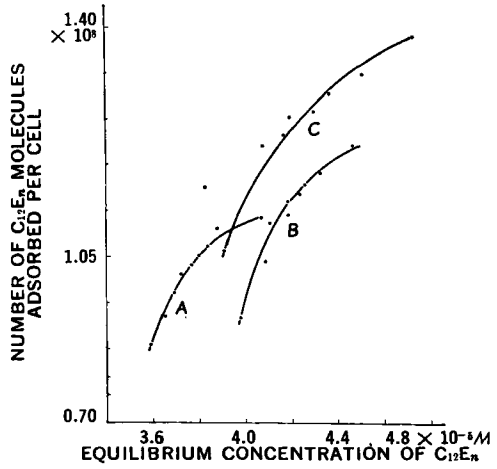

Fig. 4—Adsorption isotherms for $C_{12}E_n$ at 27°. Key: A, n = *6;* B, n = *7;* C, n = *8.*

Adsorption—The amount adsorbed of the nonionics on the red cells was estimated by an indirect method proposed by Thron (8), because several attempts have failed to determine it directly due presumably to the presence of surface-active materials released from the red cells. This method is based on the assumption that an individual cell undergoes lysis if and only if it adsorbs nonionic agent molecules in excess of a certain amount (not necessarily the same amount for different individual cells). If each cell comes into an adsorption equilibrium with its surroundings, then its uptake of the nonionic agent will be a function of the concentration of unadsorbed nonionic agent.

When the free nonionic agent concentration is b_x, where x is a given % hemolysis, the average amount adsorbed per cell has a corresponding value a_x, and the total amount adsorbed by the cells is a_xN, N being the cell count per unit volume of the system. This quantity and the free nonionic agent concentration, b_x, make up the total amount of nonionics, c_x, required to produce x% hemolysis:

$$c_x = a_xN + b_x$$

This equation means that a linear relation should hold between c_x and N. As shown in Fig. 3 the linear relation was obtained within experimental error.

Using the values of a_x and b_x, determined by the least-square method at various degrees of hemolysis, an adsorption isotherm can be set up. The results for the nonionics used at 27° are shown in Fig. 4.

As the polyoxyethylene chain length is decreased, the amount adsorbed necessary to cause lysis is also decreased. This will reflect an enhanced effectiveness in hemolysis of the nonionics with shorter polyoxyethylene chain. Thus, for example, the $C_{12}E_6$ molecules are more easily adsorbed onto the red cells from the solution and more strongly incorporated into the interior of cell membrane than are the $C_{12}E_7$ or $C_{12}E_8$ molecules. In other words, $C_{12}E_6$ causes the complete lysis at lower concentrations than does $C_{12}E_7$ or $C_{12}E_8$.

In Table III are given the amounts adsorbed of $C_{12}E_7$ per cell at 100% hemolysis. A decrease in the

TABLE III—NUMBER OF $C_{12}E_7$ MOLECULES ADSORBED PER CELL AT 100% HEMOLYSIS

Run	27°C.	37°C.
1	1.3×10^8	1.1×10^8
2	1.2×10^8	1.0×10^8
3	1.0×10^8	0.86×10^8

amount adsorbed is clearly seen with a rise in temperature.

As the slope of the adsorption isotherms at 37° was generally steeper than that at 27°, the rise in temperature would result in an increased tendency of the adsorption of nonionic agent molecules onto the red cell surface from aqueous solution owing to the temperature-dependent hydration of the molecules, thereby promoting the hemolysis. A similar adsorption behavior of the polyoxyethylene glycol monoalkyl ethers has been reported (9). The increased release of lipids from the red cells mentioned earlier may also contribute to a certain extent to the enhancement of the hemolysis at elevated temperatures.

As to the attacking site of the polyoxyethylated nonionics molecules, Mima and co-workers have concluded, based on the monolayer experiments, that the cholesterol portion in the cell membrane would be predominant (10). There still remains some doubt on this conclusion. In view of the limited scope of this study, however, any conclusion on the attacking site of the nonionics cannot be drawn.

Simple Method for Resuscitating Rats from Ether Overdosage

By L. F. SANCILIO, P. KRAUS, C. MYERS, and L. WAGNER

A simple method using compressed air for resuscitating rats from ether overdosage is described. Exposure to ether vapors for 55 and 90 sec., respectively, was lethal to 70 and 100 percent of the animals. The compressed air technique afforded protection to animals exposed to the anesthetic for 55, 90, 120, and 150 sec., while the conventional hand technique was ineffective against the 55- and 90-sec. exposure.

DURING THE PERFORMANCE of various experimental techniques in rats, *e.g.*, intrapleural injection (1), cotton pellet implantation (2), and adrenalectomy (3), using ether as the anesthetic agent, marked respiratory depression leading to death sometimes occurs unless the animal is immediately hyperventilated. This study describes a simple and effective technique used in our laboratory for reviving rats manifesting respiratory arrest following exposure to this anesthetic agent.

METHOD

Compressed air is required in performing this technique. In our laboratory, the air is pressurized at 60 p.s.i., and the tapered outlet (labcock) contains a valve to regulate its flow. The depressed animal is placed in a prone position in the palm of the hand with the head held gently but firmly between the thumb and index finger. The valve is partially opened (approximately 25%), and the air directed toward the rat's nostrils. The animal is moved back and forth rapidly across the stream of air to allow for inflation and deflation of the lungs. Spontaneous breathing is usually restored within 30 sec. An excess of pressurized air must be avoided as this will inflate the gastrointestinal tract.

The following study was undertaken to demonstrate the superiority of the compressed air to the manual technique. In the latter method, intermittent pressure was applied to hyperventilate the animal by placing the thumb on one side and the index and ring fingers on the other side of the rib cage.

Charles River CD rats (100–150 Gm.) of either sex were etherized in the following manner. One hundred milliliters of ether was poured into a 41-oz. glass dressing jar (Aloe Medical), the base of which was immersed in a water bath maintained at 39°. Ether was added periodically to replace that which had evaporated. The animal was placed on a wire mesh platform 7.5 cm. (3 in.) from the floor of the jar. After covering the jar, the exposure time to the ether vapors was determined with a Universal timer.

The animal was then removed and either placed in a prone position with its head turned to one side, or subjected to the compressed air or hand techniques. Return of the righting reflex indicated resuscitation from the effects of the anesthetic.

RESULTS AND DISCUSSION

Exposure to ether vapors for 55 sec. was lethal to 70 and 80% of the animals, and for 90 sec. all the animals succumbed to the anesthetic (Table I). Those dying from the 90-sec. exposure showed no visible respiratory movements following removal from the jar, and death ensued shortly as indicated by no palpable heart beat. The compressed air technique resuscitated all animals subjected to the ether vapors for 90 and 120 sec. and partially revived those exposed for 150 sec. In contrast, the hand method afforded no significant protection to animals exposed to the anesthetic for either 55 or 90 sec. (Table I).

These results clearly demonstrate the effectiveness of the compressed air technique and its superiority to the hand method. The compressed air method hyperventilates the animals and perhaps, activates those stimulatory reflexes present in the nasal and pharnygeal areas (4).

The simplicity of this technique is clear, and it requires equipment commonly found in the laboratory.

A Spectrophotometric Method for the Analysis of Strychnine Phosphate in the Presence of Magnesium Stearate

By JANELLE BARRETT, RAMONA PUCKETT, and R. D. POE

A spectrophotometric technique for the analysis of strychnine phosphate in the presence of certain tablet excipients is reported. Tablets containing the alkaloidal salt are well dispersed in water, basified, and extracted with chloroform. The chloroform solution of the free base is then reacted with bromothymol blue in pH 7.65 buffer and the resultant colored product is quantified by the spectrophotometric technique.

SEVERAL METHODS are available for the analysis of strychnine phosphate, but most of them have disadvantages for use in tablet analysis, such as a large sample size, lack of precision, tedious procedure, or interference from other components present in the tablet. Among these methods are a picric acid method (1), a vanadate method (2), a titration method (3), a bromophenol blue method (4), a reduction and nitrite method (5), and a silicotungstic acid method (6).

In some of the above methods, magnesium stearate gives a negative interference. This has been overcome by a bromothymol blue extraction procedure using chloroform, in which an aliquot of methanol is added to the extract prior to making to volume. This procedure is simple and gives accurate results when applied to tablet assays.

The animal was then removed and either placed in a prone position with its head turned to one side, or subjected to the compressed air or hand techniques. Return of the righting reflex indicated resuscitation from the effects of the anesthetic.

RESULTS AND DISCUSSION

Exposure to ether vapors for 55 sec. was lethal to 70 and 80% of the animals, and for 90 sec. all the animals succumbed to the anesthetic (Table I). Those dying from the 90-sec. exposure showed no visible respiratory movements following removal from the jar, and death ensued shortly as indicated by no palpable heart beat. The compressed air technique resuscitated all animals subjected to the ether vapors for 90 and 120 sec. and partially revived those exposed for 150 sec. In contrast, the hand method afforded no significant protection to animals exposed to the anesthetic for either 55 or 90 sec. (Table I).

These results clearly demonstrate the effectiveness of the compressed air technique and its superiority to the hand method. The compressed air method hyperventilates the animals and perhaps, activates those stimulatory reflexes present in the nasal and pharnygeal areas (4).

The simplicity of this technique is clear, and it requires equipment commonly found in the laboratory.

A Spectrophotometric Method for the Analysis of Strychnine Phosphate in the Presence of Magnesium Stearate

By JANELLE BARRETT, RAMONA PUCKETT, and R. D. POE

A spectrophotometric technique for the analysis of strychnine phosphate in the presence of certain tablet excipients is reported. Tablets containing the alkaloidal salt are well dispersed in water, basified, and extracted with chloroform. The chloroform solution of the free base is then reacted with bromothymol blue in pH 7.65 buffer and the resultant colored product is quantified by the spectrophotometric technique.

SEVERAL METHODS are available for the analysis of strychnine phosphate, but most of them have disadvantages for use in tablet analysis, such as a large sample size, lack of precision, tedious procedure, or interference from other components present in the tablet. Among these methods are a picric acid method (1), a vanadate method (2), a titration method (3), a bromophenol blue method (4), a reduction and nitrite method (5), and a silicotungstic acid method (6).

In some of the above methods, magnesium stearate gives a negative interference. This has been overcome by a bromothymol blue extraction procedure using chloroform, in which an aliquot of methanol is added to the extract prior to making to volume. This procedure is simple and gives accurate results when applied to tablet assays.

Received December 11, 1967, from the Alcon Laboratories, Inc., Fort Worth, TX 76101
Accepted for publication February 29, 1968.

EXPERIMENTAL

Reagents—Chloroform A.R., methanol A.R., phosphate buffer pH 7.65 were used. Mix 50 ml. of 0.1 *M* sodium dihydrogen phosphate with 450 ml. of 0.1 *M* disodium hydrogen phosphate. Bromothymol blue: Prepare 0.018% in pH 7.65 buffer and wash twice with chloroform before use. Ammonium hydroxide, 10% aqueous. Strychnine phosphate standard: the commercially available salt should be thoroughly investigated by the usual

TABLE I—RECOVERY OF STRYCHNINE PHOSPHATE FROM LOT 1 BY VARIOUS METHODS

Method[a]	Average Percentage[b] Found
1	73%
2	87%
3	82%
4	74%
5	90%[c], 88%[d]

[a] Code number explanation: 1, bromothymol blue method with no methanol, 2, modified bromothymol blue method with methanol added, 3, bromophenol blue, 4, ammonium vanadate method, and 5, picric acid method. [b] Averages of four to six samples. [c] Calculated from absorbances at the 400-mμ peak. [d] Calculated from absorbances at the 360-mμ peak.

techniques of melting point, infrared, ultraviolet spectroscopy, and thin-layer chromatography to assure its purity and identity as a "house standard."

Preparation of Standard—Accurately weigh approximately 43.2 mg. of dry strychnine phosphate standard. Dilute to 200.0 ml. with water and mix well. Pipet 4.0 ml. of the standard into a 125-ml. separator.

Preparation of Sample—Stir two tablets (0.432 mg. strychnine phosphate per tablet) in 7 ml. of water until well disintegrated. Transfer quantitatively with a small amount of water to a 125-ml. separator.

Procedure—Add 0.5 ml. of the ammonium hydroxide to each separator. Extract four times with 20 ml. of chloroform, combining the extracts in 150-ml. beakers. Evaporate the extracts to about 5 ml. on the steam bath. Cool and transfer to a 125-ml. separator, washing each beaker with about 5 ml. of chloroform, and adding these washings to the corresponding separator. Add 10 ml. of pH 7.65 buffer and 10 ml. of bromothymol blue reagent to each one and to a third separator containing 10 ml. of chloroform. Shake well and allow to separate. Transfer the chloroform layers to 50-ml. volumetric flasks. Add 15.0 ml. of methanol to each volumetric flask.

Extract the buffer layers again with two further 9-ml. portions and one 5-ml. portion of chloroform, and drain the chloroform extracts into the volumetric flasks each time. Make to volume with chloroform. Mix well and determine the absorbance against the reagent blank at approximately 410 mμ on a suitable spectrophotometer, using 1-cm. cells. Calculate against the standard.

DISCUSSION AND RESULTS

Two lots of a tablet containing strychnine phosphate have been analyzed using the above method. The first lot was also analyzed by several other procedures. Comparison of the results by the different procedures is listed in Table I. The second lot, analyzed by the modified bromothymol blue method, gave an average recovery of 100% for three assays.

To ascertain whether lot No. 1 was actually low, or whether all of the techniques were inapplicable to the tablet in question, individual samples of the other ingredients (calcium glycerophosphate, dibasic potassium phosphate, lactose, starch, and acacia) were weighed to approximately the amounts present in the tablet. These samples were added individually to aliquots of the standard and were assayed against the standard. (The procedure used was the bromothymol blue without the addition of methanol.) Only magnesium stearate gave any appreciable difference. The others gave an average recovery of 99%. A precipitate was noticed in the magnesium stearate extract. The addition of methanol cleared the extract.

TABLE II—RECOVERY OF STRYCHNINE PHOSPHATE IN THE PRESENCE OF MAGNESIUM STEARATE

Amount of Magnesium Stearate Added, mg.	Percentage of Strychnine Phosphate Found
2	103
4	102
8	100
12	100
	Average 101

Further work indicated that the addition of methanol to blank, standard, and sample gives good results.

The results in Table II were obtained using the methanol modification of the bromothymol blue method for analysis of strychnine phosphate in the presence of varying amounts of magnesium stearate.

Investigations comparable to the above were conducted using calcium stearate, zinc stearate, and stearic acid. The recovery of strychnine phosphate averaged 101% in the presence of 2–10 mg. of zinc stearate. The recoveries in the presence of calcium stearate and stearic acid were not quantitative by the procedure described above. However, addition of 1.5 ml. of ammonium hydroxide in lieu of the stated 0.5 ml. and filtration (Whatman No. 40) after the dye-alkaloid extraction resulted in an average recovery of 100% in the case of calcium stearate but only 92% in the case of stearic acid.

Although the picric acid method and the bromophenol blue method gave comparable results, the modified bromothymol blue method was found to be preferable for the tablet being analyzed because it was less tedious than the bromophenol blue method and more precise than the picric acid method. (One or more washing steps were absolutely essential to remove interference in the picric acid method.)

Synthesis and Antibacterial Activity of Certain β-Aminoketones

By RAJENDRA S. VARMA and W. LEWIS NOBLES

A series of β-aminoketones has been synthesized under the conditions of the Mannich reaction. Most of the compounds have exhibited antibacterial activity.

β-AMINOKETONES (Mannich bases) have been synthesized and screened as antispasmodics, local anesthetics, analgesics, and antibacterial agents (1–11). In a recent article from this laboratory the authors described the synthesis of a group of β-aminoketones derived from 1-(*N*-β-hydroxyethyl-4-piperidyl)-3-(4-piperidyl) propane (12). Several of these compounds have exhibited antibacterial and antiviral activity (13). In this communication the synthesis and antibacterial activity of β-aminoketones obtained from 4-(3-phenylpropyl)-piperidine is described.

BIOLOGICAL DATA

The β-aminoketones listed in Table I were screened *in vitro* against four organisms: *Pseudomonas aeruginosa*, *Staphylococcus aureus*, *Mycobacterium smegmatis*, and *Klebsiella pneumoniae* by agar diffusion technique. Filter paper disks (6.35 mm. diameter) saturated with the solution (20 mg./ml.) of the test compound were placed on the agar. After 72 hr. of incubation, the zones of inhibition around the disks were measured. The results are recorded in Table I. A negative sign indicates no observable inhibition.

EXPERIMENTAL

Melting points were recorded on a Thomas-Hoover capillary melting point apparatus and are uncorrected. Infrared spectra were observed on a Perkin-Elmer model 137 spectrophotometer in Nujol mull. Microanalyses were performed by Galbraith Laboratories, Inc., Knoxville, Tennessee.

β-Aminoketone Hydrochlorides—*Procedure A*—4-Phenylpropylpiperidine (5.07 Gm.; 0.025 mole) was dissolved in 5 ml. of ethanol. To this solution concentrated hydrochloric acid (2.5 ml.) was added followed by 5 ml. of 37% formalin and 0.025 mole of the appropriate ketone. The resulting reaction mixture was refluxed for 4 hr. At the end of this period some solvent was evaporated under vacuum. The contents were then diluted with 50 ml. of acetone. Refrigeration of the contents yielded the desired product.

Procedure B—A mixture of 0.025 mole of 4-(3-phenylpropyl)piperidine hydrochloride, 0.025 mole of the ketone, and 1 Gm. of paraformaldehyde in 10 ml. of ethanol containing two drops of concentrated hydrochloric acid was heated under reflux for 2 hr. Another 0.5 Gm. of paraformaldehyde was added, and the refluxing continued for 3 hr. At the end of this period the contents were poured into 50 ml. of acetone, after removing some solvent. The product obtained after overnight refrigeration was recrystallized from a suitable solvent.

4-Phenylpropylpiperidinoethyl-4-bromophenylcarbinol Hydrochloride (Compound 14)—β-4-(3-Phenylpropyl)-piperidine-4-bromopropiophenone hydrochloride (13.5 Gm., 0.03 mole) was neutralized with 10% aqueous sodium hydroxide with cooling. The product obtained was filtered and washed thoroughly with cold water until washings were free from alkali. After air drying, the product was suspended in 100 ml. of methanol in a 1-L. flask. Three and eight-tenths grams of sodium borohydride, dissolved in 50 ml. of methanol, was added slowly with stirring. During the additions the temperature was kept below 50°. The reaction mixture was stirred for an additional 2 hr. and then left at room temperature overnight. It was filtered and the filtrate evaporated to dryness under vacuum. Fifty milliliters of water was then added to the residual solid. The resulting mixture was extracted with ether. The extract, after washing with water, drying over magnesium sulfate, and evaporating the ether, yielded a viscous oil which soon solidified. It was dissolved in 10 ml. of ethanol, acidified with concentrated hydrochloric acid, and poured into 100 ml. of acetone. Overnight refrigeration of the acidified solution gave the desired product. An analytical sample was prepared by recrystallizing from ethanol-acetone, m.p. 173–174°; yield, 4.05 Gm. (30%). IR: 3333 cm.$^{-1}$ (OH).

Anal.—Calcd. for $C_{23}H_{31}BrClNO$: C, 61.00; H, 6.90; N, 3.09. Found: C, 61.29; H, 7.14; N, 3.00.

DISCUSSION

4-(3-Phenylpropyl)-piperidine was converted to the hydrochloride salt and condensed with formaldehyde and several substituted ketones. Paraformaldehyde, as well as aqueous formalin, yielded satisfactory products. The Mannich base hydrochlorides were usually isolated from the reaction mixture

[a] Yields are of the products obtained after first recrystallization. [b] Recrystallized from ethanol. [c] Recrystallized from aqueous ethanol–acetone. [d] Recrystallized from ethanol–acetone.

by adding acetone to it and refrigerating overnight. It was observed that while using 4-phenylacetophenone, the best results were obtained when some of the solvent was distilled from the reaction mixture before the addition of acetone. The period required to refrigerate the reaction mixture in order to get a solid product varied considerably. While using 3-nitroacetophenone, a solid product was obtained after 4 days of refrigeration. Prolonged refrigeration resulted in improved yields. The β-aminoketone from 4-bromoacetophenone was reduced to the corresponding γ-amino secondary alcohol by sodium borohydride. Infrared spectra of the β-aminoketones exhibited characteristic absorption bands for carbonyl and $\overset{+}{N}H$ (14). No carbonyl absorption was observed in the infrared spectrum of the aminoalcohol; instead, absorption due to OH group, as expected, was observed.

SUMMARY

Thirteen β-aminoketones have been synthesized using 4-(3-phenylpropyl)-piperidine and several ketones under Mannich reaction conditions. One β-aminoketone (No. 12, Table II) has been reduced to the corresponding γ-amino secondary alcohol by sodium borohydride. Antibacterial activities have been determined for all compounds described herein.

Influence of Starch Concentration on the Disintegration Time of Tolbutamide Tablets

By K. C. COMMONS, A. BERGEN, and G. C. WALKER

Disintegration tests were performed on tablets compressed from 16/20, 40/60, and 60/80 mesh granulations prepared by the method of dry granulation to contain 250 mg. of tolbutamide and corn starch concentrations of 6, 7, 8, 9, and 10 percent in each granulation size. It might be expected that disintegration time would decrease as the percentage of starch in the tablet increased. This does not appear to be the case for tolbutamide tablets. Instead, there appears to be a critical starch concentration for different granulation sizes.

In a number of instances, poor tablet formulation has been shown to cause a significant variation in gastrointestinal absorption and physiological availability of the active ingredient (1–3). Variables in the formulation and processing include such factors as particle size and shape, binders, diluents, disintegrating agents, lubricants, compression rate, and compression pressure as well as physical features of the dosage form itself. Alteration of any of these factors may influence the disintegration time, dissolution rate, and clinical effectiveness of compressed tablets.

Disintegrating agents have been widely used in compressed tablets as substances or mixtures of substances added to a tablet to facilitate its breakup or disintegration following administration (4). There have been many classifications of disintegrating agents but one of the more recent is that of Feinstein and Bartilucci (5) who divided them into starches, clays, celluloses, algins, or gums. Fakouhi *et al.* (6) point out that disintegrating agents generally fall into three classes: (*a*) agents that react with moisture to constitute a foam, (*b*) effervescent substances that react with moisture to form a gas, and (*c*) substances that react with moisture to swell (most common). The most commonly used agent has been starch from various sources but particularly corn or potato starch.

A study was undertaken to determine the influence of corn starch concentration on the disintegration of tolbutamide tablets prepared from various size granules by direct compression.

EXPERIMENTAL

Tolbutamide powder (USP XVI, 100 mesh) was dried at 100° for 24 hr. Approximately 1 Gm. of powder at a time was compressed at 10,000 lb. gauge pressure in a Carver hydraulic press using 3/4-in. flat-face punches. The slugs were granulated using a Fitzpatrick mill and the granules sieved for 5 min. through 16, 20, 40, 60, and 80-mesh screens using an automatic sieve shaker. Granule sizes were designated 16/20, 40/60, and 60/80 which refers to a passage through the first sieve size number designation and retention on the second sieve. The tolbutamide granules and corn starch (USP XVI, moisture content 9.2% w/w) were thoroughly mixed to give granulation-starch mixtures containing 6, 7, 8, 9, and 10% corn starch. Compressed tablets of 250-mg. tolbutamide content were prepared from the various granule-starch combinations using 3/8-in. shallow concave punches at 2,000 lb. gauge pressure in the Carver press. Tablets and granules were assayed, and disintegration tests performed, using the methods as outlined in the USP XVII (7).

RESULTS AND DISCUSSION

Table I shows the average disintegration time of compressed tablets prepared from different granule sizes and containing varying percentages of corn starch. This information is presented graphically in Fig. 1.

It might be expected that disintegration time would decrease as the percentage of starch in the tablet is increased. This does not appear to be the case for tolbutamide tablets. Instead, there appears to be a critical starch concentration for different granulation sizes when granulations are prepared by methods involving dry granulation and com-

Table I—Average Disintegration Times in Minutes of Tolbutamide Tablets

Approximately 1 Gm. of powder at a time was compressed at 10,000 lb. gauge pressure in a Carver hydraulic press using 3/4-in. flat-face punches. The slugs were granulated using a Fitzpatrick mill and the granules sieved for 5 min. through 16, 20, 40, 60, and 80-mesh screens using an automatic sieve shaker. Granule sizes were designated 16/20, 40/60, and 60/80 which refers to a passage through the first sieve size number designation and retention on the second sieve. The tolbutamide granules and corn starch (USP XVI, moisture content 9.2% w/w) were thoroughly mixed to give granulation-starch mixtures containing 6, 7, 8, 9, and 10% corn starch. Compressed tablets of 250-mg. tolbutamide content were prepared from the various granule-starch combinations using 3/8-in. shallow concave punches at 2,000 lb. gauge pressure in the Carver press. Tablets and granules were assayed, and disintegration tests performed, using the methods as outlined in the USP XVII (7).

RESULTS AND DISCUSSION

Table I shows the average disintegration time of compressed tablets prepared from different granule sizes and containing varying percentages of corn starch. This information is presented graphically in Fig. 1.

It might be expected that disintegration time would decrease as the percentage of starch in the tablet is increased. This does not appear to be the case for tolbutamide tablets. Instead, there appears to be a critical starch concentration for different granulation sizes when granulations are prepared by methods involving dry granulation and com-

Table I—Average Disintegration Times in Minutes of Tolbutamide Tablets

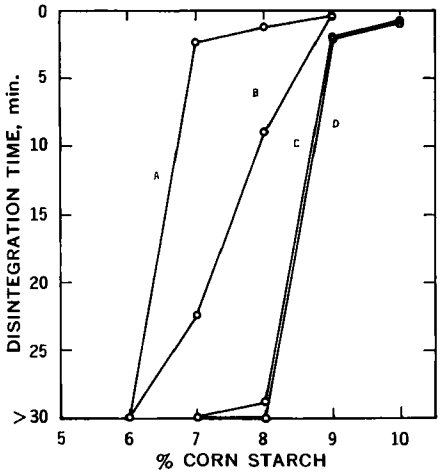

Fig. 1—Disintegration times, determined by the USP XVI method, of tolbutamide tablets prepared from different granule sizes and containing varying corn starch concentrations. Key: A, 16/20 granules; B, 20/40 granules; C, 40/60 granules; D, 60/80 granules.

pression. In most cases, tablets failed to disintegrate at a particular percentage of starch but disintegrated when the starch concentration was increased by about 1%. For example, tablets prepared from 16/20-mesh granules containing 6% corn starch failed to disintegrate within 30 min., whereas tablets containing 7% corn starch disintegrated in an average time of 2.3 min.

Curlin has suggested that the disintegration of tablets containing starch is due to capillary action (8). The more widely held view is that disintegration is caused by absorption of water by the disintegrating agent and development of pressure within the tablet caused by swelling or expansion of the disintegrating agent (8–10). Fakouhi *et al.* (6) in their studies of lactose tablet disintegration with powdered corn cob, powdered redwood bark, wood flour, powdered Douglas fir, methylcellulose, and corn starch point out that a decrease in disintegration time would be expected with an increase in concentration of the agent, but in the case of methylcellulose, redwood bark, and Douglas fir this was not experienced. The authors suggest that these substances possess adhesive or binding properties with a tendency to form adhesive gels when hydrated thus suggesting an optimum or maximum quantity of these substances beyond which tablet disintegration will be retarded. The mechanism of disintegration action for all agents is probably the same, *i.e.*, swelling in contact with water and subsequent rupture but with the necessary absorption of sufficient moisture. Forlano and Chavkin (11) used separate granulations of sodium bicarbonate, lactose, and magnesium trisilicate in mesh sizes ranging from 6–8 to 140–200 in increments of 2 mesh sizes with one at 200 mesh and finer to study the influence of granule size and capping in compressed tablets. In the case of sodium bicarbonate and lactose tablets, granules of 16–60 mesh showed the longest disintegration times. As the granule size decreased below 60 mesh the disintegration time decreased with an unexpected rise at 100–140 mesh, followed by a decrease at 140–200 mesh. In the case of magnesium trisilicate, tablets made using 12–30-mesh granules had longer disintegration times than the smaller mesh sizes. However, tablets made from granules smaller than 30 mesh showed decreased disintegration times. It is possible that the nature of the bonding is different between tablets and that the binders have different actions. In the case of magnesium trisilicate tablets the small hard core together with the nature of the substance probably prevented penetration of the center by water.

When starch is incorporated into a tablet, it is found in the channels between the granules. Starch is a relatively incompressible substance and tends to increase the porosity of the tablet. If there were no starch present in the channels, the tolbutamide granules would be deformed under compression to partially block the channels. Tablets were prepared from corn starch soaked in a saturated aqueous iodine solution and dried. Fracture of the tablet followed by macroscopic and microscopic examination suggested that the starch grains form continuous chains along the channels between the granules even at concentrations below those required to make the tablet disintegrate. However, it appears that as the percentage of starch is increased, thicker chains of starch are formed in the pore channels, thus enlarging the pores. This pore enlargement could allow water to enter the tablet more readily. Patel and Hopponen (12) have shown that where contact of starch grains in the interparticle spaces is continuous, disintegration is most rapid. They have also found that dried corn starch increased in volume by 78% when suspended in water. This increase in volume strongly suggests that swelling is the principal mechanism of action of corn starch as a disintegrator. Wurster and Seitz (13) have demonstrated that a small pore size which could be occluded by air would hinder entry of water into the tablet. This would be particularly true in the case of a hydrophobic substance such as tolbutamide. In this case, disintegration of the tablet would be slowed but could continue as the pores are enlarged by expanding starch grains near the surface of the tablet. Wurster and Seitz concluded that capillarity itself does not appear to have a disintegrating effect although it may be a factor in aiding entry of water into the tablet when pore size is favorable.

The critical starch concentration may have practical significance in both wet and dry granulation procedures, but particularly in view of the increasing tendency to use methods of dry granulation and direct compression in the pharmaceutical industry. Similar results have been secured using acetylsalicylic acid, salicylamide, and phenylbutazone. Preliminary *in vivo* studies using acetylsalicylic acid have shown good correlation between disintegration, dissolution, urinary excretion, and critical starch concentration. These results will be published shortly.

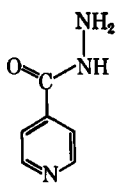
Influence of Metallic Ions on the Antituberculous Activity of Isonicotinoyl Hydrazones

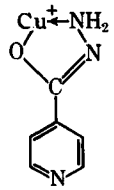
By V. A. E. VOYATZAKIS*, G. S. VASILIKIOTIS†, G. KARAGEORGIOU‡, and IR. KASSAPOGLOU‡

Eleven isonicotinoyl hydrazones were prepared and they were tested *in vitro* as antitubercular agents. The effects of cupric and cobalt ions on their activity were investigated.

THE SPECIFIC activity of isonicotinic acid hydrazide (isoniazid I) against tubercle bacilli suggests interference with an essential metabolite. It has been shown (1, 2) that isoniazid combines with cupric ions to give 1:1 Cu-isoniazid complex (II) and 1:2, respectively. It also has been claimed that the action of isoniazid against *M. tuberculosis in vitro* is increased when copper is supplied in excess of that normally present in the medium (2).



I



II

Moreover it has been shown (3) that 8-hydroxyquinoline (oxine) and related substances are toxic to bacteria only when traces of iron or copper ions are present in the medium. In this case the 1:1 metal complex has been shown to be the true toxic agent (4). The hypothesis was put forward that oxine is active due to the combination with these metal ions in the medium and that the complexes thus formed catalyze the oxidation of essential cell constituents. Cobalt can prevent injury to the cells, and it was suggested that this ion may be an essential cell constituent whose function is to protect, from oxidative destruction a vitally important chemical group. However, Albert (5) pointed out that while chelation might play some part in the activity of isoniazid, there must be some more important factor since the closely related picolinic acid hydrazide was less effective against tubercle bacilli but showed a metal affinity 10^3 to 10^6 times that of isoniazid.

Youatt (6) who investigated the effect of cupric ions on the uptake of hydrazides, found that copper prevented the development of strains resistant to isoniazid and increased the sensitivity to hydrazides of a strain which was already resistant to isoniazid. Stimulation of isoniazid uptake was still observed if the cells were exposed to copper ions and then washed before the addition of the isoniazid. This suggests that copper may first be bound to the cell and that chelation may occur on or in the cell.

Among the most active derivatives of isoniazid are its hydrazones. Fox and Gibas (7) have shown that 1-isonicotinoyl-2-isopropylidene hydrazone was very active against tubercle bacilli. Shchukina *et al.* (8) synthesized a number of isonicotinoyl hydrazones from aldehydes and ketones. Their biological tests, as antitubercular agents indicated that some of these are more active *in vivo* and far less toxic in mice. Sah and Peoples (9) reported also that a large number of isonicotinoyl hydrazones possess very high *in vivo* activity against *M. tuberculosis*, H 37 Rv, higher than that of streptomycin, and at least of the same order of magnitude as isoniazid. Recently Chakravarty, Bose, and Bose (10) synthesized some isonicotinoyl hydrazones which showed antituberculous activity comparable to that of isoniazid (Table I).

In this paper there is reported: (*a*) the synthesis of 11 isonicotinoyl hydrazones derived from substituted aromatic aldehydes and ketones having the general formula (III); (*b*) their microbiological examination *in vitro* as antitubercular agents, and (*c*) the influence of cupric and cobalt ions on their activity.

before use and their melting points were in agreement with those given in the literature (9); their infrared absorption spectra have already been reported (11).

Microbiological Examination—Test organism. Stock strains: (*a*) A strain (M K1) of *M. tuberculosis* isolated from a patient before any treatment. This strain was sensitive to isoniazid in concentration of 0.1 γ/ml. and was catalase and peroxidase positive; (*b*) A strain (M K2) of *M. tuberculosis* isolated from patient treated with isoniazid. It was resistant to isoniazid (10 γ/ml.) and was catalase and peroxidase negative. *In vitro* test: Compounds were incorporated with Lowenstein-Jensen medium before its coagulation at 80°. Their concentration is expressed in γ/ml. of medium. Thereafter, they were inoculated with a culture of *M. tuberculosis* grown in the same medium and incubated at 38° for 28 days. Control tubes containing only strain culture were maintained for comparison. All these specimens were incubated at 38° for 28 days again. In each case cultures of both strains were tested with 0.1 γ, 1 γ, and 10 γ/ml. of compound and then again with the same concentration but with the addition, separately of 1 γ, 10 γ, 20 γ, 40 γ, and 80 γ of cupric or cobalt ions, derived respectively from $CuSO_4$ or $CoSO_4$ solutions. Stability tests were performed to find out the rate at which compounds and isoniazid became inactivated by incubation at 38°. The results suggest that the proportionate loss of activity was of about the same order for all compounds and isoniazid.

RESULTS AND DISCUSSION

Strain M K1 was sensitive to all of these compounds in concentration of 0.1 γ/ml., while strain M K2 was resistant to them even in 10 γ/ml. So the results mainly concern the resistant strain M K2 and the activity of these compounds is comparable to isoniazid. Cupric ion alone, in concentration above 60 γ/ml., inhibited completely the development of cultures in both cases while cobalt ion was ineffective up to 80 γ/ml. In mixtures with isonicotinoyl hydrazones, the first notable influence of Cu^{2+} appeared in the range of 20 γ/ml. added to 0.1 γ/ml. of these compounds. Results are summarized in Table II. There was a complete inhibition, in all cases, by the addition of 40 γ/ml. of cupric ions. About the same results were obtained with 1 γ/ml. and 10 γ/ml. of these compounds.

TABLE II—EFFECT *In Vitro* OF Cu^{2+} (20γ/ML.) ON THE BACTERIOSTATIC ACTIVITY OF ISONICOTINOYL HYDRAZONES (0.1 γ/ML.) BY USING ISONIAZID RESISTANT STRAIN M K2

TABLE III—EFFECTS OF COBALT IONS ADDED TO HYDRAZONES

Compd.	Inhibition	Compd.	Inhibition
A-1	++[a]	A-7	—[b]
A-2	+++	A-8	++
A-3	+++	A-9	++
A-4	++	A-10	+
A-5	++	A-11	++
A-6	+++	Co^{2+} (80 γ/ml.) alone	[c]

[a] Each + represents 20% of inhibition. [b] No inhibition at all. [c] 10–20 colonies observed against ~500 of the control tube.

Effects of cobalt ions (40 γ/ml.) added to a concentration of 0.1 γ/ml. of hydrazones are summarized in Table III.

By adding 80 γ/ml. of Co^{2+}, to the tested compounds, still 10–20 colonies were observed against to 400–500 of the control tube.

In the mixtures used in this study, the concentration of free cupric ions was well below that which would cause inhibition by them alone. There is also a possibility of formation of cupric chelates with hydrazones and then the concentration of free Cu^{2+} will be even lower and will depend of course on its affinity to the ligand, on pH, ratio of ligand to metal, stability constants, and acid dissociation constants of the ligand.

Since the results of the inhibition due to added cupric ions to the strains studied were independent of the concentration of the compound used (between 0.1 γ/ml. and 10 γ/ml.) there is some evidence that free cupric ion may be responsible for the stimulation of isonicotinoyl hydrazone uptake as well as in the case of isoniazid (6).

Thus, development of the resistant strain M K2 was supressed and the critical quantity of cupric ions, under the experimental conditions was 20 γ/ml. even in the presence of 0.1 γ/ml. of the drug. Of course there are variations of the activity of these drugs and research on their Cu complex stability constants is continuing and the results shall be published in due time.

Potential Diazo Reagents for Colorimetric Determination

By TIBOR URBÁNYI and JOSEPH A. MOLLICA

The diazonium derivatives of 27 substituted aromatic amines were investigated as reagents for colorimetric determination. The phenolic moiety used in the study was the estrogen, estradiol. Their applicability was determined on the basis of speed, sensitivity, color stability, and reproducibility of the coupling reaction. Using these criteria, the diazotization product of 4-amino-6-chloro-*m*-benzenedisulfonamide appeared to be the most suitable colorimetric reagent for the compounds containing a phenolic hydroxyl group.

A RAPID AND SENSITIVE method for the determination of estrogens is based on their ability to couple with diazotized amines. This communication considers the results of investigations regarding the suitability of various substituted aromatic amines as analytical reagents for compounds having coupling capability. Under the experimental condition employed, 4-amino-6-chloro-*m*-benzenedisulfonamide appeared to be the most promising reagent. The mechanism for the formation of its diazonium compound and its application to the analysis of several estrogens was reported previously (1, 2).

The following criteria for suitability were established: the coupling reaction should be rapid at room temperature, the color produced should be relatively stable, and the method should be sensitive. Since speed, sensitivity, and reproducibility were the objectives, the same reaction conditions were employed for all amines. Although these conditions were not optimum for all amines tested, this procedure was selected since the goal was to find suitable analytical reagents and not to investigate the reaction for each amine.

EXPERIMENTAL

A Beckman DU spectrophotometer was used to determine the absorbance values, and a Cary model 11 spectrophotometer was used to record the absorption spectra.

All compounds were of reagent grade quality and were used without further purification.

Reagents and Solutions—Aromatic amines: a 7×10^{-3} *M* solution of the amine was prepared in either methanol or 1 *N* hydrochloric acid. Sodium nitrite, 1% aqueous solution; hydrochloric acid, 1 *N*; sodium acetate 2 *N*; sodium hydroxide 0.1 *N* and 1 *N*. The estradiol solution was prepared as follows: about 50 mg. of estradiol, accurately weighed, was dissolved in 50 ml. of methanol and then this solution was diluted 10-fold with 0.1 *N* sodium hydroxide; concentration approximately 0.1 mg./ml.

Procedure—Into a 10-ml. volumetric flask were pipeted 1 ml. of the aromatic amine solution, 1 ml. of sodium nitrite solution, and 1 ml. of 1 *N* hydrochloric acid. The solution was mixed well and allowed to stand for 1 to 2 min. Then, 1 ml. of estradiol solution and 2 ml. of sodium acetate solution were added, mixed, and the resulting solution allowed to stand for exactly 6 min. The contents of the flask were diluted to volume with 1 *N* sodium hydroxide solution. A blank solution was prepared in the same manner except that 1 ml. of 0.1 *N* sodium hydroxide was used in place of the estradiol solution. The absorbance of the sample solution was measured against the blank solution at the wavelength of the absorption maximum in 1-cm. cells.

DISCUSSION

The coupled products yielded absorption spectra with maxima in the range 450–550 mμ. The spectra were all similar to the spectrum of 4-amino-6-chloro-*m*-benzenedisulfonamide and estradiol which was published previously (2). The apparent molar absorptivity values in Table I were obtained by dividing the absorbance of the coupled solution, measured at the wavelength of absorption maximum, by the concentration of the amine employed. The molar absorptivity values reported are only apparent values since for many of the compounds investigated, the absorbance continued to increase after the 6-min. reaction time. This is due to either incomplete coupling and/or side reactions of the diazotized amine (3, 4). As stated in the introduction, the purpose of this study was not to investigate the mechanism of reaction, but to find a suitable analytical reagent. However, some conclusions regarding the effect of substituent groups on color intensity can be drawn. Comparisons of the molar absorptivity values indicate that substitution strongly influences the intensity of the coupled product, *e.g.*, 3 and 4, 13 and 15, 23 and 24; not

Sodium nitrite, 1% aqueous solution; hydrochloric acid, 1 *N*; sodium acetate 2 *N*; sodium hydroxide 0.1 *N* and 1 *N*. The estradiol solution was prepared as follows: about 50 mg. of estradiol, accurately weighed, was dissolved in 50 ml. of methanol and then this solution was diluted 10-fold with 0.1 *N* sodium hydroxide; concentration approximately 0.1 mg./ml.

Procedure—Into a 10-ml. volumetric flask were pipeted 1 ml. of the aromatic amine solution, 1 ml. of sodium nitrite solution, and 1 ml. of 1 *N* hydrochloric acid. The solution was mixed well and allowed to stand for 1 to 2 min. Then, 1 ml. of estradiol solution and 2 ml. of sodium acetate solution were added, mixed, and the resulting solution allowed to stand for exactly 6 min. The contents of the flask were diluted to volume with 1 *N* sodium hydroxide solution. A blank solution was prepared in the same manner except that 1 ml. of 0.1 *N* sodium hydroxide was used in place of the estradiol solution. The absorbance of the sample solution was measured against the blank solution at the wavelength of the absorption maximum in 1-cm. cells.

DISCUSSION

The coupled products yielded absorption spectra with maxima in the range 450–550 mμ. The spectra were all similar to the spectrum of 4-amino-6-chloro-*m*-benzenedisulfonamide and estradiol which was published previously (2). The apparent molar absorptivity values in Table I were obtained by dividing the absorbance of the coupled solution, measured at the wavelength of absorption maximum, by the concentration of the amine employed. The molar absorptivity values reported are only apparent values since for many of the compounds investigated, the absorbance continued to increase after the 6-min. reaction time. This is due to either incomplete coupling and/or side reactions of the diazotized amine (3, 4). As stated in the introduction, the purpose of this study was not to investigate the mechanism of reaction, but to find a suitable analytical reagent. However, some conclusions regarding the effect of substituent groups on color intensity can be drawn. Comparisons of the molar absorptivity values indicate that substitution strongly influences the intensity of the coupled product, *e.g.*, 3 and 4, 13 and 15, 23 and 24; not

only the substituent group, but also its position relative to the amine function affects the intensity, *e.g.*, 7 and 8, 15 and 16, 23 and 25. In general, the most sensitive amines were those possessing electron-withdrawing groups *ortho* and/or *para* to the amine function. The relative effects of various substituents on the intensity of the coupled product are in general agreement with the observations of Zollinger for various azo dyes (5).

The authors recognize that without more kinetic data the interpretation of the above-mentioned effects is limited. The data are consistent with what one could predict based on substituent effects on spectral properties or reaction rates.

Taking this into consideration, it is still felt that the data in Table I will be of value to other workers who may be desirous of utilizing a coupling procedure. The amines tested should react in an analogous manner regardless of the phenolic moiety. With perhaps slight adjustment of experimental conditions to suit particular cases, amines numbered 15, 19, 20, 22, and 23 should be more suitable as diazonium reagents than those numbered 1, 10, 11, 12, 16, 18, and 21.

SUMMARY

1. Twenty-seven aromatic amines have been investigated as potential diazo reagents for the colorimetric determination of phenolic compounds. The criteria for suitability established were speed, sensitivity, and reproducibility.

2. The compound 4-amino-6-chloro-*m*-benzenedisulfonamide was considered the most suitable based on the *criteria* established. Although compound 15 has a greater apparent molar absorptivity, it was not selected as the most suitable since the color produced was not as stable as that produced with compound 23.

3. Amines with electron withdrawing groups

ortho and/or *para* to the amine group possess the greatest potential.

Potentiometric Determination of Fluoride Ion in Toothpastes by a Specific Ion Activity Electrode

By NORMAN SHANE and DENNIS MIELE

A simple, specific potentiometric method is described for the assay of toothpastes for free fluoride ion in concentrations of about 0.1 percent, equivalent to 0.22 percent sodium fluoride or 0.4 percent stannous fluoride. The ionic fluoride content of the toothpastes is determined by relating the potential obtained with a fluoride electrode in an aqueous dispersion of toothpaste to a calibration curve constructed by adding known scaler amounts of fluoride to a blank toothpaste formulation.

THE DETERMINATION of fluoride ion concentration in toothpastes has ordinarily required steam distillation as a separation procedure and titration by thorium nitrate for the fluoride ion using a colored dye as an indicator. The classical Willard-Winter distillation (1), as modified by Grimaldi *et al.* (2), Singer and Armstrong (3), and Wade and Yamamura (4), has been the basis for most analytical procedures. Following distillation, spectrophotometric methods utilizing the blue complex formed between the fluoride ion and the cerium (III) salt of 3-amino-methyl-alizarin-*N*,*N*-acetic acid have been employed by Bellack *et al.* (5). Also, Harley and Revinson (6) and Calkins (7) have used high-frequency titration techniques, and other methods are described in review articles by Fishman *et al.* (8). Frant (9) explained the theory and operation of the fluoride ion electrode. In contrast to the potentiometric method as explained in this paper, Lingane (10) showed a titration method for fluoride ion employing the fluoride electrode.

The specific method for free fluoride ion described in this paper requires no separation steps. Fluoride ion is detected in toothpastes in the range of 0.1% F^- ion equivalent to 0.22% NaF and 0.40% SnF_2. An important consideration in this analysis is that the fluoride must be present as a free ion. The fluoride ion activity electrode model 94–09, developed by Orion Research, Inc., was used as easily as a conventional pH electrode with an Orion digital meter, model 801. A standard glass sleeve calomel reference electrode was employed in conjunction with the fluoride electrode. The electrodes were immersed in an aqueous mixture of toothpaste so as to measure the activity of ionized (free) fluoride in terms of concentration. By use of an appropriate calibration curve, the concentrations of F^- ion from NaF and SnF_2 were determined.

EXPERIMENTAL

Apparatus and Reagents—Fluoride electrode, model 94-09, obtained from Orion Research, Inc., Cambridge, Mass.; Orion Research meter 801; Beckman calomel electrode (with glass sleeve); 50-ml. Nalgene centrifuge tube; 100-ml. volumetric flask; 150-ml. beaker; Sargent magnetic stirrer.

Stirrer—Made from an electric toothbrush with a special made paddle. This paddle is a 10.1-cm. aluminum shaft and has a 3.2 mm. diameter. Two fins, each 2.5 cm. long and 1.9 cm. wide, are located at the stirring end.

NaF Stock Solution for Calibration Curve—180 mg. NaF/100 ml. aqueous solution (0.18% NaF),[1] 200 mg. NaF/100 ml. aqueous solution (0.20% NaF), 220 mg. NaF/100 ml. aqueous solution (0.22% NaF), 240 mg. NaF/100 ml. aqueous solution (0.24% NaF), 260 mg. NaF/100 ml. aqueous solution (0.26% NaF).

SnF_2 Stock Solution for Calibration Curve—To each solution is added 400 mg. of malic acid as a stabilizer. Deoxygenated water is used so as to further prevent oxidation of the stannous ion. 320 mg. SnF_2/100 ml. aqueous solution (0.32% SnF_2),[2] 360 mg. SnF_2/100 ml. aqueous solution (0.36% SnF_2), 400 mg. SnF_2/100 ml. aqueous solution (0.40% SnF_2), 440 mg. SnF_2/100 ml. aqueous solution (0.44% SnF_2), 480 mg. SnF_2/100 ml. aqueous solution (0.48% SnF_2).

PROCEDURE

For NaF and SnF_2 Calibration—Weigh approxi-

Received January 29, 1968, from the Analytical Research and Development Laboratory, Bristol-Myers Products, Hillside, NJ 07207

Accepted for publication March 18, 1968.

The authors gratefully acknowledge the assistance of Dr. J. H. Wood in writing this paper.

[1] 1 ml. of these solutions represent 0.18%, 0.20%, *etc.*, of NaF based on 1 g. of paste.

[2] 1 ml. of these solutions represent 0.32%, 0.36%, *etc.*, of SnF_2 based on 1 g. of paste.

mately five 1-g. samples of the paste[3] without NaF or SnF_2 into five 50-ml. centrifuge tubes. Add 45 ml. of water to each tube. For the SnF_2 calibration, deoxygenated water is required. For the NaF experiment 1 ml. of 0.18%, 0.20%, 0.22%, 0.24%, and 0.26% stock solutions of NaF are added to the five tubes, respectively. For the SnF_2 experiment, 1 ml. of 0.32%, 0.36%, 0.40%, 0.44%, and 0.48% stock solution of SnF_2 is added. Stir each tube vigorously for 1.5 min. with the stirrer to disperse the paste in the solution. Pour this suspended solution into a 100-ml. volumetric flask and dilute to volume with water. In the case of SnF_2 deoxygenated water must be used. Transfer the solution to a 150-ml. beaker containing a magnetic stirring rod and stir to ensure homogeneity. Immerse the fluoride and calomel electrodes into the beaker and record the millivolt reading obtained from the research meter. Temperature control of the meter should be set to ambient conditions. A working curve is obtained by plotting the mv. reading against % NaF or % SnF_2 on one-cycle semilogarithmic graph paper. A calibration curve should be prepared at least once a day. With the Orion meter, the original calibration curve can be shown on the mv. scale. If the reading on a standard solution changes by a few mv., and experience shows that the slope does not change, readings can then be taken on the REL mv. scale which is adjusted so that the standard still reads the same, and the same curve can be used. The same standard solutions can be used for the calibration curves.

For NaF Samples—Laboratory samples are run in the same manner as explained for the calibration curve. It should be noted that the fluoride electrode should be conditioned to the fluoride concentration that is to be determined. For NaF pastes, the mv. reading will become steady within 1 min.

For SnF_2 Samples—Laboratory samples are analyzed in the same manner as explained for the calibration curve. It takes 4–5 min. to condition the electrode to SnF_2 so as to obtain steady readings. After a long period of time (about 10 min.) the millivolt reading will start to increase, indicating a reduction of the free fluoride ions due to complexation. It is imperative to read the mv. reading at the steady-state condition.

RESULTS

The data obtained for the calibration curves of NaF and SnF_2 pastes are shown in Tables I and II. The results are the average composite of five different experiments; each experiment was done on 5 different days. The toothpastes without the NaF and SnF_2 were used to give the proper background for constant ionic strength conditions. NaF or SnF_2 were then added to the toothpastes and millivolt readings were taken. During a given day, the experiment was repeated and the readings were reproduced. The chart indicates linearity with respect to the semilog plot of mv. *versus* % NaF or SnF_2 for an average composite of five experiments in both cases (Fig. 1). However, because the method depends on direct measurements, the variability of the electrode characteristics, such as change of junction potential, may occur. For this reason, it is advisable to calibrate the meter once every day.

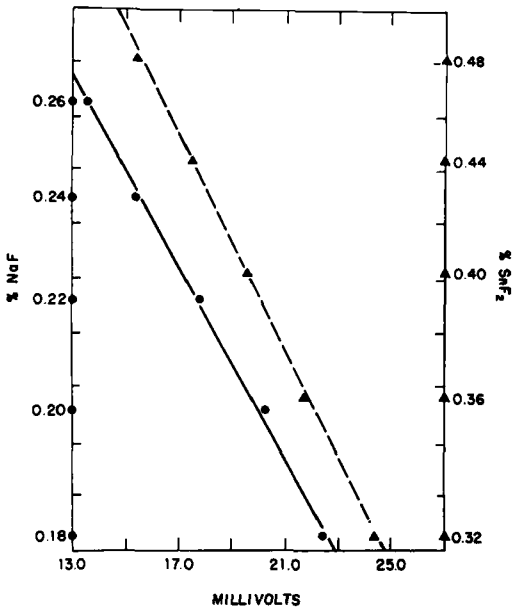

Fig. 1—Semilog plot of the percentage of NaF or SnF_2 versus mv. readings for an average composite of five experiments. Key: ———, NaF; – – –, SnF_2.

Laboratory samples of the cited toothpastes, including NaF or SnF_2 are shown in Tables I and II, which were run by the standard distillation method of Willard-Winter (1) with thorium nitrate titration using chrome azurol S as the indicator and by the fluoride electrode method. The distillation method for total fluoride, including the titration which, in the authors' opinion, gives a poor end point, takes about 40–45 min. The fluoride electrode method can be completed in 5–9 min. Since the chart is based on the % NaF or % SnF_2 for 1 g. of paste, the calculations for the samples are obtained by the graph reading of the respective percentages divided by the weight of the samples.

The statistical data of the corresponding tests, as shown in Tables I and II, indicate that there is no significant difference between the two methods.

DISCUSSION

The fluoride ion electrode is used to measure the fluoride activity regardless of sample ionic composition or total ionic strength. As described by Kielland (15), the relationship of activity to concentration of the ionized (free) fluoride is obtainable by an appropriate calibration curve. The electrode does not respond to fluorides which are bound or complexed. Since these pastes contain no calcium or other ions capable of removing fluoride, the total fluoride is equivalent to the free fluoride ion level.

A concentration working curve is prepared by plotting potential measurements of known NaF or SnF_2 concentration standards on semilogarithmic graph paper. Since the electrode responds to the activity and not to the concentration of the fluoride ion, the working curve is prepared for fluoride solutions which contain other ions, if the standards approximate the unknowns in composition. The

[3] For the NaF paste the formulation is similar to that given in *References 11* and *12* as formulation No. 3, shown to be clinically active as anticaries dentifrice (11–13). For the SnF_2 paste the formulation is that given in *References 11* and *12* as formulation No. 4, accepted as clinically active anticaries dentifrice (11, 12, 14).

activity depends on the total ionic strength of the sample. Errors will result if the standards are prepared with pure NaF or SnF_2, and unknowns containing relatively high concentrations of other ions. The calibration curves for the determination of NaF or SnF_2 were based on adding known amounts of the given NaF or SnF_2 to nonfluoride paste in order to fulfill the ionic strength requirement for the calibration curve. The activity of the working curve is a straight line within the working range.

The mathematical relationship of voltage to activity is shown by the Nernst equation:

$$E = E_s + \frac{2.3RT}{F} \log F^-$$

where E = measured potential, E_s = constant due to the system calibrated, 2.3 RT/F = Nernst factor, 59.2 mv. at 25°, R and F are constants, T = temperature in °K., F^- = fluoride ion activity in the sample solution.

The Orion meter is readable to ±0.1 mv. Since the voltage is proportional to the log of the fluoride activity by the Nernst equation, the instrument is sensitive to about 0.5 mv. change per 0.01% NaF and 1 mv. per 0.01% SnF_2 in the paste in the region of the analysis.

New Compounds: Nucleosides Derived from D-*Glycero*-D-*gulo*-heptose

By LEON M. LERNER

The preparation of new nucleosides derived from D-*glycero*-D-*gulo*-heptose are described. These nucleosides are distinguished from the naturally occurring nucleosides by their seven carbon chain and pyranose ring. The configurations and anomeric purity of these compounds are unknown.

A NUMBER of nucleosides have been prepared in the last few years, in which the sugar moiety has been altered from that which normally occurs in nature. The reason for this interest was stimulated by the discovery of antibiotics which were identified as nucleosidic substances possessing an altered structure in the carbohydrate. Nucleoside analogs have since been prepared with the intention of obtaining useful agents which would possess antitumor or antimicrobial activity.

The first synthesis of a nucleoside derived from a heptose was described by Kohn *et al.* (1), who prepared 9-β-D-*glycero*-D-*gulo*-heptofuranosyladenine. This compound, as well as several nucleosides derived from hexopyranoses (2), was found to be inhibitory to the multiplication of *Herpes simplex* virus.[1] A natural outcome of these observations was the preparation of some nucleosides derived from a heptopyranose, which is the subject of this communication.

The acetic anhydride–acetic acid reagent described by Montgomery and Hudson (3) was used to acetylate D-*glycero*-D-*gulo*-heptopyranose. This reagent has been used to isomerize sugar acetates to the α anomer. A preponderance of the α hexaacetate was crystallized, but the expected high yield of α anomer did not materialize. Instead, a mixture of α and β anomers was obtained which was separated by fractional crystallization. Such an outcome has been noted previously in the case of D-allose (2), where the β form predominated.

Either anomer could be used in the preparation of the bromide in a hydrogen bromide–acetic acid mixture. Coupling of the bromide with 6-benzamidochloromercuripurine was achieved in refluxing xylene in the usual manner (4). The blocking groups were removed in hot methanolic sodium methoxide and the product, 9-D-*glycero*-D-*gulo*-heptopyranosyladenine, was purified *via* its picrate salt (5). Unfortunately, this procedure resulted in a significant loss of the nucleoside on the resin. When 6-benzamidochloromercuripurine and the hexaacetate were condensed in the presence of titanium tetrachloride, the yield was only about 10% of that obtained by coupling with the bromide. This was in contrast to the results of other workers (6, 7), who have claimed that the yields are increased, often considerably, over that obtained by prior formation of the halogenose. However, Tong *et al.* (8) have had a similar experience to that reported in this paper during their attempt to couple 1,2-di-*O*-acetyl-5-*O*-benzoyl-3-*O*-methyl-D-ribofuranose to a purine.

1-D-*Glycero*-D-*gulo*-heptopyranosyluracil was obtained by the coupling of the bromide with bis(trimethylsilyl)uracil in benzene at room temperature. The intermediate acetate was purified by chromatography on silicic acid and the blocking groups were removed with sodium methoxide. The nucleoside was obtained as a hard, very hygroscopic glass, which migrated as a homogeneous spot in four solvent systems on TLC plates, but did not give a proper analysis. Benzoylation of this substance yielded the pentabenzoate, which served the purpose of being a derivative of the desired product and offered an alternative purification route. However, removal of the benzoate groups yielded a product whose elementary analysis was not much improved over that obtained previously. Application of column and preparative TLC gave further evidence of one component, but the analyses were still relatively poor. The identity of this nucleoside is based upon its ultraviolet spectrum and the preparation of the crystalline benzoate derivative.

The anomeric configuration of 9-D-*glycero*-D-*gulo*-heptopyranosyladenine has been tentatively decided upon as β by reference to the *trans* rule (9). This rule states that a heavy metal salt of a purine or pyrimidine will substitute at the anomeric carbon *trans* to the acyloxy group at C-2 of the sugar. However, the rule is not applicable to the coupling of the halogenose to bis(trimethylsilyl)uracil. Application of nuclear magnetic resonance spectroscopy[2] at 60 Mc. failed to resolve the anomeric configuration of the pentabenzoate derivative of 1-D-*glycero*-D-*gulo*-heptopyranosyluracil.

EXPERIMENTAL

D-*Glycero*-D-*gulo*-heptopyranose was prepared from D-*glycero*-D-*gulo*-heptono-1,4-lactone as described by Wolfrom and Thompson (10). Elementary analyses were performed by the Spang Microanalytical Laboratories, Ann Arbor, Michigan. Thin-layer chromatography (TLC) was performed on Silica Gel HF plates (E. Merck, AG, Darmstadt). Spots were located with an ultraviolet lamp and the plates were routinely exposed to the chromic acid charring method to test for homogeneity. Evaporations were done *in vacuo* at a bath temperature of 40–45°.

Hexa - O - acetyl - D - glycero - D - gulo - heptopyranose—The acetylation of D-*glycero*-D-*gulo*-heptopyranose was carried out directly with the acetylation reagent as described earlier (2, 3). After a reaction time of 5 days followed by the usual workup (2, 3) the α anomer was crystallized from a large

volume of ethyl ether in an open flask, m.p.[3] 155–158°. Recrystallization in the same manner gave the α anomer in 55% yield, m.p. 164–165°, $[\alpha]_D^{25}$° + 85.5° (c 3.10, $CHCl_3$). Lit. (11) m.p. 164°, $[\alpha]_D^{20}$° + 87°.

The mother liquors from these crystallizations were combined and the solvent was removed *in vacuo*. The β anomer was crystallized from 50% aqueous ethanol in an open beaker. The long needles had m.p. 128–130°. Recrystallization in the same manner gave the pure product in a 20% yield, m.p. 133.5–134°, $[\alpha]_D^{22}$° +3.5° (c 6.03, $CHCl_3$). Lit. (11) m.p. 135°, $[\alpha]_D^{20}$° +4.8°.

When a shorter reaction time was used the product distribution was nearly one α to one β.

9-D-Glycero-D-gulo-heptopyranosyladenine—To 25 ml. of a saturated solution of hydrogen bromide in acetic acid was added 2.0 Gm. of hexa-*O*-acetyl-D-*glycero*-D-*gulo*-heptopyranose. After 2 hr. at room temperature the solvent was evaporated *in vacuo* at a bath temperature below 30°. Dry toluene was added and removed 5 times in a similar manner. The orange syrup which remained was dissolved in 25 ml. of dry xylene and added to a well-stirred refluxing mixture containing 6-benzamidochloromercuripurine (2.03 Gm.), diatomaceous earth[4] (1.95 Gm.), cadmium carbonate (1.03 Gm.), and 150 ml. of xylene (4). After the usual workup (4), an orange glass (2.6 Gm.) was obtained by evaporation of absolute alcohol. This material was dissolved in a mixture of sodium methoxide (350 mg.) in 60 ml. of methanol and the solution was refluxed for 1.25 hr. The methanol was removed by evaporation and the residue was dissolved in 35 ml. of water and neutralization was effected with acetic acid. The aqueous solution was washed with 35 ml. of chloroform, treated with activated charcoal (Darco G-60), and concentrated to a light orange syrup. Since the product could not be induced to crystallize at this stage, the picrate was prepared. The syrup was dissolved in 15 ml. of methanol and 25 ml. of 10% methanolic picric acid was added. The flask was chilled in an ice bath for 2 hr., the yellow precipitate was removed by filtration, and it was washed well with cold methanol and cold water. The picrate (1.11 Gm.) started to decompose at 166° and melted at 170–173°.

The picrate was converted to the free nucleoside with the carbonate form of an ion-exchange resin as described previously (2, 5). Crystallization occurred slowly from water in an open flask after 3 days of standing at room temperature. The flask was chilled for several more days in a refrigerator and 142 mg. of white crystals were collected. This material decomposed slowly starting at about 220° and melted completely with decomposition at 273–275°, $[\alpha]_D^{29}$° −7° (c 0.86, 1 *N* HCl); $\lambda_{max.}^{pH\ 1}$ 256 mμ(ϵ 13,800), $\lambda_{max.}^{H_2O}$ 258 mμ(ϵ 14,000), $\lambda_{max.}^{pH13}$ 258 mμ(ϵ 14,200). This substance was homogeneous upon chromatography on Whatman No. 1 paper with 5% aqueous disodium phosphate as the developing solvent, R_{Ad} 1.91 (R_{Ad} of adenine = 1.00).

Anal.—Calcd. for $C_{12}H_{17}N_5O_8$: C, 44.03; H, 5.25; N, 21.40. Found: C, 44.00; H, 5.25; N, 21.45.

1-D-Glycero-D-gulo-heptopyranosyluracil—To 30 ml. of hexamethyldisilazane and 0.6 ml. of trimethylchlorosilane was added 2.3 Gm. of uracil and the stirred mixture was refluxed at an oil bath temperature of 170° for 3 hr., protected from moisture (12). The clear solution was cooled to below 50° and the solvent was distilled under high vacuum at a bath temperature of 50–60°, leaving a slightly turbid syrup. This syrup was dissolved in 100 ml. of dry benzene and added to a solution containing the bromide (prepared from 4.1 Gm. of hexa-*O*-acetyl-D-*glycero*-D-*gulo*-heptopyranose) in 250 ml. of benzene. Mercuric acetate (2.8 Gm.) was added and the mixture was stirred for 5 days, protected from moisture. The solids were removed by filtration, washed with 100 ml. of chloroform, and the solvents were evaporated. The residue was triturated with 150 ml. of chloroform, the insoluble material was removed by filtration, and the filtrate was washed with 30% aqueous potassium iodide, water, and dried over magnesium sulfate. Removal of the chloroform under vacuum gave a syrup weighing 5.6 Gm., $\lambda_{max.}^{EtOH}$ 255 mμ. The syrup was dissolved in a minimum amount of chloroform and applied to the top of a column of silicic acid (100 Gm., Mallinckrodt 100 mesh). The column was eluted with chloroform (750 ml.), chloroform–ethyl acetate (4:1, 500 ml.), and chloroform–ethyl acetate (1:1, 500 ml.). Various sugar derivatives were eluted with all of these solvent mixtures, but no ultraviolet absorbing material. Upon elution with ethyl acetate (500 ml.), 1.0 Gm. of the nucleoside acetate was obtained, $\lambda_{max.}^{EtOH}$ 255 mμ; $\lambda_{max.}^{smear}$ (cm.$^{-1}$) 1750 (acetate ester), 1700 (—NHCO— of pyrimidinone), 1630 (C=C of pyrimidine ring), 1230 (acetate C—O—C), 1070, 1050 (sugar C—O—). This intermediate pentaacetate could not be induced to crystallize and so the acetyl groups were removed by refluxing for 1 hr. in 50 ml. of 0.1 *N* methanolic sodium methoxide. An ion-exchange resin[5] was added until the pH was 6.5. The resin was removed by filtration and the solvent was evaporated. The syrupy material was partitioned between water and chloroform and the aqueous layer was concentrated to dryness. The clear, colorless syrup which remained would not crystallize, but it did form a hard glass upon repeated evaporation with ethanol. The glass was pulverized, yielding 225 mg. of product, which was homogeneous upon TLC in the following four developing systems: 1-butanol–water (86:14 v/v), 5% aqueous disodium phosphate, 1-butanol–acetic acid–water (5:2:3 v/v/v), and 2-propanol–25% aqueous ammonia–water (7:1:2 v/v/v). This substance had $[\alpha]_D^{25}$° −16° (c 0.51, water) and was extremely hygroscopic; ultraviolet spectrum at pH 1: maximum at 258 mμ (ϵ 7430), minimum at 230 mμ(ϵ 1930); at pH 5–7: maximum at 257 mμ(ϵ 7460), minimum at 229 mμ(ϵ 1870); at pH 13: maximum at 258 mμ(ϵ 5400), minimum at 244 mμ(ϵ 4360).

Anal.—Calcd. for $C_{11}H_{16}N_2O_8$: C, 43.42; H, 5.30; N, 9.21. Found: C, 40.74; H, 5.58; N, 7.22.

Since the pentabenzoate was also prepared (see below) as a pure derivative an attempt was made to obtain the nucleoside from this derivative. The benzoate groups were removed as described above for the acetate and the product was worked up in the usual way. The nucleoside was precipitated from methanol by addition of ethyl ether and the

[3] Melting points were obtained on a Fisher-Johns apparatus and are corrected.

white solid obtained was dried at 100° *in vacuo* over P_2O_5.

Anal.—Calcd. as for above. Found: C, 42.08; H, 5.59; N, 7.00.

1 - (Penta-O-benzoyl - D - glycero - D - gulo-heptopyranosyl)uracil—To 19 ml. of dry pyridine was added 88.6 mg. of 1-D-*glycero*-D-*gulo*-heptopyranosyluracil and the mixture was stirred in an ice bath. Benzoyl chloride (2 ml.) was added dropwise and after 0.5 hr. at 0° the mixture was stored at room temperature for 21 hr. It was then heated on a steam bath for 20 min., cooled, 50 ml. of benzene was added, followed shortly thereafter by 50 ml. of water. The mixture was stirred for several minutes and the layers were separated. The benzene solution was washed three times with 50-ml. portions of 2 *N* sulfuric acid solution, once with 50 ml. of water, 4 times with 50-ml. portions of saturated sodium bicarbonate solution, and finally with 50 ml. of water. The dried ($MgSO_4$) solution was evaporated to a thin, orange oil. This was triturated with hot petroleum ether and cooled in an ice bath for 1 hr. The petroleum ether was decanted and the procedure was repeated. A hard syrup remained which was dissolved in warm methanol and placed in a freezer. A solid was filtered off in two crops (203 mg.). Recrystallization from chloroform–ethanol in an open flask at room temperature yielded beautiful, clear, star-like clusters of large rods, 117 mg. in two crops; m.p. 123–124.5° (to a very viscous liquid) with prior softening at 119°. $[\alpha]_D^{28}$° −55.9° (c 2.81, $CHCl_3$). λ_{max}^{film} (cm.$^{-1}$) 1730 (benzoate ester), 1680 (—NHCO— of pyrimidinone), 1600 (C=C of phenyl and pyrimidine ring), 1260 (benzoate C—O—C), 1100, 1090, 1065 (sugar C—O—), 706 (monosubstituted phenyl). The product was homogeneous on TLC. The R_f was 0.84 using chloroform–methanol (9:1) as the irrigating solvent.

Anal.—Calcd. for $C_{46}H_{36}N_2O_8$: C, 66.99; H, 4.40; N, 3.40. Found: C, 67.02; H, 4.48; N, 3.37.

New Compounds: Synthesis of Heterocyclic Estrogens

By LARRY GORUM* and W. LEWIS NOBLES

Several nitrogen analogs of diethylstilbestrol have been prepared by a convenient route from pyridyl lithium and the appropriate ketone. These compounds are expected to have estrogenic activity with possible greater selectivity of action than previous known synthetic estrogens.

THE INVESTIGATIONS of Dodds and co-workers (1) on synthetic compounds possessing the physiological action of the female sex hormone estrone reached a climax with the discovery of diethylstilbestrol (1). Since that time much work with molecular modification has been done in an effort to improve the selectivity of pharmacological action in the therapeutic uses of diethylstilbestrol. Endocrine therapy in metastatic prostatic cancer consists initially of estrogen therapy as first demonstrated by the pioneering investigation of Huggins (2). Oral estrogen preparations such as diethylstilbestrol are effective to a limited extent but elicit side effects such as nausea, gynecomastea, and edema. Because of these undesirable side effects it is necessary to find new compounds which possess a more selective estrogenic action.

Many compounds of this type have been prepared and tested and are described in a review by Grundy (3). However, thus far none of the compounds tested offered sufficient selective antineoplastic activity to replace diethylstilbestrol in the clinic. In the hundreds of compounds reported, several contain

DISCUSSION

This preparation involved a synthetic route employing 2-pyridyl lithium (IV) and 3-(*p*-anisyl)-4-hexanone (V) in a Grignard-type reaction. A racemic mixture of the resultant alcohol VI*a* and VI*b* was predicted by invoking Cram's rule of asymmetric synthesis (4). This rule states that the asymmetric carbon in the starting ketone is so oriented that the carbonyl function is flanked by the two smaller groups and subsequent attack by the Grignard reagent on the carbonyl carbon occurs over the smallest group.

Unexpected difficulty with the dehydration of the resultant alcohol (VI), necessitated a dehydrohalogenation approach to the olefin (VII). This was accomplished by chlorination with thionyl chloride with subsequent elimination of hydrogen chloride with potassium hydroxide to afford 3-(2-pyridyl)-4-(*p*-methoxyphenyl)-3-hexene (III). Assurance that the reaction afforded the *trans* olefin has strong support from studies by Cram and Greene (5). Reduction of the olefin using 15% palladium on carbon resulted in a good yield of the desired 3-(2-pyridyl)-4-(*p*-methoxyphenyl)-hexane (VIII). Extensive work on similar systems by Wessely (6) demonstrated that a *d, l* pair of *threo* form enantiomers represented by structure VIII resulted from *cis* addition of hydrogen to the olefin (III).

Demethylation of VIII with a mixture of hypophosphoric acid and hydrobromic acid resulted in 3-(2-pyridyl)-4-(*p*-hydroxyphenyl)-hexane(IX). The phenol (IX) was a very hygroscopic solid foam and was converted to α, β-diethyl-4'-benzoyloxydihydro-2-stilbazole hydrochloride (X), which was a white powder suitable for instrumentation studies for structure analysis.

EXPERIMENTAL[1]

3-(2-Pyridyl)-4-(p-methoxyphenyl)-3-hexanol (VI)—A modification of the procedure of Woodward (7) was followed. To a solution of 30 ml. (0.1 mole) of *n*-butyl lithium in 100 ml. of dry ether in a nitrogen atmosphere and dry ice acetone bath was added dropwise a dry ethereal solution of 20 Gm. (0.12 mole) of 2-bromopyridine. After the addition was complete, the mixture was allowed to stir 30 min. at −40° and 10 Gm. (0.1 mole) of 3-(*p*-anisyl)-4-hexanone was added dropwise over a 15-min. period. The reaction mixture developed a dark rust color and was stirred for an additional hr. at −40°. Stirring was continued until the reaction mixture attained room temperature. The dark mixture was then allowed to sit overnight followed by filtration and washing with three 100-ml. portions of water. The early filtration facilitated work-up of the reaction by removing much of the dark reaction

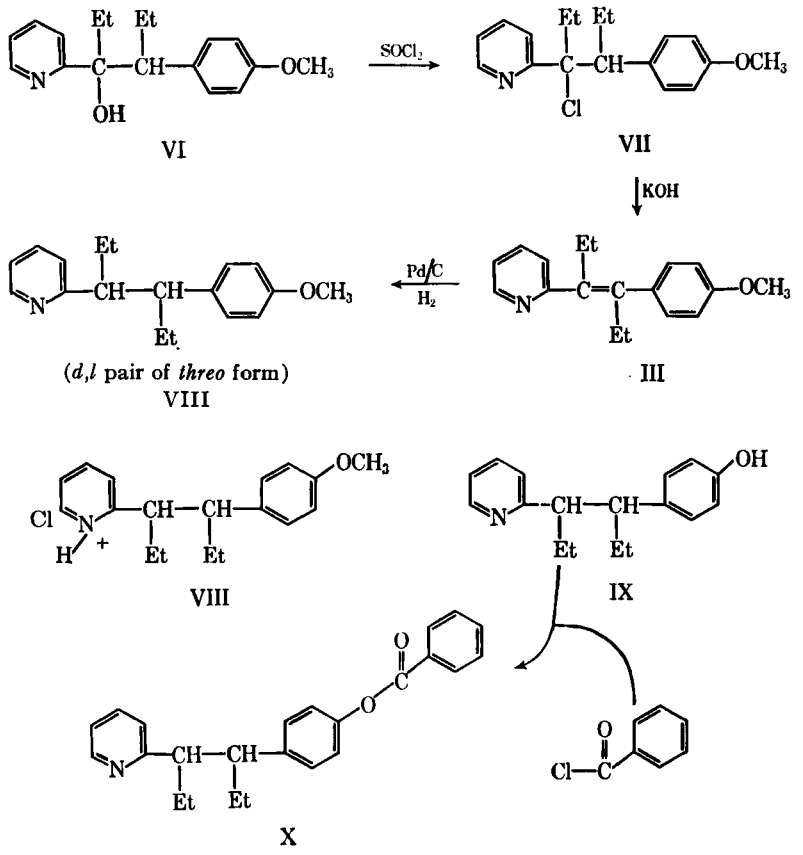
Racemic mixture of resultant alcohol $PhOCH_3$-*p*-methoxyphenyl

[1] All melting points were taken on a Thomas-Hoover Uni-melt apparatus and are corrected. The NMR spectra were taken using a Varian model A60-A instrument. The elemental analyses were determined by Dr. Alfred Bernhardt, 433 Mulheim (Ruhr), West Germany and Dr. Paul N. Craig, Smith Kline & French Laboratories, Philadelphia, Pennsylvania. The NMR spectra were measured at 60 Mc., and the chemical shifts are reported as τ-values (p.p.m.) from tetramethylsilane (internal standard). The multiplicity is shown by *s* = singlet, *d* = doublet, *t* = triplet, *q* = quartet, and *m* = incompletely resolved multiplet.



by-products. The ether phase was then evaporated *in vacuo* to leave a dark residue which was refluxed in water until crystallization occurred. The water was then decanted off and the solid recrystallized three times from ethanol to yield 7.1 Gm. (40%) of the desired alcohol m.p. 94–95°. The hydrochloride of this compound was prepared by dissolving the free base in anhydrous ether and bubbling dry HCl gas through the solution until precipitation was complete. The precipitate, collected by filtration, had a m.p. of 204–205°.

The infrared spectrum of the free base had hydroxyl group absorption at 3500 cm.$^{-1}$.

Anal.—Calcd. for $C_{18}H_{23}NO_2$: C, 75.76; H, 8.12; N, 4.91. Found: C, 75.92; H, 8.32; N, 5.08.

The NMR spectrum in carbon tetrachloride was δ = 4.79 (*s*, indicated to be OH, the peak disappeared on D_2O exchange), 0.5 (*q*, C—CH_3, 6H), 1.4 (*t*, C—CH_2, 3H), 7.00 (*q*, 2,3,5, and 6H of phenyl ring, 4H), 8.66 (*d*, 3, 4, 5, and 6H of pyridyl ring, 4H).

3 - (2 - Pyridyl) - 4 - (p - methoxyphenyl) - 3-hexene Hydrochloride (III)—Modifications of procedures by Hall (8) and Smith (9) were followed. To 1.0 Gm. (3.5 mmoles) of 3-(2-pyridyl)-4-(*p*-methoxyphenyl)-3-hexanol in a three-necked flask equipped with a stirrer, reflux condenser with calcium chloride tube, and dropping funnel in an ice bath was added dropwise 10 ml. of thionyl chloride. After the addition was complete, the solution was allowed to reach room temperature gradually and then heated to a gentle reflux for an additional hr. The cooled solution was then added slowly, under the hood, to 100 ml. of ethanol cooled in an ice bath in order to decompose the unreacted thionyl chloride. This solution was then evaporated to dryness *in vacuo* to leave a light red oil that was then dissolved in 25 ml. of ethanol. This solution was added dropwise to a cooled 25-ml. solution of 15% KOH in ethanol while the temperature was maintained at less than 50°. After addition was complete, stirring was continued for 4 hr. and the solution was allowed to stand overnight. Addition of water and evaporation *in vacuo* resulted in a light yellow oil which was extracted with three 50-ml. portions of ether. The ether extracts were dried over anhydrous magnesium sulfate and dry HCl gas bubbled through the solution to result in precipitation of a light oil. The oil was dissolved in hot ethyl acetate and refluxed until the oil crystallized into a light yellow solid. After recrystallization twice with ethyl acetate, 0.5 Gm. (42%) of the hydrochloride of the desired olefin resulted as a white powder, m.p. 146–147°. The product gave a positive $Br_2/CHCl_3$ test for an olefin.

Anal.—Calcd. for $C_{18}H_{23}ClNO$: C, 70.93; H, 7.60; Cl, 11.63; N,4.59. Found: C, 70.77; H, 7.40; Cl, 11.77; N, 4.34.

The NMR spectrum in deuterated chloroform was δ = 0.83 (*m*, C—CH_3, 6H), 1.65 (*q*,—CH_2—, 4H), 3.65 (*s*, O—CH_3, 3H), 6.00 (*s*, H of hydrochloride, 1H), 6.75 (*m*, 2,3,5, and 6H of phenyl ring, 4H), 8.81 (*m*, 3,4,5, and 6H of pyridyl ring, 4H).

3 - (2 - Pyridyl) - 4 - (p-methoxyphenyl) - hexane Hydrochloride (VIII)—A modification of the procedure by Horning (10) was followed. To 4.0 Gm. (0.014 mole) of 3-(2-pyridyl)-4-(*p*-methoxyphenyl)-3-hexene hydrochloride in 50 ml. of ethanol was

added 0.2 Gm. of 10% palladium on carbon. This mixture was then allowed to shake on a Parr hydrogenation apparatus under 45 p.s.i. of hydrogen for 48 hr. and then gravity filtered. The solution was then evaporated to dryness *in vacuo* and the residue was taken up in anhydrous ether. The ether solution was dried over anhydrous magnesium sulfate and then saturated with dry HCl gas which yielded a light yellow oil. After prolonged refluxing with ethyl acetate, the yellow oil crystallized into a light yellow solid which was collected by filtration and recrystallized twice from ethyl acetate to result in 2.59 Gm. (57%) of the desired compound, m.p. 154–155°. This product gave a negative $Br_2/CHCl_3$ test for an olefin.

Anal.—Calcd. for $C_{18}H_{24}ClNO$: C, 70.69; H, 7.91; Cl, 11.59; N, 4.59. Found: C, 71.69; H, 7.33; Cl, 11.63; N, 4.34.

The NMR spectrum in deuterated chloroform was δ = 0.85 (*m*, —C—CH_3, 6H), 1.71 (*d*, —CH_2—, 4H), 3.71 (*s*, O—CH_3, 3H), 6.00 (*m*, —CH—, 2H), 6.25 (*s*, H of hydrochloride, 1H), 7.00 (*m*, 2,3,5, and 6H of phenyl ring, 4H), 8.81 (*m*, 3,4,5, and 6H of pyridyl ring, 4H).

α,β - Diethyl - 4′ - benzoyloxydihydro - 2 - stilbazole Hydrochloride (X)—A modification of the demethylation procedure reported by Franck and Schlinghoff (11) was followed. While maintaining an atmosphere of nitrogen, 20 ml. of a mixture of hydrobromic acid and hypophosphorous acid (prepared from 0.5 Gm. of 50% hypophosphorous acid and 50 Gm. of 48.5% hydrobromic acid) was added to 1.0 Gm. of the 3-(2-pyridyl)-4-(*p*-methoxyphenyl)-hexane hydrochloride. The mixture was heated on an oil bath at 125–130° for 8 hr. and then gradually cooled to 0°. To the cold solution was added 15 ml. of ammonium hydroxide which resulted in separation of a light green oil. The oil was extracted with two 25-ml. portions of ether and the ether extracts dried over magnesium sulfate and evaporated to dryness *in vacuo* to yield a clear solid form unsuitable for purification for analysis. Preparation of the hydrochloride resulted in a similar problem. The free base was then dissolved in 15 ml. of benzoyl chloride and allowed to reflux for 2 hr. The solution was then poured into water and made basic with 10% sodium carbonate and stirred for 2 hr. before extracting the solution with three 50-ml. portions of ether. The ether extracts were dried over magnesium sulfate and dry hydrogen chloride gas bubbled through the solution until saturation was complete. The light yellow oil that separated was allowed to reflux in ethyl acetate for several minutes causing the solid hydrochloride product to precipitate as a white powder. The powder was collected by filtration and recrystallized twice from ethyl acetate and ethanol solution to yield 0.5 Gm. (36%) m.p. 187–188°.

The infrared spectrum showed carbonyl absorption at 1740 $cm.^{-1}$.

Anal.—Calcd. for $C_{24}H_{26}ClNO_2$: C, 72.81; H, 6.62; Cl, 8.96; N, 3.53. Found: C, 72.29; H, 6.00; Cl, 8.88; N, 3.54.

The NMR spectrum in deuterated chloroform was δ = 1.0 (*m*, C—CH_3, 6H), 1.8 (*m*, —CH_2—, 4H), 7.2 (*m*, phenyl protons, 9H), 8.5 (protons of pyridine ring, 4H). The spectrum did not show absorption at δ = 3.65 due to methoxy group.

Trichloroethyl Carbonate: Influence of Particle Size on Oral Toxicity in Mice

Sir:

The authors have reported that the particle size of 4-acetamidophenyl 2,2,2-trichloroethyl carbonate (ATC) has a great influence on its oral toxicity in mice and on the peak blood levels of acetaminophen it produces in mice and humans (1). These studies confirmed that, with prodrugs such as ATC which are relatively insoluble in water, particle size can have a marked influence on the onset and peak magnitude of the biological effects elicited.

Trichloroethyl carbonate,[1] a prodrug of trichloroethanol (2), has been reported to have an aqueous solubility of about 4 mcg./ml. (3). Therefore, it was expected that particle size would affect its oral toxicity in mice in a manner similar to that observed for ATC. The present study was carried out to determine the extent to which particle size influences the oral LD_{50} of trichloroethyl carbonate in mice.

means of a glass-Teflon tissue homogenizer; and coarse particle, prepared by sieving the drug and suspending the U. S. No. 140 to U. S. No. 170 mesh particles in a 0.5% dispersion of gum tragacanth in water. Photomicrographs of the suspensions are shown in Fig. 1.

The LD_{50}'s of the three particle sizes of trichloroethyl carbonate were determined orally in male Carworth Farms mice, weighing 14–21 Gm., in a manner similar to that used for ATC (1). The results (Table I) show that the three particle sizes of trichloroethyl carbonate had significantly different toxicities at the 95% confidence limit.

These results are very similar to those obtained with ATC. In the ATC study (1), the drug, in various particle sizes, was given orally to mice

TABLE I—ORAL LD_{50}'S WITH 95% CONFIDENCE LIMITS[a] FOR FINE, REGULAR, AND COARSE PARTICLE TRICHLOROETHYL CARBONATE POWDERS IN MICE

Particle Size	LD_{50} (95% Confidence Limits), mg./Kg.
Fine	1175 (1074–1502)
Regular	1775 (1573–2268)
Coarse	>2000[b]

[a] Data calculated by the logit chi-square method of Berkson (4). [b] Only 3/10 animals died at this dose.

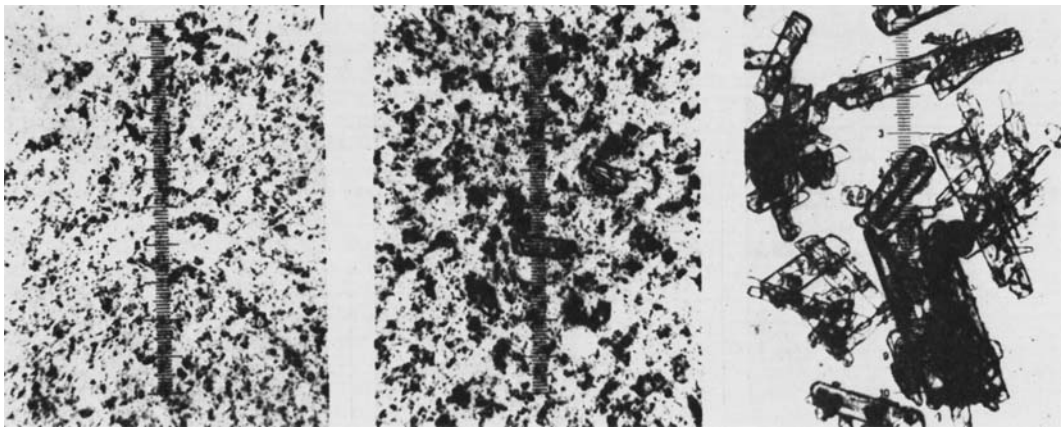

Fig. 1—Photomicrographs of the fine, regular, and coarse particle trichloroethyl carbonate used in this study (scale = 17.4 μ/small division).

The drug was prepared in three particle sizes as follows: fine particle, prepared by ball-milling a suspension of the drug in a 0.5% dispersion of gum tragacanth in water; regular particle, prepared by mixing a suspension of the drug in a 0.5% dispersion of gum tragacanth in water by

and a direct correlation was found between the oral LD_{50}'s and the peak blood levels of acetaminophen in the first 2 hr. Although no trichloroethanol blood levels were determined in this study on trichloroethyl carbonate, one might speculate that there would be a similar correlation between LD_{50}'s and peak trichloroethanol blood levels.

These studies indicate that when biologic mea-

Potential Carcinogenic Hazards from Drugs. Evaluation of Risks. UICC Monograph Series, vol. 7. Edited by Rene Truhaut. Springer-Verlag, 1 Berlin 31 (Wilmsdorf), Heidelberger Platz 3, Germany, 1967. vii + 249 pp. 16.5 × 25 cm. Price DM 68,–; U.S. $17.00.

This is the seventh volume of the monograph series sponsored by the International Union Against Cancer. It consists of a series of 24 papers presented at a symposium of the Cancer Control Commission held in Paris, November 1965.

It is quite apparent from both the formal papers and the abbreviated versions of the discussions which follow that emphasis was placed on chemical contact or ingestion as the principal etiological factor in carcinogenesis. While this orientation may be justified in a symposium dealing with drugs, it must be recognized that there are many oncologists who subscribe to the view that chemical carcinogenesis is of only minor significance in relation to the incidence of human cancer.

The initial papers in the symposium deal with the present state of methodology for evaluating the potential carcinogenicity of drugs. The statistical assessment of data from the point of view of predictability is then discussed. In view of the law prohibiting the use of carcinogenic substances as food additives, it is interesting to note the view expressed by one of the participants, Prof. I. Berenblum, that "for all practical purposes, a carcinogen is, like any other noxious substance, only harmful above a certain critical dose level." In this connection, the opinion of Prof. H. Druckrey based on his analysis of the dose–time relationships of chemical carcinogenesis, is especially pertinent. He distinguishes between the primary effect of a carcinogen at the cellular or molecular level, and the subsequent multiplication of cancer cells to the point of tumor induction. As far as the primary effect is concerned he holds to the view that "there is no indication for the existence of a subthreshold dose." Nevertheless, he recognizes that a zero tolerance for carcinogens is "not always practicable and is scientifically objectionable" and proposes as a basis for future discussion that "1% of the lowest dosage which, given daily over the whole life span to susceptible experimental animals, produces cancer only at the end of the life span, can be considered as the maximum tolerable dose for human beings."

A number of papers in this volume deal more specifically with the potential carcinogenicity of specific classes of substances such as metal-containing drugs, petroleum hydrocarbons, lactones, and hormones including progesterone. In the two reports dealing with plastics used in orthopedic or surgical practice, as well as in the discussions of these papers, the weight of evidence is in support of a physical rather than chemical explanation of the carcinogenic effect of experimental implants.

In his remarks reflecting the point of view of the pharmacologist, Professor Alastair C. Frazer emphasizes the need for discrimination and judgment in deciding when a drug should be subjected to life-span study for potential carcinogenesis, and questioned the need for identifying "extremely feeble" carcinogenic drugs intended for use over short periods in people whose life expectancy is unlikely to provide time for any effect to be induced.

This monograph is required reading for those who wish to keep up with current thought among the experts in drug safety evaluation. Although the discussions following each presentation reveal the lack of unanimity on many aspects, there is agreement that much remains to be done to get at the root of these problems from both the methodological and interpretative standpoints.

Advances in Pharmaceutical Sciences. Vol. 2. Edited by H. S. Bean, A. H. Beckett, and J. E.

CARLESS. Academic Press Inc., 111 Fifth Avenue, New York, NY 10016, 1967. x + 329 pp. 15.5 × 23 cm. Price $14.00.

In the preface to this series the editors state that their task "is to present topics of current and growing interest, written by experts, so that the development of the subject is portrayed in depth rather than providing a condensed review article." The contributors to this volume have successfully fulfilled the editors' objectives. Besides being an invaluable reference to the topics covered through 1965, *Advances in Pharmaceutical Sciences* can serve as a primary text in pharmaceutics courses at the graduate level.

The two central chapters, "Particle-Size Analysis" by I. C. Edmundson and "Flow Properties of Powders" by Barbara S. Neumann, complement one another. The former chapter reviews the problems encountered in particle-size specification and discusses statistical and graphical representation of particle-size data. Methods of particle-size measurement are described in sufficient detail to enable one to appreciate their limitations. The lengthy analysis of the Coulter counter method, including a review of its application in dissolution studies, is particularly useful. The chapter on powder rheology by Mrs. Neumann, while brief, updates her contribution in "Flow Properties of Disperse Systems," now out of print.

The first chapter in the book, "Kinetics and Mechanisms in Stability of Drugs" by Edward R. Garrett, brings up to date Dr. Garrett's review article in the September 1962 issue of *J. Pharm. Sci.* The current version is improved by discussion of the stability of specific drugs and classes of drugs in separate sections. While this review primarily emphasizes solvolytic degradation, it also discusses drugs which degrade through oxidation. The inclusion of a general description of autoxidative mechanisms would have broadened the usefulness of this chapter.

The last chapter, "Water Determination and its Significance in Pharmaceutical Practice" by C. A. Johnson, complements the first chapter by emphasizing the significance of water in relation to physical and chemical stability. The principle, methodology, limitations, and advantages of each method of water determination is detailed. Methods covered in depth include drying, distillation, the Karl Fischer titration, dielectric measurements, spectroscopy, and gas chromatography. Techniques adaptable to continuous measurement of water in processes are also reviewed.

The index, in conjunction with the outlines included at the head of each chapter, is adequate for one to find most specific topics covered in the book.

Glass Electrodes for Hydrogen and Other Cations. Edited by GEORGE EISENMAN. Marcel Dekker, Inc., 95 Madison Ave., New York, NY 10016, 1967. xii + 582 pp. 15 × 22.5 cm. Price $24.75.

The twenty-one international contributors to this volume have combined to give a comprehensive treatment of the theory and practice of cation-sensitive glass electrodes. The book covers the advances in knowledge made in the past ten years, and it is to the editor's credit in selecting his authors that these advances have been made largely by the contributors to this volume.

The book is organized so as to present first the principles upon which the functioning of ion-sensitive electrodes is based and then to examine modern practice in making and using such electrodes. The volume is divided into nineteen chapters; however, I believe that the pharmaceutical scientist interested in using cation-sensitive electrodes as an analytical tool will find the following eight sections of primary interest: Interpretation of pH and Cation Measurement, Cation-Sensitive Glass Electrodes in Analytical Chemistry, Ion-Sensitive Electrodes and Individual Ion Activity Coefficients, Hydrogen and Cation Analysis in Biological Fluids *in Vitro*, H^+ and Cation Analysis of Biological Fluids in the Intact Animal, Cation-Selective Microelectrodes for Intracellular Use, Glass Microelectrodes and Their Uses in Biological Systems, and Clinical Application of Cation-Sensitive Glass Electrodes.

The authors have done a good job of defining the present limits of cation-sensitive electrodes, and most have taken the opportunity to outline the problems that still must be solved. The latter facet of the book should catalyze the ingenious investigator to envisage many new uses for cation sensitive electrodes. As one author points out, the advent of glass electrodes which can be made to respond selectively to various cations, has opened a veritable "Pandora's box" for investigators in the biological sciences. With such glass electrodes a non-destructive, continuous, high-sensitivity measurement of ionic activity may be made either *in vitro* or *in vivo*.

Each chapter in the volume is essentially self-contained, with its own table of contents and references, and can usually be read independent of the preceding chapters. The book can, therefore, serve as a valuable reference and should be in the library of anyone planning to use cation-sensitive electrodes (hydrogen or otherwise) as an analytical tool.

Steroid Hormone Analysis. Vol. I. Edited by HANS CARSTENSEN. Marcel Dekker, Inc., 95 Madison Ave., New York, NY 10016, 1967. xiii + 493 pp. 15 + 23 cm. Price $23.50.

A series of reviews in steroid methodology are presented as individual chapters of two types. The majority of chapters are technique oriented and have the following titles and scope: "Isotope Derivative Methods for the Determination of Steroid Hormones with ^{35}S-Sulfonylating Reagents," "Elementary Aspects of Infrared Spectroscopy of Steroids," "Outline of the Application of Nuclear Magnetic Resonance to the Investigation of Steroids," "Chromatography of Steroids on Paper," "Gas Chromatography of Steroids." In addition, there are two chapters that center on compounds rather than technique. These chapters are entitled: "Testosterone" and "Analysis and Identification of Steroid Conjugates."

CARLESS. Academic Press Inc., 111 Fifth Avenue, New York, NY 10016, 1967. x + 329 pp. 15.5 × 23 cm. Price $14.00.

In the preface to this series the editors state that their task "is to present topics of current and growing interest, written by experts, so that the development of the subject is portrayed in depth rather than providing a condensed review article." The contributors to this volume have successfully fulfilled the editors' objectives. Besides being an invaluable reference to the topics covered through 1965, *Advances in Pharmaceutical Sciences* can serve as a primary text in pharmaceutics courses at the graduate level.

In addition, there are two chapters that center on compounds rather than technique. These chapters are entitled: "Testosterone" and "Analysis and Identification of Steroid Conjugates."

While the change in emphasis would appear to be arbitrary and does lead to some duplication of material, this is not a serious difficulty. It does, however, serve to illustrate the completely independent nature of individual chapters. Each review is designed to stand alone without cross references to other chapters nor is the progressive interchapter development of concepts attempted.

It is evident from the chapter titles given above that material significant to a work on steroid analysis is being covered. However, a real problem in balance must be raised. Forty percent of the present volume is devoted to the chapter on paper chromatography. This certainly is at the expense of other, at least equally as important, material such as the physical methods. One can only hope that thin-layer chromatography and column chromatography will have its day in Volume II.

The editor has implied in his preface that the book is designed primarily for the biologist. For the most part, a format of general discussion of the technique followed by specific applications in the steroid area is employed and serves the biologist well. By necessity, the discussion of techniques are brief and serve essentially to introduce the subject. It is, therefore, the use of steroid examples that recommends the book to not only the biologist but also to the analyst who lacks experience in the steroid field.

Review Article

Particle-Size Analysis of Emulsion Systems

By M. J. GROVES and D. C. FRESHWATER

BECHER (1) reviewed the definitions of an emulsion and suggested the following as a basis for discussion: "An emulsion is a heterogeneous system, consisting of at least one immiscible liquid intimately dispersed in another in the form of droplets, whose diameters, in general, exceed 0.1 μ. Such systems possess a minimal stability, which may be accentuated by such additives as surface active agents, finely divided solids, etc." Becher's definition is satisfactory on most counts. His limitation on the lower size of the disperse phase particles is clearly not intended to be anything other than a broad generalization. Indeed, Becher himself recognized this since in a later section (p. 44) he stated that: "Emulsions are essentially unstable heterogeneous systems; they are partly dispersions, partly colloids"; the use of the term, colloid, inferring submicron sizes.

The influence of particle size upon the physical properties of emulsions and suspensions has been reviewed by others (1–6). It is generally agreed that stability, viscosity, rate of heat transfer, and optical properties of emulsions are dependent upon the particle size or the particle-size distribution of the disperse phase. However, there is at present no satisfactory correlation of the relationship. For example, Rutgers (5) reviewed the literature (up to 1962) on the relationship between relative viscosity and dispersion concentration. He concluded that absolute particle size was of importance, but not one of the 97 equations discussed by this author contained an expression for size or distribution of size. Sherman (6) also concluded that the bulk of the published literature on the viscosity of emulsions contained little or no reference to the state of the dispersion beyond broad statements to the effect that an emulsion was "fine" or "coarse."

Reexamining the published work that attempts to derive a correlation between some physical property of an emulsion and the state of dispersion, it was noted that many of the size measurements had been obtained by optical microscopy (Table I). However, it is widely accepted that this method of size analysis cannot adequately differentiate between particles of less than 1μ diameter owing to the limited resolution of the light microscope as the particles approach the wavelength of the incident radiation (7–9). Thus even if one accepts Becher's definition of an emulsion and his arbitrary limitation to disperse phase particles exceeding 0.1μ diameter, the accuracy of measurement of the smaller particles that could be present in a system, and the assessment of the significance of the results must at least remain suspect. The purpose of this review is to consider the particle size of emulsion systems and the alternative methods at present available for its measurement.

MEANING OF PARTICLE SIZE

In practice it is rarely found that all the particles in a system under examination have the same size parameter. Accordingly, size measurements on polydisperse particle systems indicate the probability that a given particle picked at random has a specified size. Thus the particle sizes re-

Received from the Research Department, Boots Pure Drug Co., Nottingham, England, and the Department of Chemical Engineering, Loughborough University of Technology, Loughborough, England.

ported for any material are associated with their frequency of occurrence; being the number of particles, or the weight greater or smaller than a stated size, or range of sizes. The purpose of a particle-size measurement technique is to discover the true frequency distribution of particle size, either as a number distribution or a weight distribution.

Form of Size Distribution for Emulsion Systems

Jellinek (10) suggested that it was unlikely that emulsions prepared by different methods and with different materials would have similar mathematical forms of distribution. Nevertheless, Herdan (11) noted that many systems appeared to obey some standard forms of distribution function such as arithmetical or logarithmic forms of normal (Gaussian) distribution, or exponential distributions of the Boltzmann law type.

The earliest attempt to derive a statistical function of this type was by Rossi (12) who considered the mechanism of subdivision as a random process. Rossi's model had certain deficiencies which Dobrowsky (13), van den Tempel (14), and Lederer (15) attempted to overcome. Jellinek found that Rossi's equation fitted experimental data for homogenized bitumen except for the largest particles present.

Troesch (16) applied statistical theory to the breakdown of droplets under turbulent flow conditions, and deduced that the droplet-size frequency followed a normal Gaussian distribution. Brodnyan (17), considering emulsion polymerization processes, found that in some cases radii were distributed normally although in other examples a log-normal distribution occurred.

A Gaussian distribution is absurd in many ways since it implies that a fraction of the particles, even though a small one, has to be expressed as having negative diameters (18). Nevertheless, the concept is useful since moments can be calculated by the use of algorisms (11). Cooper (7, 8) found that the Rossi equation appeared to apply only to the main drops in the emulsion. The presence of small daughter droplets always means that the size distribution is skewed and this also applies to a Gaussian plot. However, empirically, one method of removing this skewness (that is, make the distribution more evenly spaced out) is to plot it as a function of the logarithm of the particle size. Kottler (19), in 1952 reviewed the use of a logarithmico-normal distribution and cited examples back to 1924. Although Kottler's analysis of the statistical aspects of the log-normal distribution was confined to photographic emulsions, he demonstrated that if a distribution were not linear when plotted on log-probability paper it was an indication that

the sample contained at least two different populations.

Mugele and Evans (20) critically compared Rossin-Rammler and Nukiyama-Tanasawa distributions with log-probability plots and showed that the first two were largely unsatisfactory. They found that the log-probability equation predicted the general distribution trend correctly for most data and gave good results for the mean diameter calculations. These authors showed that the emulsion data of Harkins and Beeman (21) and of Cooper (7, 8) fitted this presentation satisfactorily despite the extremely small size of the emulsion particles.

Gwyn, Crosby, and Marshall (22) considered bias in particle-size analyses resulting from the use of a log-normal distribution. Many analyses indicate the existence of maximum size classes but the log-normal distribution is in fact infinite in extent. Thus, the results tend to be biased, an occurrence implicitly recognized by Mugele and Evans. Gwyn *et al.* assumed that the sample was taken from a population with a true log-normal distribution and adjusted the data for bias. They suggested that the analysis could be carried out in two parts, a few particles being first counted to establish the central portion of the distribution, and a larger number of particles falling above, say, 5% of the total distribution based on the central portion. As noted by Gwyn *et al.*, if a single distribution applies over the entire range of sizes the curve for the upper range will exactly, or very nearly, coincide with the extension of the curve for the central portion of the distribution.

Rajagopal (23) derived a rigorous proof of the log-normal distribution by considering the randomness due to violent break-up of the interface during cavitation, the formation of daughter droplets, the disruption due to collisions, and coalescence due to the same cause. The process was considered as a Markoff chain and the empirical applicability of a log-probability law to emulsion particle-size distribution was placed on a firm theoretical basis.

Schwarz (24) introduced a so-called universal distribution law and this was later amplified and confirmed in two papers by Schwarz and Bezemer (25, 26). This equation, derived on statistical grounds, is also a variation upon the truncated log-normal distribution. From the data supplied by these authors, the equation appears to be less universal in application than their claims suggest. However, Sprow (27) found that the equation was useful when investigating droplet sizes produced in turbulent liquid-liquid dispersions.

There are a number of advantages in utilizing a distribution law of the log-normal type to describe a particle-size distribution, as discussed by Smith and Jordan (28). Thus, on a number basis a particle-size distribution is defined uniquely by two parameters, M, the geometric mean particle diameter, and σ_g, the geometric standard deviation. Both these parameters can be readily obtained by plotting the size-distribution data as a cumulative undersize curve on log-probability paper, a point also brought out by Kottler (29). In establishing line of best fit Kottler pointed out that preference should be given to those points lying closest to the midvalue of 50 cumulative percent. Due to the distortion of the probability axis, the distance by which points are displaced from a straight line becomes increasingly significant as one considers points progressively closer to the 50% mark. For this reason some investigators such as Drinker and Hatch (30) fit the best line to those points within the 20–80% limits, ignoring points outside these marks.

Espenscheid *et al.* (31) criticizes the use of log-normal distribution functions obtained from light-scattering data. They suggested that this was a new distribution function with different parameters and physical properties. However, Honig (32) pointed out that the suggested distribution function was readily reduced to the usual log-normal distribution function and this was the only one which could be determined experimentally.

One other approach deserves mention since the method of presenting the size analysis is unique. Broadbent and Callcott (33) suggested that a size analysis could be presented in the form of a matrix, leading to the derivation of a single parameter, the breakage function (π), which was defined as the proportion of particles that are broken during a grinding process. This approach, requiring distributions at different times, was developed in a series of papers (34–36) in the context of coal grinding and assumes that the chance of breakage is the same irrespective of the particle size. Furthermore, in its suggested form it could not be applied to emulsion systems since no account is taken of coalescence which always occurs during an emulsification process. Nevertheless, the concept of presenting the size analysis as a matrix is an attractive mathematical model since it is not necessary to assume any "law" controlling the emulsification process, and it might be possible to derive a single parameter to describe any one distribution. Arbiter and Harris (37) extended the concept to include a time relationship in grinding, but the approach

does not appear to have been used in the context of emulsions and might be a fruitful approach for a future investigation.

To summarize, there is considerable agreement that a size distribution follows a log-normal distribution, being characterized by the mean size and the slope, or standard deviation. This distribution can be plotted on log-probability paper and, although a relatively insensitive method of presenting results, it must be regarded as satisfactory when considering such factors as sampling error and repeatability of a particular size analytical method.

METHODS OF PARTICLE-SIZE ANALYSIS

The Society for Analytical Chemistry in 1963 published a classification of methods for determining particle size (38). This, supplemented by the standard textbooks on the subject by Herdan (11), Orr and Dallavalle (39), Rose (40), and Cadle (41), and review articles such as that by Scarlett (42), are sufficient background. It is not proposed therefore, to discuss the methods in general but rather to select certain aspects for comment and deal with two methods, the Coulter counter and the centrifugal photosedimentometer, in detail.

MICROSCOPE MEASUREMENT OF EMULSION PARTICLES

Most of the work carried out on correlation of properties of emulsions to the particle size of the disperse phase has relied upon optical microscopy for the particle-size measurement (Table I). The microscope has the advantage that it is direct and inexpensive, but the measurements in themselves may be extremely lengthy and tedious.

Mounting techniques for emulsions have been discussed and described by Simmonite (43). The emulsion under examination must first be diluted before mounting, and care is required to ensure that the system is not affected by this treatment. Various dilution media have been proposed including aqueous gelatin, acacia solution, and diluted polyols such as glycerin or propylene glycol (9). Various techniques have been described for examining the particles and classifying them into size groups. The simplest form utilizing a micrometer eye-piece or calibrated graticule has been widely employed (44). Harkins and Beeman (21) used a projection microscope, thereby reducing eye strain and improving the accuracy of the method. Smith and Grinling (45) introduced a counting technique using a hemocytometer slide and Cockton and Wynn (46) improved this by using a shallow Helber counting chamber. Levius and Dromond (9) criticized the previous papers and suggested a camera lucida method which they found to be an improvement over the counting techniques. Photographic methods were employed by, for example, Cooper (7, 8) who measured the particle size from prints. Photomicrography of emulsions is difficult since particles in the micron range exhibit Brownian movement, necessitating very short exposure times with subsequent loss of contrast.

Automatic scanning methods have been described (294) in an attempt to reduce the tedium of microscope analysis and improve speed and accuracy. Collins (295) investigated the sources of error using a Mullard type L188 "flying-spot" analyzer. Fisher (296) described a new scanning instrument which includes a computer to produce secondary information such as total projected area, total numbers of particles, or parameters such as mean Feret's or Martin's diameter.

The necessity of sizing large numbers of particles to obtain meaningful results has received some attention, the most serious attempt being probably that of Fischer and Harkins (47) who counted 50,000 particles in each of their systems However, as discussed by Becher (1), statistically significant counts can be obtained with only 300 particles. A count of 300 particles will result in a cumulative distribution in which the error at any value will be less than 8% ($p = 0.95$) and to lower this to 5% would require a count of 2,960 particles. Kaye (48) also discussed this point and showed that errors arising from sampling were such that a 10-fold increase in count only produced a slight increase of accuracy. The statistics of sampling are discussed (49).

Cooper (7, 8) carried out the classical critical evaluation of microscope sizing methods for emulsions. He pointed out that photographic methods were limited by the depth of focus since no lens is available which can give a clear image of particles of 1 μ or less and yet have a depth of focus of 20 μ, the thickness of a hemocytometer cell. Direct visual counting, in which the focus of the microscope can be continually varied, was found always to show a higher value for the number of particles in the smallest size range, confirmed by van Kreveld (50). As the particle approaches the wavelength of the incident light, the resultant halo makes estimation of the actual particle diameter extremely difficult so that sizing of particles below, say, 2 μ cannot be carried out with 100% efficiency, a point also confirmed by Saylor (51). Lucas (52) noting that rubber lattices contained particles well below 0.5 μ, attempted to improve the light microscope by reducing the wavelength of the radiation to the

ultraviolet range (λ = 2573 Å). The technique was extremely difficult since the source was not stable. van den Tempel (14) showed from Lucas's data that there are a considerable number of particles present in his system below the visibility limit of 0.12 μ, probably more than 60% being below the limit. van den Tempel considered the use of the light microscope for such small particles to be meaningless and favored the ultramicroscope which can be used to detect and count particles down to 0.02 μ diameter but is unable to differentiate particle sizes.

Although Cooper showed that microscope measurement of particles below 2 μ was of limited value, the method has continued to be used up to the present. King (53) implied that misleading results were occasionally obtained when correlating emulsion stability with particle sizes of 0.5–1 μ diameter. Knoechel (54) and Knoechel and Wurster (55), investigating o/w emulsion stability, discussed the inability of the microscope to take into account submicron particles, concluding: "The experimental evidence indicates that the presence of sub-visual particles could lead to unreliable values for various diameters and interfacial areas during the period in which minute globules coalesce to a visible size." This conclusion was echoed by Sherman (56, 57, 292, 293) who proposed that the only way out of this dilemma was to allow all the minute particles to coalesce until they could be measured microscopically. The value of this suggestion for unstable systems may be doubted, but the idea clearly cannot be applied to those which are stable or in which the particles do not coalesce. Sherman pointed out in the discussion of a later paper (58) that submicroscopic particles are "cancelled out" when determining a mean size. He made a tentative proposal for utilizing a reciprocal mean diameter, thereby bringing out the importance of submicron particles in a system.

ELECTRON MICROSCOPE

The early development of electron microscopy and its application to the investigation of materials below the limits of light-microscope discrimination was reviewed by Anderson (59). Walton (60) and Watson (61) reviewed the application of the instrument to particle-size measurement and described some of the limitations of the technique. The method has some advantages compared with light scattering, sedimentation, and other methods. In particular any peculiarities in shape can be observed directly (62). As noted by Walton (60), major difficulties are sampling and the effects of drying under vacuum. Local heating effects in the electron beam are often important when examining soft materials such as emulsion particles. Cravath *et al.* (63) improved the sampling of suspensions by depositing small droplets of the suspension from a mist (aerosol) onto a specimen film treated to promote wetting. The entire residue left by a single droplet could then be examined. Nixon and Fisher (64) used an aerograph gun to produce droplets and dispersed their material in bovine serum albumin which dried out to yield a transparent matrix supporting the particles. The basic technique of Nixon and Fisher was later improved by Craik who used a more concentrated albumin solution and stained the protein with osmium to improve contrast at the edges of the particles where the maxtrix was thickest, described by Groves and Scarlett (65).

Other methods of supporting suspensions for examination have been reported (66, 67). Soft polymeric materials which distort in vacuum have been hardened before examination by bromination (68) or cross-linking with hard polymers using high energy irradiation (62, 69, 70). However, in general these hardening techniques have not been applied to the electron microscopy of liquid-liquid emulsion systems.

Particle-size analysis using the electron microscope requires the measurement of a large number (at least 3,000) of particles by a photographic method since the image is often not sufficiently stable for more than a few minutes. The problems associated with this aspect of the method were described by Crowl (71) who proposed a mechanical method for sizing from photographic plates. The alternative approach of image shearing proposed by Rippon (72) may also offer a solution for future development.

However, the use of electron microscopy for measuring the particle size of emulsion particles below about 1μ diameter would appear to be the only direct method at present available.

ULTRAMICROSCOPE AND LIGHT-SCATTERING METHODS

Recent work on ultramicroscope methods has been devoted to either counting particles in a flow cell (73) or using a flow method to separate particles out according to their size and counting in a flow ultramicroscope (74–76).

Particle sizes can also be measured in principle by optical methods depending on the measurement of the reduction of light directly transmitted through a dispersion (turbidimetric or nephelometric methods) or by light scattered at some definite angle (usually 90°) from the light path.

Krishnan (77) appears to have been one of the first workers to investigate the light scattering in dilute emulsion systems, and Sing (78) showed that for small particles secondary scattering could no longer be neglected. This author utilized the Mie theory and the approach was investigated theoretically by van der Hulst (79).

The relationship between the scattering of light, the wavelength of the light, and particle size is complicated, but for particles small relative to the wavelength of light it assumes the simplified form originally derived by Rayleigh:

$$S = 24\pi^3 \left[\frac{m^2 - 1}{m^2 + 2}\right] \frac{V^2}{\lambda^4} \qquad \text{(Eq. 1)}$$

where S = total amount of light of wavelength, λ, scattered by a sphere of volume, V, and relative refractive index, m, per unit intensity of illumination.

This equation holds for spherical transparent particles when $r \leqslant 0.1\lambda$. When a particle is comparable in size or large relative to the wavelength of the incident radiation the scattered light will be the resultant of light waves originating from various parts of the particle. The phase and intensity of such waves are related in a complicated manner, predicted by the Mie equation (80, 81), written in the form:

$$S = \frac{\lambda^2}{2\pi} \sum_{v=1}^{\infty} \left(\frac{a_v^2 + p_v^2}{2v + 1}\right) \qquad \text{(Eq. 2)}$$

where S = total scattering by one spherical particle per unit intensity and the a_v's and p_v's are functions of X $(2\pi r/\lambda)$ and β $(2\pi rm/\lambda)$, r being the particle radius.

This equation has been discussed in detail by van der Hulst (79) and numerous tables of solutions to the Mie series have been published (80).

When S is divided by πr^2, the scattering per unit cross-sectional area of the particle, known as the scattering coefficient K, is obtained. Equation 2 then becomes

$$K = \frac{s}{\pi r^2} = \frac{\text{light obscured by particle}}{\text{light obscured if laws of geometric optics were valid}}$$

$$= \frac{2}{X^2} \sum_{v=1}^{\infty} \left(\frac{a_v^2 + p_v^2}{2v + 1}\right) \qquad \text{(Eq. 3)}$$

Thus, K is a function of r/λ and when the scattering coefficient is known for a particular value of r and λ its value is established for the ratio regardless of the individual values.

Equations 1–3 have been derived for scattering from single particles, but unless the number concentration of particles in a suspension is very high the scattering from a suspension can be considered to be the sum of the scattering by the individual particles. In practice, fine particles usually have a range of size as well as being of irregular shape. Thus, although the total scattering is the sum of the scattering by individual particles, the scattering coefficient may vary widely from one particle to another. If the ratio of r/λ is greater than 50, the value of K is constant and can be taken as unity. For smaller ratios the value of K becomes a complex function of r/λ. The effect of adding the scattering from a number of particles of varying size would be expected to damp out the wide fluctuations in scattering coefficient with varying size that occur for single particles. Gumprecht and Sliepcevich (82) considered the problem and proposed a quantitative relationship between Mie theory and K which enabled them to obtain a size-frequency distribution. The approach was simplified and does not appear to have gained wide acceptance. Goulden (84) used scattering-coefficient data calculated by van der Hulst (79) to apply the Mie equation to determining the particle size of homogenized milk (85–89). However, his method can only yield a mean particle size, and although useful for control purposes, cannot be employed for other than relatively monosized systems.

When a measure of total scattering is desired, it is much more convenient to measure the percent transmission than to attempt to integrate the intensity of the scattered light. Transmission methods have been used in many fundamental studies of light scattering and form the basis of a number of methods of particle-size determination.

When a beam of light is passed through a suspension of particles, the intensity of the beam is attenuated as a result of the scattering, and the decrease in intensity obeys the exponential law:

$$I/I_0 = \exp.(-\tau l) \qquad \text{(Eq. 4)}$$

The initial intensity = I_0, the intensity after the light has traversed distance 1 is I and τ is the absorptivity, τl being termed the absorbance.

Equation 4 can be rewritten for monosized systems as

$$I/I_0 = \exp.(-K\pi r^2 n l) \qquad \text{(Eq. 5)}$$

where n = the numbers of particles of radius, r, per unit volume of suspension, and K is the scattering coefficient as defined in Eq. 3. For very small particles which obey the Rayleigh relationship Eq. 1 can be rewritten as

$$I/I_0 = \exp.\left[-\frac{128\,\pi^5 r^6}{3\lambda^4}\left(\frac{m^2 - 1}{m^2 + 2}\right)\right] n l \qquad \text{(Eq. 6)}$$

On the other hand, when the particle diameters

are large K approaches a value of 2. Lothian and Chappel (83) discussed the fractional loss of intensity of a beam of light passing through a layer of emulsion particles, and showed that the absorbance of a dilute suspension of spheres was a function of their particle size. After strong criticisms of turbidimetric methods by Skinner and Boas-Traube (90), an improved instrument was described by Branson and Dunning (91). This device was further developed by Rose (40) who narrowed the angle of acceptance to reduce forward scattering. Other investigations were carried out by Kaye (48) and by Hodkinson (92). The latter made measurements of the angular scattering distribution over the range of 0.5–90° using suspensions of powdered flint, diamond, anthracite, and bituminous coal. Smooth curves were obtained which were quite unlike those for single particles or monodispersed spheres. Mie theory was therefore not applicable to these irregular particles, and K was found to rise slowly from 0 to 2. Kaye, and later Kaye and Allen (93) investigated the optical scattering cross-sections of small particles using white light and a wide angle of acceptance. Under these conditions, they also found that fluctuations of K were much reduced and for many purposes it was sufficient to take it as unity. Thus, the claim by Bolton and Marshall (94) that a simple turbimeter could be used to measure wax particles down to 0.06 μ diameter must be viewed with caution. It is not clear if these authors used a white light source, but it is of interest to note that they found values for K as low as 0.04 for their smallest particles.

Trice and Rodger (95) measured interfacial areas using a light-transmittance method similar to that used earlier by Langlois *et al.* (96) for coarse, unstable emulsions.

Reflectance relationships for emulsions are, if anything, more complex. This was noted by Lloyd (97) who incorporated a red dye in the oil phase and found that the reflectance at wavelengths at which the colored internal phase partially absorbed the incident light was inversely proportional to a power of the surface-area particle diameter. This relationship was claimed to be independent of the particle-size distribution. Schulman and Friend (98, 99), and van der Waarden (100) both used the Rayleigh formula to calculate the mean size of very small droplets (up to 400 Å. diameter). La Mer (101) investigated monodisperse aerosols using the higher-order Tyndall spectra method. Heller *et al.* (102) verified experimentally that Mie theory was applicable to light-scattering methods and tabulated the data required to transform light-scattering measurements into particle-size distributions (103, 105). Although initially confined to relatively monodisperse polymer lattices, Wallach (104) claimed that the method was applicable to the study of size distributions of dimethylnaphthalene–water emulsions.

Gledhill (106), Wales (107), and Weber (108) have all described methods for measuring particle-size distributions by measurement of turbidity spectra using methods similar to Heller. La Mer and Plesner (109) described a rapid method of sizing a monodisperse suspension by measuring the light scattering as a function of the angle between the incident beam and scattered light and the method was extended by Dezelic and Kratohvil (110, 111). Kratohvil and Wallace (112) reexamined the claims made by Heller and Tabibian (113), and by Wales (107), and found them unreliable.

To summarize, there is general agreement that light scattering and turbidity methods can give a measure of the mean particle size present in a system although there is some disagreement on the method by which the size distribution can be determined. Simplified techniques, making a number of assumptions, have been applied to determining particle-size distributions by a combination of sedimentation methods and turbidity measurements.

COULTER COUNTER

Coulter described his instrument in 1956 (114) and the device has come to be widely accepted as a convenient and valid method of size analysis. The Coulter counter determines the number and size of particles suspended in an electrically conductive liquid. This is done by forcing the suspension to flow through a small aperture having an immersed electrode on either side. If the suspension is sufficiently dilute, the particles will pass through the aperture one at a time. As each particle passes through, it displaces its own volume of electrolyte thus changing the resistance across the aperture. An electrical current passing between the electrodes converts the resistance change into a voltage pulse, whose amplitude for a given current and electrolyte is proportional to the volume of the particle. The voltage pulses resulting from a known volume of suspension passing through the aperture are fed to an electronic counter fitted with an adjustable threshold level such that all pulses above the threshold are counted. In this manner the number of oversize particles is obtained at different levels of particle volume so that a particle-size distribution by number or by weight can be determined. Detailed descriptions of the in-

strument and its principle of operation have appeared in the literature (114–127) and it is not proposed to repeat them here.

As might be anticipated with any new advance the Coulter counter has been subjected to critical evaluation by many workers in recent years (128–137). However, to date no fundamental flaw in the principle or mode of operation has been detected and it is generally agreed that the instrument is a unique and valuable contribution to the science of particle-size analysis.

Theoretical Response of the Coulter Counter

Batch (115) and Gregg and Steidley (279) have considered the theoretical response of the Coulter counter for various shapes of particles. The current between the electrodes is maintained at a constant level so that any change in the resistance of the cell results in a change of voltage across the cell. The presence of a particle of different resistivity in the aperture will therefore result in a change of resistance, the amount of change being in some way proportioned to the value of the particle.

Consider an orifice of cross-sectional area A, diameter D, filled with an electrolyte of resistivity, r_0, and containing a particle of resistivity, r. If a is the projected area of the particle at the portion of an elemental section of length dl then the resistance of this element of the particle in the direction of the orifice axis is $r\,dl/a$, and the resistance of the annulus of electrolyte is $r_0 dl/(A - a)$. The total resistance across the element is

$$dR = \frac{r_0 r\,dl}{ar_0 + r(A - a)} = \frac{r_0\,dl}{A - a(1 - r_0/r)}$$

and the increase of the resistance of the element due to the particle is

$$d(\Delta R) = \frac{r_0 dl}{A - a(1 - r_0/r)} - \frac{r_0 dl}{A}$$

$$= \frac{(1 - r_0/r)r_0 a\,dl}{A^2[1 - (1 - r_0/r)a/A]} = \frac{ar_0 k\,dl}{A^2(1 - ka/A)} \quad \text{where } k = (1 - r_0/r)$$

Thus, the total resistance change is

$$R = \frac{r_0 k}{A^2}\int \frac{a\,dl}{(1 - ka/A)} \qquad \text{(Eq. 7)}$$

For a rod-shaped particle lying along the axis this equation can be solved simply because a is not a function of 1 so that

$$R = \frac{rkv}{A^2(1 - ka/A)}$$

Batch solved Eq. 7 for spherical and cone-shaped particles by expanding the expression under the integral sign. Gregg and Steidley obtained exact solutions by solving the integral explicitly before expansion. The resulting equations for change in resistance are summarized in Table II.

The equation for a sphere approximates to

$$R = \frac{r_0 v}{A^2}\left[1 + \frac{0.3K^2 + 0.13K^4}{(1 - K^2)^{-1/2}} + + +\right] \qquad \text{(Eq. 8)}$$

Thus, for any shaped particle, provided a/A, or d/D, $= K$ is small, the change in resistance is directly proportional to the volume of the particle. Allen (132) has shown that this assumption is valid for particle–tube ratios of up to 20%. The assumption of the linear response for up to 40% ratio can lead to an error in particle diameter of 7.8% for rod-shaped particles, and 3.6% for spherical-shaped particles.

The error term in Eq. 8

$$\frac{1 + 0.3K^2 + 0.13K^4}{(1 - K^2)^{-1/2}}$$

can be used to assess error due to assuming a linear response, as shown in Table III. Thus it will be seen that, strictly, the response of the Coulter counter is not linear with particle volume and the nonlinearity is dependent upon particle

Table II—Summary of the Equations[a] Relating Particle Shape and Total Resistance Change in an Orifice Containing an Electrolyte

Particle Shape	ΔR[b]	ΔR[c]
Rod length $\gg$ dia.	$\frac{rkv}{A^2}\left(1 + \frac{ka'}{A} + \frac{k^2a'^2}{A^2} + \ldots\right)$	$\frac{r_0 v}{\pi^2 D^4}\frac{1}{(1 - K^2)}$
Rod length $\sim$ dia.	—	$\frac{r_0 v}{\pi^2 D^4}\frac{1}{(1 - K^2)}\left[t\pi r_1^2 + \sigma\pi r_1^3\right]$
Sphere	$\frac{rkv}{A^2}\left[1 + \frac{4}{5}\frac{ka'}{A} + \frac{24}{35}\frac{k^2a'^2}{A^2} + \ldots\right]$	$\frac{2r_0}{\pi D}\left[\frac{\tan^{-1}[K(1 - K^2)^{-1/2}]}{(1 - K^2)^{1/2}} - K\right]$
Cone	$\frac{rkv}{A^2}\left[1 + \frac{3}{7}\frac{ka'}{A} + \frac{3}{7}\frac{k^2a'^2}{A^2} + \ldots\right]$	—

[a] Where A = area of orifice of diameter D, a' = maximum cross-sectional area of particle. The value of k is $(1 - r_0/r)$, where r is the resistivity of the particle and r_0 the resistivity of the electrolyte. Gregg and Steidley assume r/r_0 to be negligible and define K as d/D = particle diameter/orifice diameter, where t is the length of rod and σ is a constant. [b] From *Reference 115*. [c] From *Reference 279*.

TABLE III—MAGNITUDE OF THE ERROR IN ASSUMING A LINEAR RESPONSE FOR THE COULTER COUNTER (EQ. 8)

d/D	0.1	0.2	0.3	0.4	0.5
$\Delta R \cdot A^2/V$	1.008	1.033	1.077	1.145	1.26
Error in volume, %	0.8	3.3	7.7	14.5	26.0
Error in diameter, %	0.3	1.1	2.9	4.8	8.7

shape. However, it should be emphasized that in practical terms the error is not significant if the largest particle is of the order of 40% of the tube diameter. Particles larger than this can be measured providing the "error" is recognized although blockage of the orifice by such large particles generally means that in practice the size analysis would be carried out using a larger orifice tube. Experimentally Eckhoff (283) has found that spherical and comminuted particles of identical volumes give rise to voltage pulses of identical amplitude; the effect may, therefore, prove to be less significant than was earlier thought.

The resistivity of the particle has a theoretical effect upon the response of the instrument. Thus, from Batch's equations (Table II), if $k = (1 - r_0/r)$ is less than 1, the magnitude of the errors shown in Table III will be increased. However, in practice it has been found that the majority of powders, whether conducting or not, behave in the electrolyte as particles with infinite resistance (116). Thus the assumption that $k = 1$ can generally be assumed to be good. It is interesting to note, however, that if the particles showed the same resistivity as the electrolyte there would be no "size" error.

Lower Limit of Size Measurement by the Coulter Counter

Coulter's Laboratory Manual (1966) claims that, with a 20-μ nominal diameter orifice tube, the instrument will detect particles of 0.4-μ equivalent sphere diameter. Kubitschek (120) claimed to detect particles of 0.2 μ diameter with a resolution of 0.04–0.06 μ^3. This claim must be viewed with caution although Princen (private communication) has confirmed it and suggests that it may be due to instrument idiosyncracy. It is widely accepted that the instrument is useful for particles of diameters down to 1 μ, and will detect particles down to 0.5 μ diameter (138). However, in this range the instrumental background caused by electrical effects, especially heating within the orifice, and cavitation by the passage of material through the small orifices which are required for these sizes make actual detection of submicron particles less certain. In addition, the loss of count caused by "shadowing" of small pulses by larger ones makes the detection of small particles difficult in the presence of large ones (129). The practical difficulties in obtaining electrolyte free from particulate contamination are also considerable. The instrument is therefore limited to approximately the same size range as optical microscope methods but has the overwhelming advantage that a vastly greater number of particles is actually counted for any one size distribution.

Coincidence Correction and Dilution of the Sample

The theory of the Coulter counter assumes that only one particle will be found in the volume defined by the orifice at any one instant of time. However, even with very dilute suspensions there is a finite possibility of two or more particles passing through at the same time. Clearly the more dilute the suspension the lower the probability of coincidence. Wales and Wilson (130, 131) recognized two forms of coincidence: (*a*) All pulses from two or more simultaneous particles add so as to produce a single pulse whose maxima is the sum of the two individual pulses, and (*b*) The pulses from two or more simultaneous particles behave as one pulse whose maximum corresponds to the largest particle.

Princen and Kwolek (280) showed that type *a* coincidence should predominate and would result in overcounting of large particles. The methods of correction for the coincidence error were discussed by these authors and Edmundson (135, 281) has proposed an alternative method. At low counts, however, the required correction will be approximately 1–3% of the total count and the method of calculating this relatively small error is not likely to be significant. For this reason, it is better to operate the Counter at dilutions which will give low total counts and this itself is sometimes a source of difficulty. Groves (139) pointed out that dilutions of the order of 1 : 50,000 or more are often required for emulsion systems and great care is required when making these dispersions for analysis.

Effect of Electrolyte on Dilute Emulsion Systems

Parfitt (282) has recently described the theoretical background to the preparation of dispersions and their subsequent stability. Emulsion particles are often stabilized with surface-active agents and emulsion systems diluted with water

will sometimes flocculate on standing. However, the addition of electrolyte to such a dilution will frequently cause flocculation because the energy barriers preventing aggregation and coalescence are reduced. Although electrolyte is necessary for a Coulter counter analysis, few authors appear to have encountered this phenomenon when using the instrument to measure the particle-size distribution of an emulsion system. Singleton and Brown (140) found that the count of the systems in their investigation changed with time. They noted the elapsed time to the beginning of counting for each of the sizes being measured; counts were then corrected for the time effect by extrapolation to zero time. Groves (139) reported the same effect for an emulsion stabilized with cetrimide and found that the flocculation could be minimized by carrying out the dilution in sodium chloride solution containing cetrimide at a concentration in excess of the critical micelle concentration. The results obtained in this manner agreed with those obtained independently using other size analysis methods. Some dangers of extrapolating to zero time in the manner suggested by Singleton and Brown are illustrated by the results shown in Fig. 1. The phenomenon has been noted in systems stabilized with other surface-active agents (278). Aggregation of an emulsion system is therefore possible during a Coulter counter size analysis, and the analyst should be at least aware of the possibility.

Use of the Coulter Counter for Sizing Emulsion Systems

Wachtel and La Mer (127) employed the Counter to size o/w emulsion systems, using the device to measure the degree of dispersion

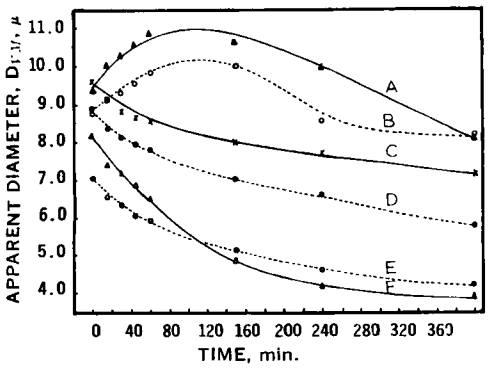

Fig. 1—Change of apparent mean particle size of a cetrimide emulsion measured with a Coulter counter as a function of time. All primary dilutions were made in 0.0003 M *cetrimide in normal physiological saline. Key: secondary dilutions were made in saline containing the following concentrations of cetrimide: A, 0.00003* M; *B, 0.000015* M; *C, 0.0003* M; *D, 0.00015* M; *E, 0.003* M; *F, 0.03* M. achieved by the use of a Sinclair aerosol generator for making monodisperse emulsions. Higuchi (141, 142) investigated factors influencing the aggregation of emulsions, followed by Lemberger and Mourad (143), and Swift and Friedlander (125). Shotton and Davis (284) investigated the influence of soap concentration on creaming rates of liquid paraffin emulsions in potassium laurate, and Singleton and Brown (140) used the Counter while investigating i.v. fat emulsions. Rowe (144) and Mima and Kitamori (145) studied emulsion-stability parameters as reflected in changes of particle-size distribution. Princen, Stolp, and Kwolek (146) examined the factors controlling the emulsification of linseed oil and Marshall and Taylor (147) described the use of the counter for following changes produced in an emulsion during the evaluation of different homogenizers. In general terms, Schrenzel (148, 149) discussed the use of the Coulter counter for the size analysis of pharmaceutical emulsions. Whittlestone (285) showed that the counter could be used for determining the size distribution of fat globules in cows milk but found no detectable systematic trends in the distribution pattern. However, later Cornell and Pallansch (286) improved the technique and demonstrated the effects of homogenization, pasteurization, and cream separation. The instrument has therefore been applied to many different types of emulsions.

As noted by Edmundson (281), "although simple in principle and reliable in operation, the Coulter Counter is a highly sophisticated apparatus, not to be regarded as a 'black box' that gives the right answer automatically." To summarize this section, therefore, the instrument covers approximately the same size range as the optical microscope but has the overwhelming advantages of improved speed and accuracy; the proper methods for using the instrument and interpreting its results are still being developed.

GRAVITY SEDIMENTATION METHODS

As noted by Becher (1), if an emulsion creams at an observable rate, measurement of the amount creamed per unit time permits the construction of a distribution curve. Most methods which depend on this principle, such as that of Kraemer and Stamm (150), measure the change of density. More recently Matsumoto (151–154) has described a method in which the viscosity changes in a creaming emulsion are used to build up a particle-size distribution of the system. Following the design of a cell to measure emulsion stability using creaming rate monitored by dielectric measurements (155), Kaye and Seager have described a similar device to measure the particle size of o/w

emulsions (156). The method is confined to systems of mean particle size around 100 μ and does not appear to be useful for diameters below 15 μ; it is therefore of limited application to pharmaceutical emulsion systems which have particles well below the lower limit of the method (1). Figurovskii and his co-workers (157–160) examined sedimentation methods and stated that they offered the fastest and most reliable means of determining the degree of dispersion of dispersed systems. Unfortunately, gravity sedimentation methods are not applicable to particles below about 10 μ diameter since the particles "cream" too slowly. In addition convection and displacement currents as well as Brownian movement all tend to disturb the sedimentation pattern. Hence the use of gravity sedimentation is of limited use for most pharmaceutical systems where particle sizes of 1 μ and below are common.

CENTRIFUGAL SIZING TECHNIQUES

One obvious way to increase the settling rate is to centrifuge the suspension. Orr and Dallavalle (39) described a number of centrifugal sedimentation techniques and other devices have been developed in recent years.

The first attempt to use a centrifuge to obtain a size distribution was that of Dumanskii, Zabotinskii, and Evseyev (218). Using an ordinary centrifuge, they determined the amount sedimented by ultramicroscope counts before and after centrifuging, but obtained poor agreement with the ultramicroscope method. Svedberg and Pederson (219) suggested that this was probably due to convection currents caused by serious deviation from ideal sedimentation conditions. Nichols and Svedberg developed a centrifugal densitometer, a two-arm centrifuge in which the boundary of particles was observed by taking photographs at different stages of the analysis. Nichols and Liebe (220) used a much improved version of this early instrument which rotated at 20,000 rpm and had better balancing and freedom from vibration. The obscuring power, related to the cross-sectional surface diameter of the particles, was measured for six colloidal lithopone samples by measuring the absorbance from light absorption measurements. The method was described in detail later by Bailey, Nichols, and Kraemer, (221) and by Bailey (222), the former group showing how it could be applied to the particle size analysis of emulsions. Nichols and Bailey (223) gave a worked example of how to calculate a size distribution of an emulsion using the so-called "low-speed Svedberg ultracentrifuge."

Nichols and Liebe (220) equated the viscous force due to Stokes' law with centrifugal force, ignoring the Coriolis force or accelerating force which is also present. Robison and Martin (224, 225) were able to demonstrate that this assumption would not lead to any significant error. Cheng and Schachman (226), after an intensive investigation of the ultracentrifugal sedimentation behavior of polymer lattices, concluded that Stokes' law was valid under these conditions.

Marshall (227–229) suggested a two-layer technique in which particles are considered to start from substantially the same position. This technique has a superficial attraction but is fraught with many difficulties, including that of irregular sedimentation, a point noted by Keen and Schofield as early as 1930 (230). This technique and methods for overcoming the problems have been discussed (72, 231, 232) and the streaming problem for particulate solids subjected to a two-layer sedimentation technique has been effectively overcome. However, the approach is only applicable to materials which are denser than the sedimentation liquid, *i.e.*, the particles are thrown to the outer periphery of the vessel. Since emulsion particles are usually less dense than water and soluble in organic liquids which have a lower density, the use of a centrifugal sedimentation method is mainly confined to a homogeneous technique. Thus emulsion particles move inward from the outer periphery toward the center of the sedimentation vessel. It is therefore necessary to consider in more detail centrifugation techniques and methods for the solution of a homogeneous system.

Centrifugal Techniques

The early techniques as noted above used centrifugal tubes. Martin (233), and later Robison and Martin (224), reviewed breaker-type centrifugal sedimentation and concluded that it had advantages, not the least being that collisions between the particles and the walls of the vessel are minimized. Robison and Martin developed the theoretical approach and described the application of a modified beaker- or sector-shaped centrifuge cell from which samples were withdrawn at the end of a variable time at a fixed depth (225). Brodnyan (17) used a similar method for polymer lattices but with an ultracentrifuge. Kamack (234) improved the theoretical method and described a similar sector-shaped cell to which was attached a sampling device that removed a sample at a fixed depth while the centrifuge was still running, thereby removing the danger of stirring the suspension during the slowing-down phase. Kamack had to use concentrated suspen-

sions of the order of 1% and only one point on the distribution curve could be obtained from each run. Owing to hindered settling (235, 236) the method was also probably inaccurate. Nevertheless, the method of calculating the experimental results was retained when Donoghue and Bostock (237) introduced the complete disk centrifuge. This particular instrument resulted in the introducion of a centrifugal analog of the Andreasen pipet by Slater and Cohen (238), the Sinko centrifuge. Gupta (239) also described a version of the centrifugal Andreasen pipet technique.

Moser and Schmidt (240) described a centrifugal photosedimentometer using a shallow cylindrical tank or disk rotating in the horizontal plane. The absorbance of the suspension was followed as a function of time by passing a thin beam of light through a fixed point on the tank onto a photoelectric cell. The authors used a nomograph to relate the recorder curve to the percentage of particles of a given size calculated from Stokes' law and stress was laid on the fact that an instrument of this type must first be calibrated by some other method owing to variable factors such as particle shape and opacity. Moser (private communication) stated that the instrument was a prototype which was not developed further.

Later Kaye (241) patented a photosedimentometer which was essentially similar to that of Moser and Schmidt. The new instrument employed a servosystem which compared the attenuated light beam with the unattenuated beam, using the difference signal to rotate an optical wedge to cancel the difference. A potentiometer attached to the optical wedge was used to control the recorder so the instrument plotted out the absorbance of the suspension. The instrument was described in more detail by Kaye (48) and evaluated with Burt (242–244). A simplified instrument, omitting the servo unit, was described and evaluated by Groves, Kaye, and Scarlett (245). The light beam was allowed to fall onto an unbalanced photocell after passing through the centrifugal disk. The instrument was used with the two-layer technique and was insufficiently sensitive to detect the streaming later investigated by Rippon (72). A prototype of an improved version has been described and evaluated (246, 247, 231, 278) and is shown in Figs. 2 and 3.

Other disk centrifuges have also been described. Martin, Brown, and de Bruyn (248) used a hollow aluminum disk centrifuge similar to Kaye's design to size analyze submicron powders containing elements of high atomic density such as lead

glass, an X-ray beam passing through it and onto a proportional counter.

Hildreth (249, 250) described a simple photoextinction type of disk sedimentometer, similar in principle to that described by Groves *et al.* An initially homogeneous suspension was used on the variable-time system (*vide infra*), the transmittance *versus* time curve being related to transmittance weight curve by obscuration factors. As noted by Rippon (72), this is an oversimplification of the theory and is not a tenable method.

Atherton, Cooper, and Fox (251), Atherton and Tough (252), and Murley (253) described a small diameter disk centrifuge in which the two-layer technique is used in conjunction with a rotating-probe sampling device, the I.C.I.-Joyce Loebl centrifuge, Figs. 4 and 5. Thus, liquid and suspended contents are removed for subsequent analysis after predetermined centrifugation times at a known radius while the centrifuge is still rotating. This centrifuge has been investigated in our laboratories using a homogeneous suspension method. Irregular sedimentation behavior was observed at the high concentrations of an emulsion required for subsequent analysis. In addi-

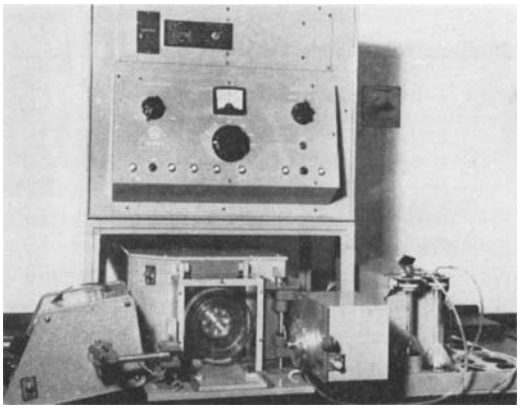

Fig. 4—Photograph of the Joyce-Loebl centrifuge, showing the disk probe, and sampling equipment.

tion considerable turbulent disturbance was observed when the sampling probe was inserted into the suspension (Groves, unpublished results). However, Jones (private communication) claims that the instrument has been used to obtain the particle-size distributions of submicron polymer emulsion systems.

Theory of Homogeneous Suspension Methods

When the material to be analyzed is dispersed in the sedimentation liquid to produce a homogeneous dispersion, three main modes of operation are possible as noted by Murley (253). (*a*) The inner radius of the liquid surface and the outer radius of collection are kept constant, samples being collected after varying running times of the centrifuge. (*b*) The running time of the centrifuge is kept constant, as is the inner radius of liquid and the outer collection radius is varied. (*c*) The running time of the centrifuge is kept constant as before, but the outer collection radius is kept constant for successive measurements, while the inner liquid surface radius is varied.

In all cases the centrifuge speed is kept constant. Donoghue and Bostock (237) gave solutions for solving methods *b* and *c*, to which Murley added another proof. However, Donoghue and Bostock also stated that no analytical proof exists for the derivation of the particle-size distribution of a sample when time is varied, unfortunately the precise situation relevant to the centrifugal photosedimentometer. Murley agreed that this was correct but pointed out that iterative methods could now be developed for calculating the required results using modern computer techniques at relatively low cost. The variable time mode of operation offers a number of important experimental advantages and as a result many attempts have been made to find a solution, or the best approximation.

Although the position of a particle relative to its initial position can be described mathematically, it still remains difficult for a distribution function to be derived from the experimental information. This is complicated by the fact that, from the initially homogeneously dispersed particulate system, particles are accelerated proportionally to their position from the axis of rotation. At any given reference or sampling zone, after a certain time t it can be said that all particles greater than a certain size d_t will have passed, where d_t is the Stokes' diameter of the particle which started from the free surface and in time t had transversed to the sampling zone. Subsequently the theory was developed for a disk centrifuge which is an ideal form of a sector-shaped cell since wall collisions are reduced to a minimum. The size distribution is considered to be continuous, containing in an infinitesimal range of diameters a fraction of $F(y)dy$.

Referring to the sector of the disk centrifuge, the distance from the axis to the free surface is S; that to the sampling zone, R.

Hence a particle of diameter d is defined as that particle which will just travel from the surface at S to R during the centrifuging. From a consideration of the centrifugal forces:

$$\ln \frac{R}{S} = \frac{(\rho - \sigma)\omega^2 d^2 t}{18\,\eta} \qquad \text{(Eq. 9)}$$

where ω = angular velocity, ρ = density of particle, σ = density of sedimentaion liquid, and η = the viscosity of the liquid. Thus,

$$\ln \frac{R}{S} = kd^2t, \text{ where } k = \frac{(\rho - \sigma)}{18\,\eta}\,\omega^2 \qquad \text{(Eq. 10)}$$

These particles of diameter d and all larger particles will have been sedimented as well as a fraction of the particles smaller than d (*i.e.*, those which were nearer to the sampling zone than those at the surface) in time t.

If p is the total fraction of material deposited, then p is given by the equation

$$p = \int_d^\infty Fy(dy) + \int_0^d \frac{R^2}{(R^2 - S^2)} [1 - e^{-2ky^2t}] \, Fy \cdot dy \quad \text{(Eq. 11)}$$

Differentiating Eq. 11 with respect to time gives:

$$\frac{\delta p}{\delta t} = \int_0^d \frac{R^2}{(R^2 - S^2)} - 2ky^2 e^{-2ky^2t} \, Fy \cdot dy \quad \text{(Eq. 12)}$$

This equation is not capable of analytical solution although Romwalter and Vendl (254) obtained Eq. 11 and invalidated their solution by an error. This error was detected by Brown (255) who obtained Eq. 11 but solved it by making ($R - S$) variable. Robison and Martin (224) used an iterative method to produce a set of approximate solutions which were claimed to give better accuracy than that due to normal experimental errors. Kamack (234) improved the iterative technique to give an approximate general solution to Eq. 12 in recursive form:

$$F_i = \frac{1}{2}(S + S_{i-1,i})C_i + \sum_{i=1}^{i=1} \left[\frac{S + S_{i-1,i}}{S_{j+1,i} + S_{j,i}} - \frac{S + S_{i-1,i}}{S_{j,i} + S_{j-1,i}} \right] F_j \qquad i = 1,2 \ldots n \quad \text{(Eq. 13)}$$

where $F = F(D)$ = fraction by weight of particles smaller than diameter D. C = concentration of suspended solids, as a fraction of the concentration of uniform suspension prior to settling, and $S = (R/S)^2$.

Others have attempted to obtain a solution of the variable-time equation. Nichols and Liebe (220) published a result which would not, however, give a weight-distribution function. Parkinson (256) overcame the variation due to the centrifugal field by the simple process of ignoring it. More practically, Jacobsen and Sullivan (257) employed a very low value of R/S (1.05), but this was experimentally difficult since only small volumes of material were available for analysis. Dana (258) employed a pipet method using an inclined-tube centrifuge for which mathematical analysis was found to be inapplicable. Other attempts were critically reviewed by Robison and Martin (224). It must be concluded that an exact solution of the theory for deriving a distribution function from an initially homogeneous dispersion centrifuged for various time intervals is not possible. As noted by Murley (253) approximate methods of an order of accuracy better than that due to experimental techniques are, however, available.

Light Scattering as Applied to Centrifugal Techniques

The use of a beam of radiation to measure the concentration of particles in a centrifugal cell has many attractions, especially as it is not necessary to disturb the sedimenting system in order to obtain an analysis which can be made continuous. The pioneer investigations of Svedberg and Nichols and Liebe, and Nichols and Bailey have been mentioned. However, it is usual to employ Schlieren techniques to follow boundary changes in analytical ultracentrifugation, the boundary being detected by changes of refractive index between solvent and suspension. This method was used by Hermans and Ryke (259) to determine the particle size of colloidal silica particles. Bierman *et al.* (260) used the technique to measure particle-size distributions of the chylomicrons, the submicron lipoprotein particles found in plasma after meals of fat, and found that the turbidity of their suspensions sometimes interfered with observation of the boundary. McCormick (261) noted that by increasing the intensity of the light beam with a mercury arc lamp the Schlieren patterns could still be obtained for concentrations up to 0.05% polystyrene latex particles with diameters of 2500 Å. He was therefore able to adapt conventional analytical ultracentrifugal techniques for the size analysis of a number of polymeric emulsions. Averink *et al.* (262) criticized McCormick's method since the turbidity forced him to use such low concentrations that the Schlieren peaks were very small, leading to poor accuracy. Averink *et al.* showed that the applicability of Schlieren optics was restricted to a range of particle diameters ranging from 200 to 2,400 Å. They concluded that with absorption optics the range could be greatly extended and described a method for achieving this. A graphical method was used to relate absorbance to concentration in order to calculate the size distribution. Using monochromatic light this method would appear to be the most satisfactory currently available.

Using a simple beam of light of mixed wavelengths, Groves, Kaye, and Scarlett (245) emphasized that their method could not be absolute for particles whose diameter approximates to the wavelength of the incident light but was useful for the detection of differences between samples. Kaye and Jackson (263) applied a modified centrifuge developed from the earlier models to the size analysis of polymer emulsions of narrow size range, and were able to deduce that these

materials had a wider range than that claimed by the manufacturers.

Thus, although the technique is relatively unsophisticated it may have some use where the particles are still big enough to cause interference with a light beam (>0.01 μ), since these particles are separated according to Stokes' law. The quantitative expression of the actual particle concentration may not be exact and may result in an overemphasis of the fines (277). The relationship between this effect and errors due to, for example, inadequate dispersion of the fine particles remains to be established. An adaptation of the technique described by Schleusener and Read (287) for detecting sedimenting particles with a 6328 Å./He-Ne gas laser may offer some improvement for future investigation.

Other Centrifugal Techniques for Sizing Emulsion Particles

The ultracentrifuge has been used to determine emulsion stability, measuring the free oil and compacted emulsion boundaries as a function of time (264–269). By analogy with gravity sedimentation methods this technique could be applied to particle-size determinations. Pinter and Zilversmit (270), and Zilversmit (271) described a density-gradient method for the ultracentrifugal size measurement of chylomicrons. This technique is used in studies on living materials (272) and the approach might well be applicable to emulsion systems.

ADSORPTION METHODS

Brodnyan and Brown (288) estimated the soap concentration adsorbed onto polymer emulsion particles. Assuming a monolayer of absorbed molecules of known molecular cross-section, they were able to calculate the total interfacial area and an average particle size from a knowledge of the phase volume. A similar method has been described by Groot (289) for paraffin oil emulsions stabilized with sodium lauryl sulfate. Since analytical methods for estimating a wide variety of surface-active agents are now available, the method may be generally applicable.

DISCUSSION AND CONCLUSIONS

The range of particle sizes in operationally usable pharmaceutical emulsions may be within the arbitrary limits 0.01 and 10 μ (297), although some have claimed that particles of up to 100-μ diameter may be found (156). From a practical standpoint it should be pointed out that emulsion droplet sizes well below Becher's (1) limit of 0.1 μ have been reported in the literature. For example, droplet diameters in transparent emulsions investigated by Bowcott and Schulman (273) were of the order 100–500 Å. van der Waarden (100) prepared emulsions with particle diameters varying between 250 and 900 Å. Kiyama *et al.* (274, 275) reported particle sizes varying between 0.08 and 0.2 μ, finding up to 30% w/w of their material below 0.08 μ in some instances. Lucas (52) found that rubber latex particles were generally below 0.1 μ, and chylomicrons have a size range extending down to 150 Å. (260). Schoenholz and Kimball (276) showed that bright-drying wax polish emulsions contained particles in the range of 0.05–0.1 μ, the particle size decreasing if the ratio of emulsifier–wax was increased. Thus, although it seems that emulsion systems may contain particles below the limit of detection by the light microscope, as shown in Table I, many workers have chosen arbitrarily to ignore them. It is true that on a weight basis these particles may only represent a small fraction of the total dispersed phase. On the other hand, when considered in terms of surface area, or number, the small particles could have a disproportionate influence on the behavior of an emulsion system, as noted by Sherman (56, 57, 292, 293). The problem can therefore be resolved into one of deciding which method of particle-size analysis to utilize; it is clear from this review that no one method in isolation is adequate to cover the wide range of particle sizes which occur in emulsion systems.

This problem was considered by Groves, Scarlett, and Freshwater (277) who determined the particle size of a model emulsion system by a variety of experimental techniques. An appreciable amount of submicron material was found to be present and results obtained are shown in Fig. 6. It is useful to remember when comparing results by different methods that different particle-size parameters are often measured. For example the light and electron microscopes both measure a cross-sectional diameter by direct observation or measurement of a photographic image. The Coulter counter measures the volume of the particle, and the result is derived as the diameter of a sphere of equivalent volume. Similarly, sedimentation methods yield a Stokes' diameter, which is the diameter of a sphere of identical density sedimenting under streamline-flow conditions at the identical velocity. Although it is generally assumed that emulsion droplets are spherical this may not always be the case (65, 298, 299). Nevertheless, emulsion particles are approximately spherical and the different derived parameters representing the particle diameter would be expected to show a reasonable measure of agreement. As will be

seen from Fig. 6, in this system there is general agreement above 1 μ, with the light microscope results tending to give a slightly higher size. This may be due to the difficulties previously noted of resolving and measuring particles below 2 μ. There is good agreement on the size of the largest particles present. The electron microscope results diverge but this was explained by sampling difficulties, the area presented by the electron photomicrograph field being 10 × 12 μ. The chance of sampling a 4-μ diameter particle is clearly reduced so that it would require an inordinate number of photographs or samples before this method would give results consistent with those from other methods.

However, it is below 1 μ that the methods show their greatest divergence. The system contained particles down to at least 0.02 μ diameter, well below the limiting discrimination level of the Coulter counter or light microscope. Rajagopal (23), recognizing that submicron particles could exist in an emulsion system, suggested that these could be determined by extrapolation of a log-probability plot and Batch (115) suggested a similar process. However, as can be seen from Fig. 6, extrapolation of both the Coulter counter and the light-microscope results yields a serious under estimate of the size of the smallest particles. The extrapolation techniques are clearly untenable for the model system examined by these authors and the validity of the approach was questioned. Comparing all these results with those obtained by the centrifugal photosedimentometer, it will be seen that this instrument

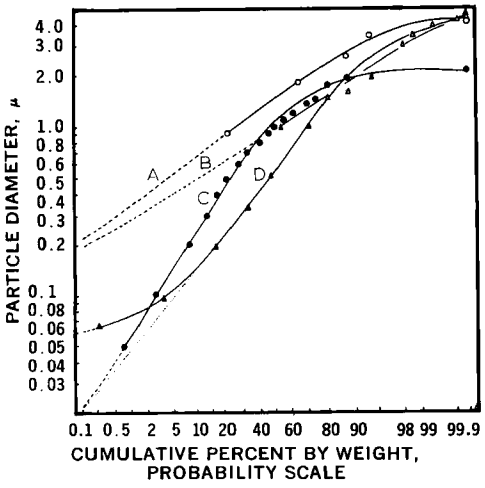

Fig. 6—The particle-size distributions of a model emulsion system determined by: A, light microscope; B, Coulter Counter; C, electron microscope; D, centrifugal photosedimentometer. Extrapolations are shown as broken lines. [Reproduced with permission from Proc. Particle Size Anal. Conf., *Loughborough 1966, paper No. 22, p. 281.]*

was capable of detecting the majority of submicron particles known to be present in the model system. The size range indicated by the instrument depends upon the particle sedimentation velocity and is therefore probably realistic. On the other hand, the quantitative measurement depends on the light-scattering properties of these small particles which are less predictable as they approach the magnitude of the wavelength of the incident radiation, resulting in overemphasis of the fines. In addition, as pointed out by these authors elsewhere (246), there is a marked tendency for small particles to adhere to the larger ones. Divergence from the electron microscope results may therefore be also due to inadequate dispersion of the system before sedimentation.

From this investigation it was concluded that the Coulter counter and centrifugal photosedimentometer offered the best combination at present available for carrying out an adequate measurement of the relatively wide size distributions that can exist in some emulsion systems. This conclusion has now been explored in more detail (278). The centrifugal photosedimentometer is limited to particles below about 10 μ diameter since above this size sedimentation is no longer under streamline-flow conditions, and a realistic lower limit is approximately 0.05 μ. The Coulter counter was used with a 70-μ orifice tube covering the range 1–25 μ. Using the two methods together on emulsion systems stabilized with a wide range of surface-active agents showed that in most cases on a log-probability plot the results were parallel over the common range of particle size. This enabled a log-probability plot to be built up over the whole of the distribution by a normalization process which was shown to be statistically valid. The particle-size distribution was therefore defined as the midpoint of the log-probability distribution lying between 20 and 80% probability (22, 28–30). As noted earlier, this method is a relatively insensitive method of presenting results. However, when considering such factors as sampling error and repeatability of a particular size analytical method it must be regarded as satisfactory and represents a considerable advance over many methods used before.

Examination of the flow behavior of emulsion systems for which the particle sizes had been determined in this manner suggested that the relationship between these two properties may be more complex than has been indicated from earlier studies (6). The ideal situation has not yet been reached whereby it is possible to predict emulsion behavior from a knowledge of the

particle-size distribution. However, with improved methods which will give a reasonably accurate picture of the state of dispersion further investigations may well allow prediction of rheological properties with greater precision. Similarly, as noted by Garrett (297), the study of emulsion stability problems would also be assisted by the use of improved methods. The evaluation of emulsification equipment (147) and control of production batches of pharmaceutical emulsion are other examples where, in the long run, a more complete understanding of the quantitative relationship between the particle size and performance may be beneficial. Similarly, emulsion formulation studies would be materially assisted if the effects of surface-active agents, both quantity and quality, and the concentration and type of disperse phase could be predicted with greater accuracy than the rule-of-thumb calculations which are all too prevalent in everyday practice. Becher's excellent text (1) shows that there is a vast fund of knowledge of emulsions; nevertheless there is still room for improvement in many areas and it has been the purpose of this review to highlight just one of these.

"For out of olde fieldes, as men seith
Cometh al this newe corn froe yeer to yere;
And out of olde bokes in good feith,
Cometh al this new science that men lere." (300).

Drug Release from Compressed Hydrophilic Matrices

By H. LAPIDUS* and N. G. LORDI

This study is concerned with the release of drugs from the planar surface and the whole surface of a hydrophilic polymer tablet matrix. The sustained drug-release characteristics of hydroxypropyl methylcellulose 15,000 cps. previously described was found to be the result of a hydration layer being formed at the tablet surface. As long as the integrity of the hydrated polymer was maintained, the release of drug was diffusion controlled. Environmental conditions have been investigated. Diffusion coefficients for the drugs used were calculated by means of the model equations predicting drug release from inert matrices and ointment bases. Comparison of the rates of drug release from the planar surface of a compressed polymer matrix with theoretically predicted values was made.

A PHYSICAL BARRIER is used in the majority of prolonged-action dosage forms to decrease the rate of drug release to the absorption site. One type of prolonged action tablet can be prepared by compressing a mixture of a hydrophilic polymer and drug (1). In contact with moisture, the tablet swells, effecting delayed release of drug. Huber, Dale, and Christenson (2) proposed that drug release was controlled both by drug diffusion through and attrition of the gel sheath formed around the tablet. However, their data precluded quantitative interpretation of the exact mechanism of release.

Recently, the authors reported data characterizing the release of chlorpheniramine maleate from a hydroxypropyl methylcellulose ether matrix (3). Release patterns measured from one face of flat-surfaced tablets could be linearized when plotted as a function of the square root of time. This suggested to us that equations derived by Higuchi (4) and Higuchi (5) for drug release from insoluble matrices and from homogeneous ointments were applicable to this system. A question was also raised concerning the significance of the rate of water penetration through the hydrated matrix as a factor in controlling drug release.

Further data are presented here to establish the extent of application of the Higuchi equations to the availability of both water-soluble and insoluble drugs from hydratable matrices. In addition, the effect of temperature, added diluent, and polymer type on release patterns measured from plane surfaces and whole tablets is reported. Whole-tablet release data were utilized to estimate the relative contributions of attrition and diffusion to drug availability from this type of dosage form. A technique for measurement of drug release from the fully hydrated polymer was also developed in order to ascertain the relative importance of the rate of water penetration and drug diffusion in the gel matrix.

EXPERIMENTAL

Materials—A hydroxypropyl methylcellulose ether 90 HG,[1] 15,000 cps. was selected for detailed study as a base material because of its demonstrated effectiveness in retarding drug release from tablets (2). The other polymers employed as base materials were hydroxypropyl methylcellulose 90 HG, 25 cps., methylcellulose MC, 4,000 cps., sodium carboxymethylcellulose (Hercules Company, Wilmington, Del.), carpolene,[2] and polyvinylpyrrolidone K30 (General Aniline and Film Corp., New York, N. Y.).

Table I lists the drugs employed in this study. Included are the solubilities measured at 37°, the wavelengths used for their spectrophotometric assay, and the moles of drug required to produce an absorbance value of 1.00 in 1 ml. of water. Beer's law was followed in all instances. Chlorpheniramine maleate (CPM) and sodium salicylate were included as examples of water-soluble drugs; benzoic acid and benzocaine were representative of water-insoluble drugs.

Lactose (USP) and tricalcium phosphate (NF) were added as diluents. Neither the diluents nor gums, with the exception of carpolene, interfered with the spectrophotometric analysis. An absorbing species was extracted from carpolene matrices necessitating blank corrections.

Drug Release from Tablets—Tableting granulations were prepared by mixing the drug with the base material and granulating with USP ethanol, except for tablets where polyvinylpyrrolidone and carpolene were used as bases. In these cases, the powders were blended and compressed directly.

In some experiments with hydroxypropyl methylcellulose 90 HG, 15,000 cps. hydroalcoholic solutions were used to granulate in order to assess the effect of initial water content on drug-release patterns. Water was added to the USP ethanol in varying concentrations (10 and 20%), and all of the solution was used for the granulation. Increased water concentration in the granulation did not provide any observable effect in drug release from the tablet matrix.

Details of the tableting procedures were previously reported (3). Compression forces of both 3,000 and 10,000 lb. were utilized. However, no significant difference in drug-release patterns was observed from tablets of differing density. This observation has been confirmed by Huber and Christenson (6).

The techniques, equipment, and composition of the solvents used to measure drug release from both the single face of a tablet and whole tablets were previously described (3). Flat-faced tablets of 1.11 cm. ($^7/_{16}$ in.) diameter, weighing 300 mg., were used in all experiments. In cases where the drug concentration was altered or where diluents were added, the polymer concentrations were increased or decreased to produce a 300-mg. tablet.

Two-layer tablets were prepared for some experiments in which the inner layer contained drug and the outer layer was a placebo. This was accomplished by lightly pretamping the drug layer initially placed in the die, adding the placebo granulation, and then compressing the combined granulations.

Drug Release from Gels—Predetermined amounts of drug, diluent, and hydroxypropyl methylcellulose 90 HG, 15,000 or 25 cps. were added to a tared beaker. Approximately 10 ml. of boiling water was added with careful stirring, ensuring complete dispersion of the gum and either dispersion or solution of the drug and diluents. Care was taken to ensure that the stirring did not introduce air into the system. The beaker was then covered with plastic wrap and placed in the freezer compartment of a refrigerator for 15 min., after which time the plastic wrap was removed and the total weight of the beaker and contents recorded. From these values an accurate calculation of total water content was made, thereby determining the exact gel concentration. At this time the gel was completely transparent and contained no air bubbles.

The density of the gel was measured by weighing a quantity of hydroxypropyl methylcellulose 90 HG, 15,000 cps. into a tared graduate having a ground-glass stopper. Approximately 10 ml. of boiling water was then added to the graduate and the contents stirred gently and cooled. From the final weight and volume of the gel, the density was calculated. This figure was used to determine the w/v % drug in the gel.

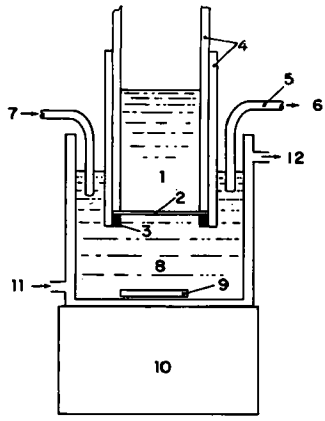

Fig. 1—Sketch of the diffusion cell used to measure drug-release rates from a fully hydrated polymer matrix. Key: 1, hydrated gel; 2, Gelman membrane; 3, Kel-F gasket; 4, Kel-F tubing; 5, Tygon tubing; 6, to Beckman flow cell; 7, from Beckman flow cell; 8, solvent; 9, stirring rod; 10, magnetic stirrer; 11, inlet for water jacket; 12, outlet for water jacket.

The gel was forced into the internal cylinder of the diffusion cell, a sketch of which is shown in Fig. 1, and cut so that it was flush with the bottom of the tube. A precut Gelman Acropor membrane, type AN-3000, pore size 3.0 μ, and 85% porosity (7) was placed over the exposed gel and kept firmly in place by an 0.31-cm. ($^1/_8$-in.) gasket composed of the same Kel-F material. A thin film of silicone grease was applied to the external walls of the inner tube and the tube and gasket forced (telescoped) into the outer sleeve of polymer material. The cylinders were designed to ensure a tight fit in order to prevent any water seepage between the walls. The inner tube was then corked to prevent any water evaporation and the entire cell secured in a jacketed beaker containing 125 or 300 ml. of water maintained at 37°. The volume of solvent was varied, depending on the concentration and absorbancy of the drug being studied. The water level was maintained just above that of the gel plug. The beaker rested on a magnetic stirrer, and a stirring bar was rotated in the beaker at a rapid rate in order to ensure adequate mixing. The release medium was cycled through the flow cell of the spectrophotometer and a continuous recording of the drug release obtained.

Analysis of Results—In applying the Higuchi model to release of drug from a compressed hydrophilic matrix, water penetration is visualized as a front moving into the tablet, hydrating the polymer, and dissolving the active material, which then diffuses out through the swollen matrix. If the drug has limited water solubility such that it has not completely dissolved when the polymer is hydrated, then diffusion will commence from a saturated solution. The expression describing drug release from the single face of a tablet would be (4)

$$\frac{W_r}{t^{1/2}} = S\left[D'\epsilon C_s\left(\frac{2W_0}{V} - \epsilon C_s\right)\right]^{1/2} \quad \text{(Eq. 1)}$$

where W_r is the amount of drug released in time t, W_0 is the dose of the drug, S is the effective diffusional area, V is the effective volume of the hydrated matrix, C_s is the solubility of the drug in the release medium, ϵ is the porosity of the hydrated matrix, and D' is the apparent diffusion coefficient of drug in the hydrated matrix. The following expression relates D' to the actual diffusion coefficient, D, of the drug in the release medium: $D' = D/\tau$ where τ is the tortuosity of the hydrated matrix.

If the drug has completely dissolved when the matrix is hydrated, then the following expression should apply (5):

$$\frac{W_r}{t^{1/2}} = 2W_0\left(\frac{S}{V}\right)\left(\frac{D'}{\pi}\right)^{1/2} \qquad \text{(Eq. 2)}$$

If the assumptions made in the derivation of Eqs. 1 and 2 hold for measurements of drug release from compressed hydrophilic matrices, the right-hand side of these expressions should be constant. The experimental conditions were established so that drug release was measured in a near-perfect sink, since the concentration in the release medium was insignificant compared to that in the tablet. In addition, the percent drug released was significantly less than 30% of the initial dose, conforming to the restrictions placed on Eq. 2 by Higuchi (5). However, the S and V terms are larger than the corresponding surface area and volume of tablet prior to immersion in the solvent, owing to swelling of the matrix when hydrated.

Experimental data in the form of absorbance readings were fitted to a linear function of $t^{1/2}$ using the least mean squares criterion. Absorbance readings at 34 time intervals were obtained over a period of 115 min. for this purpose. The slopes computed in absorbance units were converted to moles/min.$^{1/2}$ using appropriate conversion factors. The variance observed for the slopes in all cases analyzed never exceeded 2% and generally were less than 1% of the slope values, indicating excellent linearity.

Although Eqs. 1 and 2 predict a zero intercept, small negative intercepts were observed in all cases, including both measurements of release from the tablets and gels. This was attributed largely to failure of the systems to immediately attain the state of diffusion described by Eqs. 1 and 2.

RESULTS AND DISCUSSION

Effect of Drug Concentration—Figure 2 shows square root of time plots for representative runs of sodium salicylate, benzocaine, and benzoic acid used as the drug contained within the hydroxypropyl methylcellulose 90 HG, 15,000 cps. polymer matrix. Although the solubilities of all the drugs tested vary, their rates of release were apparently linear with the square root of time.

In the previous publication (3) it was noted that a plot of the slopes of the lines obtained as a function of the dose of chlorpheniramine maleate in the tablet was linear up to a 25% concentration of the drug. This is reproduced in Fig. 3 along with sodium salicylate data. The conclusions drawn in that publication suggesting that Eq. 1 applies to this system were in error. Equation 1 was derived assuming $(W_0/V) \gg C_s$. In the case of chlorpheniramine and sodium salicylate, however, C_s is greater than W_0/V.

Further investigation showed that a portion of the standard tablet containing 14.4% of the tablet mass swelled to a volume of 4.34 times that of its original volume. The estimated value of $2W_0/V$ in Eq. 1, considering the swelling of the hydrated portion of the tablet, is 0.074 g./ml. in a 16.6% chlorpheniramine maleate tablet. This is much smaller than C_s (0.615 g./ml.), therefore, invalidating the application of Eq. 1 for the more water-soluble drugs.

If Eq. 2 applies in this situation, one would also expect a linear relationship as the concentration of drug is increased, all other parameters remaining constant. However, the $S/V(D')^{1/2}$ term is subject to variation as the drug-to-polymer ratio is increased. The surface-to-volume ratio would be a function of the extent to which the polymer swells on hydration and its resistance to attrition. That the hydroxypropyl methylcellulose 90 HG, 15,000 cps. resists attrition under the conditions of measurement is indicated by the linear $t^{1/2}$ relation observed at even 5:1 drug-to-polymer ratios. No significant difference in the surface-to-volume ratio was observed at the different polymer levels studied. The diffusion coefficient, being a function of the drug concentra-

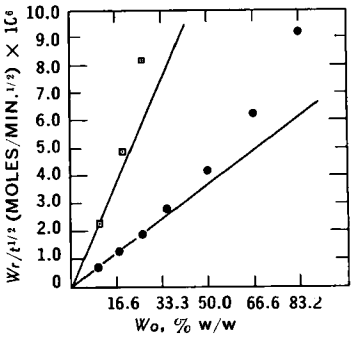

Fig. 3—Rates of drug release in water as a function of drug concentration in a hydroxypropyl methylcellulose 90 Hg, 15,000 cps. tablet matrix. Key: ⊡, sodium salicylate; ●, CPM.

tion, decreases as the concentration is increased (8). Therefore, the positive deviation in linearity shown in Fig. 3 must be the result of a change in tortuosity of the hydrated polymer. The tortuosity of a gel is an inverse function of polymer concentration (9); therefore, as the drug is increased beyond the 25% level, one could expect τ to decrease significantly. At the lower drug concentrations, τ remains essentially constant. Hence, linearity is apparently maintained, and the results conform with those predicted from Eq. 2.

The plot of $W_r/t^{1/2}$ *versus* W_0 for sodium salicylate, Fig. 3, shows a similar relationship to that for chlorpheniramine maleate except that deviation appears to occur at lower drug content. The greater apparent effect of sodium salicylate in decreasing the tortuosity of the gel may be due to the greater ability of sodium ion, compared to the chlorpheniramine ion, to dehydrate the polymer.

The effect of concentration of benzocaine and benzoic acid can be seen in Fig. 4. This result is predicted by Eq. 1. Since the C_s term is very small, *i.e.*, 1.2×10^{-3} g./ml. at 37° in the case of benzocaine, Eq. 1 reduces to:

$$\frac{W_r}{t^{1/2}} = S\left[\frac{2D'\epsilon C_s W_0}{V}\right]^{1/2} \qquad \text{(Eq. 3)}$$

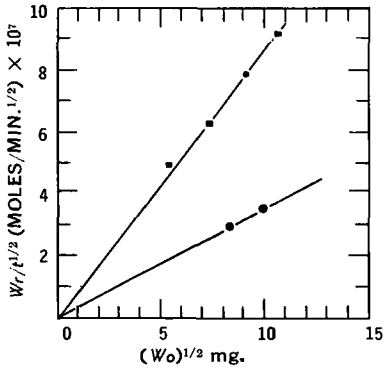

Fig. 4—Rates of drug release from 0.3-g. tablets as a function of the square root of W_0 *assuming the effective volume of the matrix is constant. Key:* ■, *benzocaine;* ●, *benzoic acid.*

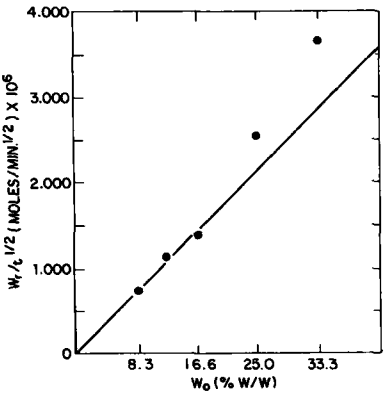

Fig. 5—Rates of drug release as a function of chlorpheniramine concentration in a hydroxypropyl methylcellulose 90 HG, 15,000 cps. tablet matrix at pH 1.5.

A linear relationship should be observed if drug-release rate ($W_r/t^{1/2}$) is plotted *versus* $(W_0)^{1/2}$ assuming that $S/V^{1/2}$ is constant. This is apparently a correct assumption since Fig. 4 shows such linearity.

Limited data were obtained in the case of benzoic acid due to the low degree of sensitivity found in the assay for benzoic acid. The concentrations of the solutions obtained from tablets containing less than 25% by weight of benzoic acid were not high enough to give acceptable absorbance readings.

A plot of drug-release rates for tablets with varying concentrations of chlorpheniramine maleate in a pH 1.5 medium is shown in Fig. 5. Comparison of these results with those shown in Fig. 3, where water was the solvent, showed a deviation from linearity at a lower drug level. Deviation occurred after 16.6% w/w of drug in 0.1 *N* HCl in comparison to 25% w/w of drug in water. These results are understandable if, in addition to the decrease in tortuosity due to the dissolution of drug in tablets with high drug levels, consideration is given to the additive effect of lowered viscosity introduced by protonation (3). In the acid medium the tortuosity has been lowered by both the decreased viscosity of the gel due to less tightly bound water molecules and the effect of drug dissolution.

Effect of Diluents—The effects of the addition of the water-soluble diluent lactose, and the water-insoluble diluent tribasic calcium phosphate, to 16.6% by weight chlorpheniramine maleate in a hydroxypropyl methylcellulose 90 HG, 15,000 cps. matrix (to be referred to as the standard tablet) can be seen in Fig. 6. The increase in specific release rates was similar for both diluents up to the addition of 33% by weight of diluent. At a dilution level of 50%, however, a marked divergence occurred which was accentuated at the 66.6% level.

The observed divergence can be explained by the difference in solubility of the diluents and their subsequent effects on the tortuosity factor. As the water-soluble diluent dissolved, it diffused outward and decreased the tortuosity of the diffusion path of the drug. On the other hand, the tricalcium phosphate did not diffuse outward, but rather became entrapped within the matrix and effected an increase in release

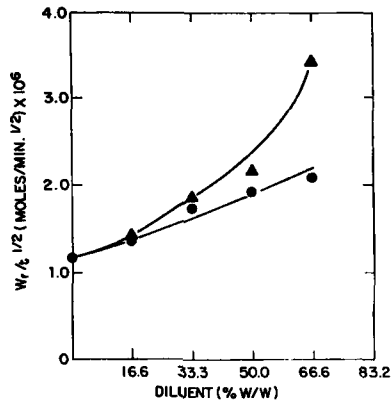

Fig. 6—Effects of addition of tablet diluents on the rate of chlorpheniramine maleate release from a hydroxypropyl methylcellulose 90 HG, 15,000 cps. tablet matrix. Key: ▲, *lactose;* ●, *tricalcium phosphate.*

TABLE II—DRUG RELEASE FROM HYDROXYPROPYL METHYLCELLULOSE HG 15,000 cps. TABLET MATRICES FROM VARIOUS SOLVENTS AND TEMPERATURES

Drug	% Drug (w/w)	Solvent	$W_r/t^{1/2}$ (Moles/Min.$^{1/2}$) × 10^6 25°	37°	50°
CPM	16.6	Water	1.05	1.16	1.24
CPM	16.6[a]	Water	1.48	1.83	2.22
Benzocaine	8.3	Water	0.43	0.47	
CPM	16.6	0.15 *M* Na_2SO_4	0.93	0.95	∞
CPM	16.6	0.20 *M* Na_2SO_4	1.06	∞	
CPM	16.6	0.1 *N* HCl	1.38	1.40	1.66

[a] The tablet base had 33.3% w/w lactose in addition to the polymer.

of drug only by the fact that its presence necessarily decreased the gum concentration.

Further evidence for these conclusions was obtained when the hydrated portions of the following three tablets mentioned were removed from the tablet after 2 hr. of exposure to the solvent, weighed, dried, and the residue reweighed. Measurements were made in triplicate. The results for the standard tablet were 11.8 ± 0.4% residue, 8.0 ± 0.8% residue, for the tablet containing an added 16.6% lactose and for the tablet with 16.6% tricalcium phosphate 9.5 ± 0.7% residue. These results were consistent with the fact that a lower concentration of polymer produced faster drug release, and the addition of a soluble diluent acted to further increase release due to its dissolution and, therefore, complete elimination from the matrix.

Effect of Temperature—The experimental results summarized in Table II show the expected increase in release rate of all drugs tested as the temperature was increased.

For systems governed by Eq. 2, only the diffusion coefficient and the tortuosity term should be affected by an increase in temperature. Furthermore, if the work by Longsworth (10) on the temperature dependence of diffusion coefficients in aqueous solutions is considered, the diffusion coefficient for molecules of somewhat similar properties to those of the drugs used here appears to increase by about 33% when the temperature is raised from 25 to 37°. Since $W_r/t^{1/2}$ is proportional to $D^{1/2}$, a 15% increase in slope measured at 37° over that measured at 25° would result. A less than 33% increase in the diffusion coefficient would be expected when the temperature is raised from 37 to 50° since an Arrhenius-type relationship with temperature should be observed. A 10% increase in slope is observed from 25 to 37° and a 7% increase from 37 to 50° for the standard tablet. The apparent diffusion coefficient would appear to have a smaller temperature dependence than the bulk diffusion coefficient. However, an increase of over 20% in the slopes is observed when lactose is substituted for polymer. This must be attributed to a significant temperature-induced decrease in tortuosity.

In the case of an insoluble drug in suspension which would be characterized by Eq. 2 in addition to the diffusion and tortuosity terms, the solubility term (C_s) is also increased. Although the relative increase in release rate observed for benzocaine is very similar to that observed for chlorpheniramine maleate, this does not seem contradictory if consideration is given to the fact that C_s is very small. The solubility of benzocaine is 9×10^{-4} g./ml. at 25° and 1.2×10^{-3} g./ml. at 37°, both values being negligible in comparison to $2W_0/V$ (0.37 g./ml.).

It is of interest to note the effect of increased temperature on release of chlorpheniramine maleate from hydroxypropyl methylcellulose 90 HG, 15,000 cps. tablets into 0.1 *N* HCl (Table II). In relation to this experiment, it has been shown that as the gel point is approached, small increments of temperature produced greater changes in viscosity than at lower temperatures (11). Therefore, since the gel at 25° has already been disoriented, as indicated by the 30% increase in release rates over that for water, an increase in temperature to 37° showed a small effect. On the other hand, the change from 37 to 50° brought the matrix much closer to its gel point at which temperature-induced discontinuities and diminished tortuosities became exaggerated. These results illustrate the similarity between temperature, salt, and pH effects on the hydroxypropyl methylcellulose 90 HG, 15,000 cps. matrix.

Extremely rapid release of chlorpheniramine maleate was observed within minutes after the standard tablet was placed in 0.2 *M* solutions of either sodium or magnesium sulfate at 37° (Table II). As was reported previously (3), a noticeable elongation of the tablet was observed, similar in appearance to a "gum drop." This same effect was duplicated by immersing a similar tablet into water held at a temperature (95°) above the gelation point of hydroxypropyl methylcellulose 90 HG, 15,000 cps. which was reported to be 85° (12). As the gel point for a polymer of this type is reached, the bound water molecules are removed from the hydration shell.

When the concentrations of both salts reached 0.2 *M*, hydration of the polymer along with almost instantaneous dehydration of the formed gel produced a solid aggregation of polymer particles with massive discontinuities and no inhibition for outward diffusion. The effect is similar to that of decreasing the gel point of the polymer to 37° by aiding the withdrawal of water from the gelled matrix with the use of dissolved electrolytes. Proof of this conclusion was shown by running an experiment in 0.2 *M* Na_2SO_4 at 25° and obtaining a normal release pattern with no gum drop effect. As can also be seen in Table II, a similar effect was observed in 0.15 *M* Na_2SO_4 solution. Whereas 37° was a sufficient temperature to reach the gelation point in 0.2 *M* salt solutions, 50° was necessary in 0.15 *M* solutions.

Effect of Polymer Type—Hydroxypropyl methylcellulose 90 HG, 25 cps. was chosen for investigation in order to determine the effect of polymer molecular weight on drug release. Initially, this tablet was positioned so that its surface was set flush with the edge of the Kel-F holder. A plot of absorbance *versus* the square root of time for a 16.6% by weight chlorpheniramine tablet showed linearity for ap-

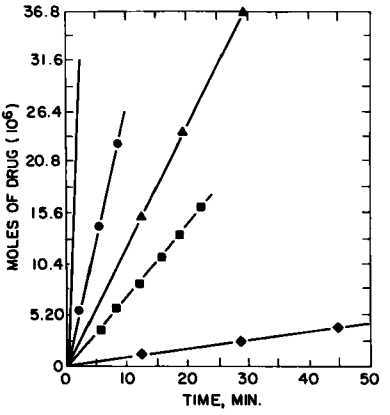

Fig. 8—Drug release from various compressed polymer matrices. Key: ●, CPM from polyvinylpyrrolidone; ▲, sodium salicylate from sodium carboxymethylcellulose; ■, CPM from methylcellulose MC, 4,000 cps.; ◆, CPM from sodium carboxymethylcellulose; ———, CPM from lactose.

proximately 25 min. An upward deviation from linearity was observed at later times as can be seen in Fig. 7. When this same tablet was recessed in the Kel-F holder and the assay procedure repeated, the drug release pattern was shown to remain linear with the square root of time for the entire 115-min. time period.

In the former case, hydration of the lower molecular weight polymer occurred rapidly, and the gum resisted attrition for the first 25 min. After this period, significant erosion of the surface due to the convective movement of the solvent past the tablet was observed. The eroded particles exposed greater surface area for drug release, resulting in a progressive increase in release rate. When the tablet was recessed 0.15 cm. in the holder, convection maintained the hydrated layer within the boundary of the holder.

Figure 8 shows the release of chlorpheniramine maleate from a tablet where lactose, polyvinylpyrrolidone, methylcellulose MC, 4,000 cps., and sodium carboxymethylcellulose had been used as the tablet matrix. The tablets contained 16.6% by weight of drug in all cases, and the release of drug maintained linearity when plotted against time at 37°.

Lactose served as a base line for a matrix which undergoes simple dissolution. The very water-soluble polyvinylpyrrolidone forms a hydrated layer that is very susceptible to attrition. The drug-release rate from this tablet was slightly less than that of lactose but by such a small degree as to indicate the formation of a hydration layer of minor significance.

The release of chlorpheniramine maleate from a methylcellulose MC, 4,000 cps. matrix was slower than that from the polyvinylpyrrolidone matrix but still maintained a straight-line relationship with time. The retarding action can be directly attributed to the formation of a hydration layer by this polymer. This hydration layer, however, did not resist attrition and remain intact. The MC variety of polymer is less hydrostable than the hydroxypropyl derivative. Consequently, attrition becomes more important than diffusion; the hydrated layer dissolved away almost as rapidly as it formed. Recessing this tablet did not alter its linear release pattern but merely reduced the slope slightly.

When the sodium carboxymethylcellulose tablet was removed from the flow cell, it was found to be misshapen and had the distinctive gum drop appearance. The outer area of the hydrated portion was clear and showed greater continuity than had been found in the previous two cases. When a tablet containing 16.6% by weight of sodium salicylate was analyzed, the same linear relationship with time was observed, although a more rapid release was apparent (Fig. 8). The significantly higher release rate of sodium salicylate as compared to chlorpheniramine maleate from the carboxymethylcellulose matrix shown in Fig. 8 indicated that the latter drug interacted with the polymer. Since sodium salicylate was an anionic drug, interaction with sodium carboxymethylcellulose was not likely, while complexation of chlorpheniramine maleate could be expected with the polymer on the basis of the work performed by Kennon and Higuchi (13).

It appears that the polymer which forms the hydration layer least susceptible to erosion and dissolution will show the greatest retarding action on drug release. If the hydrated layer remains intact, the drug diffuses through that layer, and the release pattern is linear with the square root of time. If the hydrated layer does not maintain its integrity, the release of drug will be linear in relation to time as is expected from a system of constant surface area subject to dissolution in a perfect sink.

Another polymer material used as a tablet matrix was carpolene. The advantage of this acidic polymer, as stated by Mayron (14), was that the polymer did not dissolve or hydrate in gastric juice but was neutralized and became water dispersible in the intestinal tract. The result of the neutralization was proported to increase the rate of release of the drug. In this study of carpolene rapid and continued release of chlorpheniramine maleate was obtained in 0.1 *N* HCl throughout the 115-min. period of analysis (Fig. 9). The decreased release rate observed in pH 7.5 buffer could be attributed to the increased gelation of the polymer in an alkaline media and interaction of the cationic chlorpheniramine with the polymer. The pKa of carpolene is 6.6 (15);

therefore, the polymer is almost completely dissociated at pH 7.5.

The rapid release of sodium salicylate in contrast to the slow release of chlorpheniramine maleate observed in water (pH ≈ 5.5) indicated that the latter reacted with the polymer. Precipitation of a carpolene complex with chlorpheniramine was observed when the polymer was added to an aqueous solution of the drug.

Barrier-Layer Effect on Drug Release—Figure 10 shows the release of chlorpheniramine maleate from a standard tablet and a standard tablet with a 25- or 50-mg. barrier layer of compressed hydroxypropyl methylcellulose 90 HG, 15,000 cps. on its surface. The quantity of drug released after 115 min. for the tablet with the 25-mg. barrier layer was 18% of that which was observed with the standard tablet. In addition, a time lag of 2.2 min. was noted before drug appeared in the solvent. The release curve was linear with time rather than with the square root of time. The tablet with a 50-mg. barrier layer showed slower drug release than the tablet with the smaller barrier layer. The time lag was approximately 5 min. for this tablet. The delay in the observance of drug release is clearly due to the time required for the water to pass through the barrier layer and then for the dissolved drug to pass back through this partially hydrated layer. This delay also accounts for the apparent zero-order release rate. The drug is not depleted very rapidly from the barrier layer; therefore, this layer acts as a "buffer" zone of constant concentration and area. Since this is the case, the concentration gradient does not change, and a zero-order release rate is observed. Deviation from zero-order release should be subsequently observed. The rate will ultimately decrease as drug is depleted from the core.

The 2-min. delay before drug release is observed as an indication of the time required for the water to penetrate the additional thickness provided by the barrier layer. A thickness of the standard tablet equivalent to the barrier layer contained about 4 mg. of chlorpheniramine maleate. Since only 4.7 mg. of drug is released from this tablet after 115 min. under standard conditions, it appears that the penetration of water into the tablet is not the rate-determining step for drug release.

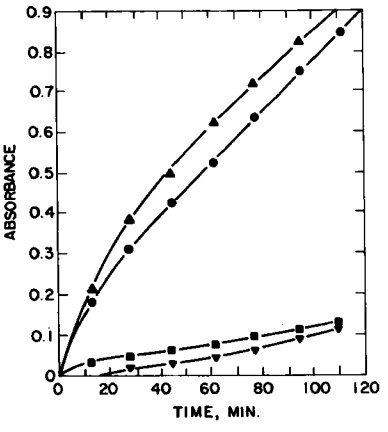

Fig. 9—Drug release from a carpolene compressed tablet matrix in various solvent media. Key: ▲, CPM, in pH 1.5 solution; ●, sodium salicylate in water; ■, CPM in pH 7.5 buffer; ▼, CPM in water.

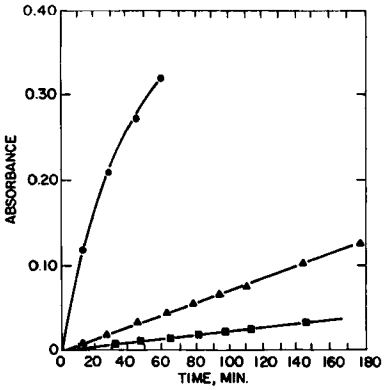

Fig. 10—Effect of a barrier layer on chlorpheniramine maleate release from the planar surface of a standard tablet. Key: ●, standard tablet; ▲, 25-mg. barrier layer; ■, 50-mg. barrier layer.

Another indication that water penetrability is not the rate-determining step is shown by Higdon and Robinson (16) whose calculation of the diffusion coefficient for water through an 8% sodium carboxymethylcellulose gel was 2.06×10^{-5} cm.²/sec. A value for the diffusion coefficient of benzoic acid was given by Higuchi *et al.* (17) as 1.1×10^{-5} cm.²/sec. Therefore, the diffusion coefficient of water in the polymer is about twice the value of a typical drug investigated in this study.

Diffusion Measurements from a Hydrated Polymer—The objective in making diffusion measurements in a fully hydrated hydroxypropyl methylcellulose 90 HG, 15,000 cps. polymer gel was to establish that diffusion was the controlling mechanism in drug release from the tablet. If the diffusion coefficients of the drugs used in this study could be obtained, then by substitution into Eqs. 1 and 2, it would be possible to confirm the application of these equations to drug released from the plane surface of a tablet matrix without attrition.

The data obtained are summarized in Table III. Drug-release rates from a fully hydrated polymer gel were evaluated for all the drugs used in the tablet study. The relative effects were similar to those observed with tablets.

Since $W_r/t^{1/2}$ equals the slope obtained from this particular system, the following equation may be used to calculate the apparent diffusion coefficient of water-soluble drugs in the gel.

$$D' = \frac{\pi}{60}\left(\frac{\text{slope}}{2S \cdot C_0}\right)^2 \qquad \text{(Eq. 4)}$$

where C_0 is the initial concentration of drug in the gel in moles/ml. The cross-sectional area of the diffusion cell was 0.094 cm.². The Gelman membrane had a porosity of 85%; hence, the actual diffusional area (S) was 0.59 cm.².

Extrapolation of a plot of D' as a function of polymer concentration indicated an approximate diffusion coefficient for chlorpheniramine maleate of 8×10^{-6} cm.² sec.$^{-1}$, which seemed reasonable for a molecule of its molecular weight. Approximate diffusion coefficients and tortuosities were calculated using this value and are listed in Table III.

The relative values of the experimentally observed release rates for the soluble drug are understandable in terms of τ values obtained for each diffusion

CPM	25	5.37	21.4	1.62	1.29	6.2	8.0

measurement. An increase in the polymer concentration showed a corresponding increase in tortuosity for the same concentration of drug. If the τ value is assumed to be independent of drug concentration, the data indicate an overall decrease in diffusion coefficient of about 25% as the chlorpheniramine maleate concentration is increased from 2.7 to 8%. In addition, the lower expected tortuosity of the 25 cps., as compared to the 15,000 cps. hydroxypropyl methylcellulose 90 HG, was confirmed.

An approximate diffusion coefficient of 18.3 × 10^{-6} cm.^{2} sec.$^{-1}$ at 37° was indicated for a 5.35% sodium salicylate solution. This value compares favorably with the value reported by Desai *et al.* (18) which was 10 × 10^{-6} cm.^{2} sec. at 30° for a 6.8% solution.

The following form of Eq. 1 was used to calculate the apparent diffusion coefficients of the insoluble drugs in the gel.

$$D' = \frac{1}{120 \times C_s \times C_0}\left(\frac{\text{slope}}{S}\right)^2 \text{cm.}^2 \text{ sec.}^{-1}$$

The diffusion coefficient of benzoic acid, estimated using the τ value which characterized a 10–11% gel, is too large. Higuchi *et al.* (17) report a value of 11.1 × 10^{-6} at 30°. This suggested that the τ values characterizing release of benzoic acid and benzocaine from the gel were close to unity. This did not seem unreasonable when the length of the diffusional path was considered. A greater amount of drug is concentrated in the surface layer of the gel in the suspension case. In the same 2-hr. period, molecules diffusing from a suspended solid phase had a much shorter distance to travel and, therefore, a less tortuous path than molecules diffusing from a solution. It is also reasonable to assume that as the concentration of the solid phase is increased, the tortuosity value should be progressively lowered.

The estimated diffusion coefficient of benzocaine, 9.4 × 10^{-7}, is too low and cannot be considered the true diffusivity for this drug. Since benzocaine is very insoluble, solution of the drug at the gel interface becomes the rate-determining step rather than diffusion of the drug through the gel matrix. Therefore, the apparent diffusion coefficient is in error.

Correlation of Diffusion Data with Drug Release from a Tablet—Apparent diffusion coefficients derived from gel-diffusion measurements were substituted in Eqs. 1 and 2 and theoretical drug-release rates from hydroxypropyl methylcellulose 90 HG, 15,000 cps. compressed matrices calculated. The dry-tablet volume was 0.311 ml. for the standard tablets. Analysis of the swollen portion of a tablet showed that the polymer matrix swelled 4.3 times its original volume during the 2-hr. test period. The surface-to-volume ratio of the hydrated tablet was assumed constant during the course of the experiment and the lateral swelling of the tablet was ignored. The S term, or the effective diffusional area calculated on a dry basis of flat face, was 0.98 cm.^{2}. A standard tablet recessed 0.15 cm. in the holder so as to prevent lateral swelling, yielded a 10% lower slope than a tablet that was not recessed. The apparent diffusion coefficients estimated in 10.4–10.7% polymer gels were substituted in Eqs. 1 and 2. An average value of 11.8 ± 0.6% polymer was obtained when the hydrated portion of a stan-

TABLE IV—COMPARISON OF THE RATES OF DRUG RELEASE FROM THE PLANAR SURFACE OF A COMPRESSED HYDROXYPROPYL METHYLCELLULOSE 90 HG 15,000 cps. MATRIX WITH THE THEORETICALLY PREDICTED VALUES

Drug	% Drug in Tablet (w/w)	D' × 10^6	Theoretical Release ($W_r/t^{1/2}$) moles/min.$^{1/2}$ × 10^6	Actual Release ($W_r/t^{1/2}$) moles/min.$^{1/2}$ × 10^6	% Theory
CPM	16.6	2.04	1.13	1.16	103
Sodium salicylate	16.6	4.68	4.44	4.85	109
Benzoic acid	33.0	14.66	6.06	4.38	72
Benzocaine	16.6	0.94	0.42	0.47	112

dard tablet after a 2-hr. assay was removed, dried, and weighed. This polymer concentration will vary, however, depending on the drug or diluent content. Some actual and theoretical release rates are summarized in Table IV.

The actual drug-release rates obtained from the tablet containing 16.6% chlorpheniramine maleate and sodium salicylate came within 3 and 9% of theory, respectively, as calculated by Eq. 2. The theoretical value for benzocaine was 12% of the experimental value, while in the case of benzoic acid, a 28% faster release rate was predicted than was observed. This deviation reflects the high D' value calculated for benzoic acid. The agreement between actual drug-release rates and theoretical values appears to confirm the fact that diffusion is the major factor in determining drug release from a planar surface of a tablet prepared from a hydroxypropyl methylcellulose 90 HG, 15,000 cps. matrix.

Although the theoretical values predicted by Eq. 1 for insoluble drug systems are in good agreement with the actual values obtained, the error encountered in determining diffusivity must limit any conclusions that might be drawn.

Drug Release from Whole Tablets—The results obtained when drug release from a plane surface of a standard tablet was analyzed for 5 hr. showed linearity for the entire run (Fig. 11) when percent total drug released was plotted *versus* the square root of time. This established that an intact hydrated layer was maintained over this period of time; therefore, diffusion was the most important factor contributing to the rate of drug release in this system. However, when release from a whole tablet was analyzed rather than from a plane surface, linearity was not maintained, since other factors influenced the drug-release rate.

In Fig. 11 plots of percent of total drug released *versus* the square root of time show the release of chlorpheniramine maleate from the whole standard tablet. The release pattern in 0.1 *N* HCl is also shown together with drug release from a similar tablet containing 33% by weight lactose as a diluent in addition to the drug. It can be seen that the standard tablet showed a linear relationship for approximately 100 min., after which time there was a positive deviation. If diffusion were the only factor involved in drug release from the tablet, linearity would have been maintained as in the release from the plane surface.[3]

Attrition of the tablet surface accounts for the positive deviation. If attrition is considered to be the wearing away of the external surface of the hydration layer, the eroded material will go into solution quickly and provide drug in addition to that already available from diffusion.

When the standard tablet was exposed to 0.1 *N* HCl, the drug-release rate was faster than that observed in water. The tablet containing lactose showed release of drug to be somewhere in between that for the water and acid. These results are similar to those obtained in the flow cell. A whole tablet containing tricalcium phosphate was also

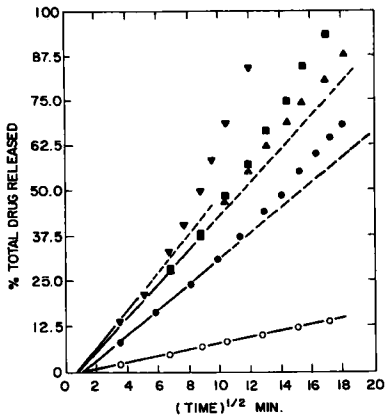

Fig. 11—Chlorpheniramine maleate release from a whole tablet. Key: ▼, hydroxypropyl methylcellulose 90 HG, 25 cps.; ■, standard tablet in pH 1.5 solution; ▲, 33.3% w/w of polymer replaced with lactose in the standard tablet; ●, standard tablet in water; ○, planar surface of a standard tablet.

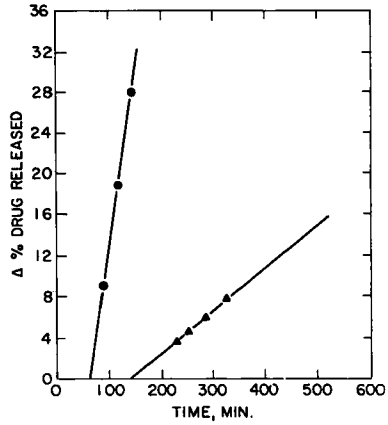

Fig. 12—Difference between the linear extension of the drug plot versus $t^{1/2}$ *and the actual drug release from a whole tablet. Key: ●, hydroxypropyl methylcellulose 90 HG, 25 cps.; ▲, hydroxypropyl methylcellulose 90 HG, 15,000 cps.*

evaluated in this manner but is not graphically illustrated. The release of drug was faster in this tablet than the standard, but this could not be numerically evaluated due to the diluent producing opacity in the circulating media. This was not encountered in measurements from plane surfaces. Therefore, the fact that attrition of the hydrated layer is important in determining release from the whole tablet was confirmed.

The difference between the linear extension of the drug release plot *versus* $t^{1/2}$ and the actual drug-release data on Fig. 11 was plotted for hydroxypropyl methylcellulose 90 HG, 25 cps. and hydroxypropyl methylcellulose 90 HG, 15,000 cps. matrices. A straight line is obtained in both cases (Fig. 12). Assuming that the deviation in drug release from linearity is considered the result of attrition, it is not possible to determine the relative contribution made by this factor drug release. By extrapolating the data in Fig. 11, it was determined that the

[3] Higuchi (4) has described a theoretical treatment of drug release from a spherical pellet of a homogeneous matrix. He concluded that for the first 50% of release there should be no deviation between a sphere and a plane of the same area. Thereafter, the rate of release would be less from a sphere. The swollen standard tablet maintained essentially cylindrical geometry under the conditions of measurement.

hydroxypropyl methylcellulose 90 HG, 15,000 cps. matrix would release 82% of drug through diffusion in approximately 9.5 hr. Attrition, based on the slope obtained in Fig. 12, would contribute 18% drug at 9.5 hr. Similarly, the hydroxypropyl methylcellulose 90 HG, 25 cps. matrix would be totally depleted of drug after 2.8 hr. Attrition accounts for 36% of drug release in this case while diffusion contributes the remainder. It appears from these data that the lower molecular weight polymer is approximately two times more susceptible to attrition than the higher molecular weight species.

The area of the planar surface of the tablet is 0.98 cm.^{2}. The area for the standard whole tablet is 3.06 cm.^{2}. The ratio of experimental drug-release rates between the whole tablet and the planar surface was 4:1, while the ratio for the dry, unhydrated surfaces was 3:1. These results are not unexpected if the hydrated surface is considered in both cases. Hydration of the planar surface results in essentially a projection of the same area. Hydration of the whole tablet, however, changes the tablet diameter resulting in an increase in the area of the planar surface in proportion to the square of the radius. In addition, the increase in the circumference provides more area to the rim of the tablet in proportion to the radius. The added diffusional area resulting from hydration would account for the increased drug release observed over that expected from the unhydrated surface.

Chlorpheniramine maleate release patterns obtained from methylcellulose MC, 4000 cps. tablets appear to be completely dependent on attrition since a straight-line relationship holds when drug release is plotted against time.

It would appear that since the surface of the tablet was diminishing, a nonlinear release rate would be expected. However, erosion was not uniform, and fragmented particles continued to add to the drug concentration.

Renal Metabolizing Activity Studied in Dog and Monkey by the Isolated Perfused Kidney *In Situ*

By G. BENZI, F. BERTÉ, A. CREMA, and E. ARRIGONI

The drug metabolizing power of the renal tissues in an isolated *in situ* kidney preparation has been evaluated in the dog and monkey. Under these experimental conditions, the kidney remained connected to the other parts of the living animal, except for blood circulation which was supplied by a pump-oxygenator system. The disappearance of the tested substances (oxazepam and aminopyrine) from extracorporeal blood was partially replaced by their metabolites. In fact, both the drugs and the metabolites were present at different concentrations in the excreted urine and in the cortical and medullar renal tissues.

IN PREVIOUS PAPERS (1–3) the techniques were described for the perfusion of isolated areas of the body (liver, brain, uterine–fetal complex) to study some of their drug-metabolizing activities, such as demethylation, acetylation, and glucuronide conjugation.

In a systematic investigation (4, 5) on drug

Renal Metabolizing Activity Studied in Dog and Monkey by the Isolated Perfused Kidney *In Situ*

By G. BENZI, F. BERTÉ, A. CREMA, and E. ARRIGONI

The drug metabolizing power of the renal tissues in an isolated *in situ* kidney preparation has been evaluated in the dog and monkey. Under these experimental conditions, the kidney remained connected to the other parts of the living animal, except for blood circulation which was supplied by a pump-oxygenator system. The disappearance of the tested substances (oxazepam and aminopyrine) from extracorporeal blood was partially replaced by their metabolites. In fact, both the drugs and the metabolites were present at different concentrations in the excreted urine and in the cortical and medullar renal tissues.

IN PREVIOUS PAPERS (1–3) the techniques were described for the perfusion of isolated areas of the body (liver, brain, uterine–fetal complex) to study some of their drug-metabolizing activities, such as demethylation, acetylation, and glucuronide conjugation.

In a systematic investigation (4, 5) on drug

metabolism and tissue distribution, the present research was extended to the metabolizing activity of the kidney isolated *in situ* in living animals.

The techniques of the perfusion *in vitro* of isolated kidney suspended in a special box and placed in an extracorporeal circuit have been utilized for about a century (6, 7).

The present research, instead, utilizes the concept of Creech *et al.* (8) that various anatomic regions of the living animal can be isolated from the general circulation, supplied with a separate extraneous system for pumping and oxygenating the blood, and maintained for varying periods of time under these conditions without significant damages.

To test the metabolizing activity of the kidney isolated *in situ*, some transformations of oxazepam (glucuronide conjugation) and of aminopyrine (demethylation and acetylation) have been examined.

METHOD

The simple abdominal technique of kidney perfusion *in situ* was carried out on 39 dogs (9.8–18.8 kg.) and six monkeys (*C. hamadryas:* 7.8–13.8 kg.) preanesthetized with urethan (0.4 g./kg. i.p.). Anesthesia was induced and maintained in closed circuit by nitrous oxide, cyclopropane, or ethyl ether.

The animals were given artificial ventilation by a tracheal Warne tube placed during succinylcholine chloride action (1 mg./kg. i.v.). Arterial blood pressure was measured from a cannula inserted into a femoral artery and connected with a Polygraph-Schwarzer recorder.

After laparatomy, the left kidney and the upper part of the left ureter were exposed; the peritoneal sheath around the left ureter was opened 3–6 cm. from the renal pelvis to expose the ureter and the vessels of the surrounding fat. All the vessels were ligated and a polythene catheter was gently inserted in the ureter, pointing towards the renal pelvis.

The left adrenal gland was removed and the adrenal vessels ligated. The left renal artery and vein were isolated from the surrounding fat and a chain of loose ligatures placed around the vasal connection of the renal area. Both isolated left renal artery and vein were ligated, cannulated, and connected with a pump-oxygenator system; the ligatures around the vasal renal area were tightened to block the communications between the left kidney and the remainder of the body. The time from clamping of the renal artery until the start of perfusion was between 3 and 6 min.

The renal perfusion apparatus employed (9) consists of a venous reservoir, an oxygenator with gas meter, a roller-type pump with flow meter, a glass-wool or a polyester staple blood filter, an apparatus to eliminate blood foam, a blood exchanger with telethermometer, and a perfusion pressure regulator connected with a Polygraph-Schwarzer recorder.

Before the extracorporeal kidney perfusion, the pump-oxygenator system was filled with 400–600 ml. of heparinized blood drawn from donors. The collected blood was filtered through cloth, preserved by ampicillin (1:10,000), and stored in a refrigerator. The perfusions were made with (*a*) whole blood, (*b*) blood diluted with Tyrode solution (3:1), (*c*) blood diluted with Tyrode solution (3:1) and added to glucose (10%), (*d*) blood diluted with Tyrode solution (3:1) and added to both glucose (10%) and cyproheptadine (5–10 mcg./ml.) plus dibenamine hydrochloride (2.5–5 mcg./ml.). When whole blood was used, this was obtained from a donor 20 min. prior to use, to prevent the accumulation of lactic acid which would require a subsequent large neutralization. Before the perfusion, the heparinized blood, compatible with that of the subject, was filtered through glass wool or polyester staple, and adjusted to pH 7.35 using 1 *M* sodium bicarbonate. The priming blood was circulated through the pump-oxygenator system fully oxygenated and warmed. A flow of O_2 or O_2–CO_2 mixture (95:5) into the oxygenator was maintained at the rate of 4–6 l./min.; at the beginning of the extracorporeal renal perfusion, the blood flow was kept at the rate of 5–7 ml./kg./min. related to a pressure equal to the initial systemic pressure of the animal (90–145 mm. Hg). The time of kidney perfusion was limited from 60 to 120 min. Blood samples from extracorporeal circuit were collected every 15 min. for determination of hematocrit, clotting time, arterovenous blood oxygen, pH, and plasma electrolytes (Na, Cl, K). The urine from isolated and perfused kidney was collected and measured every 15 min. for determination of flow, pH, and electrolytes excretion (Na, K, Cl).

The metabolizing activity of the kidney isolated *in situ* was investigated by (*a*) the glucuronide conjugation, by evaluating the transformation of oxazepam to glucuronide (10) after addition of 10–20 mcg./ml. of oxazepam into the extracorporeal circuit, (*b*) the demethylation, by evaluating the transformation of aminopyrine to 4-aminoantipyrine (11) after addition of 40–80 mcg./ml. of aminopyrine into the extracorporeal circuit, (*c*) the acetylation, by evaluating the transformation of 4-aminoantipyrine to *N*-acetyl-4-aminoantipyrine (11) under the conditions mentioned in *b*.

The eventual leakage of perfusate into the systemic circulation was evaluated by taking samples of blood and lymph, to verify the absence of the tested substance or of its metabolites.

RESULTS AND DISCUSSION

The most frequent observation during an extracorporeal kidney perfusion isolated *in situ*, was the steady increase of blood perfusion pressure at constant rates of flow.

In the experimental conditions, the authors preliminarly minimized one of the various responsible factors by filtration of the blood through glass wool or polyester staple to remove both platelet aggregates and fibrin clots that tend to block the microvasculature of the organs (12–14).

Table I shows occurrence and degree of the increase of the renal vascular resistance, in different experimental conditions of dog's extracorporeal kidney perfusion *in situ*. A mixture of 5% carbon dioxide and 95% oxygen, used instead of pure oxygen in the aeration of the extracorporeal blood, reduced the degree of the perfusion pressure increase, in agreement with the results of Bachrack *et al.* (15),

TABLE I—OCCURRENCE IN DOG OF INCREASE OF THE RENAL PERFUSION PRESSURE AT CONSTANT RATE OF BLOOD FLOW (5–7 ml./kg./min.) IN DIFFERENT EXPERIMENTAL CONDITIONS

Aeration in Oxygenator		Medium of Perfusion					Occurrence After 2 Hr. of the Increase of Perfusion Pressure in Comparison with the Initial Values		
				With Addition of					
O_2(100%)	O_2(95%) + CO_2(5%)	Whole Blood	Diluted Blood (3:1)	Glucose (10%)	Cypro heptadine + Dibenamine	No. of Dogs	<10%	10–30%	>30%
yes	—	yes	—	—	—	8	1	2	5
—	yes	yes	—	—	—	8	1	4	3

—	yes	—	yes	yes	yes	8	2	3	3

Malette *et al.* (16), and Steyn *et al.* (17). In comparison with the whole blood, the use of the blood diluted with Tyrode solution (3:1) and added to glucose (10%) reduced occurrence and degree of the increase of vascular resistance, in agreement with the data of Dottori *et al.* (18), Harvey (19), and Steyn *et al.* (17). The use of antihistaminic, antiserotoninic, and adrenergic-blocking agents was without any effect in reducing the increase of renal perfusion pressure, in partial agreement with Steyn *et al.* (17) and in contrast with Hollenberg *et al.* (20) and Belzer *et al.* (14). During the extracorporeal renal circulation *in situ*, no significant difference was observed between initial and terminal values of both the plasma electrolytes concentration of the perfusing blood, and the urine pH and electrolytes excretion, as indicated in Fig. 1.

In the extracorporeal circuit of both dog and monkey, the decrease of oxazepam plasma levels was 52% (42–58%) in 60 min.; the drug disappearance was partially replaced by its glucuronide. Both oxazepam and its studied metabolite appeared in the urine, as shown in Fig. 1; the oxazepam urine concentration decreased with the decrease of plasma concentration as the glucuronide urine concentration increased with the increase of its plasmatic concentration.

In the extracorporeal circuit of both dog and monkey, the decrease of aminopyrine plasma levels was 35% (28–41%) in 60 min.; the drug disappearance was partially replaced by its metabolites. Aminopyrine and its demethylated and acetylated metabolites appeared in the urine as indicated in Fig. 2. Figures 1 and 2 show the cortical and medullar concentrations of the drugs and their studied metabolites after the perfusion of the kidney: the affinity for aminopyrine, or instead for oxazepam, seems similar in both animal species.

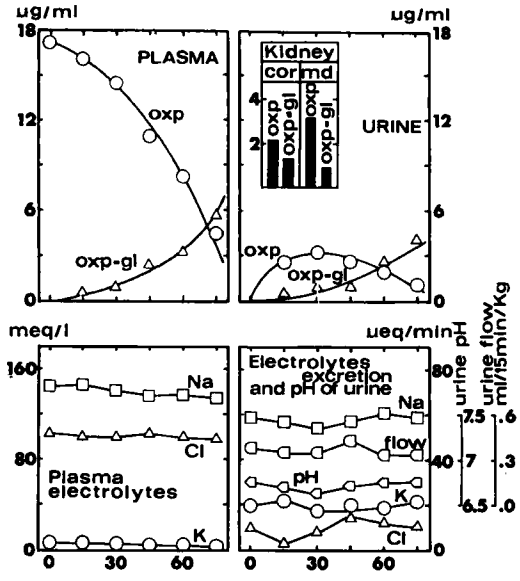

Fig. 1—Oxazepam metabolism studied by the isolated kidney perfusion in situ *in a dog weighing 18.2 kg. Blood in kidney extracorporeal circuit = 520 ml.; blood flow rate of extracorporeal circuit = 110 ml./min.; initial concentration of oxazepam in the plasma of the extracorporeal circuit = 17.5 mcg./ml. Top, at left the plasma concentration curves (mcg./ml., in ordinate) of oxazepam (oxp) and its glucuronide (oxp-gl), assayed every 15 min., for 75 min. At right, the urine concentration curves (mcg./ml., in ordinate) of oxazepam and its glucuronide; insert shows the cortical (cor) and medullar (md) renal concentration (mcg./g., in ordinate) of oxazepam and its glucuronide, evaluated 75 min. after the extracorporeal kidney perfusion with addition of oxazepam. Bottom, at left the plasma electrolytes concentrations (meq./l.) of the extracorporeal circulating blood assayed, every 15 min., for 75 min. At right, the urine pH, flow (ml./15 min./kg., in ordinate) and electrolytes excretion (meq./min., in ordinate) assayed as above indicated.*

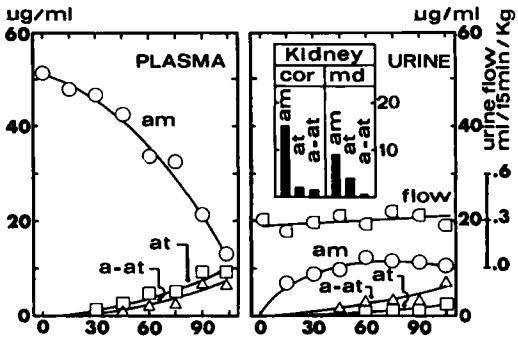

Fig. 2—Aminopyrine metabolism studied by the isolated kidney perfusion in situ *in a monkey* (C. hamadryas) *weighing 12.3 kg. Blood in kidney extracorporeal circuit = 480 ml.; blood flow rate of extracorporeal circuit = 74 ml./min.; initial concentration of aminopyrine in the plasma of the extracorporeal circuit = 51.9 mcg./ml. At left, the plasma concentration curves (mcg./ml., in ordinate) of aminopyrine (am), 4-aminoantipyrine (at), and N-acetyl-4-aminoantipyrine (a-at) assayed every 15 min. for 105 min. At right, the urine flow (ml./15 min./kg., in ordinate) and urine concentration curves (mcg./ml., in ordinate) of aminopyrine and its mentioned metabolites. Insert shows the cortical (cor) and medullar (md) renal concentrations (mcg./g., in ordinate) of aminopyrine and its two metabolites, assayed 105 min. after the extracorporeal kidney perfusion with addition of aminopyrine.*

CONCLUSIONS

The kidney isolated *in situ* shows a good metabolizing power evaluated by studying the glucuronide conjugation of oxazepam and the demethylation and acetylation of aminopyrine, both in the dog and the monkey. The tested substances and their metabolites were present in the excreted urine and in the renal tissues. During the extracorporeal renal perfusion (from 1 to 2 hr.) no significant differences were observed between the initial and final values of plasma electrolytes concentrations and urine pH, flow, and electrolytes excretion.

In comparison with the metabolizing power of other organs isolated *in situ* the kidney shows a lower activity than the liver (1) and a higher activity than the brain (2).

Influence of Calcium and Antiarrhythmic Drugs on Palmitate Uptake by Rabbit Heart Slices

By C. M. MOKLER* and P. P. MATHUR

Nonesterified fatty acids diffuse into myocardial cells at a rate which is proportional to the concentration of unbound acid, and are used in intracellular oxidative and synthetic reactions. Quinidine is known to inhibit cellular oxidative processes. The effects of quinidine, disopyramide, and pronethalol on oxygen consumption and palmitate uptake by rabbit ventricle slices were determined by standard Warburg manometric techniques. In the absence of Ca^{++}, all three drugs in concentrations of 10^{-5}–10^{-4} moles/l. induced marked increases in the rate of palmitate uptake from its albumin-bound form in incubation media without significant changes in tissue Q_{O_2}. This effect was not seen at drug concentrations of 10^{-6} or 10^{-3} moles/l., or when 2 m*M* Ca^{++} was present. A relationship is suggested between palmitate, Ca^{++}, antiarrhythmic drugs, and extracellular protein, which may involve the binding of fatty acid to the protein moiety.

PLASMA NONESTERIFIED FATTY ACIDS (NEFA) serve an important function in mammalian myocardial nutrition (1). They apparently diffuse across cell membranes and become available to cytoplasmic and mitochondrial enzyme systems in quantities which are related to the molar ratio of NEFA–plasma albumin (2) because of the reversible manner in which NEFA are bound to plasma albumin. Quinidine is also bound to plasma albumin (3), as is ionic calcium (Ca^{++}) (4), which is known to play an important role in cardiac function (5). Nayler (6) has shown an additional relationship between Ca^{++}, quinidine, and cell lipids. Quinidine will inhibit the movement of Ca^{++} from an aqueous phase into a chloroform phase which contains lipids extracted from myocardial membranes and

microsomes. A similar effect was demonstrated with pronethalol and propranolol (7) which also possess antiarrhythmic properties. These findings suggest that the antiarrhythmic drugs may modify the affinity of membrane lipids for Ca^{++}, or that they may compete with these lipids for Ca^{++}.

The work described here will show a further interaction of quinidine, pronethalol, and disopyramide with myocardial cells which results in modified uptake of palmitate by these cells, and a reversal of the effect with extracellular Ca^{++}.

METHODS

Standard Warburg manometric techniques were employed. Healthy, male, nonfasting animals were used in this study. New Zealand white rabbits were stunned by blows on the head and hearts were removed and placed in chilled buffer without substrate. Thin longitudinal slices (0.5 mm.) were taken from ventricles with a Stadie-Riggs slicer. Slices were halved and distributed equally between control and drug-containing vessels. Each Warburg reaction vessel contained 150–200 mg. of tissue in buffer containing the drug but no substrate. Each experiment included a thermobarometric control flask (no tissue) and at least four control flasks which contained tissue and buffer but no drug. Calcium levels were the same in all flasks of a given experiment. The low calcium buffers contained 88 m*M* NaCl, 5 m*M* KCl, 2 m*M* $MgCl_2$, 40 m*M* Na_2HPO_4, and either no calcium or 0.2 m*M* $CaCl_2$. The high mmoles calcium buffer differed only by having 2 m*M* Na_2HPO_4, 2 m*M* $CaCl_2$, and 124 m*M* NaCl to keep ionic strength constant. The pH of each solution was adjusted with 1 *N* HCl to 7.4 before use. The substrate solution was prepared by adding warm sodium palmitate solution dropwise with stirring to a solution of bovine albumin (Cohn's fraction V[1]), to give 3 mg. palmitate per ml. of 16% albumin solution. This mixture was refrigerated overnight and filtered at least once before use. When added from the side arm of the Warburg flask, 0.5 ml. gave flask concentrations of 5–8 μmoles palmitate and 80 mg. albumin per 3 ml. of medium, or a molar ratio of about 5:1.

The reaction vessels were gassed for 5 min. with 100% oxygen, equilibrated for 5 min. at 37 ± 0.1° and, after initial manometer readings, substrate was added from the side arm. Manometer readings were made every 15 min. for 2 hr, but calculation of oxygen consumption was based on readings from the first hour.

At the end of the incubation period, flasks were immediately chilled in crushed ice. A 2.0-ml. aliquot of medium was quickly removed from each flask, the fatty acids were extracted, and the concentration of fatty acids in each extract was determined by the microtitration method of Dole and Meinertz (8). To calculate tissue uptake of palmitate, the quantity remaining in the medium of each control and experimental flask was compared with that remaining in the thermobarometric control flask.

Tissue slices were blotted, weighed, and dried overnight at 104° before the final weighing. Oxygen consumption was expressed as Q_{O_2}, or microliters of oxygen used per milligram dry weight of tissue per hour.

Drugs used were quinidine sulfate (USP crystals, Mallinckrodt), crystalline disopyramide,[2] and pronethalol.[3] Drug concentrations ranged from 10^{-6} *M* to 10^{-3} *M*.

The data from drug-treated heart slices were compared with those from untreated control slices by Fisher's *t* test, using the 5% significance level.

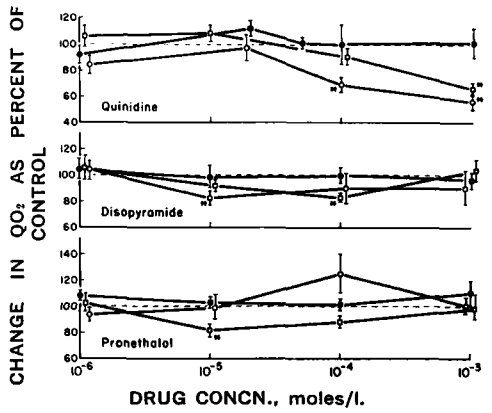

Fig. 1—Comparison of drug-treated heart slices with untreated control slices with respect to the oxygen consumption at varying concentrations of drugs and calcium ions. Asterisk (*) indicates significant difference from controls (p < .05). The vertical bar in each figure indicates the standard error of the change from control found with each treatment. Key: ●, No Ca; □, 0.2 mM Ca; ○, 02.0 mM Ca.

RESULTS

Figure 1 summarizes the effects of varying drug concentrations and Ca^{++} levels on the rate of oxygen consumption by rabbit ventricle slices. Significant changes in Q_{O_2} were found only with 2 m*M* Ca^{++} at quinidine concentrations of 10^{-6} to 10^{-3} *M*, and with 0.2 m*M* Ca^{++} only at 10^{-3} *M* quinidine. That this effect may be due to Ca^{++} is illustrated by Table I, which indicates a significant reduction in Q_{O_2} in untreated heart slices when incubated with 2 m*M* Ca^{++}. This reduction of Q_{O_2} was in general

not seen when disopyramide or pronethalol was present.

Figures 2–4 show how these factors altered the rate of disappearance of palmitate from the medium of Warburg flasks. The rate of palmitate uptake appears to be inversely related to the Ca^{++} concentration at the intermediate drug levels in each case, but is less dependent on Ca^{++} concentration at higher and lower concentrations of drugs. In the absence of drugs, palmitate uptake was not depressed by increasing Ca^{++} concentrations (Table I).

While reasonably small differences in Q_{O_2} and palmitate uptake were observed between control slices from any one heart, considerable variation between hearts was observed. Thus, the treated slices from any heart were compared only with untreated control slices from the same heart, and results are expressed as the observed change from control values.

Control studies revealed no significant differences between vessels containing 2 m*M* phosphate and those containing 40 m*M* phosphate with respect to either Q_{O_2} or palmitate uptake from the medium (Table II).

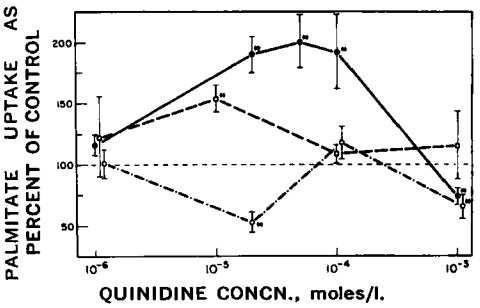

Fig. 2—Changes in palmitate uptake by heart slices as induced by quinidine at various levels of calcium. Changes in Q_{O_2} of these slices are shown in Fig. 1. Asterisk (*) indicates significant difference from controls ($p < .05$). *Key: ●, No Ca; □, 0.2 mM Ca; ○, 2.0 mM Ca.*

DISCUSSION

As Evans (2) has indicated, the movement of fatty acids across cell membranes is probably a physical process since the rates of its loss from the medium (9) and its oxidation to CO_2 (10) appear to be dependent on the quantity of unbound or loosely bound NEFA in the medium. The experiments described here show that quinidine, disopyramide, and pronethalol will, at certain concentrations, enhance the rate of disappearance of palmitate from the medium in which rabbit ventricle slices are incubated. The effect is not present when calcium is added in concentrations (2 mmoles/l.) which approach the normal concentrations found in plasma. The increased rate of palmitate uptake is not accompanied by a parallel change in the rate of oxygen consumption by the ventricle tissue. Thus, although additional palmitate appears to be moving into the cells under these conditions, it must be used in nonoxidative or synthetic reactions of a nature which is not revealed by these experiments.

Several possible explanations of this phenomenon exist. One such explanation is related to the binding of fatty acids to plasma albumin. Goodman (11) has shown that palmitate is bound to plasma albumin in molar ratios of up to 27:1, with approximately 20 moles of palmitate per mole of protein having a relatively low association constant. If the antiarrhythmic drugs alter this binding to lower the association constant or to displace fatty acid from this binding, more NEFA will be available to be taken up by intacellular proteins (2). That quinidine is also bound to albumin (3) increases the plausibility of such an explanation, although there is no *a priori* reason to believe that albumin could not bind both fatty acid and quinidine independently.

At the higher drug concentrations where palmitate uptake is reduced to control values or below, explanations for the observed data become more speculative. It is possible that, even though palmitate is made more available for diffusion into the cells, less is taken up because of drug inhibition of intracellular enzyme systems which would normally utilize the fatty acid as a substrate in oxidative or synthetic reactions. The concentration gradient for diffusion of fatty acids into the cells would not be as great as normal under these circumstances. There is evidence that palmitate oxidation is inhibited (12) by quinidine in concentrations (greater than 10^{-4} *M*) at which the rate of uptake (Fig. 2) begins to diminish. Other workers have demonstrated inhibited oxidation of citric acid cycle intermediates (13, 14) in the presence of high concentrations of quinidine.

However, the rate of oxygen utilization (Fig. 1) did not diminish with increased quinidine concentration in those slices (no Ca^{++}) which showed the greatest change in fatty acid uptake. Nor was the Q_{O_2} much altered by disopyramide or pronethalol, both of which induced similar changes in palmitate uptake. These observations could mean that the rate of incorporation of the fatty acid into neutral lipid molecules is diminished by the higher concentrations of the drugs, but additional experiments are needed to support this theory. A more plausible explanation for the quinidine data is that quinidine inhibits endogenous substrate oxidation, but that the absence of calcium permits easier entry of palmitate into the cell where it is available for oxidation and prevents a fall in the oxygen consumption. This possibility also requires additional experimentation for support.

The role of Ca^{++} in cancelling the drug effect is also obscure. Ca^{++} itself is bound to plasma protein, to quinidine (15), and to fatty acids, and thus could significantly affect acid release from albumin in several ways.

A third possible explanation for the phenomenon may be seen in the alteration of cell-membrane permeability by Ca^{++} and the antiarrhythmic drugs. It is known that Ca^{++} and quinidine have definite effects on membrane electrical characteristics which are, in turn, dependent on the relative movements of ions across the membrane. It is possible that Ca^{++} and the antiarrhythmic drugs could alter the permeability of myocardial cell membranes to palmitate and exert their individual effects on NEFA uptake in this manner.

The alteration of palmitate uptake by heart slices which is caused by antiarrhythmic drugs in the absence of Ca^{++} ions reveals a relationship between the three factors which may have some bearing on the action of this class of drugs. The intracellular presence of quinidine and fatty acid is measurable and relatively constant during therapy, and sarcoplasmic Ca^{++} concentrations vary considerably during the cardiac cycle. If fatty acid binding to intracellular proteins varies inversely with the drug concentration, the presence of these drugs may alter the availability of the fatty acids for enzymatic processes, and thus affect the economy of the cell.

Thin-Layer Chromatographic Assay of Vitamin D in High-Potency Preparations

Analysis of Fat-Soluble Vitamins IX

By K. H. HANEWALD, F. J. MULDER, and K. J. KEUNING

Attention is called to the reversible thermal isomerization of calciferols (D) to precalciferols (P) as a factor interfering with vitamin D assay. Distinction is made between potential vitamin D content (D + P) and actual vitamin D content (D only). The potential D content can be determined by the well-known Nield reaction. For the determination of the actual D content the Bolliger TLC method was modified to make it suitable for irradiation products: tachysterol is eliminated, the protection against oxidation was improved, P and D are isolated and may be determined separately. Applying this method, the isomerization rates of vitamins D_2 and D_3 were proved to be equal; the effects of boiling in solutions, saponification, and Soxhlet extraction on the ratio of P and D were examined. "Glassy" vitamin D resins appear to isomerize very slowly; "pasty" resins isomerize at the same rate as dilute solutions.

DISCREPANT RESULTS of vitamin D assays are frequent. Though admittedly the analytical techniques of the determination of ergocalciferol (D_2) and cholecalciferol (D_3) are not simple, a very real source of error is the neglect of the slow reversible isomerization, calciferol $\rightleftharpoons$ precalciferol (P) (1). It induced this laboratory to investigate the influence of the isomerization reaction on the results of vitamin D assay methods.

Potential and Actual Vitamin D Content—In vitamin D analysis the first thing necessary is to define what is meant by "vitamin D content." Distinction must be made between the *actual* vitamin D content, that is the amount of calciferol alone, and the *potential* vitamin D content, meaning the sum of calciferol and precalciferol, which is independent of the ratio of both components. The authors posit that the actual vitamin D content alone does not give any useful information and that only the potential vitamin D content is suitable for the evaluation of preparations. Simultaneous determination of both components D and P separately gives additional information, if wanted.

Isomerization of the Calciferols—Only in solutions do the calciferols isomerize reversibly to the corresponding precalciferols, forming an equilibrium mixture (2–4).

Hanewald (5) determined by ultraviolet absorptiometry the first-order rate constants for

$$P_3 \underset{k_2}{\overset{k_1}{\rightleftharpoons}} D_3$$

and their dependence on temperature:

$$\log k_1 = \frac{-4200}{T} + 10.29 \quad \text{and}$$

$$\log k_2 = \frac{-5180}{T} + 12.53$$

(k in min.$^{-1}$; T in °K.).

From these rate constants the fractions P/(P + D) and D/(P + D) can be calculated at a given temperature, as can the time needed to approach the equilibrium (1).

From the literature it is not clear if the isomerization rates of $P_2 \rightleftharpoons D_2$ and $P_3 \rightleftharpoons D_3$ are equal. Using the analytical methods described below this equality was affirmed. Furthermore, the isomerization rates in the crude irradiation products of 7-dehydrocholesterol were investigated, which after evaporation to dryness have a resin-like consistency. Besides the commercial importance of these resins, it is of interest to compare the rates in the resins with those in solutions which seem to be temperature dependent only and with those in the solid state (crystalline state is temperature independent).

Determinations of Potential and Actual Vitamin D Content—Since too little attention has been given to the isomerization of the calciferols, few methods of vitamin D assay give reliable values either of the potential or of the actual vitamin D content. Most methods lead to results between these two values (1).

The *potential* vitamin D content can be determined directly by absorptiometry, at 500 mμ, of the pink color obtained with antimony trichloride (Nield reagent). The result is identical for D, P, and tachysterol (6). Vitamins A and E and many other polyenes interfere and are eliminated beforehand (7).

Received December 13, 1967, from the Philips-Duphar Research Laboratories, Weesp, The Netherlands.
Accepted for publication April 15, 1968.

The *actual* vitamin D content of solutions containing only D and P can be determined by an ultraviolet-absorptiometric two-component analysis. It is calculated from the absorbance at 265 mμ and the potential vitamin D content known from Nield reaction or other sources (5, 6). The P content is obtained simultaneously. Separation is not required. In solutions of irradiated ergosterol or 7-dehydrocholesterol, by-products such as lumisterols and tachysterols interfere.

Biological assay can give the potential vitamin D content, provided that the necessary precautions for equilibration of sample and standard are observed; the actual vitamin D content cannot be determined by biological assay (1).

A reliable and not too vulnerable determination of the actual vitamin D content requires the separation of D and P. Presently this can be done only by thin-layer chromatography (TLC), or in a much longer time by paper chromatography (8). Bolliger and König (9) published a useful TLC method for vitamin D assay in 1965; for previous work, most of it qualitative or semiquantitative, the authors refer to the paper (9) and to Bolliger's chapter in Stahl's handbook on TLC (10). Bolliger succeeds in separating calciferol and precalciferol; unfortunately, in an attempt to correct for its biological activity, only part of the precalciferol is included in the determination which results in values between the potential and actual vitamin D content. Isomerization of samples and standard solutions before and during the analysis is not taken into account, nor is the contamination with tachysterol, often present in vitamin D preparations, which is not separated from calciferol by TLC (11). Tachysterol gives the same absorptivity with Nield reagent but can be eliminated in the analysis of irradiation products by the addition of maleic anhydride (MA) at 75° (6).

As no practical method for the determination of the actual vitamin D content and of previtamin D was available, the Bolliger method was modified for this purpose (*a*) by collecting the P and D spots separately for quantitative analysis, (*b*) by preventing oxidation more thoroughly, (*c*) by elimination of tachysterol (TA) from the D + TA mixture isolated by TLC.

EXPERIMENTAL[1]

Chromatography—On silica plates as described below the R_f values were measured for the calciferols (D), the precalciferols (P), lumisterol (L), and tachysterol (TA), using the solvent media: cyclohexane + ether (1 + 1) (9):0.32 (D), 0.42(P), 0.37 (L), 0.32 (TA); benzene + ether (3 + 2): 0.37 (D), 0.48 (P), 0.43 (L), 0.37 (TA); benzene + ether (4 + 1) (solvent III):0.29 (D), 0.42 (P), 0.34 (L), 0.29 (TA). D and TA are not separated.

BHT (0.01%) in the solvent medium suffices to prevent oxidation during development; squalane is necessary for protection during the application. The protection is demonstrated easily with ^{14}C-labeled cholecalciferol. Using both squalane and BHT no tailing occurs, but with only BHT tailing by deterioration is evident. The developed and dried plate is stable for 1 day.

Elimination of Tachysterol—In the manufacture of vitamins D by irradiation P is formed, which is isomerized to D. The resins are obtained by evaporation of the solvent. Of the by-products, only the tachysterols interfere with the Nield reaction. Tachysterols, calciferols, and precalciferols are converted by addition of maleic anhydride into adducts indifferent to antimony trichloride, but the addition rate of TA is much larger, therefore TA can be eliminated. In the chemical assay this has been done at 75° (6). To avoid side reactions like oxidation and to simplify the analysis, this temperature was lowered to 25°, but the rate was restored by a 10-fold MA concentration. One milligram of tachysterol was dissolved in 1 ml. of 10% MA solution in benzene; 15, 30, 60, and 120 min. after dissolving, the solution was diluted with benzene and the residual tachysterol content determined with Nield's reagent.

No color was observed in any of the four experiments, thus at least 98% of the tachysterol had been eliminated within 15 min. The chosen reaction time for addition at room temperature was 0.5 hr. The same experiments with 1 mg. of pure cholecalciferol gave calciferol recoveries of 98.1, 98.6, 99.7, 99.0%. Recovery experiments with mixtures of tachysterol and calciferol gave the same results (recovery TA = 0%, recovery D = 99%).

Thin-Layer Chromatographic Determination of Actual Vitamin D and Previtamin D in the Presence of Tachysterol

Reagents and Chemicals—Benzene, thiophene-free; ether, free from peroxide and acids; dichloromethane, distilled; ethanol, 96% v/v, free from aldehyde and acids. Solvents: (I) 0.01% BHT in benzene; (II) 1% squalane and 0.01% BHT in benzene; (III) benzene + ether (4 + 1 vol.) + 0.01% BHT. Maleic anhydride (MA), freshly distilled, 10% w/v solution in benzene. Calciferol standard solution, 10 mcg./ml. crystalline cholecalciferol in solvent I (stable for at least 3 months in an amber-colored bottle in the dark, control occasionally by comparing with a fresh standard solution). Nield reagent, 20% $SbCl_3$ and 2% acetylchloride in chloroform; for preparation the authors refer to *Reference 12*.

Apparatus—Chromatoplates, 200 × 100 × 4 mm. with a thin layer (0.25 mm.) of Soxhlet extracted (24 hr. with methanol and 24 hr. with dichloromethane) Silica Gel GF 254 (Merck) and dried at 110°; vacuum collectors with porous-glass disk and ground joints; spectrophotometer, *e.g.*, Coleman Junior with 19 × 105-mm. cells; rapid-delivery pipet, 5 ml.

Procedure—Dissolve *w* g. of sample (containing approximately 50 mg. of D) in 50.0 ml. of solvent I

[1] With the collaboration of Mrs. M. Damen-van't Sant.

(for oils) or solvent II (for resins and for ethanolic solutions after evaporation to dryness *in vacuo* at room temperature with 3 × 10 ml. of benzene). Pipet 0.5 ml. of the solution on a 8-cm. line at 15 mm. from the lower edge of a chromatoplate. Develop with solvent III until the front is 17 cm. past the origin and dry the plate. Mark in ultraviolet light (254 mμ) the P region (R_f = 0.42) and the D + TA region (R_f = 0.29) and remove the light. Scratch (9) or suck (13) the silica from between the marks quantitatively into two dry collectors. Clean both open spaces on the plate with cotton wool moistened slightly with ethanol and put each plug into the corresponding collector. Extract P from its collector with 2 × 25 ml. of dichloromethane (nitrogen pressure). Evaporate extract to dryness *in vacuo* (cold), release vacuum with nitrogen, and dissolve P residue in 5.00 ml. of benzene. [According to USP XVII (14) 1,2-dichloroethane can be used instead.] Extract D + TA similarly but collect and evaporate the extract in a 50-ml. volumetric flask. Dissolve D residue in 1.00 ml. of MA solution. Keep at room temperature for 30 min. Then make up to volume with benzene.

Measurement—Pipet 1 ml. of the final benzene solution (P or D, respectively) into a cell. Add 5 ml. of Nield reagent from rapid-delivery pipet, swirl, and 60 sec. (stopwatch) after addition, measure the absorbance at 500 mμ against air ($=A$). Reagent blank: treat 1 ml. of benzene accordingly (absorbance = A_b). Standard: treat 1 ml. of standard solution accordingly (absorbance = A_s). The cholecalciferol (ergocalciferol) and the precholecalciferol (preergocalciferol) contents of the sample are:

$$\frac{C_s}{C} \times \frac{A - A_b}{A_s - A_b} \text{ mcg./g.}$$

C_s = concentration of standard solution in mcg./ml. (= 10); C = sample in the final benzene solution in g./ml. (= w/500 for P, and w/5000 for D).

Remarks—This modified determination of actual D and P simultaneously by TLC is suitable for samples containing irradiation products and vitamin D resins. However, in the determination of the actual D content the conditions starting from the moment of sampling should be such that isomerization virtually cannot occur, *i.e.*, by handling at low temperature.

By this method the actual D content in oily concentrates can only be determined in samples containing at least 6 mg. (240,000 I.U.) of vitamin D per g. of oil. At lower concentrations the oil must be removed, for which Bolliger and König (9) made suggestions. The problem is to maintain unchanged the ratio of P and D. Generally, high-potency vitamin D preparations do not contain vitamin A. Vitamin A, thus far not separated from P and D and thus contaminating the isolated spots, should be eliminated before the Nield reaction is carried out, *e.g.*, by chromatography on Florex (7, 9). The modified TLC method also gives the potential D content by adding the contents found for D and P. If only the potential D is desired both removed regions can be combined and thereafter treated as a single sample of D + TA.

APPLICATIONS AND RESULTS

In the following experiments determinations were done by the TLC method described above, by absorptiometric two-component analysis, and by Nield reaction.

Absorptiometry—The absorptivity $a(= A_{1\text{ cm.}}^{1\%})$ is independent of the solvents used here; this applies to each of the compounds D_2 (475), D_3 (485), P_2 (208), and P_3 (218). All absorbances were measured at 265 mμ, the absorption maximum of D_2 and D_3, though the absorption maximum of P_2 and P_3 is 260 mμ. The fractions of P and D can be calculated from the difference of the absorptivities (a = sample, a_D = pure D; a_P = pure P):

$$[P] = \frac{a_D - a}{a_D - a_P} \cdot 100\% \quad \text{and} \quad [D] = \frac{a - a_P}{a_D - a_P} \cdot 100\%.$$

Nield Reactions—All were performed in the same way: aliquot parts of the solutions to be analyzed were evaporated to dryness *in vacuo* at room temperature and redissolved in a measured volume of benzene to obtain a concentration near 10 mcg./ml. These solutions were treated as described in the TLC procedure, starting at "Measurement."

Isomerization by Boiling for 0.5 Hour in Various Solvents—Ergocalciferol and cholecalciferol were dissolved in cold methanol, ethanol, and isooctane and refluxed for 0.5 hr. in a nitrogen atmosphere. The absorbances of the cold solutions were measured at 265 mμ, immediately after preparation and again after refluxing. The TLC and the absorptiometric determinations were done in the same solutions. In Table I the fractions of P and D are given in % of potential D content (P + D) found. The recovery is the potential D found in % of submitted calciferol.

Saponification—Crystalline cholecalciferol was dissolved in peanut oil at low temperature. The potential as well as the actual D content = 47.5 mg./g.

Two grams of the oily solution was saponified by heating for 0.5 hr. under nitrogen with 5 ml. of 2 *N* KOH in methanol, in ethanol, or in glycol-monomethylether (purified) at 60, 80, and 100°, respectively. After cooling (nitrogen), 8 ml. of methanol and 20 ml. of water were added. The liquids were extracted with 4 × 40 ml. of ether and washed with 2 × 50 ml. of 0.5 *N* aqueous KOH and 4 × 50 ml. of water.

In all samples the following determinations were done: (*a*) D + P with Nield's reagent (potential D content). (*b*) The apparent vitamin D content, by absorptiometry at 265 mμ (actual D + part of P). (*c*) D and P separately by TLC (actual D content). The effect of the saponification temperature on actual and potential vitamin D contents is seen in Table II.

Soxhlet Extraction—The samples consisted of 1 g. of cotton seed oil, containing 48.8 mg. of cholecalciferol, adsorbed on 5 g. of cellulose powder. These were extracted during 5 hr. under nitrogen, with ether, cis-dichloroethene, *n*-hexane, cyclohexane, or isooctane, each containing 0.01% of BHT, at 35, 60, 68, 80, and 100°, respectively, and the extracts analyzed (see Table III): (*a*) P + D with Nield reagent (potential D content), (*b*)

D (actual D content) and P separately by TLC.

Storage and Analysis of Resins—In the experiments of Table IV samples of resins were stored at different temperatures during times in which diluted calciferol solutions are equilibrated completely. In Table V stored resins are compared with solutions of the same in oil; in this case the storage time is insufficient to reach the equilibrium for solutions.

P + D + TA was determined by Nield reaction absorptiometry in this solution. P and D + TA were isolated by TLC of 0.5 ml. of the solution (containing approximately 0.5 mg. of D) and P determined by Nield reaction. From D + TA the TA was eliminated by MA addition and the remaining D determined by Nield reaction. The values for P + D in Table IV were obtained by adding those for P and for D. The values for TA

TABLE IV—STORAGE OF A SOLID (GLASSY) VITAMIN D_3 RESIN IN NITROGEN DURING TIMES NEEDED BY DISSOLVED CALCIFEROL TO REACH P-D EQUILIBRIUM

Determined \ Storage Time and Temp. →	% w/w: After 1 Month, 20°	After 1 month, 20° and: 11 Days, 30°	3.8 Days, 40°	1.7 Days, 50°
P + D + TA	68.5	67.3	69.6	69.9

TABLE V—COMPARISON OF THE P-D RATIO AFTER STORAGE OF NONCOOLED (LIQUID OR PASTY) VITAMIN D_3 RESIN AND OF THE SAME RESIN DISSOLVED IN OIL

Compd.	P and D Fractions, % of Potential D_3: Start Resin	Start Oil	19 Days at 20°C. Resin	19 Days at 20°C. Oil	6 Days at 30°C. Resin	6 Days at 30°C. Oil	2 Days at 40°C. Resin	2 Days at 40°C. Oil
P	25	23	10	12	9.5	9.5	11	13
D	75	77	90	88	90.5	90.5	89	87
Potential D, % w/w	60.7	5.4	61.5	5.9	59.2	6.0	60.0	5.9

were obtained by subtracting P + D from P + D + TA. Determination of TA or D + TA by Nield reaction after TLC is wrong as TA decomposes during TLC.

The samples of Table IV were obtained by weighing 500 mg. of briefly heated (100°) vitamin D_3 resin into volumetric flasks, sealing the flasks under nitrogen, and storing them for 5 hr. at −25° at which time the resin had solidified and taken its glassy appearance. These samples were stored for the times mentioned in Table IV, then dissolved in solvent III at room temperature and promptly analyzed.

In Table V, vitamin D_3 resin was heated for 2 hr. at 85°. The 500-mg. portions were sealed in volumetric flasks under nitrogen and stored immediately at the temperatures of the storage tests. Ten grams of the same vitamin D_3 resin was heated for 2 hr. at 85° in 90 g. of peanut oil. The solution was stored in completely filled, stoppered 5-ml. flasks.

DISCUSSION

Recovery—The recoveries of the sum of P and D found by the described TLC method (Table I) and the comparison with potential D content found by Nield reaction before chromatography (Tables II and III) are satisfactory.

Isomerization, Equilibrium, and Rate—In the experiment of Table I the equilibrium is reached within 30 min. at 100°, as can be calculated from the rate constants (1); at 65 and 78°, 8 and 3 hr. would be needed. Accordingly at 100°, the P fractions are near the equilibrium value of 28.5%; at 65 and 78° they are much lower than the equilibrium value (4.5 instead of 17.6% and 13 instead of 21.4%, respectively). It is evident that the P and D fractions, even those measured *during* the conversion, are virtually equal for ergocalciferol and cholecalciferol. This means that the equilibrium and the isomerization rates of vitamin D_2 and vitamin D_3 differ only very slightly.

Saponification—From Table II it is clear that the actual D content decreases considerably during saponification and progressively so with increasing temperature; the potential D content remains unchanged. In a comparison of Tables I and II the P and D fractions found after saponifying 0.5 hr. at 60 and 80° agree reasonably with the values found without KOH at 65 and 78° after 0.5 hr., experimentally and calculated. At 100° there is a certain discrepancy. The conclusion is that the rate, and thus the equilibrium P ⇌ D is not altered by the presence of KOH if the temperature does not exceed 80°, but that at 100° KOH causes other effects. Without trying to explain the effect of KOH, the authors advise saponification only at temperatures of 80° or less.

Extraction (Table III)—After extraction at 68, 80, and 100° the P and D fractions are in fair agreement with the equilibrium fractions. Below 68° the agreement fails because 5 hr. is too short a time to reach equilibrium.

Resins—The effect of temperature on glassy resins appears to be very small, which emphasizes their solid character (Table IV). Unlike the glassy vitamin D_3 resin the viscous noncooled vitamin D_3 resin of Table V isomerizes at the same rate as its solution.

Pharmacokinetics of Acetylsalicylic Acid and Salicylic Acid After Intravenous Administration in Man

By MALCOLM ROWLAND and SIDNEY RIEGELMAN

The pharmacokinetics of acetylsalicylic acid (ASA, 650 mg.) and salicylic acid (SA, 500 mg.) were studied following intravenous administration in males. The resultant plasma concentration-time curves were described by bi-exponential equations. The half-life of the first exponent was 2–5 min. for both compounds while that of the second exponent was 13–19 min. and 3.5–4.5 hr. for ASA and SA, respectively. Over the dose range 0.3–1.2 g. ASA, the area under the ASA plasma concentration-time curve was proportional to the dose administered. Also SA was shown to be the exclusive metabolite of ASA. Analysis of the present results, over the dose range and duration of study, showed that the data could best be fitted by conceiving the body to act as a two-compartmental open system with respect to these drugs. The significance of these findings on measurement of the rate constants of metabolism, volume of distribution, and other pharmacokinetic parameters are discussed.

It is an interesting fact that, although acetylsalicylic acid (ASA) has been consumed in tremendous quantities since its introduction in 1899, only scant information is available pertaining to the pharmacokinetics of this drug in man. This is all the more surprising as the salicylates have been the subject of two monographs (1, 2) and a symposium (3). Essentially, the problem has been an analytical one in that previous assays either did not differentiate between ASA and its metabolite, salicylic acid (SA), or estimated ASA as the increase in SA upon hydrolysis of the sample (4, 5), which is at best an insensitive method. More recently attempts have been made to increase the specificity of the assay using paper chromatography or selective extraction (6, 7).

Although ASA is known to be rapidly metabolized to SA *in vivo*, only the mean data of Leonards (8) and Lange and Bell (6) allow any estimate for the apparent elimination half-life, and values of 17 min. and 30 min. are obtained, respectively. However, in both studies, the drug was given orally so that estimates could be influenced by continued absorption of ASA during the decline of drug blood levels. The total urinary recovery of ASA as SA or its metabolites (9) suggests that SA is the only metabolite of ASA while 1.5% has been reported to be excreted unchanged in the urine of man (10). Much more information is available relating to SA owing to its high plasma levels, relatively long half-life, and ease of analysis (1–3). Nevertheless, there are little data on the kinetics of distribution of this drug in man.

In the present paper both ASA and SA have been given intravenously to man as their *N*-methylglucamine salt. The kinetics of distribution, metabolism, and excretion of each drug was then determined. Over the duration of this study it was found that the results can only be adequately explained by proposing as a minimum a two-compartmental open-system model for each drug. A preliminary communication of these results have been reported elsewhere (11).

EXPERIMENTAL

The dose of either ASA or SA was administered as its *N*-methylglucamine salt. Equivalent amount of acid and base were mixed together and dissolved in water for injection so that each dose was contained in 10-ml. final product. The solutions were passed through a bacterial filter into a sterile, multidose container and used immediately after preparation. The solutions were assayed for SA, and ASA, by UV, spectrophotofluorometric, and gas-liquid chromatographic procedures to verify contents.

Five male subjects were used in the study and each received a rapid intravenous injection (over 5–10 sec.) of 650 mg. ASA while on another occasion four of these subjects received 500 mg. SA. Blood samples (5 ml.) were usually taken at 0, 1, 2, 4, 6, 8, 10, 12, 15, 20, 25, 30, 35, 40, 50, 60, 70, 80, 90, 105, 120, 180, 240, 300, 360, and 480 min. following ASA administration, while slightly less frequent samples were taken in the SA study. In addition one subject was given 325 mg. ASA i.v. and in another study received a zero-order i.v. infusion of 1.24 g. ASA over a 50-min. period using a Harvard infusion pump. In the ASA study the collected blood samples were immediately placed into cooled tubes containing heparin and potassium fluoride (which inhibits further hydrolysis of ASA) and centrifuged. The plasma was then analyzed specifically for ASA using gas-liquid chromatography

while SA was determined spectrophotofluorometrically (12).

RESULTS AND DISCUSSION

In all subjects the ASA plasma-concentration-time curve following 650 mg. ASA i.v. was described by a bi-exponential equation of the form $C_p = Ae^{-\alpha t} + Be^{-\beta t}$ (*e.g.*, Fig. 1).[1] Both the initial distribution phase and the so-called elimination phase are extremely short with average half-lives of 2.8 and 15 min., respectively (Table I). Consequently, no ASA is present in the body 1 hr. following the intravenous dose. The rapid *in vivo* hydrolysis of ASA to SA causes the SA plasma level to rise sharply (40–50 mcg./ml.) and owing to its metabolic stability, the disposition half-life[2] was 3.0–4.5 hr. in this study, SA remains in the body for a long time after all the ASA has been eliminated.

The bi-exponential plasma curve can be interpreted in terms of a two-compartmental open system depicted as in Fig. 2.

In this model k_{12}, k_{21}, are the first-order rate constants for distribution of the drug between the central and so-called peripheral or tissue compartment while k_{13} is the elimination (metabolism and excretion) rate constant. V_p,C_p are the volume of the central compartment and the plasma concentration of drug, respectively, while V_T,C_T are the corresponding values for the tissue compartment (expressed relative to the central compartment). It follows from this model that dose administered = $V_pC_p^0$, where C_p^0 is the plasma concentration at zero time and can be seen to be numerically equal to the sum of the coefficients A and B in the bi-exponential equation describing the plasma concentration-time curve. The values of k_{12}, k_{21}, and k_{13} are calculated from A, B, α, and β (13). Also the model shows ASA distributing between two compartments while metabolism and excretion occur only in the central compartment, which includes the liver, kidneys, as well as blood. Needless to say, the model is an over-simplification of the body, but it is the minimum model required to fit the observed ASA data. Having assumed such a model, the various parameters were determined for each subject (Table II). As expected the distribution rate constants k_{12}, k_{21} are extemely fast with mean half-lives of 8.6 min. and 5.8 min. (*i.e.*, $0.693/k_{12}$, $0.693/k_{21}$). More noteworthy is the value of the elimination rate constant k_{13}, which is of the same magnitude as k_{12} and k_{21}, and is approxmately twice that of the disposition rate constant β (Table I). In fact, the only reason that the latter phase has a half-life as long as 15 min. ($0.693/\beta$) instead of 6.7 min. ($0.693/k_{13}$) is due to distribution of ASA into the peripheral compartment so that effectively less is available for immediate metabolism.

In further experiments subject A received 325 mg., 650 mg., and 1.24 g. ASA i.v. on separate occasions and the ASA areas (area/g. dose) were 1460, 1460, and 1390, respectively. Thus, proportionality between area and dose exists over the range studied and could only occur if the rate constants do not change with dose. Since the disposition half-life of SA is dose dependent, increasing with higher doses, proportionality between SA area and dose is not expected.

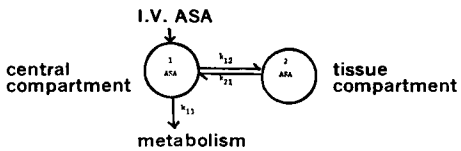

Fig. 2—Schematic diagram showing the distribution and metabolism of ASA following i.v. administration.

[1] As discussed by Riegelman *et al.* (13), the terms α and β are the fast and slow disposition rate constants, respectively, while the term disposition half-life is the value $0.693/\beta$ referred to by others as the elimination or biological half-life.

[2] The authors observed, among others (14,15), that the disposition half-life of SA varies with dose. The half-life values reported here are those obtained following either 650 mg. ASA or 500 mg. SA.

Mean			3.8	238

Before attempting to interpret the SA plasma levels resulting from the ASA dose, SA was given intravenously. A dose level of 500 mg. was chosen as this would result from complete hydrolysis of 650 mg. ASA. The resulting plasma levels, like those of the ASA study, showed a bi-exponential curve in the four subjects examined. However, whereas the distribution half-life (3.8 min.) is similar to ASA, the disposition half-life[3] is much longer (Table III). As with ASA, the results were interpreted in terms of a two-compartmental model, and the corresponding rate constants k_{12}, k_{21}, and k_{13} were calculated (Table IV). These analyses confirm that the major difference between ASA and SA is one of metabolic stability since the corresponding k_{12}, k_{21} values of SA and ASA for each subject are similar whereas the k_{13}^{ASA} is 15 times k_{13}^{SA}.

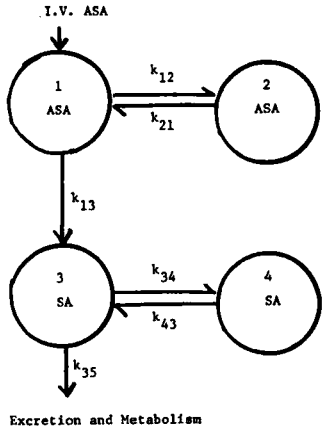

Fig. 3—Schematic diagram for the distribution and elimination of ASA and SA following an i.v. dose of ASA (650 mg.).

this model k_{13} is shown to be the only route of elimination of ASA and to be equal to the rate constant for conversion of ASA to SA. Obviously urinary excretion of unchanged drug and other metabolites are also possibilities. However, the contribution of excretion is small as only 1.5% of the dose has been reported to be excreted unchanged and may be ignored (10). The second possibility was discounted

Mean		0.078	0.110	0.0049	9.1	6.2	142

From the foregoing results and discussion, the scheme in Fig. 3 is proposed to describe the pharmacokinetics of ASA and SA following an intravenous injection of ASA to man. In this diagram, $k_{34} = k_{12}^{SA}$, $k_{43} = k_{21}^{SA}$ and $k_{35} = k_{13}^{SA}$ as in Table IV. In when calculations showed that the SA area[4] following 650 mg. ASA was equal to that obtained from 500 mg. SA administration (Table V). Since 650 mg. ASA is equivalent to 500 mg. SA the above result can only occur when SA is the sole metabolite of ASA,

[3] After the distribution phase the SA plasma levels for the 8-hr. period over which most studies were conducted could be fitted by a straight line when plotted on semilogarithmic paper. Literature evidence (16) and the authors' observations, however, show that SA plasma levels exhibit a curvature if followed long enough. Hence the β^{SA} and k_{13}^{SA} values calculated are only apparent constants but are adequate for describing the levels observed during the course of these experiments.

[4] In calculating the total area under the SA concentration time curve, it was assumed that the observed apparent disposition half-life (0.693/β) would not change with time so that the extra area subsequent to the 8-hr. study is determined by $C_{8A} \cdot 1/\beta$ where C_{8A} is the last plasma data point. It was reasoned that even if curvature of the plasma SA took place it would be similar for both i.v. SA and SA produced from ASA, so that the error introduced in comparing the relative areas would not be appreciable.

and therefore, k_{13} has the meaning depicted in Fig. 3.

The pharmacokinetics of these salicylates were studied further using a PACE TR 48 analog computer (the differential equations and analog diagram of which are given in the appendix). As expected the computer curves fitted the observed i.v. ASA, and SA data (Fig. 4). Additional evidence in favor of the proposed model (Fig. 3) was obtained when, using the rate constants calculated for each subject (except E which received no i.v. SA), there was an excellent fit between observed and predicted SA levels resulting from i.v. ASA, *e.g.*, Fig.

TABLE V—COMPARISON OF THE AREA UNDER THE SALICYLIC ACID PLASMA CONCENTRATION-TIME CURVE FOLLOWING 650 MG. ASA AND 500[a] MG. SA I.V.

[a] Areas corrected to a 500-mg. SA dose.

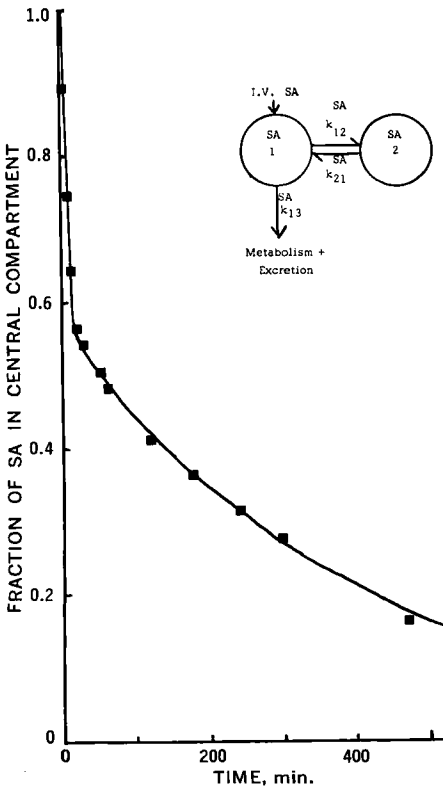

Fig. 4—Graph showing the observed and predicted values for the fraction of SA in the central compartment following 484 mg. i.v. SA administration. Subject B. Key: ■, experimental SA; ———, predicted analog computer curve.

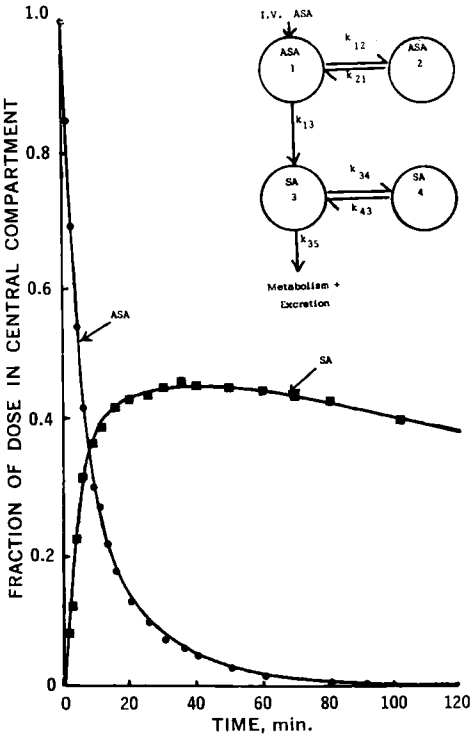

Fig. 5—Graph showing the observed and predicted values for the fraction of the dose as ASA and SA in the central compartment following i.v. administration of 650 mg. ASA. Subject D. Key: ●, experimental ASA; ■, experimental SA; ———, predicted analog computer curves.

5. It should be noted that in Fig. 4 and in subsequent analog computer curves the concentration terms have been replaced by the fraction of each drug present in the central compartment, otherwise overloading of the computer can occur. For the intravenous doses the fraction term is simply obtained by dividing the plasma concentration by the corresponding value of C_p^0. The SA data obtained from i.v. ASA were normalized by making the maximum SA plasma concentration equal to the peak fraction of the dose as SA in the central compartment which had been obtained from the analog computer curves.

It is apparent that an alternative model, in which ASA hydrolysis takes place exclusively in the peripheral compartment or partially in both, may also account for the observed data. The former was eliminated since it is known that ASA is hydrolyzed in whole blood which is an essential part of the central compartment. The latter model was further examined using the analog computer and like the model depicted in Fig. 3 it also fitted the ASA plasma data (*e.g.*, Fig. 6). However, unlike the originally proposed model, the one assuming partial peripheral metabolism resulted in a lower rate of appearance of plasma SA than the experimental data. Any attempts at varying the SA rate constants, while maintaining the same ASA constants determined for the model involving peripheral metabolism of ASA (model B, Fig. 6), in order to increase the rate of appearance of plasma SA but still fitting the i.v. SA data, proved unsuccessful in all subjects. It was,

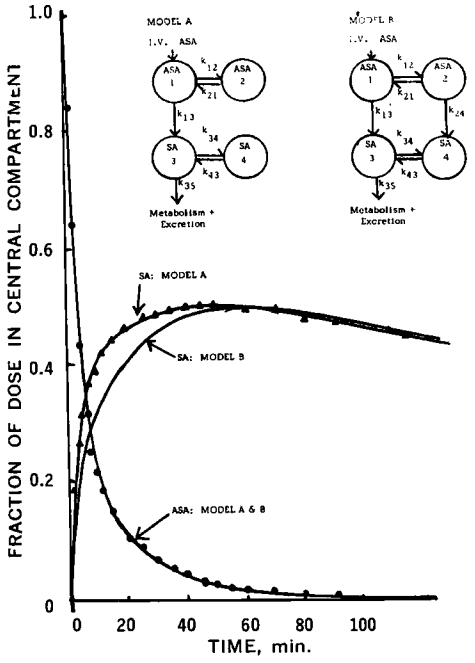

Fig. 6—Graph showing the observed and predicted values for the fraction of the dose as ASA and SA in the central compartment following i.v. administration of 650 mg. ASA. Model A assuming metabolism of ASA only in central compartment while model B assuming metabolism occurs in both compartments. Subject A. Key: ●, experimental ASA; ▲, experimental SA; ———, predicted analog computer curves. Model A, k_{12}, k_{21}, k_{13}, are 0.083, 0.104, 0.117 min.$^{-1}$, respectively. Model B, k_{12}, k_{21}, k_{13}, k_{24}, are 0.128, 0.094, 0.090, and 0.030 min.$^{-1}$, respectively, while k_{34}, k_{43}, and k_{35}, are 0.070, 0.105, and 0.0044 min.$^{-1}$ for both models.

therefore, concluded that the model proposed in Fig. 3 describes the observed kinetics of distribution, metabolism, and excretion of both ASA and SA.

The volume of distribution is another parameter which is used to characterize a drug. In terms of the two-compartmental model this is defined by the relationship (17).

$$V_{d_{ss}} = V_p \left(\frac{k_{12} + k_{21}}{k_{21}} \right) \qquad \text{(Eq. 1)}$$

where $V_{d_{ss}}$ is the volume of distribution at steady state of equilibrium, and is the only definition independent of k_{13}, the elimination rate constant. Assuming a single-compartmental model, the volume of distribution, V_d, is obtained by dividing the dose administered by the extrapolated intercept value for the concentration at zero time which, in terms of the two-compartmental model, is expressed by:

$$V_d = \frac{\text{dose}}{B} \qquad \text{(Eq. 2)}$$

The values of $V_{d_{ss}}$ and V_d for ASA and SA following their respective i.v. doses have been calculated and are listed in Table VI. Comparison of the respective values for ASA shows that the V_d may be twice as large as $V_{d_{ss}}$ due to significant metabolism of ASA occurring during the distribution phase of this drug, which is ignored in the single-compartment

TABLE VI—VALUES OF V_p[a], $V_{d_{ss}}$, AND V_d FOR ASA and SA

model. Had the V_d term been used to compare these drugs, one could be led to the erroneous conclusion that the volume of distribution of ASA is almost twice that of SA. Contrary to this, the V_p and $V_{d_{ss}}$ for these two drugs are very similar with the ASA values being slightly larger than those of SA in each subject. This may be due to protein binding since SA has a much greater affinity for albumin than ASA (18) so that more SA would be held in the plasma and lower V_p and $V_{d_{ss}}$ would be expected. Other possible factors are differences in pKa and lipid solubility. Nevertheless, the difference between these drugs is not very great.

In contrast to ASA there is only a very small difference between the $V_{d_{ss}}$ and V_d for SA owing to negligible elimination occurring during the distribution phase of this drug. Therefore, with respect to the above calculations for SA either compartmental

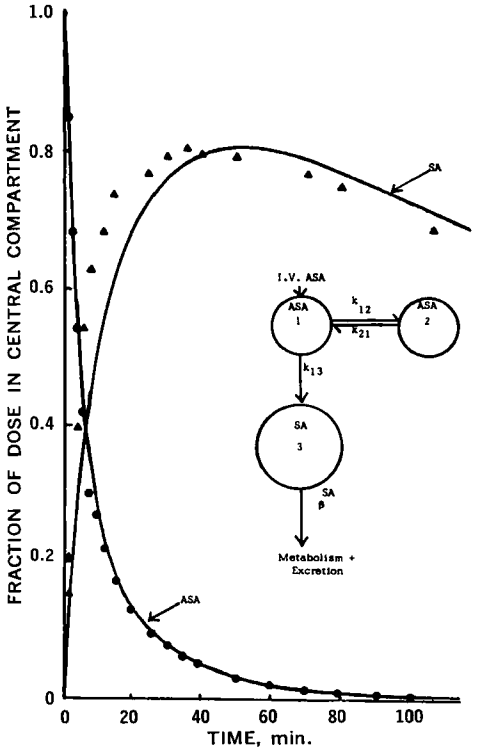

Fig. 7—Graph showing the observed and predicted values for the fraction of the dose and ASA and SA in the central compartment following i.v. administration of 650 mg. ASA and assuming single compartment for SA. Subject B. Key: ●, experimental ASA; ▲, experimental SA; ———, predicted analog computer curve.

model would be satisfactory. However, the two-compartmental model cannot be reduced to the single-compartmental model in all situations. If the latter model were substituted for SA in the schematic diagram describing the pharmacokinetics of ASA and SA (Fig. 3), the resultant predicted SA levels rise much more slowly than the observed values (Fig. 7). This results from the rapid metabolism of ASA to SA, such that SA builds up in the central compartment faster than it distributes. Hence, higher plasma levels are observed than one would expect using the single-compartment SA model which assumes spontaneous distribution of this drug. The V_p is a constant of the model, and although it is approximately 6 l. for either salicylate, it should not be equated to a physiological space such as the blood volume, even though their sizes are similar. Thus had whole blood been used instead of plasma, then as 70–80% of the salicylate is in the plasma (19), V_p values of approximately 10.1 would have been calculated.

Cummings (20, 21) observed that, following 0.65-g. plain aspirin tablets, peak plasma salicylate levels were at 1 hr. while excretion rate reached a maximum after 3 hr. To explain these results he suggested that distribution of SA was extremely slow in man, 3 or more hr. being required for equilibrium and that it was the tissue concentration, rather than the plasma, that controlled the excretion of this drug. Examination of the present data shows that distribution is very rapid and equilibrium (when tissue concentration is at a maximum) can be achieved within 20 min. following i.v. SA (Fig. 8). Probably, the explanation of Nelson and Levy (22) is correct in which they showed that the assay used by Cummings measures both SA and its glycine conjugate, salicyluric acid. Since plasma contains

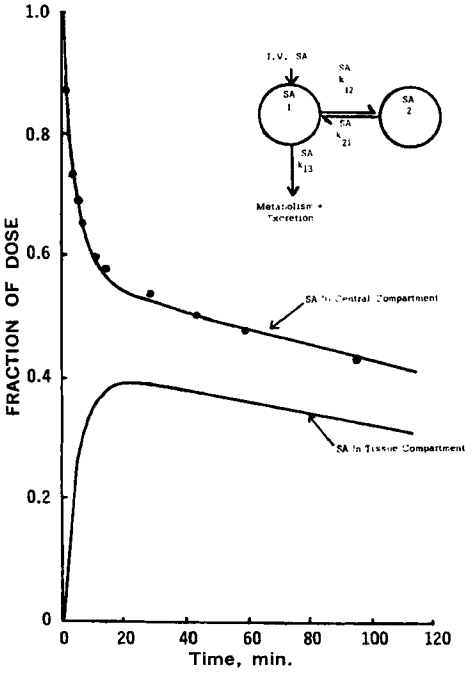

Fig. 8—Graph showing fraction of the dose in the central and tissue compartment following i.v. administration of SA. Subject B. Key: ●, experimental SA; ———, predicted analog computer curve.

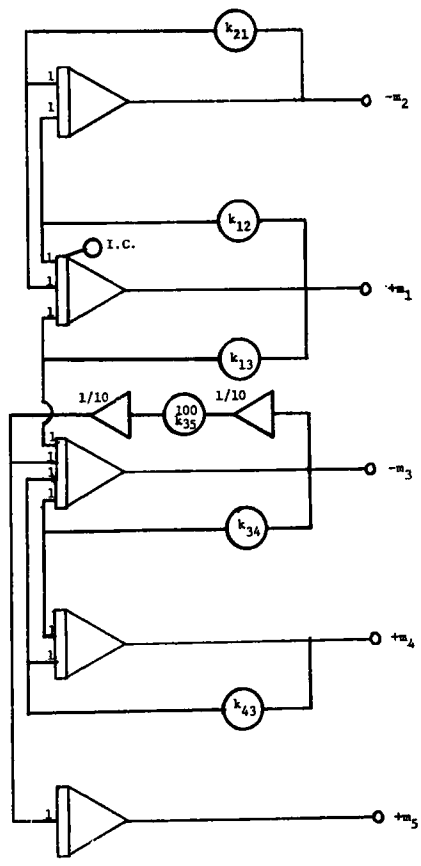

Fig. 9—Analog computer program.

predominately SA and urine mostly salicyluric acid (9) it follows from the precursor–product relationship that the maximum rate of excretion of total salicylate will be later than the peak plasma level.

An estimate of the contribution of whole blood to the *in vivo* hydrolysis of ASA in man can be made from the present data. Since the *in vitro* rate constant for the hydrolysis of ASA in human whole blood at 37° is 0.023 $min.^{-1}$ (23) and the blood volume is 5 l., the expected *in vivo* clearance (volume × rate constant) of ASA by blood is 115 ml./min. From the i.v. data the whole body clearance ($V_p \cdot k_{13}^{ASA}$) of ASA is 660 ml./min. (6,600 × 0.103). Consequently, whole blood only accounts for approximately 20% of total hydrolysis in man, and probably liver and perhaps kidney, are the major sites of ASA esterase activity. The implication that liver is the important metabolizing organ for ASA has been subsequently demonstrated (11). Obviously, as all the hepatic portal blood must pass through the liver this high hepatic clearance of ASA will significantly influence the amount of intact ASA which reaches the general circulation following oral administration of ASA.

Analysis of the present results has allowed a clearer understanding of the pharmacokinetics of ASA in man. Comparison shows that other than metabolic stability the pharmacokinetics of ASA and SA are very similar. However, even though the present model is useful, it must be emphasized that this model only describes the disposition kinetics

of SA at essentially one dose level, and consistency at one level is no test of a model. Since it is known that SA elimination kinetics do change with dose, more information is needed before a model can be proposed which will adequately describe the observed data at all dose levels of this drug.

APPENDIX

The mass equations describing the scheme in Fig. 3 are:

$$-\dot{m}_1 = k_{12} \cdot m_1 + k_{13} \cdot m_1 - k_{21} \cdot m_2 \quad \text{(Eq. 1a)}$$

$$\dot{m}_2 = k_{12} \cdot m_1 - k_{21} \cdot m_2 \quad \text{(Eq. 2a)}$$

$$\dot{m}_3 = k_{13} \cdot m_1 - k_{34} \cdot m_3 - k_{35} \cdot m_3 + k_{43} \cdot m_4 \quad \text{(Eq. 3a)}$$

$$-\dot{m}_4 = -k_{34} \cdot m_3 + k_{43} \cdot m_4 \quad \text{(Eq. 4a)}$$

$$-\dot{m}_5 = -k_{35} \cdot m_3 \quad \text{(Eq. 5a)}$$

$$\text{Dose} = m_1 + m_2 + m_3 + m_4 + m_5 \quad \text{(Eq. 6a)}$$

where m_x is the amount of durg in compartment x. The analog computer program for this scheme is shown in Fig. 9.

Differential Ninhydrin Chromatographic Assay for the Gentamicin Complex

By GERALD H. WAGMAN, JANET V. BAILEY, and MORTON M. MILLER

A differential ninhydrin chromatographic assay has been devised to quantitatively determine the proportions of the three gentamicin components in gentamicin preparations. The technique consists of separation of the antibiotics on paper using the lower phase of a solvent system composed of chloroform, methanol, and 17 percent ammonium hydroxide (2:1:1 v/v). After development, strips containing the antibiotic are treated with ninhydrin reagent, developed, and color intensities read on an integrating scanner from which component proportions can be determined. Results are in excellent agreement with the microbiological method.

RECENTLY, Weinstein *et al.* (1) reported that preparations of the gentamicin complex consist of three antibiotic components which have been designated C_1, C_1a, and C_2 and that there are no significant differences in their biological properties. It became desirable therefore to devise methods for detection, isolation, and assay of these components. Thin-layer, paper, and column chromatographic separation techniques have been described by Wagman *et al.* (2) using a solvent system composed of chloroform–

Differential Ninhydrin Chromatographic Assay for the Gentamicin Complex

By GERALD H. WAGMAN, JANET V. BAILEY, and MORTON M. MILLER

A differential ninhydrin chromatographic assay has been devised to quantitatively determine the proportions of the three gentamicin components in gentamicin preparations. The technique consists of separation of the antibiotics on paper using the lower phase of a solvent system composed of chloroform, methanol, and 17 percent ammonium hydroxide (2:1:1 v/v). After development, strips containing the antibiotic are treated with ninhydrin reagent, developed, and color intensities read on an integrating scanner from which component proportions can be determined. Results are in excellent agreement with the microbiological method.

RECENTLY, Weinstein *et al.* (1) reported that preparations of the gentamicin complex consist of three antibiotic components which have been designated C_1, C_1a, and C_2 and that there are no significant differences in their biological properties. It became desirable therefore to devise methods for detection, isolation, and assay of these components. Thin-layer, paper, and column chromatographic separation techniques have been described by Wagman *et al.* (2) using a solvent system composed of chloroform–

Accepted for publication April 23, 1968.

methanol–17% ammonium hydroxide (2:1:1 v/v).

A differential paper chromatographic microbiological assay has been reported (3) which utilizes this solvent system and is based on bioanalytical methods for determinations of penicillin mixtures. The method consists of chromatographing samples containing gentamicin together with a series of standards on paper strips, bioautographing the strips against *Staphylococcus aureus* on standardized assay plates, and measuring the diameters of the zones of inhibition of the separated components. Standard curves are constructed, and the concentration of each of the components in a sample of unknown composition is determined from an appropriate curve.

A chemical method has now been devised to carry out the differential analysis of the gentamicin components and is described here. While this new technique uses the chromatographic solvent system as reported in the bioanalytical assay, it does not require biological procedures. After chromatographic separation the papers are treated with ninhydrin, heated at 105° to develop the color, and run through an integrating scanner. The quantities of the individual components are determined by the peak intensities of the chromatogram zones. Although the quantity of material required in this method is somewhat greater than in the microbiological assay procedure, the technique is simple and reproducible.

EXPERIMENTAL

Apparatus and Materials

(*a*) Standard rectangular chromatographic tanks with troughs 30.5 × 30.5 × 61 cm. high (12 × 12 × 24 in.); insulate the outsides completely with paper.

(*b*) Schleicher and Schuell No. 589 blue ribbon chromatographic paper cut to size 20 × 58 cm. (along grain).

(*c*) Integrating scanner—instrument used for the determinations to be described was the model RB Analytrol, manufactured by Beckman Instruments, Inc., Fullerton, Calif.

(*d*) Reagents—the purest available reagent grade chemicals were used. The 17% ammonium hydroxide was made by mixing 600 ml. concentrated NH_4OH with 400 ml. water. Gentamicin C_1, C_1a, and C_2 standards were obtained as the sulfates and converted to their respective free bases by use of small columns of IRA 401S resin (Rohm and Haas) in the hydroxyl form and the solutions lyophilized. All standards were dried at 60° under vacuum for 3 hr. prior to use. Ninhydrin reagent (triketo hydrindene hydrate) was prepared fresh daily as a 0.25% solution by dissolving in a 1:1 mixture of pyridine–acetone.

Methods

Chromatographic Solvent and Conditions—The solvent is prepared by mixing together chloroform, methanol, and 17% NH_4OH in a ratio of 2:1:1 (v/v) in a separator and allowing the layers to separate. The lower layer is placed in the bottom of the chromatographic jar, and the upper layer is placed in a beaker with a wick at the bottom of the jar. The jar is equilibrated for several hours prior to use. The lower layer is used for development of the chromatograms. Optimum temperature for development is in a range of from 20 to 25°, and it is important that the temperature at which the chromatograms are run be maintained at a constant level.

Preparation of Standards and Samples—Gentamicin standards consisting of individual solutions of the C_1, C_1a, and C_2 components, either all as the sulfates or all as free bases, are dissolved in water to give concentrations of exactly 50 mg./ml. Equal volumes of each component standard are mixed together to give a solution containing the three components in a 1:1:1 ratio. Three replicate standard solutions are prepared in this manner. Samples in which the ratios of the gentamicin components are to be determined are dissolved in water to give a concentration of about 50 mg./ml.

Preparation and Development of Chromatograms—A line is drawn approximately 7 cm. from the end of each strip and 5-μl. quantities of each standard mixture are pipeted twice on triplicate spots equidistant from each other. This results in three chromatographic sheets containing a total of nine standard mixtures at a level of 500 mcg./spot.

The samples to be assayed are spotted in exactly the same manner as the standards, three spots for each unknown, using 10 μl./spot (two increments of 5 μl.).

The papers are placed in the chromatographic jars and solvent added to the troughs immediately. No equilibration is necessary. The papers are developed, descending, for 18 hr., and air dried for 15 min. to remove solvent. The sheets are pulled through a trough of ninhydrin reagent, dried in a fume hood, and heated for 5 min. at 105° to develop the color. The gentamicin C_1 zone is found nearest to the front, followed by C_2, and the zone closest to the origin is designated as C_1a. A chromatogram showing the relative positions of the components is illustrated in Fig. 1.

Scanning Chromatograms and Computations—The chromatograms are cut into strips 3.2 cm. (1¼ in.) in width and reference lines are marked on both ends of the papergrams beyond the last zone and before the origin. The strips are put through the integrating scanner using a slit width of 1.5 mm., and the zone intensities are automatically plotted and integrated. The chromatogram is lined up with

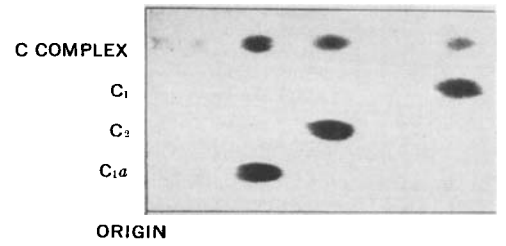

Fig. 1—Ninhydrin-treated chromatogram illustrating separation of gentamicin components using chloroform–methanol–17% ammonia (2:1:1 v/v) solvent system.

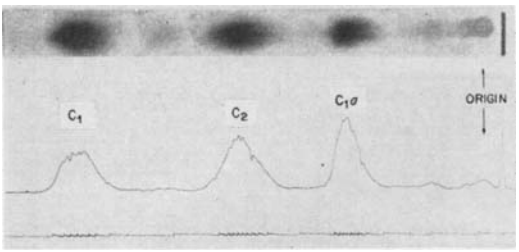

Fig. 2—Integrated scan of ninhydrin reaction following paper chromatography. Instrument used was Beckman Analytrol model RB, slit width = 1.5 mm. Upper curve is densitometer scan; lower, sawtooth line is integrator trace.

its scan using the reference marks, and the total scan area and area under each peak is determined for each chromatographic strip. A typical chromatogram of a gentamicin mixture and its integrated scan is illustrated in Fig. 2. Ratios of ninhydrin intensity of standards in a mixture containing equal weights of components can then be calculated as will be described. Results for each group of nine reference standards are averaged to obtain a final set of values.

Comparison of ninhydrin reactivity for each of the gentamicin base component standards showed that the intensity of color varied with $C_1a > C_2 > C_1$. This was true also for the sulfates, but the ratios were somewhat different. For the free bases, if C_1a is assigned a ninhydrin peak value of 1.00, then an equal quantity of C_2 results in a less intense color reaction and a value of 0.58 (58% of the intensity of color for an equal weight of C_2 compared to C_1a). For the C_1 component, the value is 0.52. Therefore, in order to calculate the correct proportions of components in an unknown mixture, it is necessary to multiply the C_1 and C_2 peak integrations by the appropriate factor (the reciprocal of the color intensity) to compensate for the differences in intensity between those components and C_1a. Similarly, for the sulfates, this compensation must also be made. The peak intensities and correction factors (reciprocals) for the bases and sulfates are summarized in Table I.

TABLE I—COMPARISON OF INTENSITY OF NINHYDRIN REACTIONS ON CHROMATOGRAMS FOR INDIVIDUAL COMPONENTS OF THE GENTAMICIN COMPLEX

Derivative	Component	Relative Intensity of Ninhydrin Spot	Factor, Reciprocal of Intensity
Base	C_1a	1.000	1.00
	C_2	0.578	1.73
	C_1	0.518	1.93
Sulfate	C_1a	1.000	1.00
	C_2	0.485	2.06
	C_1	0.397	2.52

Samples of unknown composition are run in a manner similar to that for the standard mixtures. After integration of component peaks, the peak areas are multiplied by the appropriate factors for each compound and the corrected intensities for each zone are added together. The percentage of each component can be calculated by dividing the number of integrations for each chromatogram zone by the total number for the complex. The three replicate sets of chromatogram data are averaged to obtain final results.

RESULTS AND DISCUSSION

Assay responses using the ninhydrin differential assay were compared to results obtained by the previously described microbiological method on six lots of gentamicin sulfate. Using the antibacterial potencies of C_1, C_1a, and C_2 gentamicins (assayed against the same working standard) it was possible to convert the percentages by weight to percentages based on activity.

Table II indicates the average assay results obtained using the ninhydrin assay both by weight and activity compared to the results obtained for the same samples in the microbiological assay. Assay variation as determined by a series of completely randomized analyses of variance indicates the residual error to be in excellent agreement with the biological procedure.

It has been found that a significantly high correlation ($p < 0.01$) exists between the biological assay and the ninhydrin assay, both by weight and activity. The product-moment correlation coefficient indicates the degree of association between the two assay procedures where −1.0 indicates perfect negative correlation and +1.0 indicates perfect positive correlation. These data are summarized in Table III and are a reflection of the data given in Table II, where each observation is a mean of three values.

TABLE V—CORRELATION OF NINHYDRIN DIFFERENTIAL ASSAY WITH MICROBIOLOGICAL ASSAY FOR GENTAMICIN BATCHES CONVERTED TO THEIR FREE BASES

Component	Correlation Coefficient—Weight	Activity
C_1	0.98	0.97
C_1a	0.98	0.98
C_2	0.93	0.96

As a second step, the six samples under consideration were converted to their free bases by means of an ion-exchange resin. The identical assay was performed using factors for the ninhydrin intensities of the compounds determined on known mixtures of the free bases of all of the components (Table I). The average response for these samples by weight and activity are presented in Table IV and are compared to the results obtained in the microbiological differential assay.

The correlations between the two assays using the free base mixtures measured by weight and activity are shown in Table V. All of the correlations are significant ($p < 0.01$).

The differential ninhydrin assay which has been described for the quantitative determination of the components of the gentamicin complex is highly reproducible and easier to perform than is the microbiological method. A significant correlation exists between the results obtained in the two procedures, and this new assay should therefore be very useful in determining proportions of the three gentamicin components in mixtures of the complex.

Dissolution Kinetics of Drugs in Human Gastric Juice—the Role of Surface Tension

By PER FINHOLT and SISSEL SOLVANG

The kinetics of *in vitro* dissolution of phenacetin and phenobarbital in human gastric juice have been determined and compared to those in hydrochloric acid containing various amounts of polysorbate 80. The surface tension of the dissolution medium is shown to have an appreciable effect on the dissolution kinetics of the drugs studied.

DURING THE LAST YEARS, a number of rate studies on the dissolution of drugs have been conducted. An excellent review of these is given by Wurster and Taylor (1). Various dissolution media have been used, but, surprisingly enough, not that solvent, in which the dissolution process takes place *in vivo*—that is, human gastric juice.

The purpose of this investigation was to study the rate of dissolution of drugs in human gastric juice. In addition, a closer examination of the

TABLE V—CORRELATION OF NINHYDRIN DIFFERENTIAL ASSAY WITH MICROBIOLOGICAL ASSAY FOR GENTAMICIN BATCHES CONVERTED TO THEIR FREE BASES

Component	Correlation Coefficient—Weight	Activity
C_1	0.98	0.97
C_1a	0.98	0.98
C_2	0.93	0.96

As a second step, the six samples under consideration were converted to their free bases by means of an ion-exchange resin. The identical assay was performed using factors for the ninhydrin intensities of the compounds determined on known mixtures of the free bases of all of the components (Table I). The average response for these samples by weight and activity are presented in Table IV and are compared to the results obtained in the microbiological differential assay.

The correlations between the two assays using the free base mixtures measured by weight and activity are shown in Table V. All of the correlations are significant ($p < 0.01$).

The differential ninhydrin assay which has been described for the quantitative determination of the components of the gentamicin complex is highly reproducible and easier to perform than is the microbiological method. A significant correlation exists between the results obtained in the two procedures, and this new assay should therefore be very useful in determining proportions of the three gentamicin components in mixtures of the complex.

Dissolution Kinetics of Drugs in Human Gastric Juice—the Role of Surface Tension

By PER FINHOLT and SISSEL SOLVANG

The kinetics of *in vitro* dissolution of phenacetin and phenobarbital in human gastric juice have been determined and compared to those in hydrochloric acid containing various amounts of polysorbate 80. The surface tension of the dissolution medium is shown to have an appreciable effect on the dissolution kinetics of the drugs studied.

DURING THE LAST YEARS, a number of rate studies on the dissolution of drugs have been conducted. An excellent review of these is given by Wurster and Taylor (1). Various dissolution media have been used, but, surprisingly enough, not that solvent, in which the dissolution process takes place *in vivo*—that is, human gastric juice.

The purpose of this investigation was to study the rate of dissolution of drugs in human gastric juice. In addition, a closer examination of the

relationship between the surface tension of the fluid and the dissolution rate of drugs was felt needed. The reason for this was that previous studies on the rate of dissolution of drugs from powders, granules, and tablets had shown that the surface properties of the solid particles was an important factor (2, 3).

EXPERIMENTAL

Materials—The powdered drugs used were of Pharmacopoea Nordica grade. They were separated into the desired size fractions by sieving.

The gastric juice was delivered from a hospital department engaged in testing the gastric secretion of patients under examination for diseases of the stomach.[1] It would of course have been desirable to use gastric juice from healthy persons; but such large amounts were needed for the experiments that it was quite impossible to get enough from healthy volunteers.

The gastric juice obtained from each patient was collected on an empty stomach, 1 hr. before and 1 hr. after stimulation with large doses of histamine (subcutaneous injection). Immediately after collection the gastric juice was frozen at about −20° and stored at this temperature in a freezer until it was to be used. The time of storage was usually 3–4 weeks. However, the gastric juice could be stored at −20° for months, without changing properties like pH and surface tension.

When gastric juice was to be used as dissolution medium, samples from 25–30 different persons were mixed and then diluted with an equal amount of water. Water was added since powders and tablets normally are swallowed with water and the dissolution process *in vivo* thus takes place in a mixture of gastric juice and water.

Determination of Dissolution Rate—The dissolution rate was determined by the beaker method of Levy (4) with minor changes.

Procedure A—The dissolution assembly consisted of a 1-l. Pyrex beaker immersed in a constant-temperature bath adjusted to 37.5°, and a flat, straight-blade (6 cm. diam. and 1.5 cm. high) stainless steel stirrer attached to an electric stirring motor giving the stirrer a constant and easily adjustable speed of rotation.

Five-hundred milliliters of the dissolution medium was placed in the beaker and permitted to equilibrate to 37.0°. The stirrer was immersed into the middle of the liquid and rotated at a speed of 50 r.p.m. A certain amount of the drug powder (1.0 g. of phenacetin, 2.0 g. of phenobarbital, 2.4 g. of sodium phenobarbital) was gently spread over the surface of the fluid. During the test the powder would partly remain on the surface and partly settle down through the fluid. At appropriate intervals 5-ml. samples were withdrawn by means of pipets provided with short plastic tubings filled with glass wool or fritted-glass immersion filter tubes of medium porosity for filtration of the sample. The samples were analyzed and the drug concentration found was plotted *versus* time.

Procedure B—A 250-ml. beaker, a flat, straight-blade (4 cm. diam. and 1.5 cm. high) stirrer, 100 ml. of the dissolution medium, and 0.5 g. of the drug were used and 2-ml. samples were withdrawn. Otherwise Procedure B was the same as Procedure A.

Analytical Methods—*Determination of Phenacetin*—The samples withdrawn were diluted with water and absorbancies were measured at 245 mμ with a Beckman DK 2A spectrophotometer.

Determination of Phenobarbital—The samples withdrawn were mixed with borate buffer pH 9.5 and diluted with water. Absorbancies were measured at 240 mμ.

Determination of Solubility—The solubilities of the drugs were determined by using the beaker method and following the dissolution process until the dissolution medium became saturated with drug.

RESULTS AND DISCUSSION

Effect of Surfactant on Dissolution Rate—Phenacetin was chosen as model substance because of its hydrophobic properties. Polysorbate 80 was used as surfactant.

Figure 1 shows the rate of dissolution of phenacetin in 0.1 *N* HCl to which different amounts of polysorbate 80 had been added. An increase in the

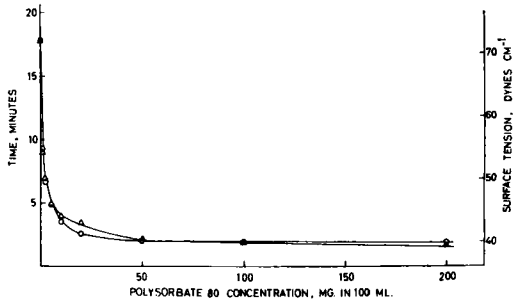

Fig. 2—Relationship between the polysorbate concentration of the dissolution medium (0.1 N HCl) and the time necessary for dissolution of 100 mg. of phenacetin (0.21–0.30 mm.); and the relationship between the polysorbate concentration of the dissolution medium and the surface tension of the same. Key: ○, time; △, surface tension.

[1] The authors want to thank Dr. J. Myren, Medical Department IX, Ullevål Hospital, Oslo, for the gastric juice and for information about the gastric secretion rate of the patients.

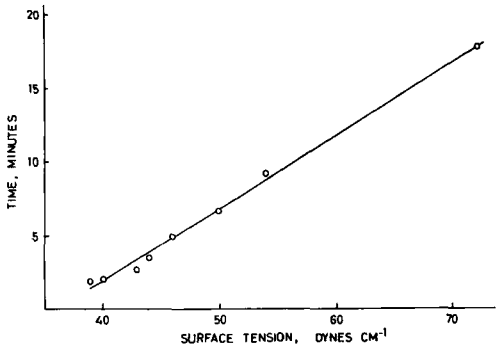

Fig. 3—Relationship between the surface tension, the dissolution medium and the time necessary for dissolution of 100 mg. of phenacetin (0.21–0.30 mm.). Dissolution media: 0.1 N HCl containing different amounts of polysorbate 80.

polysorbate concentration from 0 to 0.01% causes a significant increase in dissolution rate. Addition of further amounts of the surfactant has very little effect.

The times necessary for dissolution of 100 mg. of phenacetin in the different polysorbate–HCl mixtures can easily be picked from Fig. 1. In Fig. 2 these times are plotted *versus* the corresponding polysorbate concentrations. The same figure also shows the surface tension of the dissolution medium in relation to the concentration of polysorbate 80. The surface tension was measured at 20° with a Cenco Du Nouy tensiometer. It will be seen that the two curves are nearly superimposed. This means that a nearly linear relationship exists between the surface tension of the dissolution medium and the time necessary for dissolution of 100 mg. of phenacetin. This relationship is clearly demonstrated in Fig. 3.

The solubilities of phenacetin at 37° in 0.1 *N* HCl containing 0%, 0.001%, 0.01%, or 0.1% of polysorbate 80 were found to be 1.18 g./l., 1.26 g./l., 1.26 g./l., and 1.29 g./l., respectively. Polysorbate 80 in the concentrations used thus has a very small influence on the solubility of phenacetin in HCl. This means that the effect of polysorbate 80 on the rate of dissolution of phenacetin is due only to a small extent to its solubilizing power, but is caused mainly by its ability to decrease the interfacial tension between the substance and the dissolution medium. This result is in accordance with observations by Levy and Gumtow (5), who found that sodium lauryl sulfate enhanced the rate of dissolution of salicylic acid from compressed tablets. This effect was assumed to be due to increased wetting and to better solvent penetration into the tablets and granules as a result of the interfacial tension lowering effect of the surfactant.

Surface Tension of Human Gastric Juice—Since the surface tension of the dissolution medium seems to be a deciding factor as far as dissolution rate is concerned, it is of great interest to know the surface tension of human gastric juice. However, no values could be found in the literature. Therefore, a determination of the surface tension was made using gastric juice collected from a large number of persons under examination for diseases of the stomach. Samples of fasting as well as of histamine-stimulated secretion were tested. Table I shows the gastric secretion rate and the pH and surface tension of the gastric juice from some of the persons tested.

The results of the whole test are shown in Fig. 4, where the surface tension of the samples is plotted *versus* their pH. There is no significant correlation between these properties. The calculated correlation coefficient was less than the theoretical one at the 5% probability level. From these experiments it appears that the surface tension of human gastric juice is nearly independent of pH and secretion rate, having a value between 35 and 50 dynes cm.$^{-1}$.

water caused an increase in the surface tension of only 1–3 dynes cm.$^{-1}$.

Rate of Dissolution of Drugs in Diluted Gastric Juice[2]—Figure 5 shows that the rate of dissolution of phenobarbital (0.21–0.30 mm.[3]) in diluted gastric juice is substantially higher than the rate of dissolution in 0.1 *N* HCl. This was to be expected, since the diluted gastric juice has a much lower surface tension than the 0.1 *N* HCl. In addition, the solubility of phenobarbital at 37° was found to be slightly higher in diluted gastric juice (2.00 g./l.) than in 0.1 *N* HCl (1.90 g./l.).

Since phenobarbital is used in medicine not only as the free acid, but also as the sodium salt, the rate of dissolution of the salt in diluted gastric juice was determined and compared to the rate of dissolution of the salt in an HCl solution having the same pH as the diluted gastric juice. Figure 6 shows that initially nearly the same, high drug concentration is obtained in both dissolution media. However, the precipitation of the free acid in excess of solubility takes place at a much slower rate in gastric juice than in hydrochloric acid. Gastric juice obviously contains substances retarding the precipitation of the acid.

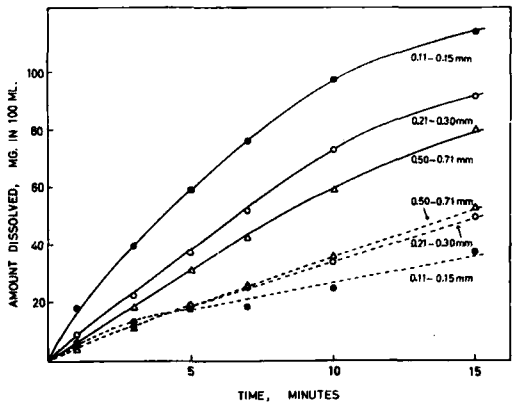

Fig. 7—Effect of particle size on dissolution rate of phenacetin in 0.1 N HCl and in diluted gastric juice. Key: – – –, 0.1 N HCl; ——, diluted gastric juice

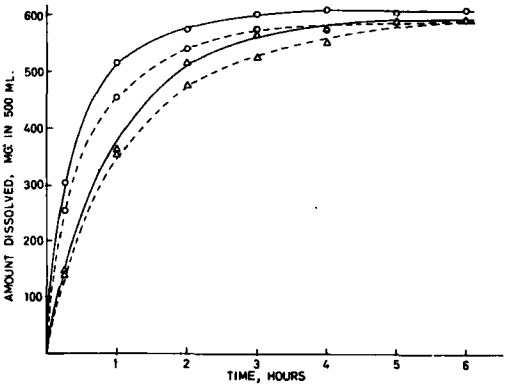

Fig. 8—Rate of dissolution of phenacetin (0.21–0.30 mm.) in diluted gastric juice and in diluted hydrochloric acid at the same pH and surface tension. Key: ——, diluted gastric juice (pH 1.6); – – –, diluted HCl + polysorbate 80 (pH 1.6); ○, surface tension 40.9 dynes cm.$^{-1}$; △, surface tension 50.7 dynes cm.$^{-1}$.

Effect of Particle Size on Dissolution Rate of Drugs in Diluted Gastric Juice—The solid lines in Fig. 7 show the effect of particle size on the rate of dissolution of phenacetin in diluted gastric juice. It is seen that the rate increases with decreasing particle size, whereas the opposite is the case when 0.1 *N* HCl is used as dissolution medium, as will be seen from the dotted lines in the same figure. These results are in agreement with earlier findings (2). Under the conditions of the experiment the rate of dissolution of hydrophobic drugs *increases* with decreasing particle size when the dissolution medium has a low surface tension, *decreases* when the surface tension is high. Figure 7 also shows that all powder fractions tested dissolve faster in diluted gastric juice than in 0.1 *N* HCl. This is due not only to the lower surface tension of the diluted gastric juice, but also to the higher solubility of phenacetin in this solvent (1.38 g./l. at 37°) compared to the solubility in 0.1 *N* HCl (1.05 g./l. at 37°).

Rate of Dissolution of Drugs in Diluted Gastric Juice and in HCl Solution at the Same pH and Surface Tension—According to Figs. 5 and 7

hydrophobic drugs such as phenobarbital and phenacetin dissolve faster in gastric juice than in 0.1 *N* HCl, mainly because of the lower surface tension of the former. The question arises whether there will be any difference between the dissolution rates in the two solvents if an HCl solut on of the same pH and surface tension as the diluted gastric juice is used. This question is important in relation to what kind of dissolution medium should be recommended for an *in vitro* dissolution test in the pharmacopeias.

The problem was studied with phenacetin as model substance. Two dilutions of gastric juice were made, one from samples of gastric juice with a relatively low surface tension (35–40 dynes cm.$^{-1}$) and one from samples with a relatively high surface tension (45–50 dynes cm.$^{-1}$). Rates of dissolution were determined using these two dilutions of gastric juice and two HCl solutions of the same pH and surface tension as the gastric juice mixtures. The surface tension of the HCl solutions was adjusted at the correct value by addition of polysorbate 80.

Figure 8 shows that phenacetin dissolves nearly at the same rate in hydrochloric acid as in gastric juice when the two media are adjusted at the same pH and surface tension. As far as this drug is concerned, an HCl solution adjusted to a surface tension of 40–50 dynes cm.$^{-1}$ is a better dissolution medium for an *in vitro* test than an HCl solution with no surfactant added. To see if this also applies to other drugs further studies are needed.

Evaluation of the Effect of Isomerization on the Chemical and Biological Assay of Vitamin D

Analysis of Fat-Soluble Vitamins X

By J. A. KEVERLING BUISMAN, K. H. HANEWALD, F. J. MULDER, J. R. ROBORGH, and K. J. KEUNING

The reversible thermal isomerization of calciferols (D) to precalciferols(P), leading to a temperature-dependent equilibrium in solutions, interferes with many chemical and biological analytical procedures for the evaluation of vitamin D products. Two quantities should be distinguished: the potential vitamin D content (precalciferol + calciferol) and the actual vitamin D content (calciferol only). Of these two, only the potential vitamin D content is of importance to the buyer of vitamin D. Biological vitamin D assays give the potential vitamin D content, provided sample and reference standard dilutions are equilibrated by heating simultaneously to be sure that all have the same P–D ratio. This equilibration is superfluous in most of the chemical determinations of the potential vitamin D content. The actual vitamin D content can be determined by chemical, but not by biological, assay.

IT IS UNFORTUNATE that the assay of vitamin D preparations still frequently gives rise to difficulties. The reproducibility of biological assays is often poor, especially when assays from different laboratories are compared. The correlation of biological and chemical determinations is often unsatisfactory.

Received April 25, 1967, from the Philips-Duphar Research Laboratories, Weesp, the Netherlands.
Accepted for publication April 19, 1968.

A source of errors which has drawn too little attention is the reversible isomerization of the calciferols in solutions to the corresponding precalciferols, forming an equilibrium mixture (1–3).

In 1931 Reerink and Van Wijk (4) observed that the physical constants of freshly irradiated solutions of ergosterol changed spontaneously. Velluz *et al.* (3) isolated the 3,5-dinitrobenzoate of the responsible intermediate in 1949 and called it

Received April 25, 1967, from the Philips-Duphar Research Laboratories, Weesp, the Netherlands.
Accepted for publication April 19, 1968.

A source of errors which has drawn too little attention is the reversible isomerization of the calciferols in solutions to the corresponding precalciferols, forming an equilibrium mixture (1–3).

In 1931 Reerink and Van Wijk (4) observed that the physical constants of freshly irradiated solutions of ergosterol changed spontaneously. Velluz *et al.* (3) isolated the 3,5-dinitrobenzoate of the responsible intermediate in 1949 and called it

precalciferol. Legrand and Mathieu (5) used infrared spectrophotometry to prove the mutual isomerization of the dinitrobenzoates of ergocalciferol (D_2) and preergocalciferol (P_2) leading to an equilibrium by first-order reactions. Verloop *et al.* (6, 7) and Velluz *et al.* (8, 9) established the structure of precalciferol. Havinga and coworkers (6, 10) investigated the chemical background of the isomerization of conjugated trienes and established that the isomerization rate is not affected by the solvent, acidity, ultraviolet light, catalysts, and free-radical reaction inhibitors.

Hanewald *et al.* (11) determined by ultraviolet absorptiometry the first-order rate constants of the isomerization of cholecalciferol, and their dependence on temperature. The isomerization rates of ergocalciferol and cholecalciferol are virtually equal (12). This should be a relief for many bioanalysts who have been compelled to standardize vitamin D_2 samples against cholecalciferol standards.

Shaw and Jefferies (13) reported an antirachitic activity of preergocalciferol of only 40% of the activity of ergocalciferol in rats; Bolliger (14) found 56% and Bekemeier and Pfordte (15) found 34%. For precholecalciferol Hanewald *et al.* (11) reported 35% of the activity of cholecalciferol in a chick test. The lower activity of the precalciferols must be due either to poor absorption or to lower intrinsic activity, the latter possibly originating exclusively from calciferols formed within the animal body by conversion of precalciferols (11, 13). A solution prepared from pure calciferol or pure precalciferol will after a time contain both compounds in a ratio dependent on storage time and temperature. This is also true for vitamin D preparations prepared from irradiation mixtures because during the photochemical manufacture of both calciferols, primarily the precalciferols are formed and the calciferols are formed from these by thermal isomerization. Whether the equilibrium will be reached clearly depends on the processing time and temperature, and if these are short or low, respectively, the ratio precalciferol/calciferol in the commercial product may be higher than conforms to equilibrium ratio at the ambient temperature and it will change until equilibrium has been reached.

These facts should be taken into account when assaying vitamin D or standardizing analytical methods.

THEORETICAL CONSIDERATIONS

Actual and Potential Vitamin D Content—When defining the vitamin D content there must be a distinction between the *actual vitamin D content*, *i.e.*, the content of calciferol alone, and the *potential vitamin D content*, meaning the sum of the contents of calciferol and precalciferol. Of these two, only the potential vitamin D content of a sample is independent of conditions during, preceding, and after the analysis and only the potential vitamin D content is a lasting characteristic and as such suitable for the evaluation of preparations. The actual vitamin D content concerns the sample at one distinct moment and it has a limited value, only in connection with the sample's antecedents.

By not distinguishing between potential and actual vitamin D contents a rather chaotic situation has arisen with regard to biological and chemical vitamin D assays, standardization, reference standards and their use, declared potencies, comparison of experimental results, stability tests, *etc.* Moreover, it must be emphasized that considerable errors in the actual vitamin D content may be introduced during analysis unless anything liable to change the ratio of both compounds, *e.g.*, heating, is carefully avoided (12).

Calculation of Equilibrium Compositions and Reaction Times—The isomerization constants for $P_3 \underset{k_2}{\overset{k_1}{\rightleftharpoons}} D_3$ are (11):

$$\log k_1 = \frac{-4200}{T} + 10.29$$

$$\log k_2 = \frac{-5180}{T} + 12.53 \quad (k \text{ in min.}^{-1};\ T \text{ in °K.})$$

At equilibrium the cholecalciferol fraction in % of the potential D content is:

$$f = \frac{100\ D_3}{P_3 + D_3} = \frac{100\ k_1}{k_1 + k_2}$$

The time needed to reach 0.99 × the equilibrium fraction of the formed component, starting from solutions of pure cholecalciferol or pure precholecalciferol, is

$$t_{0.99} = \frac{2 \times 2.303}{k_1 + k_2} \text{ min.}$$

Table I contains the fractions and the times calculated for a series of temperatures. These times vary from years at below 0°C. to some minutes at sterilization temperature (120°).

On the other hand, the time needed in practice to approach the equilibrium at a certain temperature, T may be reduced to a few days if one starts with a mixture equilibrated at some higher temperature T_0, as can be seen in Table I. This time is calculated from

$$t_{0.99} = \frac{2.303}{k_1 + k_2} \log 100 \left(1 - \frac{f_0}{f}\right) \text{ min.}$$

f_0 and f are the equilibrium fractions at the temperatures T_0 and T, respectively; k_1 and k_2 are the rate constants in min.$^{-1}$ at T.

Implications of the Distinction Between Potential and Actual D Content—The constancy of the potential D content and the inconstancy of the actual D content due to isomerization lead to a number of important consequences.

(*a*) Only the *potential* D content is useful for the evaluation of vitamin D preparations, because it is

TABLE I—CALCULATED EQUILIBRIUM FRACTIONS AND TIMES $t_{0.99}$ NEEDED TO REACH 0.99 × THE EQUILIBRIUM FRACTION OF THE FORMED COMPONENT (D_3 or P_3)

reproducible and independent of the antecedents of the sample.

(*b*) This applies still more to the comparison of experimental results obtained at different places and at different moments. Stability tests should never compare actual but always potential D contents since it cannot be decided whether a decreased actual D content is due to reversible isomerization or to irreversible decomposition.

(*c*) For the analysis of many formulations it is necessary to isolate or concentrate the vitamin D. This can hardly be done without saponification, extraction, and other operations involving an elevated temperature and consequently a change in P–D ratio. In such formulations the potential D can still be determined but the actual D cannot.

(*d*) It must be emphasized that knowledge of the actual D content can only be valuable if the circumstances preceding the analysis are well defined and if the potential D content is known.

(*e*) In a determination of the actual D content the circumstances starting from the moment of sampling should be such that isomerization virtually cannot occur, *viz.*, by handling at low temperature.

These points are illustrated by the following examples.

1. Preparations heated during manufacture (sterilization) and cooled abruptly have a low relative actual D content (D/D + P) which will be maintained by storing at 0° or below. If dosage is based on any actual D assay in the cooled product this will lead to overdosing.

2. Two solutions of pure crystalline calciferol in oil are prepared (*a*) by dissolving in ether, mixing with oil and evaporating the ether at 20° *in vacuo*, and (*b*) by dissolving in ethanol, mixing with oil, and evaporating the ethanol during 30 min. at 100°. The actual vitamin D content of both is determined and each is diluted with oil to make the actual D content 10 mg./ml. (solutions *a* and *b*). The fresh solution *a* contains no appreciable amount of P (0.01 mg./ml.); however, the fresh solution *b* approx. 4 mg. of P per ml.

After storage for 1 month at 20°, these solutions will show actual D contents of: (*a*) 9.3 mg./ml. and (*b*) 13.0 mg./ml. The potential D contents will be unchanged: 10.0 mg./ml. in *a* and 14.0 mg./ml. in *b*.

3. Animals having a body temperature of 40° are injected intramuscularly with dilutions of these fresh solutions *a* and *b*. Suppose half the depot has been absorbed a month after injection. The remaining half depot of *a* will contain at that moment 45% but *b* 65% of the calciferol present in the injected dose.

The conclusion of all this is that the potential D content is the value important for the consumer. Evaluation and assay of vitamin D preparations should be confined to the determination of the potential D content.

METHODS OF EVALUATION

When determining the *actual* vitamin D content (or P content), one should observe the following points. (*a*) The conditions (temperature and time) from the moment of sampling until measurement should be such that an appreciable conversion D ⇌ P does not occur, *e.g.*, <1 hr. at 40°, or <8 hr. at 20°, or <3 days at 0°, or 1 year at −20°. (*b*) D and P should be separated completely without conversion and then determined separately, or (*c*) D and P are not separated but freed from interfering contaminations and then one or both or the ratio are determined, and the sum of both (potential D).

An example of *b* is TLC followed by Nield's reaction. An example of *c* is chromatographic purification (*e.g.*, alkaline alumina), followed by a Nield determination of P + D and ultraviolet absorptiometry for the ratio. D might be determined in the presence of P by infrared absorptiometry at 900 $cm.^{-1}$ [exocyclic methylene band missing in P (5)]. Or P is converted by iodine into tachysterol of which the maleic anhydride adduct does not interfere with the Nield reaction of D (7).

The determination of the *potential* vitamin D content is not limited by the conditions mentioned above. There are three possibilities.

1. Purification without separating P and D and determination by a common reaction (*e.g.*, Nield reaction).

2. Separation and purification; the P and D fractions are analyzed separately and the results added, or the fractions are reunited and analyzed together (*e.g.* TLC, followed by extraction of the separate or combined P and D fractions, and Nield reaction).

3. Comparison of a measurable property of a (purified) sample solution and a potential vitamin D standard solution, after equilibration of both under rigorously identical circumstances (*e.g.*, ultraviolet absorptiometry or biological assay).

Effect of the Isomerization P ⇌ D on Biological Assays—The uncertainty as to the P–D ratio combined with a considerable difference between the biological activities of P and D interferes with the reliability of biological assays.

In biological assays the physiological effects of a sample and of a reference standard are compared and from this the content of the sample relative to that of the reference standard is calculated. A predominant condition for a realistic assay is the availability of a dependable reference standard.

A reference standard prepared by dissolving crystalline ergocalciferol or cholecalciferol will contain, after some time, a mixture of the original calciferol and, as a result of isomerization, precalciferol. The biological response to this standard will now represent the resultant of two compounds differing markedly in biopotency. A further complication is the new shift in isomerization that begins at the moment of administration and is caused by the animal body temperature. Even if only the actual D is biologically active the unknown degree of isomerization of the standard makes it unfit for use in the determination of the actual D (or the P) with a bioassay.

For the same reasons quantitatively equal physiological effects will not be obtained if sample and standard contain equal amounts of actual D but different amounts of P.

In other words an equal antirachitic effect does not prove the equality of the actual D contents of sample and standard unless the P–D ratios are equal.

The situation is quite different, however, in the case of the more important potential vitamin D content. In the first place the amount of potential vitamin D in a standard solution is exactly known, *viz.*, the amount of calciferol used in its preparation, provided the vitamin D has not been destroyed by irradiation or oxidation. In the second place dilutions of sample and standard, containing equal amounts of potential vitamin D (calciferol plus precalciferol) will cause quantitatively the same antirachitic effect, if beforehand any possibly different P–D ratios have been made equal by heating at the same temperature until the equilibrium pertaining to this temperature is reached.

In addition reference standard and sample should be applied in virtually identical formulations, *e.g.*, dissolved in a vegetable oil and both should be administered to the animals in the same way. Complications due to absorption differences of calciferols and precalciferols cannot occur if formulation, equilibration, and administration of all dilutions of sample and reference standard are identical.

Equilibration of Sample and Standard for Bioassay—The following example describes an equilibration of the dilutions of the sample and the reference standard for the bioassay of potential vitamin D in oil samples.

For dilution use a vegetable oil, pure and clear and free from peroxides, acids, and halogens.

Weigh sufficient quantities of sample and reference standard and dilute with vegetable oil and antioxidant solution to obtain all dilutions needed for administering, containing the required vitamin D concentrations and equal concentrations of antioxidant (*e.g.*, 0.02% of BHA). Mix each dilution thoroughly by swirling under nitrogen.

Heat all flasks simultaneously for 2.5 hr. at 80°C. in an oven. Cool simultaneously to room temperature. Proceed with the bioassay according to common practice (16–19).

The simultaneousness is essential and care must be taken to handle *all* dilutions of standard *and* sample in the same way with respect to temperature and time. When not in use all dilutions are stored in a refrigerator.

In addition to the precautions mentioned above to prevent oxidation and other irreversible conversions it is good practice to replace air by nitrogen each time after the flasks have been opened. In case the sample is not a solution in oil, some degree of isolation may be necessary to precede dilution by vegetable oil, *e.g.*, saponification, extraction, evaporation, dissolution. These operations will not alter the potential vitamin D content if they are carried out by reliable methods which prevent losses. The P–D ratio may change if heating is involved, but this will not influence the results because of the subsequent equilibration.

Drug Biotransformation Interactions in Man I

Mutual Inhibition in Glucuronide Formation of Salicylic Acid and Salicylamide in Man

By GERHARD LEVY and JOSEPHINE A. PROCKNAL

Co-administration of salicylamide (SAM) and sodium salicylate to healthy adult humans resulted in a pronounced decrease in the formation of the glucuronides of these two drugs. This is thought to be due to a limited capacity for glucuronide conjugation in man and/or to the uncoupling action of salicylate on oxidative phosphorylation. Salicylate *may* inhibit also the formation of SAM sulfate; it has no effect on the excretion rate constants of SAM glucuronide and SAM sulfate in the doses used in the investigation. The results of this study indicate that concomitant use of certain drugs which are readily available to the public may lead to appreciable interactions in biotransformation and to enhanced pharmacologic effects.

CLINICAL PHARMACOLOGIC STUDIES in recent years have led to a recognition of the important role of drug interactions in therapy and in toxicology (1). Most of these studies have dealt with enzyme induction (2), but the role of competitive and noncompetitive inhibitory effects on drug biotransformation and excretion processes is also being recognized. It is now evident that a number of important drug biotransformation processes in man have a relatively limited capacity (3–6). This in itself is not surprising since drug biotransformation involves enzymic reactions, but it was not realized until recently that "saturation" effects may be encountered when drugs are given in the usual therapeutic dose range. It may be expected that co-administration of two or more drugs which share a biotransformation pathway of low capacity will lead to competitive inhibition of the formation of the respective metabolites. Consequently, there will be a change in quantitative composition of metabolites and a decrease in the elimination rate of one or both of the drugs. This can result in enhanced pharmacologic activity or, if the metabolite produced by the capacity-limited process is the pharmacologically active species, in a decrease of the pharmacologic activity of a drug. An exploration of the mutual pharmacokinetic effects of drugs sharing a biotransformation route of low capacity in man is therefore highly pertinent. Such effects have obvious implications with respect to drug safety since they may lead to adverse reactions and intoxications; it should be recognized, however, that the judicious and informed use of such drug combinations may also result in safer and more effective medication. Finally, the study of drug metabolism interactions represents an effective research approach for identifying possible differences in the rate-limiting step in the formation of metabolites of different drugs which apparently share the same biotransformation pathway. This report is the first of a series from this laboratory in which studies of such drug interactions will be described. It is concerned with what is generally considered to be the most important, versatile, and ubiquitous drug biotransformation pathway in man, the formation of glucuronides. The relevance of such studies is emphasized further by the nature of the two drugs utilized in the investigation—salicylate and salicylamide—since they are among the most widely used and most readily available to the public.

Received March 4, 1968, from the Biopharmaceutics Laboratory, Department of Pharmaceutics, School of Pharmacy, State University of New York at Buffalo, Buffalo, NY 14214

Accepted for publication April 23, 1968.

Presented at the 52nd Annual Meeting of the Federation of American Societies for Experimental Biology, Atlantic City, N. J., April 1968.

Supported in part by grant No. 1 R01 DS00021-01 from the U. S. Public Health Service, Bethesda, Md.

EXPERIMENTAL

Healthy, male, ambulatory human subjects received orally 0.6 g. salicylamide in one test, and the same dose of salicylamide 2 hr. following oral administration of 2.32 g. sodium salicylate (equivalent to 2 g. salicylic acid) in another test. Both tests were initiated in the morning on an empty stomach. Food was withheld for at least 2 hr. after drug administration. Both drugs were given in aqueous solution. Urine was collected every 30 min. for the first 4–8 hr., then at longer intervals for a total of 24 hr. From 50 to 100 ml. water was ingested after each urine collection to assure adequate urine output. The urine samples were stored in a freezer until assayed.

Assay Methods for Salicylic Acid and Its Metabolites—Salicylic acid and its major metabolites in urine were determined by a further modification of the Smith *et al.* (7) modification of the colorimetric method of Brodie *et al.* (8) for the determination of salicylic acid in plasma. In essence, the procedure as used in the study reported here consists of (*a*) determination of salicylic acid (SA) by extraction of the sample with carbon tetrachloride and reextrac-

tion into ferric nitrate reagent solution, (*b*) determination of the absorbance due to both SA and salicyluric acid (SU) by extraction of the sample with ethylene dichloride and reextraction into ferric nitrate solution, and (*c*) determination of total salicylates [*i.e.*, SA, SU, and salicylic glucuronides (SAG)] after complete acid hydrolysis of these metabolites to SA, followed by step *a*. SU content is calculated by difference of *a* from *b*, and SAG content is obtained by subtracting SA and SU values from *c*.

The major difference between the method of Smith *et al.* (7) and the method described here is based on studies in this laboratory which have shown that SU does not partition to any significant extent into carbon tetrachloride. Partition coefficients of SU between 0.1 *N* HCl and various organic solvents were determined with a pure sample of SU obtained after several recrystallizations from water and ethanol–chloroform mixture and found free of impurities by thin-layer chromatography, elemental analysis, and by examination of the infrared spectrum. These partition coefficients are listed in Table I. The lack of significant partitioning of SU into carbon tetrachloride even in the presence of SA is evident from the data shown in Table II. The apparent extraction of SU by carbon tetrachloride reported by Brodie *et al.* (8) and Smith *et al.* (7) was probably due to contamination of their sample (both groups used material from the same source) by about 5% SA. The other modification of the method of Smith *et al.* (7) was to hydrolyze SA metabolites totally rather than partially, since differences in heating and cooling rates can affect the degree of partial hydrolysis, and thus the reproducibility of the assay results.

Procedure A—The concentration of SA in urine is determined as follows: 2 ml. of the urine sample (diluted with water if necessary), 0.5 ml. 6 *N* HCl, and 30 ml. carbon tetrachloride are placed in a glass-stoppered bottle. After shaking vigorously for 5 min., the mixture is transferred to a centrifuge tube, centrifuged to separate the phases, and the urine phase is aspirated and discarded. Ten milliliters of the organic phase and 5 ml. of ferric nitrate reagent solution are placed in a glass-stoppered centrifuge tube which is shaken vigorously for 5 min. After centrifuging if necessary to separate the layers, a portion of the aqueous phase is removed and its absorbance is determined at 530 mμ. A reagent blank value is obtained by using distilled water in place of the urine sample and applying the same procedure. The ferric nitrate reagent solution is freshly prepared by diluting 5 ml. of ferric nitrate stock solution [1.0% $Fe(NO_3)_3$ in 0.07 *N* HNO_3] with distilled water to 100 ml. All chemicals and solvents should be of reagent grade quality. An aqueous solution containing 10 mg.% SA, when subjected to the above procedure, yields an absorbance in the ferric nitrate reagent phase of about 0.14 in cells of 1-cm. path length.

Procedure B—Salicyluric acid is determined by essentially the same procedure as that described for SA, except that reagent grade ethylene dichloride is used instead of carbon tetrachloride. To account for the contribution of SA to the absorbance of the ferric nitrate reagent phase, 1.06 times the absorbance value obtained in Procedure A is subtracted. Multiplication by 1.06 corrects for the small difference in the partitioning of SA when using carbon tetrachloride and ethylene dichloride, respectively, for the extractions. This difference has been constant and reproducible during the several years that the procedure has been used in this laboratory. A solution containing 10 mg.% SU yields an absorbance of about 0.059 in the ferric nitrate reagent phase (1-cm. cell path length) while a 10-mg.% solution of SA produces an absorbance of about 0.15 in the procedure described here. Table II shows the results of assays of solutions containing known concentrations of both SA and SU.

Procedure C—Total salicylate in the urine is determined by hydrolyzing SU and SAG to SA. Three milliliters of the urine sample and 3 ml. of concentrated hydrochloric acid are heated in a sealed 20-ml. ampul at 100° for 16 hr. This length of time is necessary to bring about an essentially complete hydrolysis of SU to SA. Two milliliters of the hydrolyzed solution is then analyzed for SA by Procedure A. The concentration of SAG in the sample is determined by subtracting the sum of the SA and SU concentrations (the latter corrected for molecular weight by multiplying by 0.708) from the total SA concentration of the hydrolyzed sample.[1] Thus, $(SAG) = (SA_{total}) - [(SA_{free}) + 0.708 (SU)]$ where the terms in parentheses denote concentrations in metric (rather than molar) units, and (SAG) is expressed in terms of (SA). Urine blanks are usually somewhat less than 1 mg./hr. apparent total SA. The recovery of total salicylate following an oral dose of SA or aspirin has been consistently between 95 and 100% under properly controlled experimental conditions (*i.e.*, when complete urine collections could be monitored in the laboratory or in a clinical research center). When the dose of SA exceeds 1 g. in adults (and proportionately less in infants and children), gentisic acid (GA) determinations are necessary to account adequately for the administered dose.

TABLE I—PARTITION COEFFICIENT OF SALICYLURIC ACID IN SEVERAL ORGANIC SOLVENTS[a]

Solvent	Partition Coefficient (Organic/Aqueous)
Carbon tetrachloride	<0.002
Chloroform	0.05
Ethylene dichloride	0.15
Ether	4.0

[a] Solutions of 100-mg. % salicyluric acid in 0.1 *N* HCl were equilibrated with equal volumes of organic solvent at room temperature.

TABLE II—DETERMINATION OF SALICYLURIC ACID IN THE PRESENCE OF SALICYLIC ACID

Composition of Solutions, mg. %		Found, mg. %[a]	
Salicylic Acid	Salicyluric Acid	Salicylic Acid	Salicyluric Acid
0	25	0	24.5
5	25	5.07	24.5
10	25	10.0	24.6
25	25	25.1	24.1
50	25	50.7	24.5

[a] Average of two determinations.

[1] Determination of SAG by enzymatic hydrolysis for 16 hr. with β-glucuronidase yields results which are about 20% lower than those obtained by acid and heat hydrolysis. This appears to be due to the rather slow rate of the enzymic reaction.

TABLE III—VERIFICATION OF ASSAY METHOD FOR SALICYLATE AND ITS METABOLITES AND SALICYLAMIDE AND ITS METABOLITES IN URINE SAMPLES CONTAINING BOTH GROUPS OF SUBSTANCES

		Concentrations, as mg. % SA or SAM Equivalent

	I	21.3	0.3	11.0	10.8
	III	34.1	0.5	16.8	17.3

[a] SAMG, salicylamide glucuronide; SAMS, salicylamide sulfate; SA, salicylic acid; SAG, salicylic glucuronides; SU, salicyluric acid. [b] Roman numerals refer to a specific urine sample obtained after either SA or SAM administration.

This is due to saturation effects with respect to SU formation, resulting in an increase in the fraction of the dose metabolized to other products. GA is determined by the method of Becher (9). Experience has shown that the concurrent assay of reference solutions containing known concentrations of GA is desirable to achieve satisfactory results.

Assay Methods for Salicylamide and Its Metabolites—The procedures were those of Levy and Matsuzawa (5) with minor modifications. In the determination of total salicylamide (SAM), carbon tetrachloride was substituted for ethylene dichloride. In the assays of SAM glucuronide and SAM sulfate, the pH after enzymic hydrolysis was adjusted to 6.5 with 0.1 *N* sodium hydroxide solution instead of adding phosphate buffer. Gentisamide (GAM) was determined as such (rather than as GA). In this procedure, 3 ml. of urine sample, 2 ml. of pH 4.5 acetate buffer (0.4 *M*), and 2 ml. of beef liver beta-glucuronidase[2] are incubated at 37° for 48 hr. After adjusting the pH to 6.0 with 0.1 *N* NaOH solution, enough water is added to yield a total volume of 10 ml. Twenty milliliters reagent grade ether is added and the mixture is shaken for 5 min. Fifteen milliliters of the ether phase is extracted with 6 ml. of a 5% solution of sodium bicarbonate. To 4 ml. of the aqueous phase are added 1 ml. of concentrated HCl and 1 ml. of Folin-Ciocalteu reagent and the absorbance of this solution is determined 20 min. later at 750 mμ. Reagent blanks (using water instead of a urine sample) and controls are run concurrently.

Determination of Salicylic Acid, Salicylamide, and Their Metabolites in the Presence of One Another—The difference in the pKa of SA, SU, and SAM affords selective extraction of the latter at pH 6.5 from aqueous solution. Total SAM is determined by extraction of free SAM following enzymic hydrolysis with beta-glucuronidase and sulfatase. Absorbance values in the determination of SA and SU (Procedures A and B) are corrected for the contribution by SAM. These corrections are negligible and essentially equal to urine blank values since practically no free SAM appears in the urine. Total SA from salicylate and its metabolites is determined in the presence of SAM metabolites by subtracting the SA equivalent of the total SAM obtained by beta-glucuronidase and sulfatase hydrolysis from the total SA obtained by hydrolysis of both SA and and SAM metabolites to SA. The analytical procedures were checked by separately assaying urine samples obtained following SA administration and samples obtained following SAM administration, and then assaying mixtures of equal parts of these urines. Table III shows results obtained at low concentrations of SA and SAM metabolites, *i.e.*, under the most difficult conditions.

[2] Ketodase, Warner-Chilcott, Morris Plains, N. J.

RESULTS AND DISCUSSION

Salicylic acid is eliminated in man mainly by formation of salicyluric acid, by renal excretion of free drug, and by glucuronide conjugation (10). Salicylamide is metabolized to the sulfate, the glucuronide, and to gentisamide; excretion of free salicylamide is negligible (5). Both drugs are subject to capacity-limited effects in their biotransformation in man even in the usual therapeutic dose range. This involves the conjugation of salicylate with glycine to form salicylurate (3, 11) and the formation of salicylamide sulfate from salicylamide (5). It has been reported that at high levels of salicylamide, saturation of the glucuronide formation process also becomes evident (12). The elimination of salicylate in man is considerably slower than that of salicylamide and the experimental design of the study reported here was based on this consideration. Salicylate was administered 2 hr. before salicylamide; body levels of the former declined by less than 25% in the period of time when salicylamide and its metabolites were present in the body. The effect of salicylamide on the formation of salicylic glucuronides is shown in Figs. 1 and 2 for two subjects. Similar results were obtained in the third subject.[3] The excretion of salicylic glucuronides decreased precipitously shortly after salicylamide administration and returned to normal levels within about 2 hr. The short duration of the salicylamide effect is due to the rapid elimination of this drug. Figure 2 shows also the time course of salicylurate excretion following salicylate administration. The excretion rate of this metabolite was essentially constant during the first 12 hr., reflecting the limited capacity of man to form salicylurate

[3] Graphs of all the individual data are not shown due to space limitations but are available from the authors upon request.

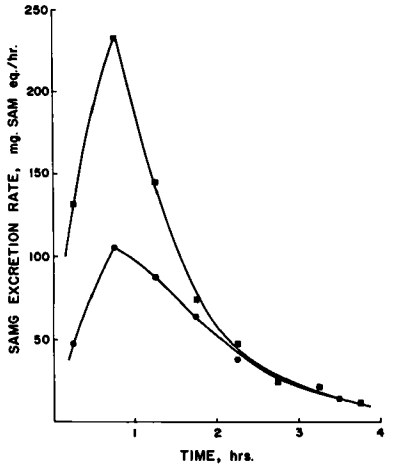

Fig. 3—Excretion rate of salicylamide glucuronide following oral administration of 0.6 g. salicylamide alone (■) and 2 hr. after 2.32 g. sodium salicylate (●). Subject A.

(3, 11). Salicylamide, which is not conjugated with glycine, had no effect on this process in any of the subjects.

The effect of salicylate on the excretion of salicylamide glucuronide is shown in Fig. 3 for one of the subjects and is representative of the data obtained in all three subjects.[3] There was a pronounced decrease in the excretion of salicylamide glucuronide in the presence of salicylate. Since the excretion of salicylamide conjugates is excretion rather than formation rate limited (5, 13), the terminal phase in the excretion rate plot reflects the excretion kinetics of the respective metabolite. Figure 4 is a semilogarithmic plot of salicylamide glucuronide excretion rate in the terminal excretion phase as a function of time. Each of the curves in the figure is displaced on the time axis relative to the others to facilitate comparison of slopes. It is evident that the excretion half-life of salicylamide glucuronide is about 0.8 hr. and that salicylate has no effect on this process. Therefore, the pronounced decrease in the excretion of salicylamide in the presence of salicylate is due to decreased formation of salicylamide glucuronide. This conclusion is substantiated by the lower total recovery of salicylamide glucuronide in the presence of salicylate (Table IV).

Figure 5 shows the excretion rate of salicylamide sulfate in one of the subjects following administration of salicylamide alone or in the presence of salicylate. Similar data were obtained with the other subjects.[3] Figure 6 is a semilogarithmic plot of salicylamide sulfate excretion rate as a function of time in the terminal phase of the process, representing an excretion half-life of about 1 hr. While salicylate has no effect on the process of excretion of salicylamide sulfate, there may be an inhibition of sulfate formation since the maximum excretion rate of salicylamide sulfate was consistently decreased in the presence of salicylate. This inhibition is also suggested by the data in Table IV, which shows the total composition of the urinary excretion products of salicylamide when given alone and with salicylate. While the output of salicylamide glucuronide decreased by about 100-mg. salicylamide equivalent in the presence of salicylate, the output of salicylamide sulfate increased by only about 20-mg. salicylamide equivalent. The major increase was in gentisamide output, which is usually very small when this dose of salicylamide is administered alone. Unfortunately, gentisamide output was determined only when salicylamide and salicylate were given together, but an estimate of

the maximum possible gentisamide output from salicylamide in the absence of salicylate has been obtained by subtracting the output of salicylamide glucuronide and sulfate from the total dose. While the lack of a significant increase in salicylamide sulfate formation may be due to the limited capacity of the body to form this metabolite (5), the decreased maximum excretion rate in the presence of salicylate is suggestive of salicylate-induced inhibition of sulfate formation. This problem is presently being studied in more detail.

The most likely reason for the mutual inhibition by salicylate and salicylamide of the formation of their respective glucuronides appears to be competition for uridine diphosphoglucuronic acid (UDPGA) or for UDP glucuronyl transferase, reflecting a limited capacity in man for glucuronide formation. Alternatively, or in addition, there may be a noncompetitive inhibition by salicylate of the glucuronide formation process. It has been suggested that high levels of salicylate inhibit the formation of salicylic glucuronides in mice due to an uncoupling effect of salicylate on oxidative phosphorylation (14); preliminary observations in this laboratory suggest that high levels of salicylate inhibit salicylic glucuronide formation also in man. Aspirin in doses as low as 0.6 g. decreases appreciably the urinary excretion of endogenous corticosteroid glucuronide in man, but not the excretion of free corticosteroid (15). The uncoupling effect of salicylate is thought to be responsible also for the decreased biosynthesis of sulfate esters following salicylate administration to rats (16); it is not unreasonable to suspect that the same effect could result in an inhibition of salicylamide sulfate formation in man. However, the results of the present study are only suggestive of salicylate-induced inhibition of salicylamide sulfate formation; the data can be explained also by assuming salicylate-induced delayed absorption of salicylamide although this latter possibility seems unlikely. The most important finding of this study is the pronounced mutual inhibition in the formation of glucuronides of and by two widely used and commonly available drugs given in usual therapeutic doses. One or both of these drugs is likely to have similar inhibiting effects on the glucuronide conjugation of other drugs; this is now being investigated in this laboratory. There is thus the possibility for frequent occurrences of interactions in drug biotransformation since many individuals taking prescribed drugs are also frequent users of mild analgesics, the latter being taken usually without knowledge of the attending physician. It is interesting also to speculate to what extent the many medicinal preparations consisting of combinations of salicylates with other drugs owe their enhanced effectiveness to a salicylate-induced inhibition of the elimination of one of these other drugs, rather than to the direct pharmacologic effects of salicylate itself.

Effect of Complex Formation on Drug Absorption VII

Effect of Complexation and Self-Association on the Absorption of Caffeine

By RICHARD H. REUNING* and GERHARD LEVY†

The effect of the formation of caffeine complexes having a higher apparent lipoid–aqueous partition coefficient than caffeine itself on the absorption of this drug from the rat stomach was investigated. In one such system, caffeine–salicylic acid, the salicylic acid actually decreased the absorption of caffeine due to an effect of the former on the gastric mucosa. In another such system, caffeine–*p*-hydroxybenzoic acid, the *p*-hydroxybenzoic acid did not increase the absorption of caffeine. The intestinal transfer of caffeine alone was studied at low concentrations (where caffeine exists mainly in monomeric form) and at high concentrations (where significant self-association occurs). The intestinal transfer rate constant of caffeine at high concentrations was significantly lower than at low concentrations. The mechanism of this effect was explored.

In the initial studies in this laboratory of the effect of complex formation on drug absorption, it was found that complexation with caffeine decreased significantly the overall[1] absorption of salicylic acid from the stomach of the rat (1). This effect was qualitatively consistent with the apparent lipoid–aqueous partition coefficient (PC) of salicylic acid and of the caffeine–salicylic acid complex; the latter showed an appreciably lower apparent PC than the former. It appeared reasonable to assume that the absorption of caffeine might be enhanced by complexation with salicylic acid, since this complex has a higher apparent PC than caffeine itself (1). Studies were therefore initiated to test this assumption. The investigation was then extended to include a study of the caffeine–salicylate ion complex and the caffeine–*p*-hydroxybenzoic acid complex. The latter was of considerable interest since it has a higher apparent PC than caffeine as well as an appreciably higher stability constant than the salicylic acid–caffeine complex (2). In the course of these studies it became apparent that the self-association of caffeine at high concentrations (3) can affect the absorption of this drug. Therefore, this effect was studied also.

[1] In the context used in this paper, "overall" refers to the combined effect or behavior of free and complexed drug.

EXPERIMENTAL

In Situ Gastric Absorption Rate Measurements—The procedure described previously by the authors (1) was followed with a few modifications. The

female Wistar rats, 150–270 g., were anesthetized with urethan (1.25 g./kg. i.p.). After the rat stomach had been exposed, it was washed once with 0.9% sodium chloride solution prior to injection of the drug solution (37°) into the ligated stomach through the pyloric sphincter. All injections were made with a blunt-tipped needle which was withdrawn while tightening the ligature around the pyloric sphincter. The absorption period was 1.5 hr. for the caffeine–salicylic acid solutions and 1.0 hr. for the caffeine–*p*-hydroxybenzoic acid solutions. At the end of the absorption period, the stomach was excised, homogenized,[2] and the homogenate was assayed for unabsorbed caffeine and, when present, for ethanol.

Assay for Caffeine in Stomach Homogenate—A modification of the method of Axelrod and Reichenthal (4) for the assay of caffeine in urine and biologic tissues was used. The stomach homogenate was adjusted to a volume of 50 ml. with water. To 15 ml. of this diluted homogenate was added 25 ml. of 0.1 *M* phosphate buffer, pH 7.5. A 3-ml. aliquot of this dilution (containing 3–5 mg.% caffeine) was placed in a 120-ml. glass-stoppered bottle along with 3 g. sodium chloride and 35 ml. washed benzene.[3] After shaking for 20 min., the phases were separated by centrifuging at about 900×*g* for 20 min. The benzene phase was transferred to another 120-ml. glass-stoppered bottle containing 3 g. sodium chloride and 3 ml. 0.1 *N* NaOH. After the bottle had been shaken for 5 min., the phases were separated as before. Fifteen or 20 ml. of the benzene phase was then pipeted into a 125-ml. separator containing 10 ml. of 5 *N* HCl. After shaking for 5 min., the separator was allowed to stand a few minutes until the phases had separated. The aqueous phase was removed and centrifuged at about 850× *g* for 30 min. to remove any remaining nonaqueous material. An aliquot of the aqueous phase was then assayed spectrophotometrically at 273 mμ. Blank values from tissues comprised about 7% of the usual absorbance and the average tissue recovery, after correction for blank values, was 96%. The amount of caffeine remaining unabsorbed was calculated from the concentration determined spectrophotometrically, the dilution factor of the assay procedure, and the corrections for blank and recovery. Each analysis was done in triplicate and the results were averaged.

Assay for Ethanol in Stomach Homogenate—Ethanol was determined by the method of Hoult and Pawan (5) as modified previously (6). It was found that neither caffeine nor salicylic acid interferes with this assay.

Partition Coefficients—The partition coefficients of *p*-hydroxybenzoic acid and caffeine between 0.1 *N* HCl and isoamyl acetate were determined at room temperature as described previously (1). Assays of the aqueous phase were done spectrophotometrically at 255 and at 273 mμ, respectively, using 0.1 *N* HCl as the diluent. When both drugs were present together, two-component spectrophotometry was used at these wavelengths. In the concentration range of the spectrophotometric assay the absorbances of the two drugs were additive.

The partition coefficients of caffeine between distilled water or Ringer's solution and chloroform 10% (v/v) in isooctane were determined at 30° as described by Guttman and Higuchi (3). The concentration of caffeine was determined spectrophotometrically in each phase.

In Vitro Intestinal Transfer Rate Measurements (Caffeine)—The procedure outlined by Levy and Matsuzawa (7) was used. This is essentially the cannulated everted intestine method developed by Crane and Wilson (8). Male Long-Evans rats, weighing 330–470 g., were anesthetized with ether. The small intestine was removed, rinsed with Ringer's solution, and everted. Two segments, 10 cm. in length when stretched by an 8-g. weight, were obtained from the section of the small intestine just distal to the duodenum. The distal ends of the segments were tied and the proximal ends were attached to the cannula of the apparatus described by Crane and Wilson (8). An equal number of first (from the proximal end) and second intestinal segments was used in each part of the experiment. Each segment was suspended in 80 ml. of caffeine in Ringer's solution (at 30°) contained in a large test tube (mucosal solution). Two milliliters of Ringer's solution was introduced into the intestinal segment (serosal solution).[4] The serosal solution was withdrawn completely every 10 min. After each withdrawal the serosa was rinsed with 2 ml. of Ringer's solution and this rinse was combined with the solution withdrawn initially. Another 2 ml. of Ringer's solution was then placed into the intestine to serve as the serosal solution for the next 10-min. interval. The everted intestinal segment was suspended for 1 hr. in a solution containing a high caffeine concentration, for an additional hour in a solution containing a low concentration of caffeine, and then again for 1 hr. in the solution containing a high concentration of caffeine. A different sequence was used with other intestinal segments. This "pairing" minimizes the effect of variability between segments from different rats which may be due particularly to differences in diameter and surface area of the segments.

Assay for Caffeine in Serosal Solution from the Cannulated Everted Rat Intestine—Caffeine was determined by direct spectrophotometry without prior extraction. At the higher caffeine concentration of the mucosal solution (0.120 mole/l.) the serosal samples were simply diluted with water and their absorbance was determined at 273 mμ. At the 0.005 mole/l. concentration, however, it was necessary to correct for the interference from the blank[5] by two-component spectrophotometry at 273 and 299 mμ. This was done on the basis of a ratio of 1.5:1 for the absorbances of the blank at 273 and 299 mμ. The average recovery of caffeine in the concentration range where corrections were necessary was 101%.

Test for Transport Against a Concentration Gradient—The everted sac method described by Wilson and DeCarlo (9) was used. The intestine of the rat was removed, rinsed, and everted as described in a preceding section. One everted sac, about 6 cm. in length, was prepared from the proxi-

[2] Multi-mix Homogenizer, Lourdes Instrument Corp., Brooklyn, N. Y.

[3] Reagent grade benzene was washed successively with 0.2 vol. of 1 *N* NaOH, 1 *N* HCl, and twice with distilled water.

[4] The pH values of the serosal and mucosal solutions at the end of the absorption period ranged from 5.0 to 6.3. In this range, caffeine is nonionized.

[5] "Blank" refers to apparent caffeine values obtained in experiments in which caffeine-free solvents were used.

mal portion of each rat intestine. The everted sac was filled with 1 ml. of pH 7.4 Krebs-Henseleit Ringer solution (10) containing 0.005 *M* caffeine (serosal solution). The sacs were then placed in 15 ml. of the same solution (mucosal solution) contained in 50-ml. conical flasks. The flasks were flushed with a mixture of 95% oxygen and 5% carbon dioxide, sealed, placed in a 30° water bath, and agitated moderately by means of a reciprocating shaker. Aliquots of the mucosal and serosal solutions were obtained after 1 hr. of incubation and were assayed for caffeine using the two-component spectrophotometric analysis described in the preceding section.

In Vitro Intestinal Transfer Rate Measurements (Caffeine in the Presence of Salicylate)—The procedure was essentially the same as that outlined in a preceding paragraph for caffeine except for the use of female Wistar rats and a Krebs-Ringer buffer (11), adjusted with HCl to pH 4, as the solvent for the mucosal solution. The mucosal solution consisted of 0.1% caffeine, alone or together with 0.3% salicylic acid. Some of the solutions also contained 2% ethanol. The serosal solution consisted of pH 7.0 Krebs-Ringer solution (11). Each experiment was carried out for 60 min. at 37°, with sampling at 15-min. intervals. Caffeine was assayed by the method of Axelrod and Reichenthal (4) and ethanol by the method of Hoult and Pawan (5).

Calculation of Intestinal Transfer Rate Constants—The application of Fick's first law (12) to the transfer of substances across a biologic membrane yields the following equation (13):

$$R = kA \frac{C_1 - C_2}{x}$$

where R is the rate of diffusion across a barrier (*e.g.*, the everted intestine) which may be expressed in units of mg./hr., k is a constant whose units are then cm.²/hr., A is the cross-sectional area of the diffusion barrier in cm.², C_1 and C_2 are the concentrations of drug in the source (mucosal) and receiving (serosal) compartments, respectively, in mg./cm.³, and x is the thickness of the barrier in cm. The transfer rate constant used in this study, k_t, is defined as:

$$k_t = \frac{kA}{x} = \frac{R}{C_1 - C_2}$$

The units of k_t are then cm.³/hr. Total replacement of the serosal solution at short intervals (every 10 min.) prevented any pronounced buildup of C_2 ($<0.17\ C_1$). Also, C_1 remained essentially constant during the experiment due to the large volume of the mucosal solution. Thus, k_t approximates R/C_1 under steady-state conditions.

RESULTS AND DISCUSSION

Caffeine-Salicylic Acid Complex—There are three likely mechanisms by which salicylic acid can affect caffeine absorption from the rat stomach. First, the complex formed by these two drugs (2) may have an absorption rate constant different from that of caffeine itself. Since about 40% of the caffeine in the administered solution was in complexed form, a pronounced difference in the absorption rate constant of free and complexed caffeine would result in an appreciable difference in the overall absorption rate of caffeine when administered alone and together with salicylic acid, respectively. Second, salicylic acid may have a direct effect on the permeability characteristics of the gastric mucosa, and third, it may affect the *in vivo* absorption rate of caffeine by a systemic effect such as a change in the rate of gastric blood flow.

TABLE I—EFFECT OF SALICYLIC ACID ON THE *In Vivo* ABSORPTION OF CAFFEINE AND ETHANOL FROM THE STOMACH OF THE RAT

Initial Composition of Solution[a] % w/v	% Absorbed[b] in 1.5 hr. Caffeine	Ethanol	Ratio of % Absorbed Values, Without Salicylic Acid : With Salicylic Acid Caffeine	Ethanol
Caffeine, 0.2 Ethanol, 2.0	37.1 (4.1)	55.9 (3.8)	1.3	1.2
Caffeine, 0.2 Ethanol, 2.0 Salicylic Acid, 0.275	28.0 (4.0)	46.1 (6.1)		

[a] 0.1 *N* HCl was used as the solvent. [b] Mean of the values from 6 rats, standard deviations in parentheses.

The effect of salicylic acid on caffeine absorption from the *in situ* ligated rat stomach is shown in Table I. It is evident that the absorption rate of caffeine was significantly decreased in the presence of salicylic acid ($p < 0.01$, t test). However, the absorption of ethanol, which was included in the drug solutions as a noncomplexed marker, was also decreased in the presence of this concentration of salicylic acid ($p < 0.02$, t test). For comparative purposes, the effect of salicylic acid on the absorption of caffeine and ethanol was expressed in terms of the ratios shown in Table I. It can be noted that salicylic acid decreased the absorption of both the complexed caffeine and the noncomplexed ethanol to a similar extent. This indicates that the decreased absorption of caffeine in the presence of salicylic acid was not due to complex formation. There was visual evidence of considerable gastric damage due to salicylic acid; the solutions containing caffeine, ethanol, and salicylic acid[6] frequently caused gastric bleeding and ulceration, while no such effects were noted with solutions containing only caffeine and ethanol. There appeared to be a rough inverse correlation between the absorption rates of caffeine and ethanol on one hand, and the extent of gastric bleeding on the other. It seems, therefore, that the decreased absorption of caffeine in the presence of a relatively high concentration of salicylic acid was due to an effect of salicylic acid on the gastric mucosa, and not to an effect of complex formation *per se*. These results demonstrate the need to distinguish between an effect of a complexing agent on the drug and a possible effect on the biologic membrane. They illustrate also the utility of a noncomplexed marker such as ethanol for this purpose.[7] It should be noted, however, that ethanol is not necessarily a suitable marker for the assessment of effects on biologic membranes involving mechanisms other than bleeding and erosions (14).

[6] The drug solution was essentially saturated with respect to free salicylic acid in order to complex as high a fraction of caffeine as possible.

[7] The absorption of ethanol is not decreased at a lower salicylic acid concentration (0.1%) which does not cause visible mucosal damage (1, 6).

TABLE II—EFFECT OF SALICYLATE ON THE TRANSFER OF CAFFEINE ACROSS THE CANNULATED EVERTED INTESTINE OF THE RAT

Composition of Mucosal Solution,[a] %		Transfer Rate[b] Caffeine, mg./hr.	Transfer Rate[b] Ethanol, mg./hr.
Caffeine, 0.1		2.38	67.6
Ethanol, 2.0		2.06	*c*
		1.95	63.8
	Mean	2.13	65.7
Caffeine, 0.1		2.06	69.2
Ethanol, 2.0		1.79	*c*
Salicylic acid, 0.3		1.86	62.0
	Mean	1.90	65.6

[a] The solvent was Krebs-Ringer buffer adjusted to pH 4. [b] Data from individual experiments, each based on 4 samplings at 15-min intervals. [c] Ethanol was not included in these experiments.

TABLE III—PARTITIONING BEHAVIOR OF *p*-HYDROXYBENZOIC ACID AND CAFFEINE, ALONE AND IN THE PRESENCE OF EACH OTHER

Initial Composition of Aqueous Phase, %	Apparent Partition Coefficient[a]
Parahydroxybenzoic Acid	
p-Hydroxybenzoic acid, 0.1	11
p-Hydroxybenzoic acid, 0.1 Caffeine, 2.2	1.6
Caffeine	
Caffeine, 0.194	0.40
Caffeine, 0.194 *p*-Hydroxybenzoic acid, 0.8	0.54
Caffeine, 0.194 *p*-Hydroxybenzoic acid, 4.0[b]	0.65

[a] Isoamyl acetate–0.1 *N* HCl, at 25 ± 2°. [b] In this instance, it was necessary to dissolve the *p*-hydroxybenzoic acid in the isoamyl acetate prior to equilibration because of the limited aqueous solubility of this compound.

TABLE IV—EFFECT OF *p*-HYDROXYBENZOIC ACID ON CAFFEINE ABSORPTION FROM THE STOMACH OF THE RAT

Initial Composition of Solution,[a] %	% Absorbed[b] in 1 hr.
Caffeine, 0.2	32.7 (3.1)
Caffeine, 0.2 *p*-Hydroxybenzoic acid, 0.83	27.7 (4.5)

[a] 0.1 *N* HCl was used as the solvent. [b] Mean of the values from 4 animals, standard deviations in parentheses.

Since caffeine forms a complex with salicylate ion having a stability constant similar to that of the caffeine–salicylic acid complex (2), the study was repeated at pH 4 by means of the everted intestine procedure (8). The results of these experiments are shown in Table II and indicate that complexation with salicylate ion had no appreciable effect on the intestinal transfer of caffeine and certainly did not increase the transfer rate of this drug. Since about 90% of the salicylate was in ionized form, it had no measurable effect on the permeability characteristics of the intestinal membrane, as reflected by the lack of any effect on the intestinal transfer of ethanol. It has recently been observed that caffeine has no effect on the intestinal transfer rate of salicylic acid at pH 5, but decreases the rate of transfer at pH 2 (15).

Caffeine–p-Hydroxybenzoic Acid Complex—Higuchi and Zuck (2) have estimated the stability constant of the caffeine–*p*-hydroxybenzoic acid complex to be at least 100 l./mole. This stability constant and the intrinsic solubility of *p*-hydroxybenzoic acid are considerably higher than the corresponding values for the caffeine–salicylic acid complex and salicylic acid, respectively, and thus permit more extensive complexation of caffeine (at least 83% in this experiment) than was possible with salicylic acid. It was observed also that *p*-hydroxybenzoic acid, unlike salicylic acid, did not visibly damage the gastric mucosa. Complexation of caffeine with *p*-hydroxybenzoic acid increases the apparent partition coefficient of caffeine to a value between that of free caffeine and free *p*-hydroxybenzoic acid, respectively (Table III). Contrary to expectations, this increase in apparent partition coefficient was not accompanied by an increased gastric absorption rate (Table IV). This study was terminated when it was found that caffeine is definitely not more rapidly absorbed in the presence of *p*-hydroxybenzoic acid.[8] The number of experiments was insufficient to determine if the apparent decrease in the absorption of caffeine in the presence of the complexing agent was real ($0.2 > p > 0.1$, t test). A discussion of possible reasons for the observed results will be deferred to a following report which deals with another complexing system and includes data which permit a more definitive interpretation of the type of effects observed with the caffeine–*p*-hydroxybenzoic acid system.

Effect of Self-Association on Intestinal Transfer of Caffeine—It is known that caffeine undergoes considerable self-association except at very low concentrations. Guttman and Higuchi (3) have made an extensive investigation of the equilibria involved in this system. Their data, which show a decrease in the apparent lipoid–aqueous partition coefficient with increasing concentration of caffeine, suggest that caffeine exists only in monomeric form in the organic phase used in their study (chloroform 10% v/v in isooctane), but that it also forms dimers and tetramers in water. These physicochemical characteristics made a study of the effect of concentration on the absorption of caffeine across biologic membranes of interest. The everted small intestine of the rat was used in this study because of the relative simplicity and sensitivity of this procedure.[9]

The results of two experiments, which involved the measurement of caffeine transfer rates from high, low, and high concentrations of caffeine (in that order) across an everted intestinal segment of the rat, are shown in Figs. 1 and 2. The data are plotted in terms of the ratio, transfer rate/mucosal concentration (to be referred to as the transfer ratio), which, in the steady state and under sink conditions, is equivalent to the intestinal transfer rate constant as defined under *Experimental*. At the high concentration of caffeine (0.12 mole/l.), the transfer ratio increased with time until steady state was

[8] This is particularly remarkable since, as is shown in the subsequent section, a reduction in the concentration of uncomplexed caffeine should, by decreasing the degree of caffeine self-association, result in more rapid absorption of the uncomplexed drug.

[9] The absorption studies of the caffeine–salicylic acid and caffeine–*p*-hydroxybenzoic acid complexing systems had to be carried out on the ligated rat stomach rather than the everted rat intestine because of the need to use solutions of very low pH to prevent ionization of the two weak acids.

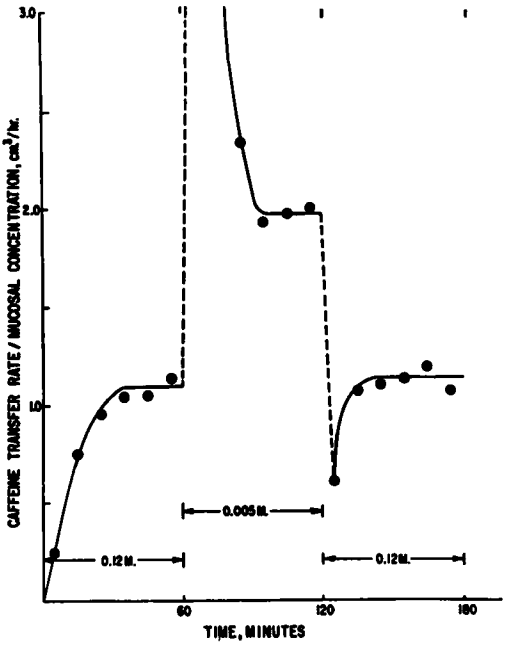

Fig. 1—Effect of concentration on intestinal transfer of caffeine. Transfer rate/mucosal concentration as a function of time, Exp. 1. The data were plotted at the midpoint of each 10-min. sampling period. The concentrations shown in the figure refer to caffeine concentration in the mucosal solution during the various time periods of the experiment. Values which were beyond the scale of the figure were: 17.1 cm.³/hr. at 65 min. and 3.9 cm.³/hr. at 75 min.

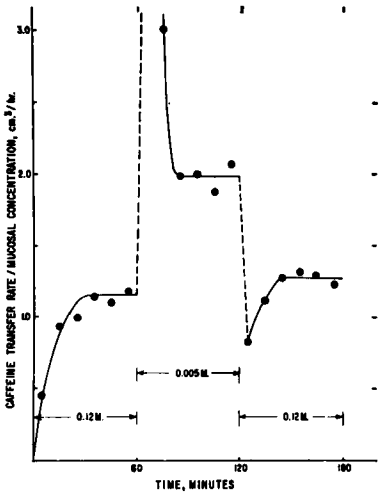

Fig. 2—Effect of concentration on intestinal transfer of caffeine, Exp. 2. Details as in Fig. 1. The value which was beyond the scale of the figure was: 12.4 cm.³/hr. at 65 min.

reached. This is due to a gradual build-up of drug concentration within the intestinal wall (16). At the low caffeine concentration (0.005 mole/l.) following the high concentration, drug which had been retained in the intestinal wall from the preceding period gradually diffused out of the wall until a new apparent steady-state concentration was attained. It is evident that the transfer ratio at the apparent steady state was considerably lower at the high concentration of caffeine than at the lower concentration. The similarity of the apparent steady-state transfer ratios in the first and third time periods indicates that intestinal permeability remained essentially constant during the 3-hr. experiment. The desirability of repeating the conditions of the first time period in a third time period to assess any possible effect of caffeine on the integrity of the intestinal mucosa made it necessary to limit each period to 60 min. Another indication that the intestinal membrane permeability remained essentially unchanged for the duration of the experiments in this study was provided by the results of preliminary experiments in which the plateau transfer ratio attained at about 30 min. (using only 0.005 mole/l. caffeine in the mucosal solution) did not change significantly ($<\pm 7\%$) in the following 3.5 hr.

Figures 3 and 4 show the results of experiments in which the sequence of caffeine concentration changes was reversed, *i.e.*, the segments were suspended for 1 hr. in a 0.005 mole/l. caffeine solution, for a second hour in a 0.12 mole/l. caffeine solution, and finally once more in a 0.005 mole/l. caffeine solution. Again, the apparent intestinal transfer rate constant of caffeine was higher at low concentrations than at high concentrations of the drug. However, the difference between the plateau transfer ratios in the first two time periods was not as pronounced in this series of experiments as in the series shown in Figs. 1 and 2. This may be due to two reasons: the initial exposure of the intestine to a high concentration of caffeine may cause an immediate increase in intestinal permeability which then remains constant throughout the experiment, or, the apparent plateau transfer ratio for caffeine

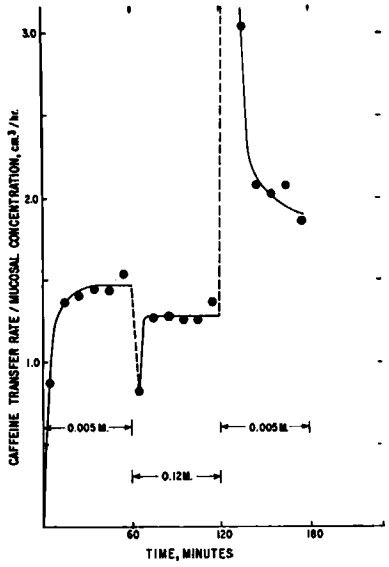

Fig. 3—Effect of concentration on intestinal transfer of caffeine, Exp. 3. Details as in Fig. 1. The value which was beyond the scale of the figure was: 12.7 cm.³/hr. at 125 min.

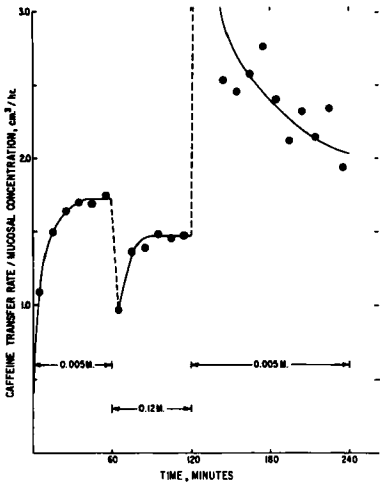

Fig. 4—Effect of concentration on intestinal transfer of caffeine, Exp. 4. Details as in Fig. 1. Values which were beyond the scale of the figure were: 14.2 cm.³/hr. at 125 min. and 3.3 cm.³/hr. at 135 min.

at low concentration following exposure of the intestine to a high concentration of caffeine (Figs. 1 and 2) may not actually reflect steady-state conditions, but rather be the result of a slow efflux of previously accumulated caffeine from the intestinal wall.

Experiments which will be reported in a subsequent publication have shown that the permeability of the everted rat intestine to salicylamide was not affected by exposure of the intestine to a high (0.113 mole/l.) caffeine concentration (17). This would tend to rule out the possibility of an effect of the high concentration of caffeine on intestinal permeability in the present study. In addition, the transfer ratio data for the third time period of the experiments shown in Fig. 3 and particularly in Fig. 4 (where the time period was extended to 240 min.) give a strong indication of a slow efflux following an initial rapid efflux of caffeine from the intestinal wall after the intestine had been exposed to a high concentration of this drug. It appears, therefore, that the transfer rate constants represented by the plateau transfer ratios in the first and second time periods of Figs. 3 and 4 are the most realistic and conservative index of the difference in the intestinal transfer rate constants of caffeine at low and high concentrations of the drug.

The study of Guttman and Higuchi (3) yields information concerning the degree of self-association of caffeine at the concentrations used in this study. It was found that the apparent aqueous–organic partition coefficients of caffeine under the conditions of their study, where distilled water was used as the aqueous phase, were essentially the same as when the aqueous system of the present study, Ringer's solution, was used (Table V). This shows that the self-association of caffeine was not measurably affected by the presence of the components of the electrolyte solution and justifies the direct use of the data from Guttman and Higuchi's study (Table VI).

The results of the intestinal transfer study are summarized in Table VI, which also shows the extent of self-association of caffeine at the two

Table V—Partition Coefficient of Caffeine Between Distilled Water or Ringer's Solution and an Organic Solvent

[d] The difference between the two mean transfer rate constants is statistically significant ($p < 0.01$) as determined by the t test for paired observations.

concentrations used. The transfer rate constants were determined from the steady-state portion of the first two time periods of only the experiments in which the transfer at low (0.005 mole/l.) caffeine concentration was determined first. These transfer rate constants reflect not only the data in Figs. 3 and 4, but also the results of two additional experiments not represented by figures. The intestinal transfer rate constant at the low concentration of caffeine is significantly higher ($p < 0.01$, t test for paired observations) than that at a high concentration. This difference would have been even more pronounced if the experiments shown in Figs. 1 and 2 had been included in the data analysis.

Incubation of everted intestinal sacs containing 0.005 mole/l. caffeine for 1 hr. in solutions containing the same concentration of caffeine in an oxygenated medium yielded no evidence of uphill transport; the mean mucosal–serosal concentration ratio was 0.97 for four experiments. Thus, the concentration dependence of the intestinal transfer of caffeine does not appear to be due to the saturation of an active transport process in the small intestine of the rat. However, other modes of specialized transport cannot be ruled out on the basis of the experimental data. But, since the structural specificity of most specialized intestinal transport processes is quite exacting, it seems unlikely that a drug such as caffeine would be transferred by this type of process. The experimental results also cannot be explained by assuming that only the monomeric form of caffeine is transferred across the intestine; the decrease of the intestinal transfer rate constant of caffeine at the higher concentration is much smaller than the decrease in the fraction of total caffeine which exists in monomeric form (Table VI). The overall diffusivity of caffeine, determined on the basis of the fraction and molecular

TABLE VII—RATIO OF THE INTESTINAL TRANSFER RATE CONSTANTS OF CAFFEINE AT LOW AND HIGH CONCENTRATION COMPARED TO THE THEORETICAL RATIO OF THE OVERALL DIFFUSIVITIES

[a] Ratio of intestinal transfer rate constants for caffeine in low and high concentration. [b] D = constant/$M^{1/2}$ (18). In this instance, $M = \Sigma M_i f_i$, where M_i is the apparent molecular weight of a particular species (monomer, dimer, or tetramer) and f_i is the fraction of total caffeine present existing as this species. [c] D = constant/$M^{1/3}$ (19), calculated as in *b*.

weight of each species (*i.e.*, monomer, dimer, and tetramer) is lower at higher concentrations of caffeine. This could affect transfer rate if diffusion of the drug to the membrane surface is transfer rate limiting or if the aggregates remain intact during transfer across the intestine. The ratio of the overall diffusivity of caffeine at low and high concentrations, as calculated by two different equations, is somewhat higher than the ratio of intestinal transfer rate constants determined experimentally (Table VII). It may be possible, however, that diffusion to the mucosal membrane surface affects the transfer rate constant of one or both of the associated species of caffeine but not that of the monomer. The experimental data may also be rationalized by assuming that each of the caffeine species is absorbed as such but that the transfer rate constant of each species is different. This may be complicated further by a possible change in the self-association equilibria at or adjacent to the rate-limiting biologic barrier (7).

The important conclusions of this study are that (*a*) drug complexes with a higher apparent partition coefficient than the free drug are not necessarily more rapidly absorbed, and (*b*) a concentration dependence in the apparent absorption rate constant of a drug does not necessarily reflect the presence of a specialized transport process, but may be due to the physicochemical characteristics of the drug as they affect passive diffusion to and across biologic membranes.

Effect of Complex Formation on Drug Absorption VIII

Intestinal Transfer Characteristics of the Salicylamide–Caffeine System

By RICHARD H. REUNING* and GERHARD LEVY†

Salicylamide and caffeine form a complex in aqueous solution which has an apparent lipoid–aqueous partition coefficient intermediate between the partition coefficients of free salicylamide and free caffeine. The transfer rate of salicylamide across the cannulated everted intestine of the rat is decreased in the presence of caffeine at a concentration sufficient to complex an appreciable fraction of the salicylamide. On the other hand, complex formation with salicylamide has no measurable effect on the intestinal transfer rate of caffeine. These observations suggest that the complex can be transferred as such and that diffusion of the drugs through the bulk solution to the membrane surface is not transfer rate limiting. A theoretical analysis of the simultaneous equilibria involved in the partitioning between an organic and an aqueous phase of two interacting drugs in the presence of one another shows that the apparent partition coefficient of a drug complex does not necessarily represent the ratio of transfer rate constants of the complex itself across the interface. For this reason, it should not be assumed that there will always be a correlation between the apparent partition coefficient and the intestinal transfer rate constant of drug complexes. The results of the reported study support this conclusion.

IN A PREVIOUS STUDY (1) salicylamide and caffeine were found to form a complex in aqueous solution. The stoichiometry and stability constant of the complex were determined at pH 5 where both drugs are essentially undissociated. The purpose of the present study was to investigate the effect of this complex formation on the overall[1] intestinal transfer of both salicylamide and caffeine and to compare the effects of complex formation on the intestinal transfer rates and on the apparent partition coefficients of salicylamide and caffeine, respectively.

The salicylamide–caffeine system was chosen as a model for a study of the effect of complex formation on drug absorption since extensive complexation of either drug is possible under suitable experimental conditions. Such extensive complexation, made possible by the adequate solubility of both drugs in water and by the relatively high stability constant of the complex (41 l./mole at 37°), is desirable because any pronounced effect of complex formation on intestinal transfer will then be reflected by a measurable change in the overall intestinal transfer rates of the two drugs.

[1] In the context used in this paper, "overall" refers to the combined effect or behavior of free and complexed drug.

EXPERIMENTAL

Intestinal Transfer Rate Determinations—The cannulated everted intestine method developed by Crane and Wilson (2) was used with the modifications described previously (3). Each everted intestinal segment, 10 cm. in length, from a male Sprague-Dawley rat (290–380 g.), was suspended in a large test tube containing about 50 ml. of mucosal solution at 37°. Krebs-Henseleit-Acetate Ringer[2] solution (KHAR), pH 5.0, containing caffeine, salicylamide, or both in varying concentrations, was used as the mucosal solution. Two intestinal segments were obtained from each rat and an equal number of first and second segments were used for each experiment. Two milliliters of the serosal solution, Krebs-Henseleit-Bicarbonate Ringer solution (KHBR), pH 7.4 (4), was introduced into the everted intestinal segment. The entire serosal solution was withdrawn every 10 min. After each withdrawal the serosa was rinsed with KHBR and the rinse was combined with the previously withdrawn solution for subsequent assay. Immediately after completion of the rinsing procedure, another 2 ml. of KHBR was placed into the intestinal segment. This frequent replacement of the serosal solution prevented appreciable build-up of drug concentration on the serosal side. In one set of experiments involving the measurement of caffeine transfer rates in the presence of salicylamide in the mucosal solution, salicylamide was also included in the serosal solution.

The serosal samples were diluted with KHAR, pH 5.0, and the amount of caffeine or salicylamide transferred was determined by spectrophotometry at 273 or 299 mμ, respectively. When both drugs were present together, two-component spectrophotometry was used at these wavelengths. The absorbances of the two compounds were additive in the concentration range of the assay procedure. A small correction for blank was necessary only in the first two 10-min. samples, as determined in

[2] This is similar to Krebs-Henseleit-Bicarbonate Ringer solution (4) except that an equimolar amount of acetate buffer was substituted for the bicarbonate buffer.

experiments in which drug-free solutions were used. When known amounts of both drugs were added to KHBR solution which had been incubated for 10 min. with an intestinal segment (*i.e.*, using the cannulated everted intestine method as described above, but without drugs), an average of 101% of added caffeine and 100% of added salicylamide was recovered.

The transfer rates were determined from the slope of a plot of cumulative amount of drug transferred *versus* time. The transfer rate constant was obtained by dividing the slope value by the mucosal drug concentration. This was possible because of frequent replacement of the serosal solution and because the volume of the mucosal solution was large enough so that the drug concentration in that solution remained essentially constant for the duration of the experiment. A derivation from Fick's law of this method of calculating the transfer rate constant has been presented previously (3).

Experimental Design—The study was designed to determine the effect of complex formation on drug absorption under conditions which also permitted an assessment of any possible alteration in the permeability characteristics of the everted intestine as a function of time or upon addition of the complexing agent. The everted intestinal segment was first suspended for 40 min. in a solution containing only the drug, then for 40 min. in a solution containing drug plus complexing agent, and then again for 40 min. in a solution containing only drug. An equal number of experiments was carried out in a different sequence. Comparison of the transfer rates observed in the first and third time periods permitted an evaluation of any possible changes in the permeability of the intestinal segment. Also, the comparison of transfer rates both in the absence and presence of complexing agent in the same intestinal segment eliminates any variability due to possible differences in the surface area, thickness, *etc.*, of different segments.

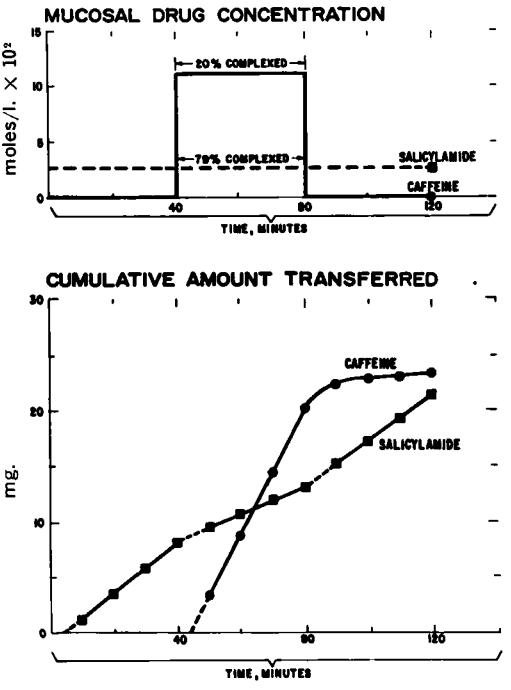

Fig. 1—Effect of complex formation with caffeine on the transfer of salicylamide across the cannulated everted intestine of the rat. In the upper portion of the figure the concentrations of salicylamide and caffeine in the mucosal solution are plotted as a function of time. In the lower portion of the figure, the cumulative amounts of salicylamide and caffeine transferred across the intestine are plotted as a function of time.

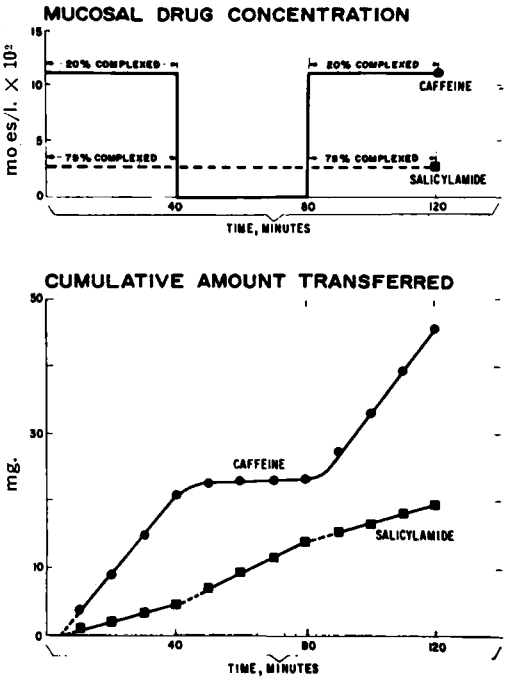

Fig. 2—Effect of complex formation with caffeine on the transfer of salicylamide across the cannulated everted intestine of the rat. Details as in Fig. 1 except that the order of addition of the complexing agent was changed.

Determination of the Extent of Metabolism of Salicylamide by the Everted Rat Intestine—Three 10-cm. segments of everted intestine from a male Sprague-Dawley rat (280 g.) were tied on one end with suture and filled with 2.5 ml. of serosal solution (KHBR, pH 7.4, was the solvent) through the open end which was then also tied off. Each everted sac was placed in a 50-ml. flask containing 15 ml. of mucosal solution (KHAR, pH 5.0, was the solvent). The flasks were flushed with 95% O_2–5% CO_2 and incubated for 1 hr. The mucosal and serosal solutions contained the same concentration of the drug(s), namely either salicylamide, salicylamide and caffeine, or solvent alone. The latter was used as a control to determine the recovery of salicylamide by adding known amounts of this drug, similar to the amounts used in the other two experiments, to the serosal solution, the mucosal solution, and to a homogenate of the intestinal segment. Salicylamide in the mucosal and serosal solutions and in a homogenate of the everted intestinal segment was assayed by a method which is specific for free drug and

excludes glucuronide or sulfate conjugates, if present. This assay, which involves extraction of the drug from a pH 7 buffer into ethylene dichloride and subsequent reextraction into a ferric nitrate reagent solution, has been described elsewhere (5).

Determination of Apparent Partition Coefficients—Apparent partition coefficients were determined (at least in duplicate) with isoamyl acetate as the organic phase and KHAR, pH 5.0, as the aqueous phase. Equilibration was carried out at room temperature for at least 12 hr. using an automatic shaking apparatus. In the determination of salicylamide partition coefficients, the drug in the aqueous phase was assayed colorimetrically as previously described (1). In the determination of caffeine partition coefficients, caffeine alone in the aqueous phase was assayed spectrophotometrically at 273 mμ. When salicylamide was present, both drugs were assayed in the aqueous phase using two-component spectrophotometry at 273 and 299 mμ.

RESULTS AND DISCUSSION

Effect of Complex Formation of Intestinal Transfer of Salicylamide and Caffeine—The effect of caffeine (2.2%) on the overall intestinal transfer rate of salicylamide (0.384%) is shown in Figs. 1 and 2. It is evident that a pronounced decrease in the overall transfer rate of salicylamide occurred when this drug was complexed extensively with caffeine.[3] The figures also show the transfer of the complexing agent, caffeine, and the degree to which it was complexed. The intestinal transfer rate constant for salicylamide alone (0.384% in the mucosal solution) was 3.5 cm.³/hr. as compared to 2.0 cm.³/hr. in the presence of 2.2% caffeine (means of the paired observations from four segments). Subsequent experiments, to be reported in a following paper (6), yielded essentially the same values for the transfer rate constants (3.4 and 2.0 cm.³/hr., respectively) when the serosal solution contained caffeine and was exchanged every 6 min. rather than every 10 min. This shows that practically sink conditions were maintained in the present study.

The transfer rates of salicylamide and caffeine were essentially the same in the first and third time periods (Figs. 1 and 2). This indicates that the permeability of the everted intestine did not change measurably during the time of the experiment, regardless of the presence or absence of a high concentration of caffeine. These results suggest that the effect of caffeine on the intestinal transfer of salicylamide is not due to a modification of intestinal permeability characteristics.

The possibility that the transfer rate data are affected by the formation of salicylamide conjugates in the intestinal mucosa was examined. When salicylamide in a relatively low concentration (0.024% as compared to 0.384% used in the transfer study) was incubated with intestinal tissue for 1 hr., no significant metabolism of salicylamide was found, regardless of the presence or absence of caffeine (Table I). These results are in agreement with those of other workers who have found significant metabolism of salicylamide in rabbit intestinal tissue, but not in that of the rat (7).

[3] The calculations of the extent of complexation in this paper are based on a stability constant of 41.1 l./mole for the salicylamide–caffeine complex (1:1) and are not corrected for caffeine dimerization (1). These calculations indicated 79% complexation of salicylamide in the experiments shown in Figs. 1 and 2; direct experimental determination showed 73% complexation (1).

TABLE I—RECOVERY OF SALICYLAMIDE FROM EVERTED INTESTINAL SACS OF THE RAT AFTER 1 HR. OF INCUBATION[a]

Initial Composition of Mucosal and Serosal Solutions, %	% Recovery[b]
Salicylamide control (no incubation)	99
Salicylamide 0.024	98
Salicylamide 0.024 } Caffeine 2.0 }	99

[a] The everted sacs were incubated at 37° in an atmosphere of 5% CO_2 in O_2. Krebs-Henseleit-Bicarbonate Ringer solution, pH 7.4, was the solvent for the serosal solution and Krebs-Henseleit Acetate Ringer solution, pH 5.0, was the solvent for the mucosal solution. [b] One of each.

The decrease in the intestinal transfer rate of salicylamide in the presence of caffeine cannot be attributed to the decreased thermodynamic activity of salicylamide and an assumption that the complex itself is not absorbed since, in the presence of caffeine, the concentration of free salicylamide was about 21% of that when caffeine was absent while the transfer rate was 58% of that when caffeine was absent. It appears, therefore, that the salicylamide–caffeine complex itself is transferred across the everted intestine but at a rate different from that of free salicylamide.

In contrast to the results for salicylamide, the intestinal transfer rate of caffeine (0.388%) was not appreciably affected when complexed to the extent of about 54% due to the presence of a relatively high concentration of salicylamide (0.543%). The data from two of the four experiments that were carried out are shown in Figs. 3 and 4. The experi-

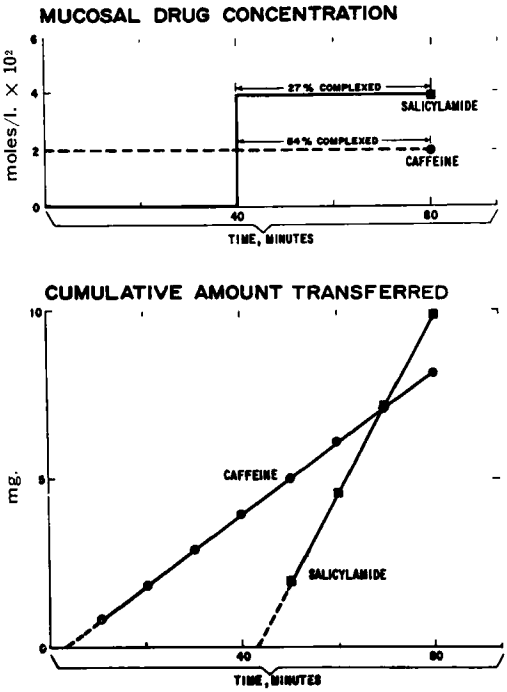

Fig. 3—Effect of complex formation with salicylamide on the transfer of caffeine across the cannulated everted intestine of the rat. Details as in Fig. 1.

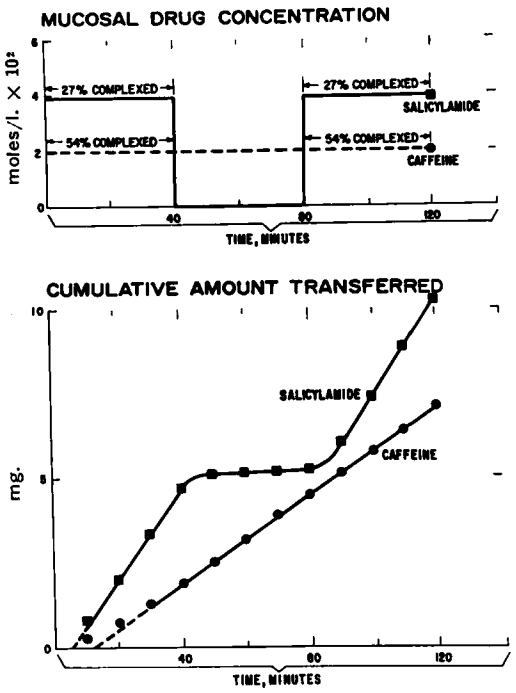

Fig. 4—Effect of complex formation with salicylamide on the transfer of caffeine across the cannulated everted intestine of the rat. Details as in Fig. 1. The order of addition of the complexing agent was different from that in Fig. 3.

ments were repeated under conditions where salicylamide was present in the serosal solution in a concentration equal to that of free salicylamide in the mucosal solution. These results, which are listed in Table II, also show that there was no appreciable difference in the intestinal transfer rate of caffeine alone and in the presence of salicylamide.

In view of the indications from the salicylamide transfer rate determinations that the salicylamide–caffeine complex is transferred as such, and considering the lack of a measurable difference in the overall intestinal transfer of free and complexed caffeine, there is strong indication that the salicylamide–caffeine complex is transferred across the intestine at the same rate as free caffeine. A consequence of this reasoning, which obtains strong support from the results of studies to be reported subsequently (6), is that diffusion of caffeine and the salicylamide–caffeine complex through the aqueous solution to the intestinal mucosa is not

Table II—Effect of Salicylamide in the Mucosal and Serosal Solutions on the Intestinal Transfer Rate Constant of Caffeine

Composition of Mucosal Solution, %	Transfer Rate Constant,[a] cm.³/hr.
Caffeine, 0.388	1.4 (0.05)
Caffeine, 0.388 Salicylamide,[b] 0.543	1.5 (0.32)[c]

[a] Mean of the values from 4 segments, standard deviation in parentheses. [b] Salicylamide was also present in the serosal solution at a concentration equal to the calculated concentration of free salicylamide in the mucosal solution. [c] The larger standard deviation in this set of experiments is due to one unusually high value (2.0 cm.³/hr.). The average transfer rate constant excluding this value is 1.4 cm.³/hr.

Table III—Apparent Partition Coefficients of Salicylamide, Caffeine, and Salicylamide–Caffeine Complex

rate limiting in the intestinal transfer of these two species.

Effect of Complex Formation on the Apparent Partition Coefficients of Salicylamide, Caffeine, and Salicylamide–Caffeine Complex—It is well known that there is a positive relationship between the lipoid–aqueous partition coefficient and the gastrointestinal absorption rate of many drugs (8, 9). It was found that the partition coefficient of salicylamide is higher, and that of caffeine is lower, than the apparent partition coefficient of the salicylamide–caffeine complex itself (Table III). The apparent partition coefficient of the complex was determined[4] at three different salicylamide–caffeine concentration ratios, with essentially the same value being obtained in each case.

An analysis of the simultaneous equilibria which will determine the apparent partition coefficient of a drug complex is appropriate to assess the likely relationship between this property and the rate of transfer of complex across a biologic membrane. These simultaneous equilibria are shown in the following model:

$$\begin{array}{ccc} A_o & + & B_o \overset{K_5}{\rightleftharpoons} A\text{-}B_o \\ \uparrow\downarrow K_1 & & \uparrow\downarrow K_2 \qquad \uparrow\downarrow K_4 \\ A_a & + & B_a \underset{K_3}{\rightleftharpoons} A\text{-}B_a \end{array}$$

where A and B are the two individual components of the drug complex and A-B is the complex itself. The subscript *o* refers to the species in the organic phase and the subscript *a* to the species in the aqueous phase. Both A and B are assumed to partition between the organic and aqueous phases. The definitions of the various constants involved in these equilibria are as follows:

$$PC_{app.} = \frac{[B_o] + [A\text{-}B_o]}{[B_a] + [A\text{-}B_a]} \qquad K_1 = [A_o]/[A_a]$$

$$K_2 = [B_o]/[B_a] \qquad K_3 = [A\text{-}B_a]/[A_a][B_a]$$

$$K_4 = [A\text{-}B_o]/[A\text{-}B_a] \qquad K_5 = [A\text{-}B_o]/[A_o][B_o]$$

[4] The apparent partition coefficient of the complex was calculated as shown below, where A represents salicylamide, B represents caffeine, and where the subscripts and constants have the meanings defined subsequently for the model in the text. (*a*) $[A_a]$, $[B_a]$, and $[A\text{-}B_a]$ are calculated from K_3 and the experimentally determined total salicylamide and caffeine concentrations in the aqueous phase at equilibrium, according to the procedure described in Method I in the appendix of *Reference 1.* (*b*) $[B_o]$ is determined from $[B_a]$ and the partition coefficient, K_2. (*c*) $[A\text{-}B_o]$ = [(total amount B in both phases)-(amount of free B in both phases plus amount of A-B in aqueous phase)] ÷ volume of organic phase. (*d*) Apparent partition coefficient of complex = $[A\text{-}B_o]/[A\text{-}B_a]$.

An increase or a decrease in the apparent partition coefficient of drug B ($PC_{app.}$) when partially complexed with drug A indicates that the ratio $[A\text{-}B_o]/[A\text{-}B_a]$ is greater or less, respectively, than the ratio $[B_o]/[B_a]$, or K_2.[5]

However, the ratio $[A\text{-}B_o]/[A\text{-}B_a]$, the apparent partition coefficient of the complex, reflects only the equilibrium condition and does not give any indication of the relative contribution of each of the several pathways by which this equilibrium can be attained. In fact, it can be shown algebraically that the ratio $[A\text{-}B_o]/[A\text{-}B_a]$ is equal to $K_1K_2K_5/K_3$ whether or not the pathway represented by K_4 actually exists.

It is evident from the above discussion that, unlike the partition coefficient of a pure substance which reflects the ratio of its interfacial transfer rate constants in both directions, the apparent partition coefficient of a complex does not necessarily reflect the rates of transfer of the complex itself from one phase to the other. Yet, it is this direct transfer of the complex itself which would most likely bring about a change in the overall absorption rate of complexed drugs. Herein lies the limitation of the use of partitioning data, which are representative of an equilibrium situation, for correlation with intestinal transfer data, which represent a rate phenomenon. The lack of correlation between the transfer rate constants and partition coefficients of salicylamide, caffeine, and the salicylamide–caffeine complex is consistent with this reasoning.

[5] This statement can be substantiated mathematically, taking as an example the case where complexation results in an increase in the apparent partition coefficient ($PC_{app.} > K_2$). If $PC_{app.} > K_2$, then

$$\frac{[B_o] + [A\text{-}B_o]}{[B_a] + [A\text{-}B_a]} > \frac{[B_o]}{[B_a]}$$

Cross-multiplying yields

$$[B_o][B_a] + [A\text{-}B_o][B_a] > [B_o][B_a] + [B_o][A\text{-}B_a]$$
$$[A\text{-}B_o][B_a] > [B_o][A\text{-}B_a]$$

Therefore,

$$\frac{[A\text{-}B_o]}{[A\text{-}B_a]} > \frac{[B_o]}{[B_a]}$$

It appears that factors which determine the rate of transfer of drug complexes across biologic membranes are likely to be resolved only by a consideration of physicochemical effects at the biologic interface and not on the basis of *in vitro* apparent partition coefficient data or transfer experiments using simple nonbiologic membranes or barriers (10). It is therefore appropriate to direct further attention to the equilibria which exist at the surface of biologic membranes in systems consisting of two interacting drugs. This will be the subject of the following paper.

Thiopental Pharmacokinetics

By K. B. BISCHOFF* and R. L. DEDRICK

A mathematical pharmacokinetic model, including flow limitations, lipid solubility, protein binding, and metabolism, is used to make *a priori* predictions of the distribution of thiopental in four body regions. Tissue binding is correlated by means of "effective" protein fractions and bovine serum albumin data. Metabolism is represented by a Michaelis-Menten rate equation. Close agreement with existing experimental data lends confidence in the model as a valuable tool for predictions in a variety of therapeutic situations.

MANY PRIOR studies of thiopental pharmacokinetics have been made, but there remains some question concerning the relative importance of metabolism and lean and adipose tissue uptakes. Some years ago, Brodie and co-workers (1, 2) made quantitative measurements of thiopental concentrations in various body regions and concluded that significant amounts were present

in adipose tissue. The overall rate of metabolism in man was about 15%/hr. and was believed insufficient to account for the observed ultrashort duration of action. Price *et al.* (3) arrived at similar conclusions from mathematical analysis and an analog computer simulation, except that they attributed more of the drug redistribution effects to the lean body mass. Mark and Brand (4) have reviewed much of this work. A somewhat different viewpoint was taken in a recent analog computer study by Saidman and Eger (5) in that a much more important contribution of metabolism was assumed.

BASIS OF MODEL

The purpose here is to devise a mathematical pharmacokinetic model incorporating as many as possible of the variables known to affect drug distribution. Previous work concerning the dynamics of vascular tracers required detailed examination of blood volume distribution and flow rates (6, 7). Since the time scale of interest in the present paper is on the order of a few minutes to several hours, it is permissible to identify certain gross "lumped" regions over which relevant values of perfusion or physical properties may be considered constant. This, then, leads to the same general breakdown used by some previous workers: (*a*) blood, (*b*) viscera (highly perfused lean tissue), (*c*) poorly perfused lean tissue, and (*d*) poorly perfused adipose tissue.

Values of the regional flow and volume parameters representing the normal adult male were taken from Mapleson's detailed data for several body regions (8). Such detail might be of use in future studies, but sufficient thiopental distribution data are not presently available to justify such a complex pharmacokinetic study at this time. Figure 1 illustrates the four body regions and representative numerical parameters.

A useful mathematical model must explicitly include resistances to mass transfer by membrane permeability and constraints caused by flow limitation. Since thiopental is highly lipid soluble, the authors assume, as have earlier workers, that membrane transport is very rapid and the controlling resistance is flow limitation for all regions. A more detailed analysis is required for other solutes which might have lower lipid solubility. For thiopental, then, only the total tissue volumes, quantities of associated equilibrium blood, and blood flows are required, as shown in Fig. 1.

A possible complication that cannot be accommodated by simple compartmental models has recently been discussed by Rackow, Perl, and co-workers (9, 10), in which direct molecular diffusion occurs between two adjacent tissue regions. This would be most likely to occur between adjacent layers of well perfused lean and poorly perfused adipose tissue where the solute is highly lipid soluble. The initial adipose uptake then could be more a result of direct diffusion from the lean tissue than from its own low perfusion. Perl *et al.* (10) considered this effect for fat-soluble gases and showed that certain discrepancies in the data could thereby be explained. For the longer time intervals of interest here, however, and for more slowly diffusing thiopental, it is felt that this effect can be neglected.

Another complication, until recently neglected in the pharmacology and anesthesiology literature, is the phenomenon of protein binding. A good general discussion has been presented by Gillette (11), who illustrated the significance of binding of several drugs. An extensive consideration of binding as it affects pharmacokinetics analyses is found in a series of papers by Krüger-Thiemer (a few of the most recent are 12–14). For cases such as sulfa drugs, only entire body blood and tissue breakdowns were used, and it was clearly shown how binding can alter the features of the mathematical model. For example, the use of an overall distribution coefficient relating blood and tissue concentrations is not possible, since these ratios are a function of the concentration level when nonlinear binding occurs. Also, since the free (unbound) concentration is presumed to be the proper basis for pharmacological action, the extent of binding must be accounted for in order to produce meaningful predictions. The present work includes binding effects; the details will be discussed later.

MATHEMATICAL MODEL

Transient mass balances can be written for each of the body regions considered, assuming flow-limiting conditions. For the blood compartment:

$$\underset{\text{accumulation of unbound drug}}{f_B V_B \frac{dC_B}{dt}} + \underset{\text{accumulation of bound drug}}{(1 - f_B) V_B \frac{dx_B}{dt}}$$

$$= \underset{\text{outflow of unbound and bound drug}}{- Q_B [f_B C_B + (1 - f_B) x_B]}$$

$$\underset{\text{inflow from other regions of unbound and bound drug}}{+ Q_V [f_{VB} C_V + (1 - f_{VB}) x_{VB}] + Q_L [f_{LB} C_L + (1 - f_{LB}) x_{LB}] + Q_A [f_{AB} C_A + (1 - f_{AB}) x_{AB}]}$$

$$\underset{\text{ingestion term}}{+ Mg(t)} \qquad \text{(Eq. 1)}$$

The physical meaning of each term is indicated below it for clarity, and the particular symbols are defined under *Notation*.

A similar mass balance for the viscera gives:

$$\underset{\text{accumulation of unbound drug in equilibrium blood and tissue}}{(f_{VB} V_{VB} + f_{VT} V_{VT}) \frac{dC_V}{dt}} + \underset{\text{accumulation of bound drug in equilibrium blood}}{(1 - f_{VB}) V_{VB} \frac{dx_{VB}}{dt}}$$

$$\underset{\text{accumulation of bound drug in tissue}}{+ (1 - f_{VT}) V_{VT} \frac{dx_{VT}}{dt}}$$

$$= \underset{\text{net inflow of unbound and bound drug}}{Q_V [f_B C_B + (1 - f_B) x_B - f_{VB} C_V - (1 - f_{VB}) x_{VB}]}$$

$$\underset{\text{rate of metabolism of drug}}{+ r_V(C_V)} \qquad \text{(Eq. 2)}$$

The metabolism rate term is written in the simple Michaelis-Menten form for the calculations:

$$r_V(C_V) = -\frac{k_V C_V}{K_{mV} + C_V} \qquad \text{(Eq. 3)}$$

Since the metabolism mainly occurs in the microsomes of the liver (11), the rate of reaction, r_V, appears in the balance for the visceral region. Similar terms could be added to the other balances if required.

The remaining mass balances have a similar form.

For lean tissue:

$$(f_{LB}V_{LB} + f_{LT}V_{LT})\frac{dC_L}{dt} + (1 - f_{LB})V_{LB}\frac{dx_{LB}}{dt} + (1 - f_{LT})V_{LT}\frac{dx_{LT}}{dt} = Q_L[f_B C_B + (1 - f_B)x_B - f_{LB}C_L - (1 - f_{LB})x_{LB}] \qquad \text{(Eq. 4)}$$

For adipose tissue:

$$(f_{AB}V_{AB} + f_{AT}V_{AT})\frac{dC_A}{dt} + (1 - f_{AB})V_{AB}\frac{dx_{AB}}{dt} + (1 - f_{AT})V_{AT}\frac{dx_{AT}}{dt} = Q_A[f_B C_B + (1 - f_B)x_B - f_{AB}C_A - (1 - f_{AB})x_{AB}] \qquad \text{(Eq. 5)}$$

Explicit relations between the various bound and free concentrations are required to solve Eqs. 1–5. For blood plasma protein binding, the results of Goldbaum and Smith (15) are used. They correlated their bovine serum albumin data with the commonly used (see *Reference 11*) two-term relation,

$$x_B = \frac{B_1K_1C_B}{1 + K_1C_B} + \frac{B_2K_2C_B}{1 + K_2C_B} \qquad \text{(Eq. 6)}$$

Goldbaum and Smith (15) also presented data on rabbit tissue binding of a number of barbiturates. In the absence of more information, it is assumed that the relationship for binding by plasma proteins could also be used for tissue protein binding. "Effective tissue protein fractions" are assigned to produce the measured tissue drug concentrations. This assumption is justified on the basis that consistent "effective tissue protein fractions" are found to result for all the barbiturates studied. Further justification of this method with other classes of compounds would be useful.

With this assumed basis, all of the binding relations take on similar functional forms, each with the appropriate free concentration inserted. For example, the viscera binding relations become:

$$x_{VT} = x_{VB} \equiv x_V = \frac{B_1K_1C_V}{1 + K_1C_V} + \frac{B_2K_2C_V}{1 + K_2C_V} \qquad \text{(Eq. 7)}$$

and the lean tissue values,

$$x_{LT} = x_{LB} \equiv x_L = \frac{B_1K_1C_L}{1 + K_1C_L} + \frac{B_2K_2C_L}{1 + K_2C_L} \qquad \text{(Eq. 8)}$$

Adipose tissue must be handled somewhat differently. The equilibrium blood plasma binding has the usual form,

$$x_{AB} = \frac{B_1K_1C_A}{1 + K_1C_A} + \frac{B_2K_2C_A}{1 + K_2C_A} \qquad \text{(Eq. 9)}$$

but the tissue "binding" here is primarily the lipid solubility for which a simple Henry's law formula is used,

$$x_{AT} = B_A C_A \qquad \text{(Eq. 10)}$$

A final simplification assumes that the fractions of protein in all the various blood regions are the same,

$$f_B = f_{VB} = f_{LB} = f_{AB} \qquad \text{(Eq. 11)}$$

These considerations lead to simplifications in Eqs. 1–5 which can now be solved if the input or ingestion function is specified. An approximation to a normalized impulse function similar to that of Bellman *et al.* (16) is used,

$$g(t) = 30\lambda(\lambda t)^2(1 - \lambda t)^2 \qquad \text{(Eq. 12)}$$

where λ is the reciprocal injection duration. This function simulates a smooth injection and is convenient for computation.

RESULTS AND DISCUSSION

Numerical values for the parameters in the above mass balance equations are provided by the data of Mapleson (8) (see Fig. 1) and Goldbaum and Smith (15), except for the metabolism term. In a comprehensive review paper, Mark (17) presents values for the overall rates of metabolism of barbiturates, which for thiopental is about 15%/hr. The parameters k_V and K_{mV} in Eq. 3 are empirically adjusted to provide values of k_V = 26.5 μmole/min. and K_{mV} = 4 (μmole/l.), which gave the desired rate. The recent data of Mark *et al.* (18) can be correlated by a Michaelis-Menten kinetic form to

TABLE I—PARAMETER VALUES

Parameter	Numerical Value
Flow distribution, l./min.	$Q_B = 5.615$, $Q_V = 4.080$, $Q_L = 1.275$, $Q_A = 0.260$
Body region size, l.	$V_B = 2.20$, $V_{VB} = 2.52$, $V_{VT} = 6.20$, $V_{LB} = 0.524$, $V_{LT} = 39.20$, $V_{AB} = 0.160$, $V_{AT} = 12.200$
"Effective" fraction water	$f_B = 0.985$, $f_{VT} = 0.963$, $f_{LT} = 0.980$, $f_{AT} = 0.20$
Binding sites, μmole/l.	$B_1 = 18{,}400$, $B_2 = 305{,}000$
Binding equilibrium constant, l./μmole	$K_1 = 0.060$, $K_2 = 0.000625$
Lipid solubility constant	$B_A = 100$

produce parameter values of the same order of magnitude as those required to obtain the 15%/hr. rate. This lends some confidence to the metabolism rate expression, but the need for more quantitative chemical kinetics work remains clear. The lipid solubility constant lies between the value for peanut oil–water from Mark *et al.* (19) and the value from Price *et al.* (3), corrected for protein binding.

Analytical solutions of the differential equations are not feasible because of the nonlinearities caused by the binding terms; the equations have therefore been solved numerically using a digital computer. As a critical test of the pharmacokinetics model, an *a priori* prediction of the experimental results of Brodie *et al.* (1, 2) on thiopental distribution in dogs was attempted. *A priori* here implies that numerical values of all the parameters in the model (except metabolism) were taken from sources other than Brodie *et al.*: human flow distribution and body region size from Mapleson (8); bovine serum albumin and rabbit tissue binding from Goldbaum and Smith (15); lipid solubility from Mark *et al.* (19) and Price *et al.* (3). The numerical values used in the computations are shown in Table I.

In the cited experiments of Brodie *et al.* (1, 2) 25 mg./kg. thiopental was injected i.v. with a 5-min. injection time. Thus, the final two parameters in the model are $M = 6630$ μmoles (for a 70-kg. man) and $\lambda = 0.20$ min.$^{-1}$.

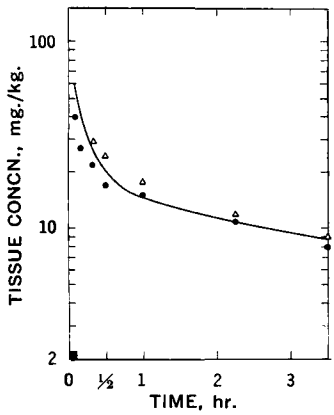

Fig. 2—Comparison of predicted and experimental values for blood. Key: ■, injection duration; ●, dog; Δ, human.

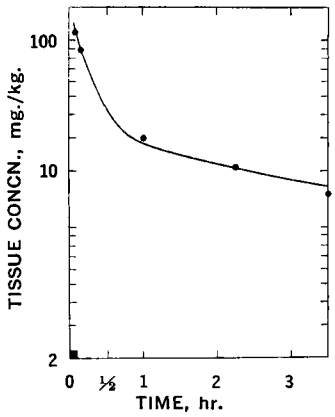

Fig. 3—Comparison of predicted and experimental values for viscera (liver). Key: ■, injection duration; ●, dog.

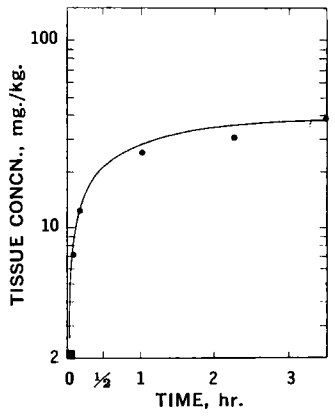

Fig. 4—Comparison of predicted and experimental values for adipose tissue. Key: ■, injection duration; ●, dog.

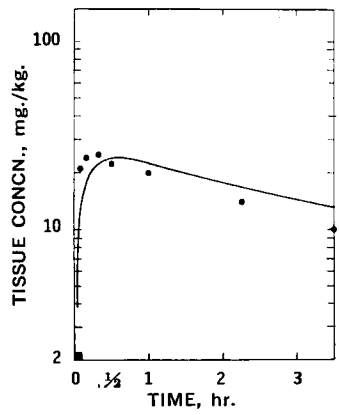

Fig. 5—Comparison of predicted and experimental values for lean tissue. Key: ■, injection duration; ●, dog.

The results of the numerical computations are presented in the graphs. Figure 2 compares the *a priori* predicted and measured values in blood for dogs and for man. The total concentration, bound plus unbound, is plotted. Several features of the graph are worthy of note. First, the pre-

dicted values from the mathematical model agree well with the experimental data. Second, the physical distribution patterns for dog and man are very similar when plotted in a consistent manner. Third, rapid fall in blood thiopental levels is observed for the first half-hour as distribution equilibrium is approached. And finally, the slope of the line at long times principally represents metabolism at the rate of 15%/hr.

Figure 3 compares the computed and experimental (dog) values for the highly perfused or viscera compartment. Again, excellent agreement is obtained. The uptake in adipose tissue is illustrated in Fig. 4, which shows the rapid and continuing solution of the drug in the lipid at the perfusion rate of 2 (ml./min.)/100 g. used (see Table I). The curve for the final compartment, poorly perfused lean tissue, is shown in Fig. 5. The overall predicted trends are correct, but there are some discrepancies between the calculated curve and the experimental data. At short time intervals, the difference can probably be explained by the fact that human flow distribution and perfusion rates are used but that experimental data were obtained on dogs. Since lean tissue of dogs is somewhat more highly perfused than that of humans [value used—3 (ml./min.)/100 g], the measured initial uptake is higher than predicted. Calculations made with a higher lean perfusion rate shift the predicted curves in the correct direction. Since the intent was to see how good an *a priori* prediction could be made, however, these "curve fitting" attempts were not pursued in any detail. The long time portion of the curve also deviates from the data, but slight changes in the lipid solubility produce better agreement; again, a better "curve fit" has not been attempted.

Figure 6 shows the computed behavior over a period of several hours. It is seen that the three nonlipid compartments rapidly approach distribution equilibrium, but that the adipose uptake rises continuously to a maximum at about 3–4 hr. This also corresponds with the observations of Brodie *et al.* (2).

A final very interesting result is exhibited by the plot of computed *free* concentrations in each of the compartments shown in Fig. 7. The blood and viscera free concentrations fall very rapidly and, more important, are essentially equal over the entire time period. This is a good illustration of the concept that blood concentrations are an excellent measure of the viscera concentrations and thus

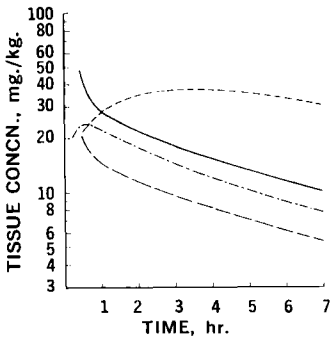

Fig. 6—Long time behavior—total concentration. Key: ———, viscera; – – – –, adipose; — · —, lean; — —, blood.

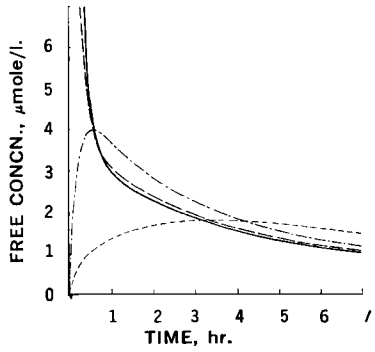

Fig. 7—Long time behavior—free concentration. Key: ———, viscera; – – – –, adipose; — · —, lean; — —, blood.

should provide a basis for correlating pharmacological action. Notice, however, that this is true *only* for the free concentrations (*i.e.*, corrected for binding), since Fig. 6 indicates that the total concentrations in the blood and viscera are not equal.

CONCLUSION

The *a priori* predictions of thiopental distribution resulting from the pharmacokinetic model, including protein binding and lipid solubility, agree closely with published experimental data. Such performance provides confidence in the model as a valuable tool for predictions in a variety of therapeutic situations if it is properly applied and sufficient data are available. One application reported elsewhere (20, 21) considers the physiological solute distributions associated with the extracorporeal treatment of blood with an artificial kidney.

NOTATION

B_A = lipid solubility in adipose tissue (dimensionless)
B_1, B_2 = protein binding sites (μmole/l.)
C = free concentration (μmole/l.)
f = fraction water (dimensionless)
$g(t)$ = injection description function (min.$^{-1}$)
k_V = metabolism rate constant or maximum rate (μmole/min.)
K_{mV} = Michaelis-Menten constant (μmole/l.)
K_1, K_2 = protein binding equilibrium constants (l./μmole)
M = amount of drug injected (μmole)
Q = flow rate (l./min.)
r_V = metabolism rate (μmole/min.)
t = time (min.)
x = bound concentration (μmole/kg.)
V = volume of compartment (l.)
λ = reciprocal injection of time (min.$^{-1}$)

Subscripts

A = adipose
B = blood
L = lean
V = viscera
AB = adipose equilibrium blood
LB = lean equilibrium blood
VB = viscera equilibrium blood
AT = adipose tissue
LT = lean tissue
VT = viscera tissue

Effect of Chlordan Pretreatment on the Metabolism and Lethality of Cyclophosphamide

By ROBERT L. DIXON

Cyclophosphamide is converted to a cytostatic agent by enzymes present in the hepatic microsomes. Prior treatment of young rats with the insecticide, chlordan, resulted in an increased cyclophosphamide toxicity. Chlordan pretreatment also increased the *in vitro* metabolism of cyclophosphamide and hexobarbital, increased the excretion of the alkylating metabolite of cyclophosphamide *in vivo*, and decreased the sleeping times of animals treated with hexobarbital *in vivo*. It is most probable that increased amounts of cytostatic metabolite occurred as a result of chlordan induced microsomal drug-metabolizing enzyme stimulation.

CYCLOPHOSPHAMIDE[1] [*N,N*-bis(β-chloroethyl)-*N'*, *O*-propylene phosphoric acid ester diamine monohydrate, NSC 26271] is a potent antineoplastic agent of the nitrogen mustard class and has been used in the treatment of patients with many types of neoplastic diseases. Cyclophosphamide is especially valuable in the treatment of patients with malignancies arising from the hematopoietic tissues. The compound can be administered by all routes (1).

In contrast to the nitrogen mustards ordinarily used in cancer chemotherapy, cyclophosphamide is inert when placed in direct contact with bacteria, leukocytes, and most tumor cells in culture. *In vivo* activation occurs in the liver and perhaps in other sites (2). The subcellular site of enzymic activation in the liver is the microsomes. These hepatic microsomal drug-metabolizing systems require oxygen and NADPH (TPNH) and are capable of altering a number of drugs (3). The microsomal enzyme that activates cyclophosphamide is influenced by a number of various drugs (3). For instance, SKF-525a (β-diethylamino-ethyldiphenylpropylacetate), an inhibitor of microsomal drug metabolism, will decrease serum levels of metabolite capable of alkylation after cyclophosphamide (4), while pretreatment of animals with phenobarbital increases the concentration of this metabolic agent three to fourfold by enzyme induction (5).

The fact that the concentration of metabolite capable of alkylation after cyclophosphamide treatment can be increased by enzyme induction

might have therapeutic possibilities. Surely it is of interest to those testing new compounds for toxic effects or action against transplantable tumors in animals. There are a large number of drugs and foreign compounds that have been shown to be effective stimulators of microsomal drug-metabolizing enzymes (2). This paper reports enhancement of cyclophosphamide metabolism and toxicity in rats after exposure to the insecticide, chlordan, which is commonly used in laboratory quarters.

METHODS

Cyclophosphamide was obtained commercially. Technical chlordan, a mixture containing 60–75% of the pure compound and 25–40% of related compounds, was used in these experiments.

Young male rats, 50–60 g., were treated with either 10 mg./kg. of technical chlordan dissolved in corn oil or received corn oil alone. The technical chlordan was dissolved in corn oil to make a 0.1% solution and each chlordan treated animal received subcutaneously 0.01 ml. of this solution per gram of body weight. Animals were pretreated with chlordan twice, 144 and 72 hr. prior to oral administration of cyclophosphamide.

Cyclophosphamide was administered orally to groups of 10–12 rats at a dose of 90, 125, 180, or 250 mg./kg. Cyclophosphamide was administered at a concentration such that each animal received 0.01 ml. of aqueous solution per gram of body weight. Deaths were recorded daily for 30 days following a single dose of cyclophosphamide.

In vitro metabolism of hexobarbital[2] (side-chain oxidation) was determined using methods, conditions of incubation, cofactors, and concentrations described previously (6).

The *in vitro* metabolism of cyclophosphamide was studied using the same conditions described above. The substrate concentration was 10 mg./5 ml. incubation. The active metabolite of cyclophosphamide was estimated by the spontaneous alkylation of α-(4-nitrobenzylpyridine) (NBP) (7, 8). Five milliliters of 6.67% trichloroacetic acid was added to the beaker following incubation. The solutions were mixed and poured into a heavy walled centrifuge tube and centrifuged prior to taking a 3.0-ml. aliquot for assay.

In vivo metabolism of hexobarbital was estimated using sleeping times after hexobarbital treatment. Hexobarbital, 150 mg./kg., was administered intraperitoneally and the time in minutes from loss of righting reflex to recovery of reflex was recorded.

In vivo metabolism of cyclophosphamide was estimated by collecting and analyzing urine for metabolites capable of alkylation after cyclophosphamide treatment. Urine was collected from each of six animals (three chlordan treated, three corn oil treated) for the first 4 hr. following cyclophosphamide treatment. Animals were placed in individual plastic metabolism cages which allowed collection of urine. Each animal received 500 mg./kg. of cyclophosphamide orally. After the 4-hr. collection period, the urine was obtained and the cage rinsed with distilled water. Urine plus cage rinsings were brought to a final volume of 25 ml. with distilled water. Three-milliliter aliquots from each total volume were then assayed for material capable of alkylating the NBP reagent.

Statistical methods used are described by Snedecor (9) and Litchfield and Wilcoxon (10).

RESULTS

Table I demonstrates the effect of chlordan pretreatment on the metabolism of hexobarbital *in vitro* and *in vivo*. It can be seen that chlordan pretreatment increased the rate of metabolism *in vitro*, and decreased the duration of sleep after hexobarbital. These data are in agreement with those of Hart *et al.* (11) and serve only to confirm the effect of chlordan on the injected animals.

In vitro studies of the metabolism of cyclophosphamide by hepatic supernatant fraction from chlordan and corn oil pretreated animals revealed that the chlordan pretreated animals produced 76% more of an alkylating substance during a 30-min. incubation than did corn oil treated control animals. The mean absorbance reading for the metabolite–NBP reagent complex formed by the chlordan treated animals was 0.294 ± 0.096 *A* units/hr./g. of tissue compared to 0.167 ± 0.052 *A* units/hr./g. of tissue for the corn oil pretreated animals. These values are significantly different ($p \leq 0.05$). Five animals were used in the chlordan treated group and four animals were used in the control group. The colored complex was developed from a 3-ml. aliquot taken from the supernatant of the incubation system (5 ml.) plus 5 ml. of TCA, and the color subsequently extracted with 7 ml. of the nonpolar phase. The absorbance readings (*A*) were converted to absolute values by using a standard curve prepared after hydrolyzing cyclophosphamide as described by Philips *et al.* (12). The reactivity of the hydrolyzed solutions of cyclophosphamide averages 99% of that of molar equivalent amounts of nor-NH_2HCl. In these studies a concentration of activated product from 10 mcg. of cyclophosphamide per ml. of the nonpolar extraction phase (acetone-ethyl acetate) had an absorbance of 0.613 when measured at 600 mμ in a 1-cm. square cell. Using this standard curve the above absorbance values represent 112 and 64 mcg. cyclophosphamide metabolized per gram liver per hour, respectively. The absorbance values were multiplied by $^{10}/_{3}$ to correct the value for the aliquot, and by 7 in order to express micrograms of metabolite in the 7 ml. of nonpolar solvent.

In vivo studies of the excretion of a metabolite capable of alkylating the NBP reagent (activated

TABLE I—EFFECT OF CHLORDAN PRETREATMENT ON THE METABOLISM OF HEXOBARBITAL

	Corn oil Treated	Chlordan Treated
In vitro metabolism[a]	3.87 ± 0.85 (4)	5.37 ± 1.17 (5)
In vivo sleeping times[b]	106 ± 14	84 ± 21

[a] Micromoles of hexobarbital metabolized per gram of liver during 45-min. incubation. Values are means ± standard deviation. Number of individual animals is indicated in the parentheses. [b] Minutes of loss of righting reflex after 150 mg./kg. of hexobarbital i.p. Values are means ± standard deviation for six animals per group.

[2] Evipal, Winthrop Laboratories, New York, N. Y.

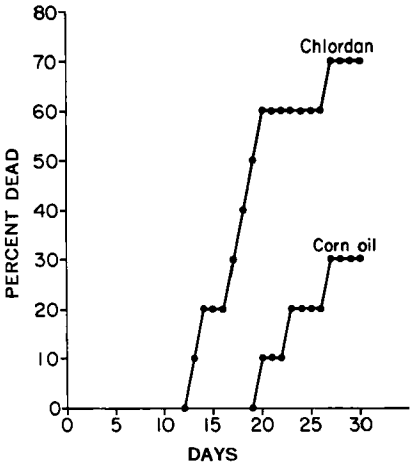

Fig. 1—Percent of animals (10 per group) which died following a single oral dose of cyclophosphamide (125 mg./kg.). The chlordan group was treated prior to cyclophosphamide administration with chlordan. Control animals received only corn oil.

metabolite) after cyclophosphamide treatment revealed that the chlordan pretreated animals excreted more of this substance in 4 hr. than did the corn oil treated controls.

Chlordan pretreated rats excreted 61% more of this metabolite than did corn oil treated controls. The average final readings determined from a 3-ml. aliquot of urine from each total volume of 25 ml. was 0.255 (0.215, 0.283, 0.267) for chlordan pretreated animals compared to a mean reading of 0.158 (0.155, 0.145, 0.173) for the corn oil treated control animals. The metabolite from the 3.0 ml. was extracted into 7.0 ml. of a nonpolar phase prior to reading the *A* with a colorimeter. Using the standard curve referred to in the *in vitro* results, the above values correspond to 242 and 148 mcg., respectively.

Figure 1 expresses the lethality data seen at one dose, 125 mg./kg., of cyclophosphamide. The same trend seen here, that of earlier and greater lethality, was seen with each of the higher doses studied.

Table II presents lethality data for cyclophosphamide for groups of corn oil and chlordan pretreated animals. It can be seen that the LD_{50} for the chlordan pretreated group is lower, 145 (125–166) mg./kg., than that for the corn oil pretreated animals which was 170 (142–204) mg./kg. Neither of the two slopes was significantly heterogeneous and they were parallel. However, the potency ratio of 1.17 was not significant at the 95% level of probability. Nevertheless, it should be pointed out that after chlordan pretreatment a dose of cyclophosphamide normally lethal to 50% of the animals tested resulted in approximately 80% dead due to the very steep dose-response slope associated with this drug.

DISCUSSION

Results presented here demonstrate that exposure to chlordan, an insecticide commonly used in animal quarters, can result in changes in drug metabolism which alter the toxicity (weight loss and diarrhea) and lethality of cyclophosphamide. Animals receiving two subcutaneous injections of chlordan,

TABLE II—EFFECT OF CHLORDAN ON LETHALITY OF CYCLOPHOSPHAMIDE

Oral Dose, mg./kg.	% Alive, 30 days	
	Corn Oil Treated	Chlordan Treated
250	10	0
180	42	20
125	70	30
90	100	100
LD_{50}	170 (142–204)	145 (125–166)

144 and 72 hr. prior to cyclophosphamide, showed signs of toxicity and died earlier and in greater number than the corn oil pretreated animals.

This increase in lethality can be explained by an induction of microsomal enzymes which convert cyclophosphamide to an active form and accounts for the increase in the levels of the cytotoxic form. Data were presented which demonstrated that animals pretreated with chlordan metabolized both hexobarbital and cyclophosphamide to a greater extent *in vitro* than corn oil treated controls. Also, animals pretreated with chlordan excreted more metabolite capable of alkylating NBP reagent in 4 hr. following cyclophosphamide than did corn oil treated control rats. The effect of chlordan was further demonstrated by a decreased sleeping time after hexobarbital administration in the chlordan treated group. This effect was similar to the increased cytotoxic action described for cyclophosphamide after phenobarbital pretreatment (5).

These data indicate that spraying animal quarters with the chlorinated hydrocarbon insecticides can result in spurious testing results concerning toxicity and perhaps effectiveness against transplantable tumors. In most cases increased metabolism of a drug would result in its decreased effectiveness and lethality. However, increased metabolism of cyclophosphamide resulted in an increase of active metabolite and enhanced drug effect.

The clinical implications for therapeutic treatment of such findings is probably less important than possible effects on laboratory animals. However, it might be possible to increase the effectiveness of this drug in patients who for some reason have a less than normal ability to metabolize cyclophosphamide. In such patients cyclophosphamide would be less effective. A decreased metabolism of drugs could possibly occur in patients who are very young, or as a result of various pathological conditions (2). These suggestions are based on findings in animals, and must be extrapolated to the clinical situation with care.

Bile Salt Potentiation of Pharmacologic Effects and Drug Uptake in Goldfish

By MILO GIBALDI and CHARLES H. NIGHTINGALE

Concentrations of 1×10^{-4} *M* and 2×10^{-4} *M* sodium taurodeoxycholate (STDC), which demonstrate no intrinsic pharmacologic activity, significantly potentiate the pharmacologic effects (*i.e.*, time required to produce overturn) of pentobarbital and ethanol in goldfish. Quantitatively similar potentiation is noted when the fish is exposed to a bile salt-drug solution or when the fish is pretreated with STDC, rinsed, and immediately exposed to drug solution. The present results suggest that potentiation is independent of the duration of pretreatment of fish with STDC. The effects of STDC are mediated very quickly, reach a maximum level within minutes, and are slowly reversible. The results are consistent with a mechanism involving adsorption of bile salt molecules on the biologic membrane, consequent alteration of membrane permeability, and a resultant decrease in the time required to observe a pharmacologic response to ethanol and pentobarbital. A 1×10^{-4} *M* STDC solution also increases significantly the absorption of 4-aminoantipyrine in goldfish.

BILE SALTS are one of the most important groups of physiologic surface-active agents found in man. Although their role in fat absorption has been studied extensively (1, 2), little attention has been given to the possible effects of bile salts on drug absorption. Recent studies (3–6) have shown that components of bile significantly affect both the solubility and dissolution rate of a number of poorly water-soluble drugs. These studies suggest that bile may serve an important function in dissolution rate-limited drug absorption.

In addition to the solubilizing effects of bile salts, certain biologic effects may also be important in drug absorption. An example is the potential effects of bile salts on the gastrointestinal membrane and on drug transport. Parkinson (7) has observed inhibition of glucose, sodium, and amino acid active transport from the rat jejunum by certain bile salts. However, there is no literature available on the effects of bile salts on passive transport, the usual pathway in drug absorption.

Numerous studies suggest that surface-active agents can affect the integrity of biologic membranes and thereby enhance drug absorption (8). Most recently, Levy *et al.* (9) have observed a significant decrease in the time required for secobarbital-induced death in the goldfish in the presence of polysorbate 80. They attribute this effect to membrane alteration by the surfactant which permits more rapid absorption of secobarbital and decreases the time required to reach a lethal concentration in the fish.

The present study concerns the influence of bile salts on the pharmacologic effects of ethanol and pentobarbital and on the uptake of 4-aminoantipyrine in the goldfish.

EXPERIMENTAL

Goldfish, *Carassius auratus*, common variety, weighing about 3–6 g. were used as the test animal. All fish used in a given experiment were from the same lot. Five different lots of fish were used during the study.

The test drugs, ethanol and sodium pentobarbital, were dissolved in water or aqueous solutions contain-

Quantitatively similar potentiation is noted when the fish is exposed to a bile salt-drug solution or when the fish is pretreated with STDC, rinsed, and immediately exposed to drug solution. The present results suggest that potentiation is independent of the duration of pretreatment of fish with STDC. The effects of STDC are mediated very quickly, reach a maximum level within minutes, and are slowly reversible. The results are consistent with a mechanism involving adsorption of bile salt molecules on the biologic membrane, consequent alteration of membrane permeability, and a resultant decrease in the time required to observe a pharmacologic response to ethanol and pentobarbital. A 1×10^{-4} *M* STDC solution also increases significantly the absorption of 4-aminoantipyrine in goldfish.

BILE SALTS are one of the most important groups of physiologic surface-active agents found in man. Although their role in fat absorption has been studied extensively (1, 2), little attention has been given to the possible effects of bile salts on drug absorption. Recent studies (3–6) have shown that components of bile significantly affect both the solubility and dissolution rate of a number of poorly water-soluble drugs. These studies suggest that bile may serve an important function in dissolution rate-limited drug absorption.

In addition to the solubilizing effects of bile salts, certain biologic effects may also be important in drug absorption. An example is the potential effects of bile salts on the gastrointestinal membrane and on drug transport. Parkinson (7) has observed inhibition of glucose, sodium, and amino acid active transport from the rat jejunum by certain bile salts. However, there is no literature available on the effects of bile salts on passive transport, the usual pathway in drug absorption.

Numerous studies suggest that surface-active agents can affect the integrity of biologic membranes and thereby enhance drug absorption (8). Most recently, Levy *et al.* (9) have observed a significant decrease in the time required for secobarbital-induced death in the goldfish in the presence of polysorbate 80. They attribute this effect to membrane alteration by the surfactant which permits more rapid absorption of secobarbital and decreases the time required to reach a lethal concentration in the fish.

The present study concerns the influence of bile salts on the pharmacologic effects of ethanol and pentobarbital and on the uptake of 4-aminoantipyrine in the goldfish.

EXPERIMENTAL

Goldfish, *Carassius auratus*, common variety, weighing about 3–6 g. were used as the test animal. All fish used in a given experiment were from the same lot. Five different lots of fish were used during the study.

The test drugs, ethanol and sodium pentobarbital, were dissolved in water or aqueous solutions contain-

ing 1×10^{-4} or 2×10^{-4} *M* sodium taurodeoxycholate (STDC). The final solutions were adjusted to pH 6.1 with either 1 *N* HCl or NaOH. Solutions were prepared daily as required. All drugs and chemicals were USP or reagent grade. Chromatographically pure STDC, obtained from Maybridge Research Chemicals, Tintagel, N. Cornwall, England, was used.

The measured pharmacologic response was the time required for the fish to lose the ability to maintain itself upright after immersion in test solution, *i.e.*, the overturn time. The use of the overturn end point for the estimation of absorption and elimination kinetics in goldfish was the subject of a previous report (10). After each experiment the pH of the solution was redetermined and found to be 6.1 ± 0.1. Preliminary experiments indicated that the overturn times in ethanol in water and in water adjusted to pH 6.1 were the same.

Overturn time was determined with individual fish immersed in 200 ml. of solution at 26–28°, under the following experimental conditions: (*a*) immersion of fish in drug solutions; (*b*) immersion of fish in bile salt solutions; (*c*) immersion of fish in drug solutions containing bile salt; and (*d*) exposure of fish to bile salt solution, followed by rinsing with water and immersion in drug solutions.

Determination of Uptake of 4-Aminoantipyrine—Goldfish were placed in large beakers containing 250 ml. of solution per fish. The control solutions contained 250 mg.% 4-aminoantipyrine (Eastman) while the test solutions contained the drug and 1×10^{-4} *M* STDC. In each case the solutions were adjusted to pH 6.1. After a 15-min. immersion period, the fish were removed rapidly from the solutions, rinsed, and killed by freezing. The fish were stored in a freezer until assayed.

The analytical method for the determination of 4-aminoantipyrine in goldfish tissue was a modification of the colorimetric assay of Brun (11) as described by Levy and Miller (12). Tissue blanks averaged 22 mcg. 4-aminoantipyrine equivalent per g. of fish tissue. Prior exposure of the fish to 1×10^{-4} *M* STDC for 15 min. yielded identical blank values. Recovery of known amounts of 4-aminoantipyrine (300 mcg./g. of fish) added to homogenates averaged 97.1% (4 determinations, range 96.2 to 97.6%). Recovery of known amounts of 4-aminoantipyrine (400 mcg./g. of fish) added to homogenates of fish which were previously immersed for 15 min. in 1×10^{-4} *M* STDC averaged 94.5% (4 determinations, range 88.5–97.7%). Blank and recovery values were used to correct the analytical results.

RESULTS

Initial studies indicated that STDC showed significant toxicity in the goldfish at concentrations of 1×10^{-3} *M* and above. However, concentrations of 1×10^{-4} *M* and 2×10^{-4} *M* were without apparent effect. Fish from various lots were placed in 2×10^{-4} *M* bile salt solution for 24–48 hr. periods and in no instance was an effect upon the fish observed. Hence, it was concluded that these concentrations of STDC had no apparent intrinsic pharmacologic activity and these levels were used for further drug studies.

The overturn times of goldfish in pentobarbital and ethanol solutions, and the effect of STDC on overturn time, are shown in Table I. A significant potention of the apparent drug activity is observed in each case. The decrease in overturn time appears to be related to the STDC concentration.

The data in Table II represent the results of a number of experiments designed to test the interaction of individual aspects of the bile salt-drug-goldfish system. The following conclusions may be drawn from these results: (*a*) After exposure to pentobarbital to induce overturn, the fish recovers completely within 24 hr. when placed in fresh water and its subsequent response to drug + bile salt is the same as that of fish having no prior exposure. (*b*) After exposure to pentobarbital + STDC to induce overturn, the fish recovers completely within 24 hr. when placed in fresh water and its subsequent response to drug is the same as that of fish having no prior exposure. (*c*) Prolonged exposure to STDC (without observing overturn), followed by rinsing with distilled water and exposure to pentobarbital, results in an overturn time significantly shorter than that observed in Groups A_1 and B_2. In fact, the overturn time of goldfish in 5 mg.% pentobarbital solution after a 24-hr. exposure to STDC is almost identical to the overturn time found when the fish were exposed to drug + STDC.

This latter phenomenon was explored further by investigating the effect of duration of exposure to bile salt on drug-induced overturn time. In each case the fish were exposed to 1×10^{-4} *M* STDC for a period of time, rinsed, placed in either 5 mg.% pentobarbital or 1% ethanol solutions and observed

TABLE II—REVERSIBILITY OF PHARMACOLOGIC EFFECT IN GOLDFISH AND INFLUENCE OF STDC PRETREATMENT ON RESPONSE[a]

[a] Values represent mean of 4 fish. [b] Determined by Student *t* test, arrows indicate significance at $p < 0.01$. [c] Control values determined by placing fish in distilled water (adjusted to pH 6.1) for 30 min. The fish were then rinsed and exposed to drug solutions.

for overturn. The results, shown in Table III, indicate that the potentiation of drug-induced overturn is independent of the duration of exposure to STDC. For example, 5-min. exposure to STDC reduces the apparent ethanol-induced overturn time to the same extent as exposure for a 30-min. period. Similar results are observed with pentobarbital.

Figure 1 shows the effect of 1×10^{-4} *M* STDC on the uptake of 4-aminoantipyrine by goldfish after a 15-min. immersion in 250 mg.% drug solution. The presence of bile salt results in a 30% increase in drug concentration in the fish tissue as compared to control values. This difference is statistically significant at the 95% level of confidence. These findings indicate clearly the ability of bile salts to modify membrane permeability.

DISCUSSION

The enhanced response of goldfish to ethanol and pentobarbital may be due to two effects. Firstly, STDC may produce an unspecified pharmacologic effect that is inadequate to promote overturn but makes the fish more susceptible to the pharmacologic action of ethanol and pentobarbital. The second possibility is that the bile salt increases the permeability of the fish membranes to the drugs and permits more rapid absorption. While both effects may be operative, the present findings are consistent with the hypothesis that the principal effect of STDC is alteration of membrane permeability.

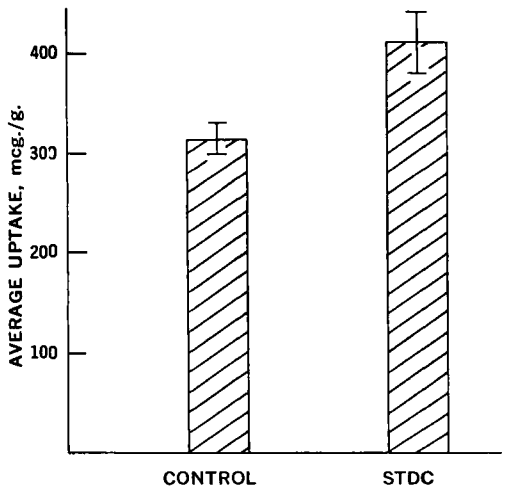

Fig. 1—Effect of 1 × 10⁻⁴ M STDC on the uptake of 4-aminoantipyrine by goldfish immersed in 250 mg.% drug solution. Each bar represents the mean of seven fish; vertical lines indicate standard error of the mean.

For example, if STDC potentiates drug effects in the goldfish by virtue of an intrinsic pharmacologic effect then when fish are first exposed to bile salt solution and immediately exposed to drug solution, one would anticipate a graded response to the drug, which is dependent on the time of exposure to the bilt salt. The data in Table III indicate that this is clearly not the case. The reduction in ethanol-induced and pentobarbital-induced overturn time is independent of the duration of preexposure to STDC solution.

Previous studies (9) of the effects of nonionic surfactants on drug absorption in the goldfish suggest an enhanced permeability to barbiturates but not to ethanol. In the present study this permeability discrimination was not observed. In fact, the observed potentiation was quantitatively similar for both ethanol and pentobarbital. This finding implies a possible difference in the mode of action of the nonionic polysorbate 80 and the anionic STDC.

The potentiation of drug effects in the absence of surfactant from the bulk drug solution, noted in the preexposure studies, has also been observed by Levy and Anello (13). These workers found that an absorption-enhancing effect occurs if the fish are first immersed in polysorbate 80 solution, washed, and then placed in a surfactant-free secobarbital solution. The rapid effects manifested by both polysorbate 80 and STDC are consistent with a mechanism involving adsorption of surfactant molecules on the biologic membrane and alteration of membrane permeability.

The use of the overturn end point rather than a death end point permitted the observation that the effect of STDC is reversible. As noted in Table II, fish exposed to STDC recover within 24 hr. in fresh water and then show the expected response to pentobarbital. Of particular interest is the fact that fish preexposed to 1×10^{-4} *M* STDC for 24 hr. gave the same enhanced response to pentobarbital as fish placed directly in an STDC-pentobarbital solution This suggests that the effect of STDC is mediated very quickly and is maximal within minutes. The persistence of potentiation even in the absence of STDC in the drug solution indicates that the effect of the bile salt is slowly reversible.

Studies with 4-aminoantipyrine suggest that extremely low concentrations of STDC can significantly alter membrane permeability. Levy (12) has previously shown that, under conditions similar to those used in the present study, 4-aminoantipyrine is absorbed by apparent zero-order kinetics. Accordingly the authors have determined an absorption rate of 21 mcg./g./min. in the absence of STDC and a value of 27 mcg./g./min. in the presence of the bile salt. The corresponding first-order absorption rate constants (k_a) were calculated from the relationship: k_a = absorption rate/drug concentration and

found to be 8.4 × 10^{-3} min.$^{-1}$ and 1.1 × 10^{-2} min.$^{-1}$, respectively.

The influence of bile salt on membrane permeability in the goldfish raises the interesting possibility of similar effects on the permeability of the intestinal membranes. The fluid bathing these membranes has significantly higher concentrations of bile salts (in the order of 10^{-2} M) than the concentrations employed in the present study. This possibility is now under investigation.

Synthesis of Tropine-Labeled Atropine IV

Labeling of the 2, 3, and 4 Positions of Atropine from Citric-^{14}C Acid

By THOMAS E. ELING, JOHN M. McOWEN, and GILBERT C. SCHMIDT*

Using a modification of the Robinson condensation, citric-3-^{14}C acid, citric-2,4-^{14}C acid, and citric-2,3,4-^{14}C acid were converted into correspondingly labeled tropine and atropine. The specific activities of the products varied from 0.62 to 1.0 depending on the labeled compound. This is the first reported syntheses of tropine or atropine labeled with ^{14}C in positions other than the *endo*-methyl group.

THE PROBLEM of selectively labeling the tropine moiety of atropine remains to be solved. For one reason or another, the biosynthetic compounds (1, 2), tritium-labeled atropine (3), and randomly labeled atropine (4) are inadequate for establishing the metabolic fate of the heterocyclic residue in atropine. Classical, microsynthetic methods for selectively labeling tropine and the tropine moiety of atropine are needed badly.

Excluding the authors' work, only Fodor (5) and Werner (6) have used classical methods to label tropine. In both instances, tropine-*N*-methyl-^{14}C and atropine-*N*-methyl-^{14}C were synthesized. Fodor's approach would not permit labeling of other positions, but Werner's use of the Robinson condensation is much more versatile. A lack of suitably labeled Robinson intermediates, other than methylamine hydrochloride, apparently prevented Werner from realizing the full potential of the condensation.

Prior to publication of Werner's work, the authors had been studying the Robinson condensation as a tool for labeling the carbon skeleton of tropine. The reaction was studied in detail, a reproducible microcondensation procedure developed, and the microesterification of tropine and tropic acid standardized (7). The overall procedure was checked by the synthesis of tropine-*N*-methyl-^{14}C and atropine-*N*-methyl-^{14}C, thereby confirming Werner's synthesis of these compounds (8). At the same time, a prototype procedure was developed for the microsynthesis of succindialdehyde and tropine from arabinose (9) which would be used to label the 1,5,6, and 7 positions of atropine.

This report describes the synthesis of atropine-2,3,4-^{14}C, atropine-2,4-^{14}C, and atropine-3-^{14}C from the correspondingly labeled citric acids. These syntheses are the first successful introductions of ^{14}C into other than the *endo*-methyl group of either tropine or the heterocyclic moiety of atropine.

EXPERIMENTAL

Microsynthetic methods for tropine and atropine, described in detail in the first three papers of the series (7–9), were modified only slightly for the synthesis of tropine-^{14}C and atropine-^{14}C from citric-^{14}C acids. In previously reported work, acetone dicarboxylic acid was not a labeled intermediate. The use of this compound as a labeled precursor to atropine required slight modification of the previously described method for handling this intermediate in the Robinson condensation.

The same procedure was used for the synthesis of atropine-2,3,4-^{14}C, atropine-2,4-^{14}C, and atropine-3-^{14}C. To simplify the description of methods, numbers indicating the position of labeling are eliminated. Earlier papers (7–9) should be consulted for additional experimental details.

Synthesis of Acetone-^{14}C Dicarboxylic Acids—Dry citric-^{14}C acid[1] (96 mg. or 0.5 mmole) and unlabeled citric acid (96 mg. or 0.5 mmole) were added while stirring constantly with a thermometer to 0.44 ml. of fuming H_2SO_4[2] (20% excess SO_3), previously cooled to −8° in an ice-salt bath. The labeled citric acid was added at a rate to maintain the temperature at −5° or lower.

After the addition was completed, the flask and content were removed from the cooling bath and stirred on a magnetic stirrer at room temperature until gas evolution ceased. The reaction mixture was again cooled to −8° and 1 g. of chipped ice added in small portions so that temperature did not exceed 0°. The resulting pale yellow solution contained acetone dicarboxylic acid-^{14}C.

Preparation of Succindialdehyde—Succindialdehyde (173 mg. or 2 mmoles) was prepared from 0.34 ml. of 2,5-diethoxytetrahydrofuran as described previously (7).

Synthesis of Tropanone-^{14}C—To the solution of succindialdehyde (2 mmoles) was added the solution of acetone dicarboxylic-^{14}C acid. The round-bottom flask which contained the acetone dicarboxylic acid was washed three times with water and the washings added to the reaction mixture. Saturated aqueous Na_2HPO_4 was added to adjust the pH to 4.5–5.0 using a glass electrode. The buffered solution was transferred to a 250-ml. side-arm conical flask and the system purged with nitrogen gas for 10 min. To the buffered reaction mixture, 135 mg. (2 mmoles) of methylamine HCl was added, the reaction volume adjusted to 50 ml., and the system quickly evacuated to remove the gas phase. The reaction vessel was closed and the mixture allowed to remain under partial vacuum for 12 hr. The slight evacuation was repeated and the reaction mixture allowed to remain at room temperature for an additional 12 hr.

Tropanone-^{14}C was extracted with 100-ml. portions of petroleum ether, exactly as previously described (7), except that extraction was continued until significant amounts of radioactivity no longer were removed. The petroleum ether extracts were dried over Na_2SO_4, transferred to a 250-ml. sublimation flask and the solvent removed, *in vacuo*, on the flash evaporator at 40°. Tropanone-^{14}C, which remained in the flask as a brown oil, was dried *in situ* overnight in a desiccator over $CaCl_2$ and NaOH. The crude product was purified by repeated sublimation at 40° and 1×10^{-4} mm. Hg. After each sublimation, the product was washed from the cold finger with small amounts of absolute ethanol. Sublimation was repeated until the washings no longer contained significant amounts of radioactivity. The combined alcoholic solutions of tropanone-^{14}C were evaporated to dryness on the flash evaporator in a previously tared 25-ml. flask. The product crystallized quickly on cooling, was dried in a desiccator for 12 hr., and was reduced to tropine.

Synthesis of Tropine-^{14}C HCl—Labeled tropanone (60–95 mg., 1 mc./mmole), prepared as described above and dried for 12 hr., was reduced over W-7 Raney nickel, by the modified Van de Kamp procedure described in the third paper of this series (8). The product was dried in a desiccator over NaOH pellets and converted to the hydrochloride in the exact manner described previously (7). Tropine-^{14}C HCl was stored in 10-ml., tared, round-bottom flasks in a vacuum desiccator over NaOH pellets, until used for esterification.

Synthesis of Atropine-^{14}C—Acetyltropic acid (150 mg.) was prepared from 395 mg. of tropic acid and 0.36 ml. of acetyl chloride in the manner described previously (7). The product was dried in a vacuum desiccator over $CaCl_2$ for 12 hr. and converted to *o*-acetyltropic acid chloride (7). To the acid chloride was added well-dried tropine-^{14}C HCl.[3] Using previously described procedures, the reactants then were esterified to form *o*-acetylatropine-^{14}C, the acetylated compound hydrolyzed to the free base, and atropine-^{14}C finally isolated. The crude product was dried in a vacuum desiccator over $CaCl_2$, and finally recrystallized from petroleum ether (7).

RESULTS AND DISCUSSION

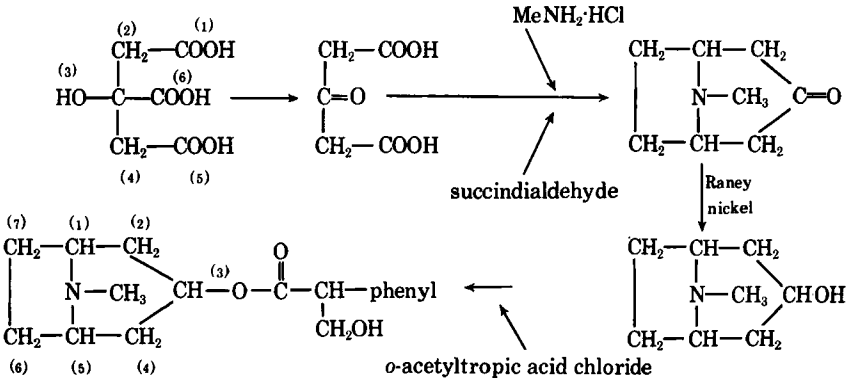
The synthesis of atropine labeled with ^{14}C in the carbon skeleton of tropine has not been accomplished previously, but recent work has simplified the problem. For the synthesis of tropine, the Robinson condensation has been adapted for radioactive synthesis (6, 8, 9). The Wolffenstein and Mamlock esterification of tropine and tropic acid has been adapted for the use of isotopically labeled intermediates (5, 6, 8, 9). Thus the problem of labeling the tropine moiety of atropine, in positions other than the *endo*-methyl group, has become that of obtaining labeled precursors of succindialdehyde or acetone dicarboxylic acid.

Citric acid is a logical precursor of acetone di-

[1] Citric-2,3,4-^{14}C; 2,4-^{14}C; and 3-^{14}C acids, each having a specific activity of 2 mc./mmole, were prepared by Mallinckrodt Nuclear, Orlando, Fla. Citric-^{14}C acids were stored in a desiccator before use.

[2] A 5-ml. round-bottom flask was used routinely.

[3] The yields of tropine-2,3,4-^{14}C and tropine-2,3,4-^{14}C HCl obtained by reduction of tropanone-2,3,4-^{14}C were lower than anticipated. To ensure that sufficient material was present for esterification to atropine-2,3,4-^{14}C, unlabeled tropine HCl was added to increase the combined total weight of labeled and unlabeled tropine HCl to 124 mg. (See *Results and Discussion* for a further explanation.)



Scheme I

carboxylic acid because high yields of the desired product can be obtained by the method of Adams *et al.* (10). Until recently, suitably labeled citric acids were not available. Citric acid must be labeled in positions other than the carboxyl groups because these are lost in conversion to acetone dicarboxylic acid and subsequent condensation to tropanone. For labeling the tropine ring, citric acid must be labeled in one or more of positions 2, 3, and 4. Of the potentially useful citric acids, citric-3-^{14}C, citric-2,4-^{14}C, and citric-2,3,4-^{14}C acid are now available commercially.

Using the commercially available citric-^{14}C acids, the correspondingly labeled atropines were prepared as illustrated in Scheme I.

Using this sequence, tropanone-3-^{14}C, tropine-3-^{14}C, and atropine-3-^{14}C were obtained from citric-3-^{14}C acid. Tropanone-2,4-^{14}C, tropine-2,4-^{14}C, and atropine-2,4-^{14}C were synthesized from citric-2,4-^{14}C acid. From citric-2,3,4-^{14}C acid, tropanone-2,3,4-^{14}C, tropine-2,3,4-^{14}C, and atropine-2,3,4-^{14}C were obtained.

As shown in Table I, the yields of the labeled atropines varied significantly from those predicted on the basis of the authors' previous studies. Previous studies (7, 8) had indicated a 65–70% yield for the formation of tropanone. The deviation from expected yields occurred in this step. In most instances 40–50% yields of labeled tropanone were obtained from labeled citric acids, although an occasional 70% yield was obtained. The critical nature of the citric acid to acetone dicarboxylic acid conversion was not apparent in earlier studies because a known weight of purified keto acid was used in the Robinson condensation. In synthesis, preparation of excess acetone dicarboxylic acid was not practical. Since the quantity of the radioactive acetone dicarboxylic acid from 1 mmole of labeled citric acid was extremely small, no attempt was made to isolate the intermediate, and the entire reaction mixture was used in the Robinson condensation. As a consequence, there are two possible explanations for the observed deviations from expected yields.

Improper labeling or impurity of the labeled citric acids was considered. Using paper chromatography, in a variety of solvent systems, the labeled citric acids were analyzed for impurities. In every instance, an impurity-free starting material was indicated, thus eliminating this potential explanation. That variability of tropanone yields is inherent in the procedure and is not associated with the labeled citric acids is indicated by the following evidence. When unlabeled citric acid was used exactly as described for the labeled compound, tropanone yields were variable and comparable to those from citric-^{14}C acid. Furthermore, yields of labeled tropanones were identical whether calculations were based on weight or on radioactivity. This would not have been the case had there been improper labeling or an isotope effect. It was concluded that the use of microquantities of citric acid made much more critical the quantity of fuming H_2SO_4 used to convert citric acid to acetone dicarboxylic acid. The authors believe this to be the cause of variability and of deviation from previously predicted tropanone yields.

There were no difficulties in the reduction of labeled tropanones to tropine or in the esterification to labeled atropine. The decreased yield of tropine-2,3,4-^{14}C, obtained by reduction of tropanone-2,3,4-^{14}C (see Table I), was due to a known, mechan-

TABLE I—LABELED COMPOUNDS SYNTHESIZED FROM COMMERCIALLY AVAILABLE LABELED CITRIC-^{14}C ACIDS

ical loss rather than to the procedure. Since this was the first compound made, unlabeled tropine HCl, sufficient to increase the total weight to the 124-mg. weight normally obtained, was added to the tropine-2,3,4-^{14}C HCl. For this reason the specific activity of the product was correspondingly decreased to 0.62 mc./mmole. In subsequent experiments, the labeled compounds were not diluted.

The radiochemical purity of the resulting labeled atropines was established by paper and thin-layer chromatography as described previously (8). Each of the labeled atropines contained an impurity that chromatographed in all systems as tropine. The impurity, varying from 2 to 6% of total radioactivity (depending on labeled product), could be removed by a second recrystallization from petroleum ether. The yields reported in Table I have been corrected for the impurity and accurately reflect the yields of the products shown.

SUMMARY AND CONCLUSIONS

Using the microsynthetic procedures described previously (7, 9), three different tropine-labeled atropines were prepared. From citric-3-^{14}C acid, tropanone-3-^{14}C (44%), and atropine-3-^{14}C (26%) were synthesized with a specific activity of 1 mc./mmole. From citric-2,4-^{14}C acid was prepared tropanone (68%), tropine (65%), and atropine (34%) having specific activity of 1 mc./mmole and correspondingly labeled. From citric-2,3,4-^{14}C acid was prepared correspondingly tropanone (54%), tropine (53%), and atropine (25%).

The labeled atropine contains a tropine impurity that varied from 2% to 6% of the total radioactivity. This impurity could be removed by recrystallization from petroleum ether.

This report described the first synthesis, by other than biosynthetic method, of tropine and atropine selectively labeled with ^{14}C in the tropine ring.

Correlation Between *In Vitro* and *In Vivo* Disintegration Times of Enteric-Coated Tablets

By SØREN RASMUSSEN

Investigations were made with enteric-coated tablets on the correlation between the first appearance of a substance in the plasma or the urine and the thickness of the vernix layer, measured by the *in vitro* disintegration time. The content of the tablets is quinine hydrochloride, sodium sulfanilate, or sodium *p*-aminosalicylate. The content of each tablet was either 50 or 500 mg. It was shown that within preparations of the same content a proportionality exists between the *in vivo* and the *in vitro* disintegration times. Between series of preparations with different content the factor of proportionality may differ significantly.

NUMEROUS PAPERS have been published on the correlation between *in vitro* tests and the therapeutic effectiveness of pharmaceutical preparations. The principal aim of such investigations is to establish a predictability of biological properties from simple *in vitro* tests.

With oral preparations of different types, much important work has been done by Levy and his collaborators (1). As to the dissolution rate, it was possible in some cases to show a correlation between the results of *in vitro* and *in vivo* determinations. In such cases it should be possible to predict from *in vitro* tests

variations in the *in vivo* dissolution rate from batch to batch.

However, with enteric-coated tablets a further problem arises. The time from the intake until the drug appears in the plasma, which is an indication of the beginning of the absorption, may vary independently of the dissolution rate and must be determined separately. Many *in vitro* tests for this disintegration time exist, but the correlation between the *in vitro* and the *in vivo* disintegration time is little investigated.

In some cases a certain connection is found, as appears from Morrison and Campbell (2). Most of the investigation has been done with commercial preparations, and information about the nature and the amount of vernix is lacking. More precise information is given by Wagner *et al.* (3–5) in works with $BaSO_4$-containing tablets coated with increasing amounts of vernix. They followed the *in vivo* disintegration roentgenographically and were able to show a correlation between the *in vivo* and the *in vitro* disintegration times. In a previous paper Rasmussen (6) showed an increase in the *in vivo* disintegration time of enteric-coated tablets of quinine hydrochloride of 50 or 500 mg. proportional to the thickness of the coating layer.

In a subsequent paper Rasmussen (7) demonstrated a rectilinear proportionality between the thickness of the vernix layer and the disintegration time *in vitro*. Measured on tablets of quinine hydrochloride, sodium sulfanilate, or sodium *p*-aminosalicylate of 50 or 500 mg. each, the same factor of proportionality was found, independent of size and content. It was still an open question if a similar constant factor of proportionality could be found between the thickness of the vernix layer and the disintegration time *in vivo*.

This paper reports investigations on the *in vivo* disintegration of tablets of quinine hydrochloride, sodium sulfanilate, or sodium *p*-aminosalicylate of various sizes and compositions and coated with various amounts of vernix.

As will be seen, it was not possible to show a proportionality factor which is independent of the content of the tablets.

EXPERIMENTAL

Preparations

The coated preparations are manufactured from tablets of the following compositions.

Tablets of Quinine Hydrochloride—Preparation No. 6–15: the composition appears from an earlier paper (6). The tablets contain either 50 or 500 mg. of quinine hydrochloride. Preparation No. 46–50: for each tablet take 50 mg. of quinine hydrochloride, 45 mg. of granulatum simplex (8), and 5 mg. magnesium stearate. Granulate by compression, mix, and compress. Spherical punches, 6 mm. diameter.

Tablets of Sodium Sulfanilate—For each tablet take 50 mg. of sodium sulfanilate and 40 mg. of starch. Mix and prepare by moist granulation. To the dried granulate add 10 mg. of talcum. Mix and compress. Spherical punches, 6 mm. diameter.

Tablets of Sodium *p*-Aminosalicylate—For each tablet take 50 mg. of sodium *p*-aminosalicylate, 45 mg. of granulatum simplex (8), 4 mg. of talcum, and 1 mg. of magnesium stearate. Mix and prepare by compression. Spherical punches, 6 mm.

The coating is made with vernix enterosolubilis (9): 10 mg. of cellulose acetate phthalate, 500 mg. of castor oil, and 89.5 g. of acetone. The vernix was applied to the tablets in an open pan. From time to time during the coating, numbers of 500–1,000 tablets were removed from the pan and dried, whereas the rest was coated further. This procedure ensures that subbatches removed during the coating only differ in the amount of vernix applied.

In Vitro Experiments—The alkaline disintegration time was determined by the following modification of the method used by the Nordic Pharmacopoea (10). Place three tablets in a conical flask in a solution of 0.285 g. of sodium phosphate, and 0.055 g. of potassium phosphate monobasic to 30 ml. of water maintained at 40°. Shake the flask gently during the whole of the disintegration. The point of disintegration is defined as the moment when the coating breaks up.

The acidic pretreatment is made as follows: Place the tablets in a mixture of 3 ml. phosphoric acid 1 *M* and 27 ml. water. Shake every 5 min. for 2 hr., pour off, and wash with 5 ml. water.

In Vivo Experiments—Eighteen healthy volunteers served as experimental subjects. The tests were started between 8:30 and 9:00 a.m., 1–1.5 hr. after a light breakfast. The test dose of 0.5 g. was ingested along with 150–200 ml. of water. Blood from the earlobe or urine was collected immediately before and every hour after the ingestion. The difference in time between the ingestion and the first appearance of the substance in the plasma or the urine was defined as the *in vivo* disintegration time. As the samples were collected every hour, the disintegration time was measured in whole hours.

Analytical

Quinine was determined in 0.1 ml. heparinized plasma by the method of Brodie and Udenfriend (11). Sodium *p*-aminosalicylate was determined in the plasma by the following method: 0.10 ml. heparinized plasma was mixed with 1 ml. water. After 15 min. the proteins were precipitated by adding 0.25 ml. 10% trichloroacetic acid. After 20 min. the tubes were centrifuged at $1100 \times g$ for 15 min.; 1 ml. of the clear supernatant was transferred to a tube containing 1.20 ml. of the following solution: 145 ml. of sodium hydroxide 1 *N*; 8.58 g. of sodium borate; to 1000 ml. of water, which gives pH = 11.

The fluorescence was read on an Aminco-Bowman

spectrofluorometer at 400 mμ, activated at 310 mμ (both uncorrected). Standards and blank were run through the procedure. No differences were found between standards made in plasma and water, and generally aqueous solutions were used. Concentrations down to 0.1 mcg./ml. are detectable with a recovery of 99–100%. The specificity of the method with respect to metabolites has not been investigated, but the appearance of a fluorescence in the plasma is taken as indication of an absorption of sodium *p*-aminosalicylate. Sodium sulfanilate was determined in the urine by the method of Morris (12).

RESULTS

Table I presents the alkaline *in vitro* disintegration times of the coated preparations with and without acid pretreatment.

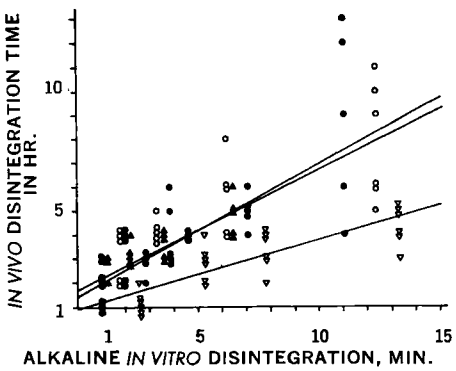

Fig. 1—In vivo *disintegration times of enteric-coated tablets* versus *alkaline* in vitro *disintegration times. Key:* ○●, *quinine HCl preparations;* ▽, *Na-p-aminosalicylate preparations;* ▲, *Na-sulfanilate preparations. The lines are drawn from the equations of regression.*

The *in vivo* disintegration times from all experiments are plotted in Fig. 1 against the means of the *in vitro* disintegration times from Table I. No difference was found between the results with the 50-mg. and the 500-mg. tablets of the preparations No. 6–15, and these preparations are treated as one group.

Regression lines were calculated from the determinations as pairs of numbers. Three instances in which no *in vivo* disintegration was detected are omitted. Tests with uncoated tablets, where the disintegration times are: *in vitro* 0 min., *in vivo* the first hour, are included in the calculations.

The equations of regression are found as follows:

$$Y_Q^{(1)} = 0.60X + 1.14 \quad r = 0.82 \quad n = 40$$
$$Y_Q^{(2)} = 0.50X + 1.96 \quad r = 0.84 \quad n = 26$$
$$Y_Q = 0.56X + 1.47 \quad r = 0.82 \quad n = 66$$
$$b/s_b = 11.6$$
$$Y_{PAS} = 0.26X + 0.98 \quad r = 0.88 \quad n = 22$$
$$b/s_b = 3.18$$
$$Y_{SUL} = 0.50X + 1.70 \quad r = 0.87 \quad n = 30$$
$$b/s_b = 11.6$$

Y is the *in vivo* disintegration in hours of tablets of quinine hydrochloride (Q), sodium *p*-aminosalicylate (PAS), and sodium sulfanilate (SUL), respectively, and X is the *in vitro* disintegration in min.

$Y_Q^{(1)}$ is calculated from tests with the preparations No. 6–15, manufactured differently from the preparations No. 46–50, from which $Y_Q^{(2)}$ is calculated. The two regression coefficients do not differ significantly from each other ($t = 1.00$, $p > 0.3$, $df = 62$), and neither do the positions of the lines ($t = 0.923$, $p > 0.3$, $df = 62$). This permits the calculation of an equation of regression Y_Q, based on all tests with the quinine preparations. The ratios b/s_b show that all regression coefficients differ significantly from zero ($p < 0.005$). The intercepts of the regression lines with the ordinate, do not differ significantly from the expected point (0.1), *i.e.*, the disintegration times of uncoated

tablets in tests with sodium *p*-aminosalicylate and quinine HCl: $t_Q = 1.6$, $p > 0.1$, $df = 64$ and $t_{PAS} = 0.71$, $p > 0.4$, $df = 28$, whereas the difference is significant with sodium sulfanilate: $t_{SUL} = 2.92$, $p < 0.01$, $df = 20$. The comparison between the regression coefficients shows: b_Q/b_{PAS}, $t = 5.25$, $p < 0.001$, $df = 28$; b_{SUL}/b_{PAS}, $t = 3.41$, $p < 0.005$, $df = 20$; $b_Q/_{SUL}$, $t = 0.61$, $p > 0.5$, $df = 84$.

DISCUSSION

The results are in agreement with those of Wagner *et al.* (3–5), who found correlation between the *in vitro* and the *in vivo* disintegration times, but a further important point has to be added. The statistical analysis of the results presented here shows that the lines fitted to tests with quinine HCl and sodium sulfanilate differ significantly from the line fitted to the tests with sodium *p*-aminosalicylate. This means that the factor of proportionality by which the *in vivo* disintegration time increases with increasing thickness of the coating layer may differ significantly with different contents of the tablets. It is thus found that tablets showing an *in vitro* disintegration time of 12 min. take about 8 hr. to disintegrate *in vivo* when the content is quinine or sulfanilate, and about 4 hr. when the content is *p*-aminosalicylate.

The *in vivo* disintegration time, *i.e.*, the time until analytically sufficient concentrations are built up in the plasma or the urine, may be influenced by the rate of dissolution from the preparations in the way that a decreased dissolution rate may increase the time between the *in vivo* break-up of the coating layer and the moment when detectable concentrations are reached, and in this way apparently increase the *in vivo* disintegration time.

If this explanation were valid, one should expect that sodium *p*-aminosalicylate were released at a higher rate than are quinine hydrochloride and sodium sulfanilate from the coated preparations in order to explain the differences found.

However, *in vitro* dissolution half-lives of some of the coated preparations, listed in Table I, show that sodium sulfanilate is released at a much higher rate than sodium *p*-aminosalicylate or quinine hydrochloride, although the former is released faster than the latter.

Another way in which the *in vivo* disintegration time may be altered is by some influence of the acid in the stomach. The influence is tested by determinations of the alkaline *in vitro* disintegration time with and without acid pretreatment. Table I shows that significant alterations are only found with preparations with such a thin vernix layer that some of the tablets disintegrate during the 2 hr. in the acid.

The delay in the *in vivo* disintegration time of the coated preparations could further be explained as a retention in the stomach. Nelson (13) calculated an average stomach retention time of 3 hr., from the results of Blythe *et al.* (14) who worked with coated $BaSO_4$ tablets. If so, the regression lines would intercept the ordinate at a point near to 3 hr., *i.e.*, at a point corresponding to the retention time. This is not the case with any of the preparations in this work. Only the line calculated from tests with sodium sulfanilate tablets has an intercept significantly different from the expected point: (0,1). This, on the other hand, may be explained by the fact that the disintegration times here are determined by the appearance of sulfanilate in the urine, where the limit of detection is not very low because of the variations in the blank readings.

CONCLUSION

Batches of enteric-coated tablets of the same substance show an increase in the *in vivo* disintegration time proportional to the increase in the *in vitro* disintegration time, independently of the size and pharmaceutical composition of the tablets.

Between preparations of different substances the factor of proportionality may differ significantly.

As a consequence, the predictability of the *in vivo* fate of the drug requires determination of the correlation between *in vivo* and *in vitro* dissolution rates, as well as the factor by which the *in vivo* disintegration time changes with the *in vitro* disintegration time. This factor of proportionality has to be evaluated for each substance.

Inhibitors of Monoamine Oxidase II

Syntheses of Some *N*-2(9)-Substituted Tetrahydro-β-carbolines and Evaluation of Their Inhibitory Activities

By BENG T. HO, WILLIAM M. MCISAAC, and K. E. WALKER

Tetrahydro-β-carbolines with alkyl or aralkyl substitution on N-9, alkyl on N-2, and alkyl on both N-2 and N-9 were synthesized and their monoamine oxidase inhibitory activities evaluated. Two different binding conformations were proposed for the 9-methyl and the 9-hydrogen series. The binding of the 9-methyl group hydrophobically to the enzyme would account for the high inhibitory activities of 9-methyl compounds. In the case of 9-hydrogen-2-alkyl series, since there is no methyl group on the indolic nitrogen, hydrophobic bonding would not be possible. Relief of steric hindrance due to the 2-alkyl would probably cause the molecule to assume another binding conformation. Of all the compounds tested, 2,9-dimethyltetrahydro-β-carboline was the most active inhibitor. Its activity was about one-third that of the previously reported 9-methyltetrahydro-β-carboline.

In a previous paper (1) on inhibitors of monoamine oxidase, the influence of methyl substitution on the inhibitory activity of β-carbolines was studied. 9-Methyltetrahydro-β-carboline was found to be a competitive inhibitor of the enzyme, being three times more active than iproniazid, a one-time clinically used antidepressant. Initial findings also indicated that the N-2 nitrogen of the tetrahydro-β-carboline could be substituted by alkyl groups as large as propyl without affecting the inhibitory activity.

Since a 35-fold increase in inhibitory activity was obtained by the substitution of a methyl group on the N-9 nitrogen of tetrahydro-β-carboline, the synthesis and evaluation of inhibitory effect of some N-9 substituted tetrahydro-β-carbolines has been undertaken, and the studies extended to include some 2,9-disubstituted compounds.

DISCUSSION

A 35-fold increase in inhibitory activity (Table I) was observed when a methyl group was introduced on the N-9 nitrogen of tetrahydro-β-carboline (I). This was attributed to either the increase in the electron density of the indole nucleus of 9-methyltetrahydro-β-carboline (II) thus giving better binding, or the binding of the 9-CH_3 group itself hydrophobically to the enzyme, or both (1). The possibility of the existence of a hydrophobic region on the enzyme in proximity to the 9-CH_3 of II was then explored. Extension of the 9-CH_3 by one carbon resulted in a 50-fold decrease in inhibitory activity of 9-ethyl compound (III). This unexpected decrease in activity was at first thought to be caused by the projection of the terminal CH_3 of the ethyl group into a possible hydrophilic region of the enzyme. In order to investigate this possibility, a hydrophilic group such as hydroxyl was chosen to replace the terminal hydrophobic CH_3 of the ethyl group, anticipating that the binding of OH to the hydrophilic region of the enzyme would result in increased inhibition.

Synthetically, it seemed more appropriate to protect the N-2 nitrogen of the tetrahydro-β-carboline by substitution so that the addition of the hydroxymethyl to the N-9 nitrogen would be exclusive. Alkylation on the N-2 position was assumed not to interfere with studies on the N-9 position, since a previous finding (1) revealed no change in inhibitory activity when alkylating the N-2 nitrogen of 1-methyltetrahydro-β-carboline (XIII) with methyl or *n*-propyl (see XIV and XV). Since

[a] Concentration of an inhibitor giving 50% inhibition of the enzyme. [b] Hydrochloride salt. [c] Data from *Reference 1*.

Received March 14, 1968, from the Biological Research Division, Texas Research Institute of Mental Sciences, and the Baylor University College of Medicine, Houston, TX 77025

Accepted for publication April 18, 1968.

This work was supported by grants MH-11168 and MH-12959, U. S. Public Health Service, Bethesda, Md., and by the Britton Fund.

The authors would like to thank Miss Patricia Kralik for her technical assistance in providing the enzyme assay data.

an N-2 ethyl substituent would be easily obtained by the reduction of the N-2 acetyl compound, 2 - ethyl - 9 - hydroxymethyltetrahydro - β - carboline (XI) was synthesized. For comparison with the 2-hydrogen series, 2-ethyl-9-methyltetrahydro-β-carboline (X) and 2-ethyltetrahydro-β-carboline (VIII) were also prepared.

The 2-ethyl compound (VIII) was first found to be a weak inhibitor, being four times less active than I. The corresponding 9-methyl compound (X) was 13-fold less active than II. Thus, it seemed that the steric hindrance by the 2-ethyl group could account for the decrease in inhibitory activity of 2-ethyl compounds when compared with the 2-hydrogen series. Of greater interest was to determine whether or not the enzyme could tolerate a smaller N-2 substituent like the methyl group. The 2,9-dimethyltetrahydro-β-carboline (XII) was indeed a very good inhibitor, being about one-third as active as II and about four times more active than X. This phenomenon was, however, not observed in the 9-hydrogen series. Here, the activity remained the same when the 2-alkyl chain was reduced from propyl to ethyl (IX → VIII). This, along with the previous finding that in the 1-methyl series XIV was equally as active as XV, suggested that it was not at all impossible to have two different modes of binding for substituted tetrahydro-β-carbolines on monoamine oxidase.

Judging from the similarity in inhibitory activities between XIV and XV, and VIII and IX, it was postulated that the 2-ethyl and 2-propyl groups of the above two series might have projected into a "noncontact" area away from the binding site. The conformation A (Fig. 1) proposed for the four compounds was different from conformation B (Fig. 2) proposed for all the 9-methyltetrahydro-β-carbolines. That a class of compounds can assume different conformations of binding to an enzyme has been presented (2). The assumption for the mode of binding of different series of substituted tetrahydro-β-carbolines is as follows.

(*a*) Since a compound always assumes a binding position giving a maximum inhibitory effect, the increase in inhibitory activity of all 9-methyl compounds was thought to be due to the hydrophobic bonding of their 9-methyl group to the enzyme (conformation B). In this conformation, any substituent on the N-2 position larger than hydrogen would cause a decrease in activity. This decrease was observed in inhibitory activity as the length of the 2-alkyl side chain was increased, therefore resulting in increased steric hindrance. This was true for XII and X.

(*b*) When there is no methyl group on the indolic nitrogen, hydrophobic bonding would not be possible, therefore relief of steric hindrance due to the 2-alkyl groups (see conformation B) became an important factor. The preferable binding conformation for both VIII and IX more likely was the conformation A, where the 2-alkyl groups could be projected to the noncontact area and away from the binding site. This could account for the unchanged activity from 2-ethyl to 2-propyl. A similar rationalization could be applied to the 1-methyl series. Apparently, in the conformation B the enzyme would not tolerate a 1-methyl group, and a "twist" to the conformation A not only relieved this steric hindrance, but also allowed substituents

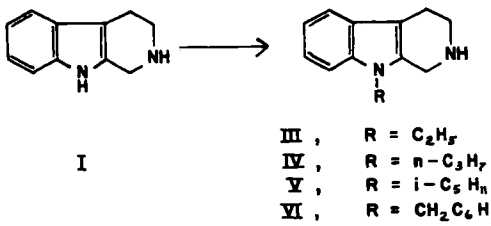
on N-2 nitrogen to be projected to the noncontact area. Note that the inhibitory activities of the 1-methyl-2-alkyl series (XIII–XV) were the same as those of the 1-hydrogen-2-alkyl series (VIII and IX).

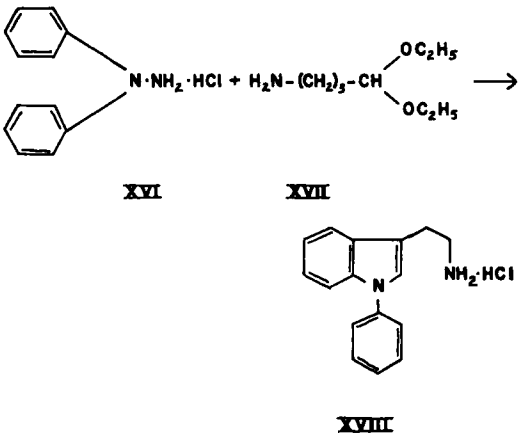
The data on the inhibitory activities of 9-alkyl and 9-aralkyl series indicated that the 9-ethyl compound (III) was 45-fold less active than the 9-methyl compound (II). Since further increase in the length of alkyl chain did not result in large decreases in inhibitory activities, it was assumed that for tetrahydro-β-carbolines any 9-alkyl or 9-aralkyl group larger than methyl would not bind in the conformation B. However, whether the binding conformation of 9-alkyl- or 9-aralkyl-tetrahydro-β-carbolines assumed the conformation A or whether there was a third conformation for the binding of these 9-substituted compounds remains to be determined. The observation that the 9-hydroxymethyl-2-ethyl compound (XI) was not as active as 9-methyl-2-ethyl compound (X) was then not to be unexpected, in view of the apparent steric requirements for conformation B. Apparently, the steric hindrance due to the terminal OH group caused XI to assume a binding conformation which was similar to that for tetrahydro-β-carbolines with N-9 substitutions larger than methyl.

CHEMISTRY

9-Alkyltetrahydro-β-carbolines were prepared by treating the sodium salt of the tetrahydro-β-



Scheme I



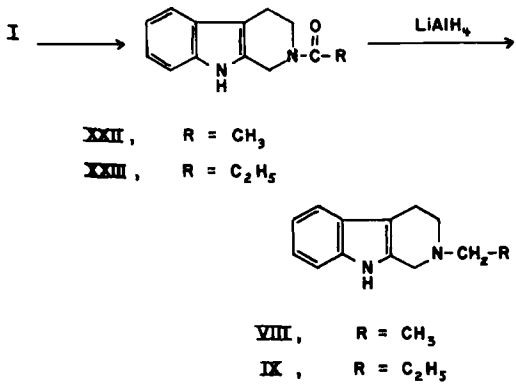
Scheme II

carboline (I) with the appropriate alkyl halides (Scheme I). Alkylation in liquid ammonia gave 9-ethyltetrahydro-β-carboline (III), 9-propyltetrahydro-β-carboline (IV), and 9-isoamyltetrahydro-β-carboline (V) in 56, 20, and 30% yields, respectively. It was found that the reaction of 1-iodo-3-methylbutane with I required longer time than with the lower alkyl halides. In a previous run, when the reaction was allowed to proceed for only 20 min. after the addition of the alkyl halide, as in the preparation of III and IV, a mixture of product and starting material was isolated.

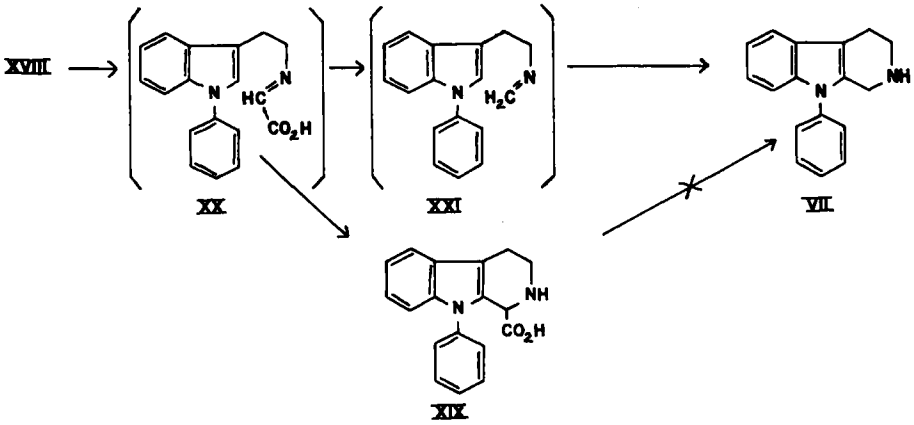
The preparation of 9-benzyltetrahydro-β-carboline (VI) was carried out by the reaction of I with benzyl chloride in dimethylformamide in the presence of sodium hydride.

Condensation of 1,1-diphenylhydrazine hydrochloride (XVI) and α-aminobutyraldehyde diethyl acetal (XVII) at 95° in the presence of hydrochloric acid according to the patent procedure (3) gave 1-phenyltryptamine hydrochloride (XVIII) (Scheme II).

For the preparation of some tetrahydro-β-carbolines the corresponding tryptamine derivatives have been previously treated with glyoxylic acid to form the 1-carboxytetrahydro-β-carbolines which were then decarboxylated yielding the desired products (1). When the same method was employed in the preparation of VII, the intermediate 1-carboxyl-9-phenyl-tetrahydro-β-carboline (XIX) failed to decarboxylate. A final solution to this was to carry out the reaction of XVIII and glyoxylic acid in refluxing aqueous solution instead of at room temperature. At the elevated temperature 1-phenyltryptamine most likely first condensed with glyoxylic acid to give the Schiff base, XX, which then decarboxylated and subsequently cyclized to 9-phenyltetrahydro-β-carboline (VII) (Scheme III). This mechanism has been proposed for the reaction of tryptamine with α-keto acids at elevated temperature (4). Since from the reaction mixture a product that had identical infrared spectrum with 1-carboxy-9-phenyl compound (XIX) formed at pH 4, it was assumed that the cyclization of XX to



Scheme IV

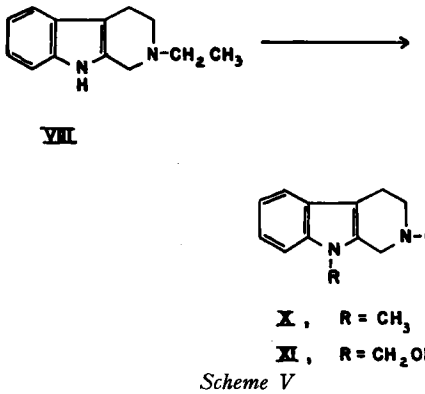


Scheme III

XIX competed with the decarboxylation of XX to give XXI and then VIII. Compound VII had been prepared *via* the condensation of 1-phenyltryptamine with formaldehyde (3).

Acylation of I without application of heat gave 2-acetyltetrahydro-β-carboline (XXII), and 2-propionyltetrahydro-β-carboline (XXIII) in 87.6 and 88.2%, respectively. These two 2-acyltetrahydro-β-carbolines were then reduced with lithium aluminum hydride to give a 66.3% yield of 2-ethyltetrahydro-β-carboline (VIII) and 71.4% of 2-propyltetrahydro-β-carboline (IX) (Scheme IV).

2-Ethyl-9-methyltetrahydro-β-carboline (X) was obtained in a 60% yield by the methylation of VIII with methyl iodide and sodium amide in liquid ammonia. Hydroxymethylation of VIII was performed in aqueous solution with formaldehyde at pH 5.5–6.0. Four days at room temperature gave 9-hydroxymethyl-2-ethyltetrahydro-β-carboline (XI) in 36% yield (Scheme V).



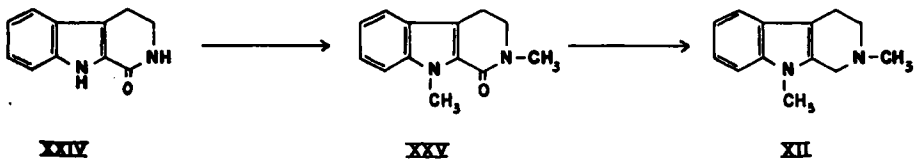
Scheme V

An incomplete methylation of 1-oxotetrahydro-β-carboline (XXIV) resulted when the reaction was carried out in liquid ammonia in the presence of sodium amide. Treatment of XXIV in boiling tetrahydrofuran with methyl iodide and sodium hydride, however, gave the desired product (XXV) in 72% yield. XXV was reduced by lithium aluminum hydride to 2,9-dimethyltetrahydro-β-carboline (XII) in 54% yield (Scheme VI).

sodium with 60–70 ml. of liquid ammonia in the presence of a catalytic amount of ferric nitrate. After all the amine had dissolved, 6.8 g. (0.04 mole) of 1-iodopropane was added slowly over a period of 30 min. Stirring was continued for an additional 20 min. The mixture was evaporated to dryness by a stream of helium while the flask was immersed in hot water. Water (15 ml.) was added to the residue and the product was extracted with toluene (2 × 200 ml.). After filtration of the combined toluene extracts with anhydrous sodium sulfate, the solvent was evaporated *in vacuo* leaving 6.3 g. of orange oil. The product was dissolved in 30 ml. of benzene, and after removal of suspended solid by filtration, the solvent was again evaporated *in vacuo* giving 6.0 g. (93.7%) of orange oil. The extraction process was repeated with 70 ml. of boiling heptane to yield a colorless oil, which was converted to 3.8 g. (50%) of yellow hydrochloride by the addition of ether–HCl to an ethereal solution of the oil. One recrystallization from ethanol gave 1.5 g. (20%), m.p. 231–232°; $\lambda_{max.}$ (KBr) 3.30, 3.88, 3.43, 3.50, 3.60, 3.70, 3.80, 3.85, 3.94, 4.10–4.15 (CH, NH_2^+); 6.20, 6.35 (C=C); 13.45 μ (indole CH); $\lambda_{max.}$ (EtOH) 204, 224, 277, 282, 292 (s) mμ.

Anal.—Calcd. for $C_{14}H_{19}ClN_2$: C, 67.0; H, 7.63; N, 11.2. Found: C, 67.2; H, 7.64; N, 11.3.

9-Isoamyl-1,2,3,4-tetrahydro-β-carboline (V)—1,2,3,4-Tetrahydro-β-carboline (6.88 g., 0.04 mole) was treated with a mixture of 1.04 g. (0.045 g. atom) of sodium in liquid ammonia and 8.91 g. (0.045 mole) of 1-iodo-3-methylbutane as in the preparation of 9-*n*-propyltetrahydro-β-carboline, except after the addition of the alkyl halide the reaction was allowed to proceed for 1 hr. After the evaporation of liquid ammonia, about 50 ml. of water was added to the residue, and the product was extracted with ether (2 × 150 ml.). The ethereal solution was shaken with 150 ml. of 15% hydrochloric acid and the aqueous layer was separated. During an extraction of the aqueous solution with about 100 ml. of ether, the hydrochloride salt precipitated. When the hydrochloride salt was neutralized by sodium hydroxide, the solid free amine was liberated, which became an oil upon drying *in vacuo*. Conversion of the free amine again into the hydrochloride gave 3.5 g. (31.2%) of yellow solid. The hydrochloride



Scheme VI

EXPERIMENTAL

Melting points are corrected and were taken on a Fisher-Johns apparatus. Infrared spectra were obtained with a Perkin-Elmer spectrophotometer model 237 B. For qualitative ultraviolet spectra a Beckman spectrophotometer model DB-G was used.

9-*n*-Propyl-1,2,3,4-tetrahydro-β-carboline (IV)—1,2,3,4-Tetrahydro-β-carboline (5.16 g., 0.03 mole) was added slowly with stirring to a sodamide solution, prepared by reacting 0.92 g. (0.04 g. atom) of salt was recrystallized from ethanol–ether to give 2.5 g. (22.3%) of white solid. A second recrystallization from the same solvent mixture yielded 1.5 g., m.p. 229–230°; $\lambda_{max.}$ (KBr) 3.28, 3.38, 3.43, 3.49, 3.60, 3.65, 3.70, 3.77, 3.83, 3.91, 4.08 (CH, NH_2^+); 6.20, 6.35, 6.80, 6.85 (C=C, CH); 7.20, 7.22 [C-$(CH_3)_2$]; 13.60 μ (indole CH).

Anal.—Calcd. for $C_{16}H_{23}ClN_2$: C, 68.9; H, 8.31; N, 10.0. Found: C, 68.9; H, 8.56; N, 10.1.

9-Ethyl-1,2,3,4-tetrahydro-β-carboline (III)—In a similar manner as in the preparation of 9-*n*-propyltetrahydro-β-carboline, 9-ethyltetrahydro-β-carbo-

line was obtained as a yellow oil. It was converted into the hydrochloride salt, m.p. 233.5–235° (ethanol). On the silica gel chromatogram in *n*-propanol–ammonium hydroxide (95:5) this hydrochloride traveled as a single spot which was different from the starting material. A portion of the yellow oil was converted into its picrate salt. The melting point (225–226° dec.) of the picrate agreed with that reported (224–225°) by Leonard and Elderfield prepared from 1-ethyltryptamine and formaldehyde (5).

9-Benzyl-1,2,3,4-tetrahydro-β-carboline (VI)—To a stirred suspension of 0.576 g. (24 mmoles) of sodium hydride (50% suspension in mineral oil) in 30 ml. of dimethylformamide (DMF) was added over a period of 20 min. a solution of 3.78 g. (22 mmoles) of tetrahydro-β-carboline in 60 ml. of DMF. After stirring for 1 hr., the resulting solution was cooled in ice while a solution of 2.9 g. (23 mmoles) of benzyl chloride was added dropwise over 10 min. At the end of the addition the mixture was stirred for 1 hr. at ice temperature. Water (150 ml.) was added and the mixture was extracted with chloroform (4 × 75 ml.). The combined chloroform extracts were washed with water (4 × 150 ml.), dried with anhydrous sodium sulfate, and evaporated under reduced pressure. The residue was extracted with 50 ml. of heptane. After the removal of insoluble solid by filtration, the heptane extract was evaporated *in vacuo* leaving an oil that was converted into 3.5 g. (53%) of hydrochloride salt, m.p. 252–258°. The hydrochloride was dissolved in 100 ml. of hot water, and after cooling the gummy insoluble substance extracted with ether (3 × 100 ml.). During the last extraction the hydrochloride precipitated from the aqueous solution and was collected on a filter; yield, 0.462 g. (7%), m.p. 277–279°; $\lambda_{max.}$ (KBr) 3.28, 3.31, 3.40, 3.45, 3.60, 3.67, 3.70, 3.77, 3.83, 3.90, 3.92, 4.09, 4.15 (CH, NH_2^+); 6.20, 6.25, 6.30, 6.35, 6.69, 6.72, 6.88 (C=C, CH); 13.45, 14.25 μ (indole and phenyl CH). $\lambda_{max.}$ (EtOH) 207, 223, 275, 282, 295 mμ. No attempt has been made to recover more product from the aqueous solution.

The m.p. of this hydrochloride agreed with that reported (276°) in a patent (3) prepared from the condensation of 1-benzyltryptamine with formaldehyde.

9-Phenyl-1,2,3,4-tetrahydro-β-carboline (VII)—To a refluxed solution of 1.2 g. (4.4 mmoles) of 1-phenyltryptamine hydrochloride (3) in 30 ml. of water was added dropwise a solution of 0.524 g. (6 mmoles) of glyoxylic acid monohydrate in 10 ml. of water. After being refluxed for an additional 1 hr., the mixture was cooled in ice and the solid (XIX) was removed by filtration. The filtrate was first made basic with 30% aqueous potassium hydroxide and the gummy precipitate was extracted with ether (2 × 30 ml.). The combined ether extracts were dried over anhydrous sodium sulfate, filtered, and mixed with ethereal HCl. The hydrochloride was collected on a filter; yield, 0.41 g. (32.5%), m.p. 230–240°. One recrystallization from ethanol gave 0.175 g. (13.8%). The melting point (260–261°) of the pure product agreed with that reported (260–262°) in the literature (3) prepared from the reaction of 1-phenyltryptamine with formaldehyde.

9-Phenyl-1,2,3,4-tetrahydro-β-carboline-1-carboxylic Acid (XIX)—To a solution of 0.898 g. (3.3 mmoles) of XVIII·HCl in 80 ml. of water was added 0.304 g. (3.3 mmoles) of glyoxylic acid monohydrate. After being adjusted to pH 4 with 5% aqueous potassium hydroxide, the mixture was stirred at room temperature for 17 hr. Concentrated hydrochloric acid (5 ml.) was added and the stirring was continued for an additional 1 hour. The resulting "jell-like" mixture was centrifuged. The precipitate washed with ethanol (2 × 40 ml.), and again centrifuged. The precipitate was finally suspended in 80 ml. of ether and collected on a filter; yield, 0.30 g. (27.7%), m.p. 225–226° (with evolution of CO_2). $\lambda_{max.}$ (KBr) 3.29, 3.38, 3.42, 3.50, 3.65, 3.85 (CH, NH_2^+), 6.16 (COO^-), 6.26, 6.66 (C=C), 13.50 μ (indole CH).

Anal.—Calcd. for $C_{18}H_{16}N_2O_2$: C, 74.0; H, 5.51; N, 9.6. Found: C, 73.7; H, 5.64; N, 9.6.

2-Propionyl-1,2,3,4-tetrahydro-β-carboline (XXIII)—Tetrahydro-β-carboline (5.16 g., 0.03 mole) and 15 ml. of propionyl anhydride was thoroughly mixed, then allowed to stand at room temperature for 10 min. After cooling briefly in ice, the mixture was poured with stirring into 100 ml. of water, and the solid was collected after 30 min.; yield, 6.0 g. (88.2%), m.p. 204–206°; $\lambda_{max.}$ (KBr) 3.08 (NH); 6.13, 6.18, 6.30 (C=O, C=C); and 13.40 μ (indole CH).

Anal.—Calcd. for $C_{14}H_{16}N_2O$: C, 73.6; H, 7.06; N, 12.3. Found: C, 73.4; H, 7.09; N, 12.3.

2-Acetyl-1,2,3,4-tetrahydro-β-carboline (XXII)—In a similar manner as in the preparation of 2-propionyltetrahydro-β-carboline, acetylation of tetrahydro-β-carboline gave 2-acetyl product in a 87.6% yield, m.p. 238–239° [lit. m.p. 237–238° (6)].

2-*n*-Propyl-1,2,3,4-tetrahydro-β-carboline (IX)—A suspension of 1.52 g. (0.04 mole) of lithium aluminum hydride in 100 ml. of tetrahydrofuran was refluxed with stirring while 4.56 g. (0.02 mole) of 2-propionyltetrahydro-β-carboline was extracted from a Soxhlet thimble. After 14 hr. of heating the cooled mixture was decomposed with water and filtered. The filtered cake was washed with tetrahydrofuran (3 × 50 ml.), and the combined tetrahydrofuran solution was concentrated under reduced pressure almost to dryness. Addition of about 100 ml. of water caused the precipitation of product; yield, 4.1 g. (97.6%), m.p. 132–136°. This crude product was dissolved in 100 ml. of 10% hydrochloric acid. After clarification by filtration through diatomaceous earth,[1] the free base was liberated by the addition of excess 10% potassium hydroxide. The free amine was recrystallized from aqueous ethanol to give 3.0 g. (71.4%) of needles, m.p. 136.5–137.5°. For analysis a hydrochloride salt was prepared; m.p. 242–243° dec. $\lambda_{max.}$ (KBr) 3.10 (NH), 3.70, 3.76, 3.80, 3.82, 3.88, 4.00, 4.10 (NH^+); 6.15, 6.25 (C=C); 13.35 μ (indole CH).

Anal.—Calcd. for $C_{14}H_{19}ClN_2$: C, 67.0; H, 7.64; N, 11.2. Found: C, 67.2; H, 7.70; N, 11.1.

2-Ethyl-1,2,3,4-tetrahydro-β-carboline (VIII)—In a similar manner as described above, a mixture of 10.6 g. (0.049 mole) of 2-acetyltetrahydro-β-carboline and 4.0 g. (0.1 mole) of lithium aluminum hydride in 550 ml. of tetrahydrofuran was refluxed for 3.5 hr. to yield 8.0 g. (81.6%) of 2-ethyltetrahydro-β-carboline. One recrystallization from aqueous ethanol gave 6.5 g. (66.3%), m.p. 153–154° [lit. m.p. 137–138° (6)]. The hydrochloride salt of the

β-carboline melted at 229–230° [lit. m.p. 227–229° (6)].

2 - Ethyl - 9 - methyl - 1,2,3,4 - tetrahydro - β-carboline (X)—In a similar manner as in the preparation of IV, 2 g. (0.01 mole) of 2-ethyltetrahydro-β-carboline was treated with a mixture of 0.345 g. (0.015 g. atom) of sodium in liquid ammonia and 2.13 g. (0.015 mole) of methyl iodide. After evaporation, the residue was dissolved in 50 ml. of water, and extracted first with 100 ml. then 50 ml. of ether. The combined ethereal extracts were dried with anhydrous sodium sulfate, decolorized with charcoal, filtered, then evaporated *in vacuo*. The oily residue was dissolved in 25 ml. of heptane, filtered, and mixed with ethereal HCl to precipitate the hydrochloride salt. Recrystallization of this crude hydrochloride with ethanol–ether gave 1.5 g. (60%) of white solid, m.p. 234–235°; $\lambda_{max.}$ (KBr) 3.28, 3.32, 3.40, 3.44, 3.47, 3.51 (CH); 3.65, 4.01, 4.12, 4.31 (NH^+); 6.20 (C=C); 13.35 μ (indole CH). $\lambda_{max.}$ (EtOH) 225, 275, 282, 293 mμ.

Anal.—Calcd. for $C_{14}H_{19}ClN_2$: C, 67.0; H, 7.63; N, 11.2. Found: C, 67.2; H, 7.82; N, 11.2.

2 - Ethyl - 9 - hydroxymethyl - 1,2,3,4 - tetrahydro-β-carboline (XI)—To a suspension of 1.0 g. (5 mmoles) of 2-ethyltetrahydro-β-carboline in 10 ml. of water was added dropwise concentrated hydrochloric acid until a solution was obtained (about 0.1 ml.). The pH of the solution was adjusted to 5.5–6.0 with aqueous sodium acetate and 5 ml. of 38% (60 mmoles) of formaldehyde was added. The mixture was allowed to stand at room temperature for 4 days. When the solution was made basic with 10% potassium hydroxide, an oil separated. The oil was extracted into 50 ml. of ether, and evaporation of ether gave a gummy product which was then dissolved in ether and converted into 0.5 g. (36%) of hydrochloride salt by mixing with ethereal HCl. The hydrochloride was hygroscopic; it decomposed when heated to 180°. $\lambda_{max.}$ (KBr) 3.10 (OH); 3.20, 3.25, 3.35, 3.45 (NH^+); 6.18 (C=C); 9.60–9.70 (C–O); 13.40 μ (indole CH); $\lambda_{max.}$ (EtOH) 204, 224, 272, 279, 289 mμ.

Anal.—Calcd. for $C_{14}H_{19}ClN_2O$: C, 63.0; H, 7.17; N, 10.5. Found: C, 62.8; H, 7.20; N, 10.5.

2,9 - Dimethyl - 1 - oxo - 1,2,3,4 - tetrahydo - β-carboline (XXV)—To a suspension of 1.44 g. (0.06 mole) of sodium hydride (50% suspension in mineral oil) in 25 ml. of tetrahydrofuran was added dropwise a solution of 3.72 g. (0.02 mole) of 1-oxotetrahydro-β-carboline in 50 ml. of tetrahydrofuran over a period of 1 hr. After being refluxed for 45 min., the mixture was cooled in an ice bath while 14.2 g. (0.1 mole) of methyl iodide was added dropwise over a period of 15 min. The resulting mixture was allowed to stand overnight at room temperature, then refluxed for 30 min. After the addition of 3 ml. of water, the mixture was heated under a stream of helium until the volume reduced to about 25 ml. A large amount of water was added and an oil separated. The oil was extracted into 150 ml. of ether and the aqueous layer was again extracted with 100 ml. of ether. The combined ethereal extracts were dried with anhydrous sodium sultate and evaporated *in vacuo* leaving an oily residue. When the oil was boiled with 15 ml. of heptane for 10 min. then allowed to cool, it solidified to give 3.1 g. (72%), m.p. 77.5–79°; $\lambda_{max.}$ (KBr) 6.10 (C=O); 6.20, 6.47, 6.70 (C=C); 13.55 μ (indole CH), $\lambda_{max.}$ (EtOH) 207, 230, 242 (s), 303. 330 (s) mμ.

Anal.—Calcd. for $C_{13}H_{14}N_2O$: C, 72.9; H, 6.58; N, 13.1. Found: C, 73.1; H, 6.63; N, 13.0.

2,9-Dimethyl-1,2,3,4-tetrahydro-β-carboline (XII)—To a stirred suspension of 0.76 g. (0.02 mole) of lithium aluminum hydride in 30 ml. of ether was added dropwise a solution of 2.14 g. (0.01 mole) of 2,9-dimethyl-1-oxo-tetrahydro-β-carboline in 30 ml. of ether. After being stirred at room temperature for 2 hr., the mixture was decomposed with water, filtered, and the filtered cake was washed with ether (3 × 20 ml.). The combined ether solution was dried with anhydrous sodium sulfate and evaporated *in vacuo* leaving a white solid. The solid product was dissolved in ether, filtered to remove small amounts of undissolved product, then mixed with ethereal HCl. The hydrochloride salt, m.p. 242–244°, weighed 2 g. (83.3%). One recrystallization from ethanol gave 1.3 g. (54.1%), m.p. 246–247°; $\lambda_{max.}$ (KBr) 3.74, 3.83, 3.89, 3.98, 4.03, 4.12, 4.20 (NH^+); 6.20 (C=C); 13.18, 13.30 μ (indole CH), $\lambda_{max.}$ (EtOH) 204, 227, 276, 282, 292 mμ.

Anal.—Calcd. for $C_{13}H_{17}ClN_2$: C, 65.9; H, 7.23; N, 11.8. Found: C, 66.1; H, 7.30; N, 12.0.

Assay

Mitochondrial monoamine oxidase from beef liver was isolated and purified as previously described (1). All the stock solutions of the hydrochloride salts of inhibitors were prepared in water. Compound VIII was dissolved in 0.01 *N* HCl and compound IX in propylene glycol. Incubation was carried out with tryptamine-2-^{14}C hydrochloride according to the previously described procedure (1).

Studies on Protein Binding I

Interaction of *para*-Hydroxybenzoic Acid Esters with Bovine Serum Albumin

By NAGIN K. PATEL, PAI-CHANG SHEEN, and KATHLEEN E. TAYLOR*

The binding of methyl, ethyl, propyl, and butyl esters of *p*-hydroxybenzoic acid (parabens) by bovine serum albumin (BSA) was investigated by an equilibrium dialysis procedure. All the compounds were found to interact with BSA. The association constants were ascertained from the dialysis data, and free energy change, ΔF^0, enthalpy change, ΔH^0, and entropy change, ΔS^0, of the interaction were computed from the data at two temperatures. The possible mechanism of the interaction is discussed. The spectrophotometric study of the interaction revealed hypochromic effects in the absorption spectra of all the parabens in the presence of BSA. The *in vitro* antifungal activity of methyl- and propylparaben was found to be related to the concentration of free or unbound drug.

INTERACTION OF NUMEROUS small molecules with serum proteins has been extensively reviewed by Goldstein and most of the drugs studied have been found to bind primarily to the albumin fraction of plasma proteins (1). Although a majority of the earlier reports were of a qualitative nature, attempts have been made to quantify the data with an ultimate aim of elucidating the nature of equilibria and forces involved in the drug-macromolecular interaction (2, 3). With the advancement of the theoretical knowledge of these interactions, considerable research has been conducted on the binding of salicylates (4, 5), sulfonamides (6–8), penicillins (9), xanthines (10), steroids (11), and other therapeutic agents with serum albumins.

In their extensive reviews Goldstein (1) and Brodie and Hogben (12) have discussed the importance of drug–protein association in the transport, distribution, and elimination of medicinal agents. In addition, it is generally recognized that the specificity of pharmacologic agents lies in the structure of complexes which they form with macromolecular systems. The investigation of the factors involved in such interactions may shed some light on the understanding of drug action.

Interactions of some benzoic acid derivatives (5) with serum albumins have been investigated. The degree of ionization and the relative size of the anion of the interacting molecule influenced the protein binding, and Boyer *et al.* (13) concluded that an anion with a fairly large nonpolar group imparted an increase in its binding capacity for BSA. Both textbook and reference works (14–16) indicate a significant loss of biological activity of some antifungal agents in the presence of protein materials and Alto *et al.* observed that the antimicrobial activity of *p*-hydroxybenzoates was diminished in the presence of protein (17). No reports could be found of experimentation on the direct correlation of binding data with the *in vitro* antimicrobial activity of *p*-hydroxybenzoates. The purpose of this work was to evaluate quantitatively the binding of a series of *p*-hydroxybenzoic acid esters by bovine serum albumin (BSA) and to show that the *in vitro* antifungal activity of methyl- and propylparaben was primarily a function of free or unbound drug.

EXPERIMENTAL

Materials—Bovine serum albumin, fraction V (BSA) purchased from the Armour Pharmaceutical Company (lots B24011 and D25901), was used throughout this study. The albumin[1] content of lots B24011 and D25901 were 97 and 95%, respectively. Both lots of albumin exhibited similar binding tendencies for methyl *p*-hydroxybenzoate. The moisture content of protein was determined and appropriate corrections were made in weighing it; a molecular weight of 69,000 was assumed. Reagent grade monobasic potassium phosphate and dibasic potassium phosphate were employed to prepare the buffer solutions. Reagent grade potassium chloride was used to obtain an equilibrium ionic strength of 0.16 where necessary. The *p*-hydroxy-

benzoic acid esters (parabens) and the synthetic culture medium were the same as described in a previous paper (18). All paraben and protein solutions were prepared immediately prior to use.

Dialysis Studies—The general approach, technique, and treatment of data of this study have been described previously (19, 20). Dialysis cells were the same as those employed by Patel and Foss (20) with the exception that seamless cellulose membranes (Fisher Scientific Company) were employed in the present work. The membranes were placed in distilled water and heated to 90° for 1 hr., and they were washed with distilled water several times in order to remove any contaminating substances in the cellophane (7). The membranes were permeable to *p*-hydroxybenzoates and impermeable to BSA. Binding data of an extensively dialyzed sample of the BSA yielded results similar to those from an undialyzed commercial material. Thus undialyzed BSA was used in the entire investigation. Binding of parabens by the membranes and the dialysis cells was found to be insignificant. Equilibrium was established at the end of 16 hr. by agitation on a rotational shaker in an Aminco constant-temperature laboratory bath (American Instrument Co. Inc.).

The dialysis studies were performed on 0.1 m*M* BSA, with the exception that in the case of propylparaben–BSA interaction, an additional 0.25 m*M* BSA was included. All parabens were studied at pH 7.4 and their initial concentrations ranged from 5.15×10^{-4} *M* to 1.32×10^{-2} *M*. Binding data were also collected for the methyl- and propylparaben–BSA systems at pH 6.6 for the purpose of approximating the pH of the synthetic culture medium (18).

Spectrophotometric Studies—Spectrophotometric examination of paraben solutions in the absence and presence of BSA was made at room temperature on a Hilger Ultrascan recording spectrophotometer, model H999. The concentration of paraben used was 6.4×10^{-5} *M*. Any interference due to the protein was eliminated by using the appropriate concentration in the reference cell.

Analysis After Equilibration—At the end of equilibrium time 1- or 2-ml. aliquots were removed from both sides of the membrane and were diluted with 0.1 *N* HCl to suppress the dissociation of parabens. The concentrations of parabens were determined using a Beckman DU spectrophotometer at a wavelength of their maximum absorbance, 256 mμ. Any interference due to the protein was eliminated by using the appropriate concentration in the reference cell and it was found that at very high dilutions employed for the analysis of parabens, there was no effect on the absorbance of parabens in the presence of BSA. Any absorption contribution by the dialyzable components in BSA was assumed to be negligible in lieu of the high dilutions employed in the analysis. The pH values of the solutions were recorded with a Beckman zeromatic pH meter, model 76, after each dialysis experiment, with no appreciable change noted.

Microbiological Studies—Observations were made on the influence of BSA on the antifungal activity of methyl- and propylparaben for *Aspergillus niger*.[2] The culture medium and methods as described previously (18, 21) were employed with the following exception in sterilization procedure. In order to avoid denaturation of protein at the high autoclave temperature, the solutions were sterilized by Millipore filtration using a hypodermic syringe, Swinney adapter, and Millipore filter.[3] Inhibitory concentrations for methyl- and propylparaben, in the presence and absence of BSA, were obtained through visual observation of samples each day for a period of 2 weeks.

RESULTS

Treatment of Data—The mathematical analysis of binding data from equilibrium dialysis studies has been described and discussed by Klotz (2, 22) and Scatchard (23). If the intrinsic association constants for all polymer sites are identical, the data can be plotted according to the equation of Scatchard (23),

$$\frac{r}{(A)} = nk - rk$$

where r = moles of bound drug/mole of protein, (A) = free drug concentration, n = number of binding sites available on each protein molecule, and k = association constant. Plotting $r/(A)$ *versus* r will give a straight line with slope = $-k$, and ordinate and abscissa intercepts of nk and n, respectively. By the method of least squares the quantities nk and k were calculated using an IBM 360/67 computer. From the value of k, the thermodynamic functions were calculated according to the following equations (2, 24):

$$\Delta F^0 = -RT \ln k$$

where ΔF^0 = the free energy change, R = gas constant, and T = absolute temperature.

$$\ln \frac{k_2}{k_1} = \frac{\Delta H^0}{R}\left(\frac{1}{T_1} - \frac{1}{T_2}\right)$$

where ΔH^0 = the enthalpy change and k_1 and k_2 are binding constants at temperatures T_1 and T_2.

$$\Delta F^0 = \Delta H^0 - T\Delta S^0$$

where ΔS^0 = the entropy change.

Dialytic Data of the Paraben-Protein Interaction—The data for the interaction of methyl-, ethyl-, propyl-, and butylparaben at pH 7.4 and at two temperatures are plotted in Figs. 1–4. Within the concentration ranges of the drugs and the protein, a linear relationship of $r/(A)$ *versus* r, as described by Scatchard's equation, was noted. The k and n values were obtained by linear extrapolation to the ordinate and abscissa axes.

Absorption Spectra in the Presence and Absence of Protein—The absorption spectra of certain molecules are altered in the presence of proteins and this spectral change is indicative of an interaction between two compounds. This change usually consists of a decrease in the absorption coefficient. The pronounced hypochromic effects of methyl-, ethyl-, propyl-, and butylparaben in the presence of increasing concentrations of BSA are depicted in Figs. 5–8. The method has been employed by var-

ious investigators (25–27) to study the binding of some drugs by proteins.

Inactivation by BSA Related to Binding—It was shown in earlier studies that the ratio, R, of total to free preservative for a given concentration of polysorbate 80 and cetomacrogol 1,000 was fairly constant (18–21). If the antifungal activity of parabens can be assumed to be due to the free or unbound form, the R value may be used to predict the minimum inhibitory concentration of antifungal agent in the presence of a definite quantity of BSA by a procedure described previously (18, 21). It is recognized that in the case of BSA the R value would not be constant over a wide range of concentrations of the parabens. However, within a narrow range of concentrations, especially around the minimum inhibitory concentration of the drug, it can be assumed to be reasonably constant, as outlined below. The R values, as obtained employing 0.1 mM BSA solution, at pH 6.6 and 30°, were 1.19 (range 1.16–1.23 with standard deviation of 0.026) and 1.75 (range 1.60–1.95 with standard deviation of 0.12) for methyl- and propylparaben, respectively. The total paraben concentrations on the protein side at the end of the dialysis experiment were 0.062–0.110% and 0.030–0.05% in the cases of methyl- and propylparaben, respectively. The results of the *in vitro* correlation of binding data with the antifungal activity of methyl- and propylparaben for *Aspergillus niger* in the presence of 0.1 mM BSA are summarized in Table I. It is evident from these data that there is a good correlation between the predicted minimum inhibitory concentration and the experimental antifungal concentration for both the parabens.

DISCUSSION

The ability of *p*-hydroxybenzoic acid esters to interact with several macromolecules has been well documented (18, 19, 28, 29). Based upon this observation, it was expected that BSA might provide binding sites for the parabens. From Figs. 1–4, it is evident that all the parabens interacted with BSA. The values for the association constants, k, and number of binding sites, n, together with the thermodynamic parameters of the interaction, are summarized in Table II. From this table it is noted that the values of n are not integers. This might be either due to the experimental error in dialytic studies as explained by Klotz (30) or due to the view that protein might not be molecularly homogeneous with respect to binding properties as theorized by Karush (31).

The exact mechanism of binding of *p*-hydroxybenzoates by BSA cannot be elucidated from this study, since the results were obtained primarily from the binding of methyl-, ethyl-, propyl-, and butylparaben. However, certain tentative conclusions may be drawn. A comparison of association constants for various parabens at a definite temperature (Table II) reveals that the binding increases from methyl- to ethyl- to propyl- to butylparaben. Due to the limited solubility of hexyl- and heptylparaben it was not possible to evaluate the association constants for these compounds by dialysis studies. An increase in the solubility of these compounds in aqueous BSA solution at pH 7.4 over their water solubility at the same pH indicated that hexyl- and heptylparaben would be bound to a greater extent than butylparaben (32). About 40% of the total amino acids in the protein are nonpolar residues (33) and it is quite possible that the association between these residues and the nonpolar moieties of the paraben molecule (aromatic ring and hydrophobic chain of ester) may contribute to the overall interaction. An examination of the data of Table II shows that the magnitude of binding increased with an increase in temperature, demonstrating that the binding process was endothermic (unfavorable positive enthalpy). More significantly, the binding was accompanied by an increase in entropy term which is typically a thermodynamic behavior in common

	20°	8.11	105	12.9	−5.24		31.5

with that described by Schachman (34) for hydrophobic bonding. The positive entropy change for this type of interaction has been ascribed by Kauzman (35) and others (36, 37) as resulting from the energy change accompanying the disruption of the "iceberg" structure of water molecules around hydrocarbon groups in aqueous solution (hydrophobic bonding). The large difference in the values of ΔH_0 and ΔS_0 of propyl- and butylparaben was probably due in part to the experimental error which resulted from a significant scatter in the experimental points in the case of butylparaben (Fig. 4), especially at 30°.

In Figs. 5–8, the degree of hypochromism increases with an increase in concentration of protein. The decrease in the absorption has been interpreted by Klotz (25) as an effect due to the formation of drug–protein complex, if the complexation involves a chromophor system of drug. Although spectrophotometric study can often yield information as to the magnitude of the interaction as well as to the nature of forces responsible for the interaction, and such study is in progress, this part of the work was limited to the qualitative nature of the interaction.

The results of correlation of binding data with the inhibitory concentration of methyl- and propylparaben for *Aspergillus niger* in the presence of 0.69% BSA are in good agreement. This part of the study shows that the protein-bound paraben is devoid of *in vitro* antifungal activity.

Human Urinary Excretion of the Quaternary Ammonium Compounds Anisotropine Methylbromide and Propantheline Bromide

By MORRIS PFEFFER, JOSEPH M. SCHOR, SANFORD BOLTON, and RALPH JACOBSEN

Urinary excretion was studied after the administration of anisotropine methylbromide p.o. and i.v. and propantheline bromide p.o. to a group of volunteers. Orally administered material was excreted in the urine for periods of 2–5 days while i.v. administered material was excreted for 16 days. In all cases, periodic excretion peaks were observed. The urinary excretion of anisotropine methylbromide and propantheline bromide seems similar.

A PRELIMINARY STUDY of the excretion of a tablet formulation of the quaternary ammonium antispasmodic anisotropine methylbromide[1] (8-methyltropinium bromide 2-propylpentanoate), in six subjects was the subject of a previous publication (1). The observation of prolonged excretion with discrete periods of peak excretion of the compound has been confirmed and extended with a larger group of subjects. Several oral formulations and an intravenous administration are included. Similar results have been obtained for propantheline bromide[2] (β-diisopropylaminoethyl 9-xanthene carboxylate methobromide) tablets, indicating that the observed pattern of excretion might be a general property of quaternary ammonium compounds (QAC's).

EXPERIMENTAL

Reagents—Anisotropine methylbromide originated and was compounded at Endo Laboratories, Inc. Propantheline bromide was obtained as a commercially available 15-mg. tablet and 30-mg. ampul. Tropaeolin 00 (orange IV) was purchased from Matheson, Coleman and Bell. The grades and sources of supply of all other reagents were indicated previously (1).

Analytical Procedures—All spectrophotometric analyses were performed with a Hitachi Perkin-Elmer 139 spectrophotometer.

The analytical methods employed for both anisotropine methylbromide and propantheline bromide are similar in that they depend upon the formation of a salt between the cationic agent and an anionic dye. The dye salt is extracted from an aqueous medium into an immiscible nonpolar solvent. The analytical procedure for anisotropine methylbromide, employing picric acid as the anionic dye, has been reported previously (1).

Propantheline bromide did not yield an extractable dye salt in the picric acid assay system, presumably due to the presence of a hydrophilic hydroxyl group on the quaternary hydrolysis product of the ester. Hydrolysis was due to the highly alkaline aqueous medium necessary for this assay system. Since Biles *et al.* (2) had successfully analyzed for propantheline bromide with tropaeolin 00, this dye was used here, and a suitable assay was developed for the estimation of propantheline cation in human urine. Absorption spectrum for the propantheline-tropaeolin 00 dye salt in chloroform following extraction from an aqueous solution is given in Fig. 1. Five milliliters of urine or neutral aqueous solution containing propantheline cation was mixed with 0.5 ml. of a saturated aqueous solution of tropaeolin 00 and this mixture was extracted with 5.0 ml. of chloroform by agitation on a Vortex Genie mixer for 15 sec. Longer agitation on a wrist-action shaker for periods up to 30 min. did not improve extraction. A plot of the absorbance at 409 mμ (A_{409}) of the chloroform-extracted dye salt *versus* the original aqueous concentration of propantheline bromide was linear over the range of 0–114 nmoles/ml. The molar absorptivity was 1.76×10^7. The sensitivity

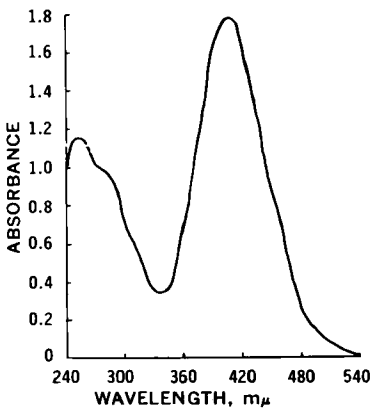

Fig. 1—Absorption spectrum of the propantheline-tropaeolin 00 dye salt in chloroform after extraction from aqueous solution. Propantheline bromide concentration 100 nmoles/ml. H_2O.

Received January 15, 1968, from the Departments of Biochemistry and Medicine, Endo Laboratories, Inc., Garden City, NY 11530

[1] Marketed as Valpin by Endo Laboratories, Inc., Garden City, N. Y.

[2] Marketed as Pro-Banthine by G. D. Searle & Co., Chicago, Ill.

of the tropaeolin 00 analytical method for propantheline cation is almost identical to the sensitivity of the picric acid method for methylanisotropinium cation (1).

The naturally occurring QAC's choline chloride, acetylcholine chloride, phosphocholine chloride, and thiamine did not yield discernible dye salt absorption spectra in chloroform extracts when tested in the tropaeolin 00 assay at concentrations up to 0.3 μmoles/ml. H_2O. These compounds had previously been found not to interfere in the picric acid assay (1).

Divatia and Biles (3) reported that the response of QAC's to tropaeolin 00 decreases as the molecular weight of the QAC decreases.

It has been reported that in the picric acid assay for methylanisotropinium ion in human urine there is a component of blank absorption as well as a systematic analytical loss (1). It was demonstrated that both these factors remained constant for any given individual, although they varied from one to another. It developed that this was equally true for the tropaeolin 00 assay for propantheline cation in urine. The blank absorptions and analytical recoveries for both assay systems in the 12 subjects used in this study were calculated by comparing analyses of 0, 5, 10, and 15 nmoles/ml. of each QAC when in deionized water and when added to their normal urines. These control urines were collected for consecutive 8-hr. periods, starting 30 min. before breakfast, over three 24-hr. periods—a collection schedule corresponding to that used during the QAC excretion studies. The resultant correction factors are listed in Table I. The magnitude of their variations are indicated by the standard deviations (*SD*).

Previously (1) the correction values for methyl anisotropinium cation in urine had been determined for 24-hr. collections. In the present series of experiments, correction values were calculated separately for each of the three 8-hr. periods to determine if there were any diurnal variations in blanks and recovery values. Analysis of variance of the blank and recovery values did not indicate significant variation, over the three 8-hr. periods, of the values for any given individual. However, there were significant differences between individuals for blanks and recoveries. There was no apparent correlation between the blank and recovery values.

The values for methylanisotropinium and propantheline cations were determined by correcting the respective A_{365} and A_{409} values obtained from experimental urine samples, for corresponding time intervals, according to the equation

$$B = (A - D)100/C$$

where B = corrected absorbance, A = observed absorbance, D = blank absorbance values for that time period, and C = calculated percentage analytical recovery for that time period. Concentrations were calculated in terms of nanomoles that were then converted back to their equivalents in mcg. of the bromide salts of the QAC's.

TABLE I—ANALYTICAL CORRECTION VALUES FOR HUMAN SUBJECTS

Times × people	220	57.8		
Times × people × formulations	620	123	0.198	
Formulations	3	3.10	1.03	$F(3,31) = 1.63$

[a] *df* = degrees of freedom (see no. of experimental subjects for each formulation in Table III). [b] *SS* = sum of squares. [c] *MS* = mean square.

Creatinine concentrations in urine specimens were determined by the method of Taussky (4). Neither anisotropine methylbromide nor propantheline bromide interfered in this determination.

Excretion Study—Twelve males were employed. None took any other medication during these experiments. None showed any abnormalities of urine specific gravity,[3] blood,[4] protein,[4] glucose,[4] or pH.[4]

The formulations administered are listed in Table III. These were taken 30 min. before breakfast, except the intravenous injection which was given at 11 a.m. Complete dosage of the liquid formulations was ensured by also administering washings of the containers.

Consecutive 8-hr. collections of urine were started immediately upon dosing and were not terminated until nine consecutive 8-hr. samples gave negative results.

The urines were preserved by the addition of SFT tablets[5] and refrigerated until analyzed. All analyses were performed within 48 hr. of sample collection. The SFT tablets did not interfere with determinations of either QAC in water or urine or with the creatinine assay.

RESULTS

The term fractional excretion represents that portion of a QAC dose excreted during any single 8-hr. interval. The mean fractional excretions reported here have been averaged for the 12 subjects for each of the different formulations for each corresponding 8-hr. period and are expressed as percent of total dose. Excretion after intravenous administration is considered separately from oral administration.

After intravenous administration of anisotropine methylbromide, approximately 50% of the dose is excreted in the first 8-hr. period (Fig. 2). Excretion continues for 16 days with a pattern of fluctuating excretion rates until an average of 108% of the administered drug is excreted.

The mean fractional excretions of the orally administered QAC's are presented in Fig. 3. The same pattern of periodic excretion peaks is seen. Although excretion from these formulations is not as prolonged as excretion from the intravenous dose, duration of excretion is still appreciable. An analysis of variance (Anova) of this data was performed (Table II). Neither *F* value obtained in the complete 3-way Anova is significant. Overall QAC excretion levels do not differ. The times × formulations interaction shows no evidence for lack of parallelism between the various fractional excretion plots. It would seem, therefore, that the correspondence in time of occurrence of the excretion peaks in Fig. 3 is real and is indicative of a fundamental similarity in excretion behavior of the two QAC's under study. Superimposition of the corresponding section of the plot for fractional excretion of i.v. administered anisotropine

TABLE III—TOTAL EXCRETION OF QAC'S

QAC	Formulation[a]	n	Dose, mg.	Mean Total Excretion, mg.	Mean Total Excretion, as % of Dose	Mean Total Excretional Time, hr.
Anisotropine methylbromide	Tablets	12	25	0.76	3.1	55
	Tablets[b]	6	20	1.42	7.1	91
	Elixir	12	25	1.42	5.7	125
	Elixir	3	20	0.99	4.9	51
	Kaolin-pectin suspension	11	25	1.49	6.0	64
	i.v. Injection	12	5	5.4	108	400
Propantheline bromide	Tablets	11	30[c]	2.20[d]	5.7	95
Anova[e]	F_1				1.63	7.48[f]
	F_2				0.47	2.96

[a] Formulation potencies: anisotropine methylbromide, 10-mg. tablet, 2 mg./ml. elixir, 0.33 mg./ml. kaolin-pectin suspension, 5 mg./ml. for i.v. injection, propantheline bromide, 15 mg./tablet. [b] Data from Pfeffer *et al.* (1) included for purposes for comparison. [c] Thirty mg. of anisotropine methylbromide is the molar equivalent of 24.2 mg. of anisotropine methylbromide. [d] Equivalent to 1.73 mg. of anisotropine methylbromide. [e] Anova excludes data from i.v. injection and the anisotropine methylbromide tablets and elixir administered at dosages of 20 mg. $F_1 = F$ for differences among all four oral dose forms. $F_2 = F$ for differences between means of the three oral anisotropine methylbromide dose forms and the propantheline bromide tablets. Significance at $p = 0.05$; $F_1 = 2.91$; $F_2 = 4.16$; at $p = 0.01$; $F_1 = 4.48$, $F_2 = 7.53$. [f] $p = 0.01$.

methylbromide (Fig. 2) onto Fig. 3 would reveal that a parallelism in excretion peaks is maintained between oral and intravenous dosage although the levels excreted differ. There was no obvious relationship between urine volume, weight or age of the subjects, and the variables reported upon here.

The mean values for total excretion time and total excretion are presented in Table III. The statistical analysis indicated that there are no significant differences between the observed QAC levels excreted after administration of the various oral formulations, either when they are compared to each other or when propantheline bromide is compared to the pooled mean excretion level of all the oral anisotropine methylbromide formulations.

The observed total excretion times of the anisotropine methylbromide in its various oral formulations also are not significantly different from the total excretion times for propantheline bromide administered as tablets.

In previous studies QAC excretion has been found to be highly variable (5–11). Despite these normally accepted variations, it is apparent that the several formulations of anisotropine methylbromide are equivalent. It is also of deep interest that the observed excretions of these two antispasmodics are very similar.

DISCUSSION

In a previous paper (1) it was indicated that, due to the nature of the picric acid assay, metabolized anisotropine methylbromide was not likely to be detected. The total mean recovery value of 108% after intravenous administration of anisotropine methylbromide has, therefore, three interesting implications: (*a*) all anisotropine methylbromide in the bloodstream may be eventually excreted through the kidneys, (*b*) this drug is apparently not metabolized to polar compounds in the human body, (*c*) if this QAC is undergoing enterohepatic recycling, the efficiency of intestinal reabsorption of the material excreted in the bile must approach 100%.

Rowland and Beckett (12) have observed successive peaks during the excretion, by humans, of amphetamine and methylamphetamine. This they attributed to the diurnal urinary pH rhythm. The degree of ionization of these weak bases shifts as the urinary pH shifts, altering the degree of reabsorption from the distal tubule to the kidney. This would not, however, appear to serve as an explanation for the periodic excretion peaks seen with QAC's. These strong quaternary bases, for which pKa's are not determinable, will not alter their degree of ionization at any physiologically attainable pH. Furthermore, the timing of the excretion peaks for these QAC's does not correspond to the timing of the diurnal pH changes reported by Rowland and Beckett.

Retention of QAC's in an intracellular tissue reservoir would not seem a likely explanation either. Although the QAC might be slowly released it should not be released in "pulses." If there is an upper limit to the amount of methyl anisotropinium cation the kidney can excrete in a given time period, it has not been approximated in these experiments. After intravenous injection of 5 mg. of anisotropine methylbromide, approximately 2.5 mg. can be excreted in an 8-hr. period and the average amount excreted in any succeeding peak is appreciably larger than the amount excreted in any peak after oral administration. Thus, in these studies, the amount excreted through the kidney would seem to be a function of the amount available to the kidney.

Enterohepatic cycling of the QAC seems to offer the best explanation of the observed phenomenon. Bile, after its formation, is stored in the gall bladder and is periodically released into the intestinal tract (13). This periodicity of bile release might correspond to the periodicity of QAC excretion. QAC excreted into the bile would therefore be held in the gall bladder to eventually be released with the bile. The QAC would be reabsorbed and a portion excreted in the kidney while the balance would be reexcreted into the bile.

By inference, the total excretions after oral dosage represent the total gastrointestinal absorption of anisotropine methylbromide. The amounts absorbed are retained *in vivo* for a prolonged period of time.

The excretion pattern and amount excreted for orally administered propantheline bromide is almost exactly the same as that of anisotropine methylbromide. The question of whether this could be a common excretion pattern for QAC's is raised.

Significance of Kinetic Aspects in the Simultaneous Administration of Drugs

By MILDRED J. TARASZKA and ARLINGTON A. FORIST

Kinetic aspects, such as half-lives for absorption and elimination, as well as limiting solubilities, which should be considered in the simultaneous administration of drugs are discussed. Two simple hypothetical cases are presented: the selection of the ratio of two drugs with different rate constants for absorption and elimination to obtain similar average asymptotic serum levels of each drug on multiple-dose administration, and the selection of the ratio of two drugs with different rate constants for absorption and elimination and different solubilities to minimize the risk of crystalluria. Extension of the latter to the triple sulfas, on the basis of solubility and human blood level data in the literature, has given a "best" ratio of 1:3:4 for sulfadiazine:sulfamerazine:sulfamethazine, respectively, rather than the 1:1:1 now used.

WHEN TWO or more drugs are combined in a single formulation or are given in separate dosage forms at the same time, several factors should be considered in choosing the individual drugs and the amounts of each drug to be used: (*a*) biological spectra, (*b*) minimum effective circulating concentrations for biological activity, (*c*) possibilities of reactions between the combined drugs, (*d*) possibility of one drug affecting the biological response to the other drug(s), (*e*) rate constants for absorption or absorption half-lives, (*f*) rate constants for elimination or biological half-lives, (*g*) rates of production and elimination of metabolites (especially if the metabolites may be active or toxic), (*h*) intrinsic solubilities of the individual drugs and/or metabolites if crystalluria is a potential side reaction.

It is the authors' opinion that drug combinations could be more beneficial if all of the above factors are considered. However, only kinetic aspects that affect drug combinations are considered in this paper; that is, all the calculations are based on the assumption that the individual drugs have the correct spectra of biological activity, similar minimum effective circulating concentrations, and that they are compatible in the *in vitro* and *in vivo* systems. The importance of the kinetic aspects can be seen if the selection of the optimum dosage schedule is considered for multiple-dose therapy with a combination of two drugs which have biological half-lives of largely different magnitudes.

DISCUSSION

Example 1—When two or more drugs are combined in a single formulation, or the drugs are given in separate dosage forms at the same time, the multiple-dose serum levels attained with each drug will depend on each biological half-life plus *other* factors. The ratio of two drugs given in combination, which should be used to attain similar serum levels on multiple dosing, can be estimated in the following manner, assuming that the intrinsic drug solubilities, biological activities, and production of metabolites do not have to be considered. Furthermore, it is assumed that the single-dose serum level and urinary data for each drug fit the following model:

$$A \xrightarrow{k_1} C \xrightarrow{k_2} D \qquad \text{(Model 1)}$$

Significance of Kinetic Aspects in the Simultaneous Administration of Drugs

By MILDRED J. TARASZKA and ARLINGTON A. FORIST

Kinetic aspects, such as half-lives for absorption and elimination, as well as limiting solubilities, which should be considered in the simultaneous administration of drugs are discussed. Two simple hypothetical cases are presented: the selection of the ratio of two drugs with different rate constants for absorption and elimination to obtain similar average asymptotic serum levels of each drug on multiple-dose administration, and the selection of the ratio of two drugs with different rate constants for absorption and elimination and different solubilities to minimize the risk of crystalluria. Extension of the latter to the triple sulfas, on the basis of solubility and human blood level data in the literature, has given a "best" ratio of 1:3:4 for sulfadiazine:sulfamerazine:sulfamethazine, respectively, rather than the 1:1:1 now used.

WHEN TWO or more drugs are combined in a single formulation or are given in separate dosage forms at the same time, several factors should be considered in choosing the individual drugs and the amounts of each drug to be used: (*a*) biological spectra, (*b*) minimum effective circulating concentrations for biological activity, (*c*) possibilities of reactions between the combined drugs, (*d*) possibility of one drug affecting the biological response to the other drug(s), (*e*) rate constants for absorption or absorption half-lives, (*f*) rate constants for elimination or biological half-lives, (*g*) rates of production and elimination of metabolites (especially if the metabolites may be active or toxic), (*h*) intrinsic solubilities of the individual drugs and/or metabolites if crystalluria is a potential side reaction.

It is the authors' opinion that drug combinations could be more beneficial if all of the above factors are considered. However, only kinetic aspects that affect drug combinations are considered in this paper; that is, all the calculations are based on the assumption that the individual drugs have the correct spectra of biological activity, similar minimum effective circulating concentrations, and that they are compatible in the *in vitro* and *in vivo* systems. The importance of the kinetic aspects can be seen if the selection of the optimum dosage schedule is considered for multiple-dose therapy with a combination of two drugs which have biological half-lives of largely different magnitudes.

DISCUSSION

Example 1—When two or more drugs are combined in a single formulation, or the drugs are given in separate dosage forms at the same time, the multiple-dose serum levels attained with each drug will depend on each biological half-life plus *other* factors. The ratio of two drugs given in combination, which should be used to attain similar serum levels on multiple dosing, can be estimated in the following manner, assuming that the intrinsic drug solubilities, biological activities, and production of metabolites do not have to be considered. Furthermore, it is assumed that the single-dose serum level and urinary data for each drug fit the following model:

$$A \xrightarrow{k_1} C \xrightarrow{k_2} D \qquad \text{(Model 1)}$$

where k_1 is the first-order rate constant for absorption, k_2 is the first-order rate constant for excretion and/or metabolite production, C is the serum compartment for the drug, and D is the excretion and/or metabolite compartment for the drug. Since more than one drug is involved, the rate constants and serum concentrations are labeled k_{1i}, k_{2i}, and C_i where $i = 1$ or 2 and denotes which drug is being considered.

According to Wagner *et al.* (1), the average asymptotic serum level of a drug on a multiple dose schedule is given by

$$\bar{C} = \frac{FD}{V_d k_2 \tau} \qquad \text{(Eq. 1)}$$

where F = fraction of dose absorbed, D = dose, V_d = volume of distribution, τ = dosage interval, and k_2 = first-order rate constant characterizing the biological half-life. This equation holds for any model as long as a series of simultaneous linear differential equations can be written describing the model; transfer from the serum is first order; and F, D, V_d, k_2, and τ are constants for each dose of the multiple-dose regimen in a given subject (1). Since two drugs are being considered, the following equations can be written corresponding to Eq. 1.

$$\bar{C}_1 = \frac{F_1 D_1}{V_{d1} k_{21} \tau_1} \qquad \text{(Eq. 2)}$$

$$\bar{C}_2 = \frac{F_2 D_2}{V_{d2} k_{22} \tau_2} \qquad \text{(Eq. 3)}$$

The same average asymptotic serum levels for the two drugs means $\bar{C}_1 = \bar{C}_2$. The ratio of the two drugs in the fomulation is found by rearranging and setting $\tau_1 = \tau_2$ since both drugs are given together.

$$\frac{D_1}{D_2} = \frac{F_2 V_{d1} k_{21}}{F_1 V_{d2} k_{22}} \qquad \text{(Eq. 4)}$$

The parameters on the right-hand side of Eq. 4, or the ratio D_1/D_2, can be calculated from single-dose data if it is assumed each drug reacts independently and will be unaffected by the presence of the other. The dosing interval τ is adjusted according to the smaller biological half-life.

Figures 1*a* and 1*b* show the effect on multiple-dose-serum levels of adjusting the ratio of two hypothetical drugs with differing absorption and biological half-lives, which are given in combination. Serum levels in Fig. 1 are computer calculated. Both drugs, 1 and 2, obey Model 1 with the listed assumptions and have the following values for their kinetic parameters: $k_{11} = 0.693$ hr.$^{-1}$, $k_{21} = 0.174$ hr.$^{-1}$, $F_1/V_{d1} = 0.025$ 1.$^{-1}$, $\tau_1 = \tau_2 = 6$ hr., $k_{12} = 1.39$ hr.$^{-1}$, $k_{22} = 0.087$ hr.$^{-1}$, and $F_2/V_{d2} = 0.0350$ 1.$^{-1}$. In Fig. 1*a*, drugs 1 and 2 are combined in the ratio of 1:1, respectively. In Fig. 1*b*, drugs 1 and 2 are combined in the ratio of 1:0.36, as predicted by Eq. 4. Identical serum-level curves of the two drugs cannot be obtained by altering the combination ratio of the two drugs; only the average asymptotic serum levels can be adjusted to be the same as seen in Fig. 1. The amount of variation about this average asymptotic serum level depends on the model, the dosing interval, and the magnitude of the absorption rate constant (1).

Example 2—The best ratio of two drugs which are given in combination to assure a minimum probability of crystallization of drug in the kidneys can be calculated, assuming the six following conditions: (*a*) each drug has an intrinsic solubility, S_1 and S_2, unaffected by the presence of the other drug; (*b*) the serum level data and urinary excretion data for each individual drug follow Model 1; when given as a single dose (the rate constants k_1 and k_2 are first order); (*c*) the absorption and elimination of each drug is unaffected by the presence of the other; (*d*) metabolites do not have to be considered; (*e*) the appearance of drug crystals in the urine is dependent on the concentration of the drug in the urine; (*f*) the urine flow is independent of the drug given.

According to Model 1, the rate of appearance of the drug in the urine is $d[D]/dt = k_2[C]$. The kinetic equations for Model 1 can be easily derived (2), and it is found that

$$[C] = \frac{[A_o]\ k_1}{k_2 - k_1} (e^{-k_1 t} - e^{-k_2 t}) \text{ when } k_1 \neq k_2 \qquad \text{(Eq. 5)}$$

where $[A_0]$ is the initial concentration in compartment A and equals FD/V_d.

The concentration of the drug in the urine at the time of saturation will equal the solubility of the drug. This time of saturation can be found from

$$[D]\Big]_0^S = \int_0^{t_s} \frac{d[D]}{dt}\, dt \qquad \text{(Eq. 6)}$$

where $[D]$ = concentration of drug in the urine, t_s = time of saturation, and S = saturation concentration (solubility at a given pH).

Substituting for $d[D]/dt$ and integrating Eq. 6 gives

$$S = \frac{[A_o]\ k_1 k_2}{k_2 - k_1} \left(\frac{-e^{-k_1 t_s}}{k_1} + \frac{e^{-k_2 t_s}}{k_2} \right) \qquad \text{(Eq. 7)}$$

The two equations corresponding to Eq. 7 can be written by using the second numerical subscript to indicate which drug is being considered and substituting FD/V_d for $[A_0]$.

$$S_1 = \frac{F_1 D_1 k_{11} k_{21}}{V_{d1}(k_{21} - k_{11})} \left(- \frac{e^{-k_{11} t_{s1}}}{k_{11}} + \frac{e^{-k_{21} t_{s1}}}{k_{21}} \right) \qquad \text{(Eq. 8)}$$

$$S_2 = \frac{F_2 D_2 k_{12} k_{22}}{V_{d2}(k_{22} - k_{12})} \left(- \frac{e^{-k_{12} t_{s2}}}{k_{12}} + \frac{e^{-k_{22} t_{s2}}}{k_{22}} \right) \qquad \text{(Eq. 9)}$$

Also,

$$D_1 + D_2 = D_T \qquad \text{(Eq. 10)}$$

where D_1 = dose of drug 1, D_2 = dose of drug 2, and D_T = total dose given.

To have the least chance for crystalluria, D_1 and D_2 have to be adjusted so the time of saturation for each drug is the same, $t_{s1} = t_{s2}$. Equations 8 and 9 are too complex to solve for t_{s1} and t_{s2} explicitly. However, they can be solved for D_1 and D_2 and substituted into Eq. 10 with $t_{s1} = t_{s2} = X$ to give:

$$\frac{S_1 (k_{21} - k_{11})\ V_{d1}}{(k_{11} e^{-k_{11}X} - k_{21} e^{-k_{11}X})\ F_1} + \frac{S_2 (k_{22} - k_{12})\ V_{d2}}{(k_{12} e^{-k_{12}X} - k_{22} e^{-k_{12}X}) F_2} = D_T \qquad \text{(Eq. 11)}$$

or

$$\sum_{i=1}^{2} \frac{S_i\,(k_{2i} - k_{1i})\,V_{di}}{(k_{1i}\,e^{-k_{2i}X} - k_{2i}\,e^{-k_{1i}X})\,F_i} = D_T \quad \text{(Eq. 12)}$$

In Eq. 11 everything is known from individual single-dose experiments except X and D_T. For a given value of D_T the value of X, which satisfies the equation, is determined by trial and error with a computer. Once X is determined the values of D_1 and D_2 are just equal to the individual terms in the summation.

When $X = \infty$ the terms on the left-hand side of Eq. 12 will become infinite. Therefore, for any value of D_T, a finite value of X exists and a given ratio of drug 1:drug 2 can be obtained to assure a minimum probability of crystalluria.

If the rate constants of absorption and elimination, the fraction absorbed, and the volume of distribution were the same for both drugs, then the best ratio of drug 1:drug 2 would be the ratio of their solubilities at the "mean" pH of human urine, $S_1:S_2$.

Application of Example 2—Example 2 has been extended to determine what ratio of sulfadiazine, sulfamerazine, and sulfamethazine gives the least chance of crystalluria in man.

According to the literature, the serum level and urinary excretion data indicated Model 2 for the absorption and elimination of sulfonamides.[1]

Both the excreted sulfonamide and the excreted acetylsulfonamide may precipitate in the urine and have to be considered. The times of saturation of the acetylsulfonamides, t_{sai}, can be found from

$$[D_i]_0^{sai} = \int_0^{t_{sai}} \frac{d[D_i]}{dt}\,dt \quad \text{(Eq. 13)}$$

where i denotes which acetylsulfonamide and S_{ai} their solubilities. Similarly, the times of saturation of the sulfonamides, t_{si}, can be found from

$$[E_i]_0^{si} = \int_0^{t_{si}} \frac{d[E_i]}{dt}\,dt \quad \text{(Eq. 14)}$$

According to Model 2, $d[D_i]/dt = k_3C_i$ and $d[E_i]/dt = k_4B_i$ and the corresponding integrated Eqs. for 13 and 14 become, respectively,

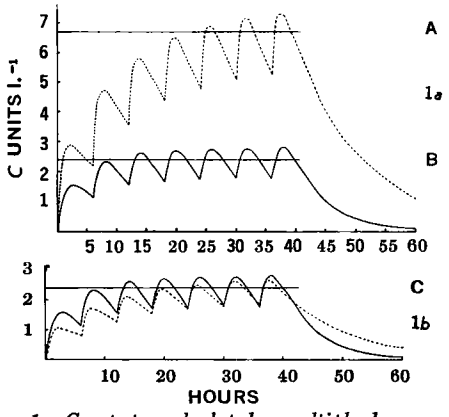

Fig. 1—Computer-calculated, multiple-dose serum levels of a combination of two hypothetical drugs with different kinetic constants. Key: ---, drug I with $k_1 = 0.693\ hr.^{-1}$, $k_2 = 0.174\ hr.^{-1}$, $F/V_d = 0.025\ l.^{-1}$ *and* $\tau = 6\ hr.$; ———, *drug 2 with* $k_1 = 1.39\ hr.^{-1}$; $k_2 = 0.087\ hr.^{-1}$, $F/V_d = 0.035\ l.^{-1}$ *and* $\tau = 6\ hr.$; *curves 1a represent 100 units each of drug 1 and drug 2 administered simultaneously; curves 1b represent 100 units of drug 1 and 35.7 units of drug 2 administered simultaneously.* A, $C_2 = 6.7$ *units* $l.^{-1}$; B, $C_1 = 2.4$ *units* $l.^{-1}$; C, $C_1 = C_2 = 2.4$ *units* $l.^{-1}$.

$$S_i = \frac{k_{1i}k_{4i}A_{oi}}{k_{2i} + k_{4i} + k_{5i} - k_{1i}}\left[\frac{e^{-(k_{2i}+k_{4i}+k_{5i})t_{si}}}{k_{2i} + k_{4i} + k_{5i}} - \frac{e^{-k_{1i}t_{si}}}{k_{1i}}\right] + \frac{k_{4i}A_{oi}}{k_{2i} + k_{4i} + k_{5i}} \quad \text{(Eq. 16)}$$

For ease of manipulation, Eq. 15 may be written as

$$S_{ai} = A_{oi}\,f_i\,(t_{sai}) \quad \text{(Eq. 17)}$$

where $f_i\,(t_{sai})$ is a function of t_{sai}, and Eq. 16 as

$$S_i = A_{oi}\varphi_i\,(t_{si}) \quad \text{(Eq. 18)}$$

Substituting $A_{oi} = F_iD_i/V_{di}$ and rearranging, Eq. 17 becomes

$$D_i = \frac{V_{di}\,S_{ai}}{F_i\,f_i\,(t_{sai})} \quad \text{(Eq. 19)}$$

and Eq. 18 becomes

$$D_i = \frac{V_{di}\,S_i}{F_i\varphi_i\,(t_{si})} \quad \text{(Eq. 20)}$$

$$S_{ai} = k_{1i}k_{2i}k_{3i}A_{oi}\left[\frac{-e^{-k_{1i}t_{sai}}}{k_{1i}\,(k_{3i} - k_{1i})\,(k_{2i} + k_{4i} + k_{5i} - k_{1i})} + \frac{e^{-(k_{2i} + k_{4i} + k_{5i})t_{sai}}}{(k_{2i} + k_{4i} + k_{5i})\,(k_{3i} - k_{2i} - k_{4i} - k_{5i})\,(k_{2i} + k_{4i} + k_{5i} - k_{1i})} + \frac{e^{-k_{3i}t_{sai}}}{k_{3i}(k_{3i} - k_{1i})\,(k_{2i} + k_{4i} + k_{5i} - k_{3i})}\right] + \frac{k_{2i}A_{oi}}{k_{2i} + k_{4i} + k_{5i}} \quad \text{(Eq. 15)}$$

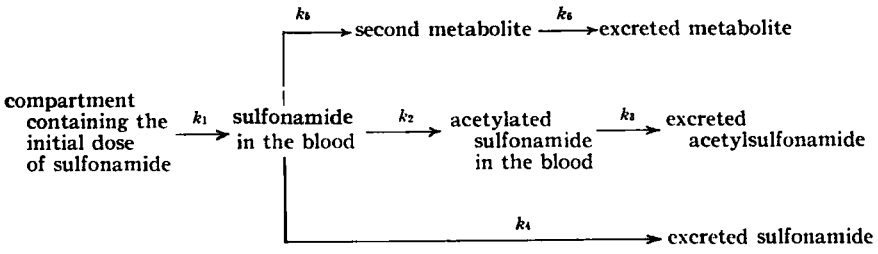
[1] Model 2 for sulfonamides does not include discrete steps for tubular reabsorption or protein binding since the problem only requires characterization of how rapidly the drug concentrates in the urine. All the estimated rate constants are really composite values representing several processes since all models are only approximations for what is really taking place *in vivo*. According to the principle of microscopic reversibility, each step in a mechanism should be reversible, but experimental techniques are not sophisticated enough to determine all discrete rate constants, only "overall" macroconstants are available. The value for k_4 characterizes how fast the sulfonamide is eliminated, and it includes effects from several processes as tubular reabsorption, the distribution of drug into various tissues according to their perfusion and partition characteristics, protein binding in these various tissues and blood as well as the discrete elimination process.

The total dose of sulfonamides, D_T, must equal the sum of the doses of the individual sulfonamides, ΣD_i. For a mixture of three

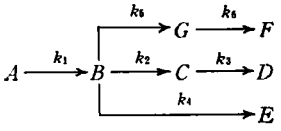
$$D_T = D_1 + D_2 + D_3 \quad \text{(Eq. 21)}$$

and three equations can be written for Eq. 19 and three for Eq. 20.

Since the parent compound and the acetylated derivative have to be considered for each sulfonamide, eight possibilities exist for Eq. 21; that is, all the possible combinations of the six equations corresponding to Eqs. 19 and 20.



in simple notation



(Model 2)

$$\text{Case A: } D_T = \frac{V_{d1}\,S_{a1}}{F_1 f_1 (t_{sa1})} + \frac{V_{d2}\,S_{a2}}{F_2 f_2 (t_{sa2})} + \frac{V_{d3}\,S_{a3}}{F_3 f_3 (t_{sa3})}$$

$$\text{Case B: } D_T = \frac{V_{d1}\,S_{a1}}{F_1 f_1 (t_{sa1})} + \frac{V_{d2}\,S_{a2}}{F_2 f_2 (t_{sa2})} + \frac{V_{d3}\,S_3}{F_3 \varphi_3 (t_{s3})}$$

$$\text{Case C: } D_T = \frac{V_{d1}\,S_{a1}}{F_1 f_1 (t_{sa1})} + \frac{V_{d2}\,S_2}{F_2 \varphi_2 (t_{s2})} + \frac{V_{d3}\,S_3}{F_3 \varphi_3 (t_{s3})}$$

$$\text{Case D: } D_T = \frac{V_{d1}\,S_{a1}}{F_1 f_1 (t_{sa1})} + \frac{V_{d2}\,S_2}{F_2 \varphi_2 (t_{s2})} + \frac{V_{d3}\,S_{a3}}{F_3 f_3 (t_{sa3})}$$

$$\text{Case E: } D_T = \frac{V_{d1}\,S_1}{F_1 \varphi_1 (t_{s1})} + \frac{V_{d2}\,S_{a2}}{F_2 f_2 (t_{sa2})} + \frac{V_{d3}\,S_{a3}}{F_3 f_3 (t_{sa3})}$$

$$\text{Case F: } D_T = \frac{V_{d1}\,S_1}{F_1 \varphi_1 (t_{s1})} + \frac{V_{d2}\,S_{a2}}{F_2 f_2 (t_{sa2})} + \frac{V_{d3}\,S_3}{F_3 \varphi_3 (t_{s3})}$$

$$\text{Case G: } D_T = \frac{V_{d1}\,S_1}{F_1 \varphi_1 (t_{s1})} + \frac{V_{d2}\,S_2}{F_2 \varphi_2 (t_{s2})} + \frac{V_{d3}\,S_3}{F_3 \varphi_3 (t_{s3})}$$

$$\text{Case H: } D_T = \frac{V_{d1}\,S_1}{F_1 \varphi_1 (t_{s1})} + \frac{V_{d2}\,S_2}{F_2 \varphi_2 (t_{s2})} + \frac{V_{d3}\,S_{a3}}{F_3 f_3 (t_{sa3})}$$

The kinetic constants and solubilities used for the sulfonamides under consideration are listed in Table I and were taken from the indicated literature.

To have the least chance for crystalluria the time of saturation for each drug has to be the same; that is, the times of saturation in each of the individual cases (*A* through *H*) have to be equal (for Case *A*, $t_{sa1} = t_{sa2} = t_{sa3} = X_A$). The case which gives the minimum total dose, D_T, for saturation will be the limiting case, and the ratio of the terms in the summation will be the best ratio for the drugs in the formulation.

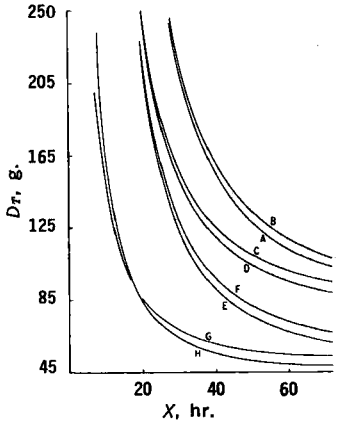


Fig. 2—Plot of D_T versus X *for the 8 cases*, A–H.

The values of D_T for various X_j's are plotted in Fig. 2 for the eight different cases (*A* through *H*). A digital computer was used to calculate the values. For a given D_T greater than the minimum asymptotic D_T for Case *H* either Case *H* or Case *G* will be limiting. Since Case *H* is limiting at lower values of the total dose, D_T, Case *H* is the one of interest. The fact that Case *H* is limiting means that for sulfadiazine and sulfamerazine the parent compounds will cause crystalluria if the dose is

TABLE I—KINETIC CONSTANTS AND SOLUBILITIES FOR THE TRIPLE SULFAS

Parameter	Sulfadiazine, $i = 1$	Sulfamerazine, $i = 2$	Sulfamethazine, $i = 3$
S_i[a] mg. ml.$^{-1}$	0.16	0.34	0.62
S_{ai}[b] mg. ml.$^{-1}$	0.33	0.35	0.74
k_{1i} hr.$^{-1}$	0.65[c]	0.60[d]	0.66[e]
$k_{2i} + k_{4i} + k_{5i}$ hr.$^{-1}$	0.0414	0.0295	0.095
k_{2i}[f] hr.$^{-1}$	0.15(0.0414) = 0.0062	0.35(0.0295) = 0.0103	0.6(0.095) = 0.057
k_{4i}[f] hr.$^{-1}$	0.85(0.0414) = 0.0352	0.45(0.0295) = 0.0133	0.4(0.095) = 0.038
k_{3i} hr.$^{-1}$	0.06	0.04	0.20
V_{di}/F_i ml.	30,000	23,000	18,000

[a] Sulfadiazine equivalent solubilities at 37° and pH = 6 for the sulfas. Taken from *Reference 3*. [b] Sulfadiazine equivalent solubilities at 37° and pH = 6 for the acetylated sulfas. Taken from *Reference 3*. [c] V_{d1}/F_1 and k_{11} were estimated from Fig. 1a of *Reference 6*. The other kinetic constants for sulfadiazine are from Table II of *Reference 5*. [d] V_{d2}/F_2 and k_{12} were estimated from Fig. 1 of *Reference 4*. The other kinetic constants for sulfamerazine are from Table II of *Reference 5*. [e] The kinetic constants for sulfamethazine are calculated from data in *Reference 4*. [f] The kinetic constants k_{2i} and k_{4i} were estimated by multiplying the overall elimination rate constant, $k_{2i} + k_{4i} + k_{5i}$, by the fraction of the sulfonamide excreted as the acetylsulfonamide or the unchanged sulfonamide, respectively. The values used for these fractions were taken from Table IV of *Reference 7*.

large enough, while for sulfamethazine the acetyl derivative will cause crystalluria (this can be seen from the equation for Case H). In order to have the largest total concentration of sulfonamides without crystalluria, the ratio of sulfadiazine–sulfamerazine–sulfamethazine should be 1:3.1:3.9 (on a sulfadiazine equivalent). This is the ratio of the terms in the equation for Case H when $t_{s1} = t_{s2} = t_{s3} = \infty$. The ratio in terms of the individual compounds instead of the sulfadiazine equivalent is sulfadiazine–sulfamerazine–sulfamethazine = 1:3.2:4.3. On the average this ratio should have the least chance for crystalluria, if the kinetic constants are the best average ones. Since the kinetic constants in some cases were only estimated from blood level curves in the literature, they may not be the best.

It should be noted in Fig. 2 that the numerical values for D_T are large. This is a result of using the best ratio of sulfas for the given set of conditions and equations which assume a constant urine volume. The effect of varying urine volume or flow rate was not considered because the objective was only to calculate the best ratio of triple sulfas which gives the least chance of crystalluria. Case H will always be limiting whatever the flow rate.

The solubilities of the sulfonamides depend on pH. Above pH 7 the solubilities increase rapidly. The solubilities at pH = 6 of the three sulfonamides in question were chosen because this approaches the normal human urine pH, and the ratio of the solubilities of the three sulfonamides is almost constant over the pH range 5.6–6.5 (3). Therefore, the calculated ratio of 1:3.2:4.3 for the three sulfonamides should be the best ratio over the pH range 5.6 to 6.5.

As the solubility and/or the biological half-life of a drug increases, the incidence for crystalluria will become less. If the three sulfonamides in a combination have similar long biological half-lives, similar half-lives of acetylated derivative production and elimination, and similar fractions absorbed and volumes of distribution, then the ratio of the sulfonamides in the formulation should be the ratio of their solubilities.

The calculations indicate that kinetic aspects can be important in the simultaneous administration of drugs. The triple sulfas was used as an example for the application of kinetics and limiting solubilities to obtain a formulation with the best margin of safety. To show this increased margin of safety, a large-scale clinical test would be needed.

Griseofulvin Absorption in Man After Single and Repeated Treatments and Its Correlation with Dissolution Rates

By SAMSON SYMCHOWICZ and BERNARD KATCHEN

Absorption of griseofulvin from six different preparations was studied in man. Plasma levels were followed for 1 day after a single oral 500-mg. dose, and for 7 days after daily 500-mg. doses. A high correlation was found between dissolution rates in simulated intestinal fluid and absorption during 0–25 hr., 49–173 hr., and 0–173 hr.

Griseofulvin is widely used for treating fungal infections in man and animals. Its relatively high dose and meager water solubility (15 mcg./ml. at 37°) might contribute to its poor and variable absorption. Because certain minimal drug-plasma levels are needed for an effective cure (1–3), griseofulvin preparations must be carefully designed to ensure maximum absorption.

The authors have shown previously (4) that

large enough, while for sulfamethazine the acetyl derivative will cause crystalluria (this can be seen from the equation for Case H). In order to have the largest total concentration of sulfonamides without crystalluria, the ratio of sulfadiazine–sulfamerazine–sulfamethazine should be 1:3.1:3.9 (on a sulfadiazine equivalent). This is the ratio of the terms in the equation for Case H when $t_{s1} = t_{s2} = t_{s3} = \infty$. The ratio in terms of the individual compounds instead of the sulfadiazine equivalent is sulfadiazine–sulfamerazine–sulfamethazine = 1:3.2:4.3. On the average this ratio should have the least chance for crystalluria, if the kinetic constants are the best average ones. Since the kinetic constants in some cases were only estimated from blood level curves in the literature, they may not be the best.

It should be noted in Fig. 2 that the numerical values for D_T are large. This is a result of using the best ratio of sulfas for the given set of conditions and equations which assume a constant urine volume. The effect of varying urine volume or flow rate was not considered because the objective was only to calculate the best ratio of triple sulfas which gives the least chance of crystalluria. Case H will always be limiting whatever the flow rate.

The solubilities of the sulfonamides depend on pH. Above pH 7 the solubilities increase rapidly. The solubilities at pH = 6 of the three sulfonamides in question were chosen because this approaches the normal human urine pH, and the ratio of the solubilities of the three sulfonamides is almost constant over the pH range 5.6–6.5 (3). Therefore, the calculated ratio of 1:3.2:4.3 for the three sulfonamides should be the best ratio over the pH range 5.6 to 6.5.

As the solubility and/or the biological half-life of a drug increases, the incidence for crystalluria will become less. If the three sulfonamides in a combination have similar long biological half-lives, similar half-lives of acetylated derivative production and elimination, and similar fractions absorbed and volumes of distribution, then the ratio of the sulfonamides in the formulation should be the ratio of their solubilities.

The calculations indicate that kinetic aspects can be important in the simultaneous administration of drugs. The triple sulfas was used as an example for the application of kinetics and limiting solubilities to obtain a formulation with the best margin of safety. To show this increased margin of safety, a large-scale clinical test would be needed.

dissolution rates in simulated intestinal fluid correlate well with drug absorption following a single 500-mg. oral dose. The present communication shows there is also a correlation between dissolution rate and absorption following 7 daily 500-mg. doses of griseofulvin. Thus, the absorption characteristics of griseofulvin preparations can be conveniently predicted on the basis of dissolution rate data.

EXPERIMENTAL

In the first part of this study, four different griseofulvin preparations (No. 1–4) were given at weekly intervals to eight normal humans in a replicated Latin square crossover design (5). Before breakfast, each subject ingested one 500-mg. tablet (preparation 2) or four 125-mg. tablets (preparations 1,3,4).

In the second part of this study, three different griseofulvin preparations (No. 2,5,6) were given to 18 normal subjects. Each subject ingested one 500-mg. tablet (preparation 2) or two 250-mg. tablets (preparations 5,6). Preparation 5 has the same composition as 1, and preparation 6 the same composition as 3.

All subjects were told to avoid foods and drugs which interfere with the griseofulvin plasma assay (6). Blood was drawn at specified time intervals (Tables I, IV), and plasma samples were assayed fluorometrically (7) in duplicate. All plasma levels were corrected for their 0-hr. values.

Mean plasma level, which is the absorption index, was calculated by dividing the area under the plasma level curve (calculated by the trapezoidal rule) by the appropriate time interval.

Dissolution rates (Table III) were measured in simulated intestinal fluid as described previously (4). Single 125-mg. tablets, half of the 250-mg., and one quarter of the 500-mg. tablets were assayed.

RESULTS AND DISCUSSION

Single-Dose Study—Table I shows the individual plasma levels at different times following ingestion of the four preparations. Plasma levels vary widely, but, in general, peak at 4 hr. There are large variations in drug absorption between subjects on all preparations. This agrees with the findings of other investigators (1, 8).

Table II—Analysis of Mean Griseofulvin Plasma Levels by Duncan's Multiple-Range Statistic

Treatment[a]	Area/25
1	1.02
4	0.93
2	0.83
3	0.74

[a] Values not connected by a solid line differ significantly. $1 > 3$ ($p < 0.05$); $1 > 2$ ($p < 0.10$); $4 > 3$ ($p < 0.10$).

An analysis of variance procedure for Latin square crossover designs (5), applied to the plasma levels in Table I, shows that treatments, time, and the treatment × time interaction are statistically significant factors ($p = 0.05$). Duncan's multiple-range test, applied to the area/25 values in Table I, shows (Table II) that preparation 1 is significantly better than preparations 2 and 3, and that preparation 4 is significantly better than 3.

Figure 1 shows a good correlation between the mean plasma levels (area/25) in Table I and the logarithm of the 30-min. dissolution values in Table III. The correlation coefficient is 0.94 ($p = 0.04$). The 15- and 10-min. dissolution values have correlation coefficients of 0.96 ($p = 0.03$) and 0.92 ($p = 0.05$), respectively. These results agree well with the authors' previous single-dose study (4).

Because griseofulvin therapy requires prolonged drug administration, the correlation between dissolution rates and drug absorption during prolonged treatment was studied. This was also of interest

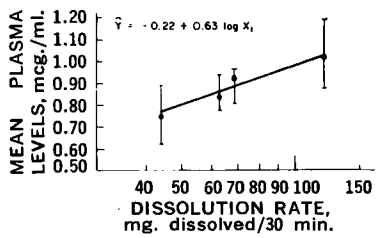

Fig. 1—Correlation of dissolution rate and mean griseofulvin plasma levels. Correlation coefficient = 0.94 (p = 0.04). Brackets enclose 95% confidence intervals of regression line.

60	99	65	52	75	100	44

[a] Preparations: 1, 3, 4—125-mg. tablets; 5, 6—250-mg. tablets; 2—500-mg. tablets. [b] This preparation is the same as preparation 2 in the authors' previous study (4).

in view of a report (9) urging caution when interpreting data from a single-dose study with griseofulvin.

Multiple-Dose Study—Table IV shows the individual griseofulvin plasma levels obtained with three preparations, in 18 subjects treated daily for 7 days with 500 mg. of griseofulvin. Table V compares the mean plasma levels in the same eighteen subjects. The data in Table IV show that the peak and residual plasma levels for each treatment group and also within most of the subjects are remarkably constant after the second or third dose. Griseofulvin mean plasma drug levels plateau after the third daily dose with all preparations (Table V).

Analysis of variance of the mean plasma levels in Table V does not show any statistically significant differences between preparations. This is probably due to the small number of subjects, large intersubject variation, and lack of a crossover design. Despite the lack of demonstrable statistically significant differences between preparations, de-

[a] Areas under curve divided by periods as indicated.

tailed inspection of the data reveals some interesting points. For example, the ranking of preparations based on mean plasma levels during the first 25 hr. (single dose) remains the same throughout the entire experiment (except for the 25–49-hr. period). Also, if the residual plasma levels are considered (values 25 hr. after the first dose, and 24 hr. after the second, fourth, and seventh doses), the following statistically significant differences emerge: at 25 hr., preparation 5 > 6 (p = 0.1, least significant difference), at 97 hr., preparation 5 > 6 (p = 0.1, Duncan's multiple-range statistic), and 5 > 2 (p = 0.05, Duncan's multiple-range statistic). Residual plasma levels may be important in griseofulvin therapy since a minimum level of 1 mcg./ml. appears to be needed for an effective cure (1).

When the dissolution values (Table III) are correlated with the mean plasma levels (Table V), a good correlation is seen (Fig. 2) between the logarithm of the 30-min. dissolution values and mean plasma levels after 25 hr. (effect of a single dose), 49–173 hr. (the plateau region), and 0–173 hr. (total experimental period). The correlation coefficients for the 3 time periods are 0.999 (p = 0.015), 0.992 (p = 0.077), and 0.995 (p = 0.056). The slope of the 0–25-hr. regression line compares favorably with the slope of the single-dose treatment (0.60 in Fig. 2 *versus* 0.63 in Fig. 1). The slopes for the later time intervals (Fig. 2) are lower than the 0–25-hr. slope because differences between the mean plasma levels of the preparations are smaller for the 49–173-hr. period.

Since dissolution rates correlate well with griseofulvin absorption after a single dose, as well as after repeated drug administration, they should serve as an effective tool for selecting therapeutically useful griseofulvin preparations.

Further Applications of Diazotized 4-Amino-6-chloro-*m*-benzenedisulfonamide

Colorimetric Determination of Pyridoxine Hydrochloride, 17β-Hydroxy-7aα-17α-dimethyl-B-homo-A-norestrane-3,6-dione and Morphine Sulfate

By TIBOR URBÁNYI and SUSAN BUDAVARI

The diazotization product of 4-amino-6-chloro-*m*-benzenedisulfonamide has been found to be a useful reagent for the colorimetric determination of a vitamin, steroid, and alkaloid. A general method, with slight modification, can be applied to those compounds which contain a phenolic or similar-to-phenolic hydroxyl group. Pyridoxine hydrochloride, 17β-hydroxy-7aα-17α-dimethyl-B-homo-A-norestrane-3,6-dione, and morphine sulfate were used as coupling components in this study. The optimum reaction conditions for coupling and color formation have been determined and the applicability of the method in the presence of commonly used ingredients is demonstrated.

A REPORT ON the colorimetric determination of estrogenic hormones by coupling with diazotized 4-amino-6-chloro-*m*-benzenedisulfonamide reagent has already been published (1). The purpose of the present investigation was to extend the application of that method to the quantitative determination of a phenolic alkaloid,

Further Applications of Diazotized 4-Amino-6-chloro-*m*-benzenedisulfonamide

Colorimetric Determination of Pyridoxine Hydrochloride, 17β-Hydroxy-7aα-17α-dimethyl-B-homo-A-norestrane-3,6-dione and Morphine Sulfate

By TIBOR URBÁNYI and SUSAN BUDAVARI

The diazotization product of 4-amino-6-chloro-*m*-benzenedisulfonamide has been found to be a useful reagent for the colorimetric determination of a vitamin, steroid, and alkaloid. A general method, with slight modification, can be applied to those compounds which contain a phenolic or similar-to-phenolic hydroxyl group. Pyridoxine hydrochloride, 17β-hydroxy-7aα-17α-dimethyl-B-homo-A-norestrane-3,6-dione, and morphine sulfate were used as coupling components in this study. The optimum reaction conditions for coupling and color formation have been determined and the applicability of the method in the presence of commonly used ingredients is demonstrated.

A REPORT ON the colorimetric determination of estrogenic hormones by coupling with diazotized 4-amino-6-chloro-*m*-benzenedisulfonamide reagent has already been published (1). The purpose of the present investigation was to extend the application of that method to the quantitative determination of a phenolic alkaloid,

Received March 25, 1968, from the Analytical Research and Development Division of CIBA Pharmaceutical Company, Summit, NJ 07901
Accepted for publication May 10, 1968.

a nonphenolic steroid, and similar-to-phenolic vitamin; morphine sulfate, 17β-hydroxy-7aα-17α-dimethyl - B - homo - A - norestrane - 3,6 - dione (steroid); and pyridoxine hydrochloride, respectively. Although the structures of these three compounds differ considerably, each has a similar functional group upon which the proposed method of determination is based.

A search of the literature reveals numerous assay methods for both morphine and pyridoxine. This attests to the importance of the compounds, as well as the difficulty involved in developing satisfactory analytical procedures which are quantitative and sensitive. For example, many alkaloids and vitamins can be determined by thin-layer chromatography (2, 3) with extreme sensitivity; but the results are not always quantitative. The numerous gas chromatographic methods available (4, 5) require great care in column preparation to secure reliable results. Ion-exchange methods (6, 7) generally suffer from the lack of reproducibility. Colorimetric techniques (8–10) can be quite sensitive and quantitative but they, as in the case of the USP procedure for pyridoxine in decavitamin capsules (11), are often time consuming and require rigidly controlled conditions. Among other colorimetric methods are the coupling reactions with diazonium salts. Diazotized sulfanilic acid reagent (12, 13) is often used, but this procedure fails to yield reproducible quantitative results. Aliev (14) proposes a method for pyridoxine determination which is based on the formation of a red-violet zinc complex with the stabilized diazo salt of norsulfazole. This method, as well as the others, proves less satisfactory than the proposed method for reasons of either poor reproducibility, length or complexity, or lack of sensitivity.

Alternate procedures for the analysis of the steroid cannot be cited since no previous references appear in the literature.

The need for a quantitative and sensitive method for the determination of pyridoxine and morphine as pure substances and in pharmaceutical formulations was apparent. Since pharmaceutical interest in steroids similar to the one presented here can be expected, the method for its analysis was included. The aim of this report, therefore, was to propose a practical and general colorimetric procedure for the analysis of these compounds.

EXPERIMENTAL

A Beckman model DU spectrophotometer was used to determine the absorbances, and a Cary model 11 recording spectrophotometer was used to record the spectra.

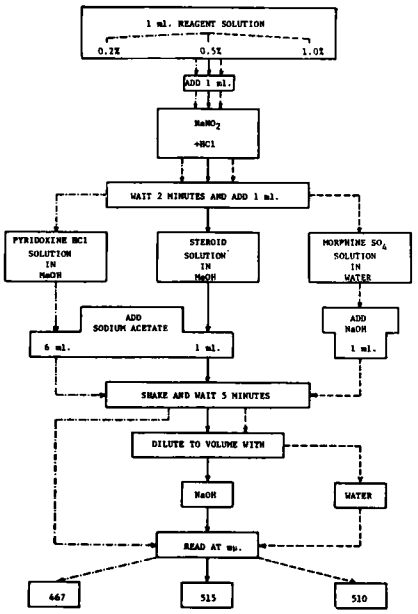

Fig. 1—Schematic diagram.

Reagents and Solutions—4-Amino-6-chloro-*m* benzenedisulfonamide (disulfonamide), 0.2, 0.5, and 1.0% methanolic solutions; sodium nitrite, 1.0% aqueous solution; hydrochloric acid, 1 *N;* sodium acetate, 1 *N* solution; sodium hydroxide, 1 *N* aqueous solution.

Preparation of Assay Solution—The compounds used in this study were dissolved in either methanol or water, whichever provided the optimum conditions for the color measurements. Solutions containing approximately 0.0025% of pyridoxine hydrochloride, 0.015% of steroid in methanol, and 0.13% morphine sulfate in water were prepared.

General Procedure for Color Development—Into separate 10-ml. volumetric flasks 1.0 ml. each of disulfonamide, sodium nitrite, and hydrochloric acid solutions were successively pipeted and mixed well. The solutions were allowed to stand 1–2 min., then 1.0 ml. of assay solution and 1.0 ml. of solvent (blank) were added. The solutions were buffered and allowed to stand approximately 5 min. at room temperature. Each flask was diluted to volume with the proper solvent, and its absorbance was determined at the given wavelength in 1-cm. cells against its respective blank.

The three compounds considered in this study belong to significantly different categories which precludes the use of a rigorous general method which can be applied to each with equal success. Since individual adaptations were made in order to obtain optimum conditions for each analysis, a schematic diagram (Fig. 1) is provided which lists the step-by-step procedure proposed.

DISCUSSION

The absorption spectra of the final coupled products of pyridoxine hydrochloride, steroid, and morphine sulfate with diazotized disulfonamide are shown in Fig. 2.

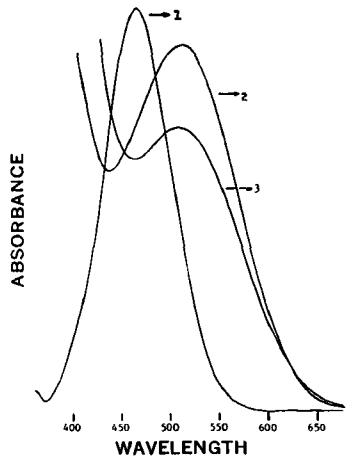

Fig. 2—Absorption spectra of coupled products. Key: 1, pyridoxine hydrochloride; 2, 17β-hydroxy-7aα-17α-dimethyl-B-homo-A-norestrane-3,6-dione; 3, morphine sulfate.

Pyridoxine Hydrochloride—It is apparent that while both the alkaloid and steroid exhibit broad absorption maxima in the 510–515-mμ region, the vitamin absorption maximum appears considerably lower at 467 mμ. This hypsochromic displacement of the absorption maximum in the case of vitamin, along with the much greater color intensity of its coupled product, can be attributed to the fact that the pyridoxine has the most favorable coupling position which is *para* to the phenolic hydroxyl group as well as *ortho* to the ring nitrogen, and thus exhibits strong electron density. Only coupling *ortho* to the hydroxyl group is possible for the morphine and the steroid. The intensity of absorbance was significantly affected by the choice of diluents and the pH of the solution. The color intensity of the final solution was increased 5–10% when the pyridoxine to be determined was dissolved in methanol rather than water. Furthermore, the fact that the intensity was significantly greater when acetate buffer was chosen as the diluent rather than sodium hydroxide is consistent with the observation of Stamm and Zollinger (15). They reported that a 10-fold increase in the concentration of acetate ions catalyzes the coupling reaction and produces five times more *para* coupling.

The most intense and reproducible color was obtained when the final pH was between 5.3 and 6.0. Therefore, 1 *N* sodium acetate, which brought the solution to the suitable pH upon dilution, was utilized as the diluent. Although the orange color developed immediately upon dilution with sodium acetate, it was found advisable to wait about 3 min. before reading the solution to avoid interference from the bubbles which develop.

TABLE I—MOLAR ABSORPTIVITIES

Compd.	ε ($\lambda_{max.}$)
Morphine sulfate	2.1×10^4
Steroid	8.7×10^4
Pyridoxine hydrochloride	35.7×10^4

The relationship between the concentration and the absorbance at 467 mμ was found to be linear over a range of 0–0.04 mg./assay. The molar absorptivity value is considerably larger than the values for morphine and steroid as seen in Table I.

Steroid—The synthetic steroid used in this study is significantly different from the phenolic estrogens considered in the previous publication (1). It is nonaromatic and has the structural formula in Scheme I.

Experimental data have indicated that the enol form of the steroid predominates in the enol–keto equilibrium, thereby making its determination as a coupling component with diazonium salts possible. Based on the above, it was evident that the pH of the solution at the coupling stage should be critically controlled. Sodium acetate was found to be the best buffering agent for this purpose. Although a stable color was obtained omitting the sodium acetate, the results were not reproducible, and a bathochromic shift was observed. An attempt was made to vary the sodium acetate buffer concentration and also to replace it with sodium bicarbonate, sodium carbonate, and sodium hydroxide solutions. Color instability was noted, and the Beer's law plots did not intersect the origin. The most reproducible values were obtained when coupling was carried out with 1 *N* sodium acetate solution at pH 5 ± 0.3, and the coupling time was 5 min. Color developed immediately upon the addition of 1 *N* sodium hydroxide and remained constant for at least 30 min. (Fig. 3). No absorption peak was obtained when the solution was diluted with sodium acetate. Beer's law was valid for this steroid at 515 mμ over a range of 0–0.25 mg./assay.

Morphine Sulfate—The rate of coupling and the color intensity of the coupled product with diazo-

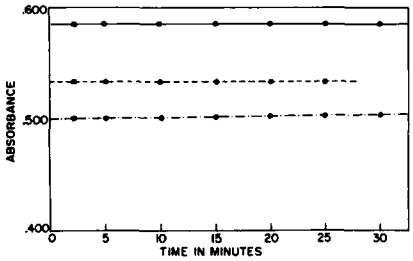

Fig. 3—Absorbance of final solution versus *time. Key: ———, pyridoxine hydrochloride; ---, steroid; ·-·, morphine sulfate.*

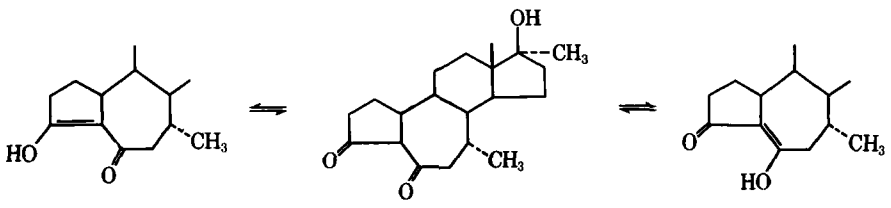
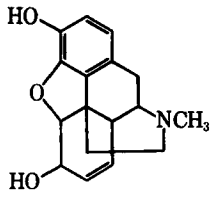
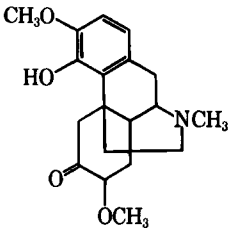


Scheme I

nium compounds are strongly affected by the structural formula of the coupling agent. Alkaloids, having *ortho* or *para* positions to the phenolic hydroxyl unsubstituted, give diazo reactions; however, the intensity of the reaction is dependent upon whether the free coupling site is at the *ortho* or *para* position. One notes that sinomenine (16), with the free *para* coupling position, gives a forty times stronger coupling reaction with diazobenzenesulfonic acid than morphine, where only *ortho* coupling can occur.



morphine



sinomenine

The experimental conditions in this study were carefully investigated to obtain the optimum coupling reaction with morphine sulfate. The concentration of disulfonamide solution was increased to 1% to provide sufficient reagent for the amounts of morphine sulfate added. An increased amount of sodium nitrite raised the color intensity of the coupled product, but the color stability was diminished. Morphine sulfate was dissolved in water, rather than methanol or 1 *N* hydrochloric acid, to obtain linear absorbance *versus* concentration plots. Sodium hydroxide (1 *N*) was abandoned as a solvent despite good color stability and satisfactory adherence to Beer's law because reproducible results were not obtained.

The morphine sulfate was allowed to couple in sodium hydroxide solution. Although acetate at coupling intensified the final color, acetate was not used since plots of absorbance *versus* concentration did not intersect the origin and color fading was noted. An intense red color developed immediately upon addition of sodium hydroxide at coupling, and the 5-min. waiting time ensured the stabilization of absorbance values upon dilution with water. Water was selected as the diluent because the final absorption of the coupled product was about 10–15% higher than when sodium hydroxide was employed. No absorption peak was observed when sodium acetate was used as diluent. Stable and reproducible results were obtained when the pH of the solution was 10.5 ± 0.5.

The absorbance was linear at 510 mμ for concentrations up to 1 mg. morphine (as the sulfate) per assay. As seen in Fig. 3, the plot of absorbance against time was quite constant and showed only about 2% increase in color intensity after 30 min.

Mixtures—The data in the tables confirm that the method already described may be satisfactorily applied even though the compounds studied are in the presence of similar vitamins or alkaloids and excipients commonly used in pharmaceutical preparations. In each of the synthetic mixtures analyzed, the ratio of the active ingredient to the additive was that of the average found in commercial preparations (if existing) rather than the optimum for analysis procedures.

It can be seen from the data in Table II that a 10- to 100-fold increase in excipient concentration resulted in a 100–101% recovery of active ingredient in the presence of sucrose, lactose, and starch.

One can conclude from Table III that pyridoxine hydrochloride can be accurately determined though compounded with a considerable amount of any of the other common B vitamins and without the need for prior separation. However, interference due to ascorbic acid, which is also often found in vitamin B complex formulations, should be first eliminated by a simple oxidation process (14).

As evident from Table IV, morphine may be assayed in the presence of certain related opium alkaloids since those alkaloids without a phenolic group, or with a substituted phenolic group, do not interfere.

The unique character of the steroid investigated here illustrates the extended applicability of this method. Since steroids with similar structural formulas are not found in the literature, 12 steroids with alcoholic or ketonic groups at the 3 position were chosen to check the applicability of the proposed method. Androsterone, ergosterol, dehydrocholic acid, *etc.*, did not give coupling reactions with diazotized disulfonamide. Of course, steroids with phenolic hydroxyl group interfere; however, such combined formulations would not normally be expected.

TABLE II—DETERMINATION OF MORPHINE, PYRIDOXINE, AND STEROID IN THE PRESENCE OF COMMON EXCIPIENTS

Additives	Morphine	Pyridoxine	Steroid

Codeine sulfate	100.8
Dionin	100.4

[a] The compound–additive ratio 1:1.

This method with its sensitivity, rapidity, and color stability provides a significant improvement over the procedures mentioned in the literature.

SUMMARY

Pyridoxine hydrochloride, steroid, and morphine sulfate which contain either phenol c, or similar-to-phenolic hydroxyl groups, form colored azo dyes with diazotized disulfonamide.

The color intensity was significantly increased when coupling occurred *para*, rather than *ortho*, to the phenolic hydroxyl group. Certain compounds showing group similarities, as well as commonly used excipients in pharmaceutical formulations, do not interfere in this determination.

By PAUL W. WILLARD and CLARENCE E. POWELL

An indoloquinoline compound prepared from lysergic acid base has been found to have an α-blocking action on *in vivo* and *in vitro* preparations. The compound reverses the blood pressure response to epinephrine from pressor to depressor in pithed and decerebrate cats. In renal hypertensive dogs, the compound produced a significant sustained decrease in blood pressure. On rat vas deferens preparations, the spasmogenic effect of epinephrine and norepinephrine was blocked by the compound similar to, but not in the same degree as that observed with dibenamine. The primary effect of the compound appears to be an interference with sympathetic transmission postsynaptically at the α-receptor sites resulting in peripheral dilatation.

COMPOUNDS DERIVED from lysergic acid are known to have a variety of pharmacological properties. Among these properties are effects on blood pressure and other cardiovascular parameters (1). Recently, a chemically unique series of indoloquinoline compounds prepared from the lysergic acid base[1] produced a sustained lowering of blood pressure in unanesthetized and anesthetized animals. This study was made to determine the mechanism of actions whereby one of the members of the series lowered blood pressure.

The compound, 9-(3,5-dimethylpyrazole-1-carboxamido)-7-methyl-4,6,6*a*,7,8,9,10,10*a*-

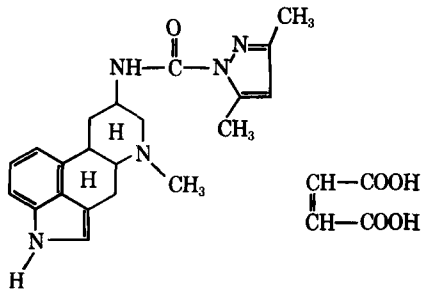
octahydroindolo [4,3-*fg*] quinoline maleate (compound PAI), has the following structural formula:



METHODS

In Vivo Preparations of Unanesthetized Animals—Renal hypertension was produced in adult male dogs by the Goldblatt procedure (2). Blood pressure responses were measured from a direct arterial puncture by a mercury manometer. Following control blood pressure and heart-rate recordings, the drug was administered orally to each of three hypertensive dogs at 5.0, 7.5, and 10.0 mg./kg., respectively. Blood pressure and heart rate were measured at 30-, 60-, 120-, 180-, and 360-min. intervals.

Subacute toxicity studies of the compound were made in adult white roosters (3). One group of three roosters received 2.0 mg. of compound PAI intramuscularly, b.i.d. for 21 days. Another group of three roosters was given 5.0 mg. of compound PAI intramuscularly b.i.d. for 31 days. In a third group of nine roosters, 5.0 mg. of the drug was given intramuscularly daily 30 min. prior to a 1.0-mg. dose of ergotamine tartrate intramuscularly for 21 days. An additional group of nine roosters received only 1.0 mg. of ergotamine tartrate intramuscularly for 21 days.

Anesthetized Animals—Ganglionic inhibition and blood pressure effects were evaluated in four cats anesthetized with chloralose (50 mg./kg.) following administration of progressively larger doses of compound PAI (0.1, 0.25, 0.5, 1.0, 2.0, 5.0, and 10.0 mg./kg.). The superior cervical sympathetic nerve was stimulated for 30 sec. by a 2- or 20-c.p.s. (9.0 v.-5 msec.) square wave from a Grass stimulator. Four minutes were allowed between stimulations for recovery of the preparation. Epinephrine (2.5 mcg./kg.) and norepinephrine (2.5 mcg./kg.) were administered to chloralose anesthetized cats following intravenous administration of compound PAI (5.0 mg./kg.).

In Vitro Preparations—The adrenergic blockade of compound PAI was compared with dibenamine using a method modified from that described by Leach (6). Isolated vas deferens from adult rats, 250–600 g., were suspended in either 2-ml. or 10-ml. muscle chambers containing Tyrode's solution warmed to 36° and gassed with 95% oxygen and 5% carbon dioxide. Responses of the muscles were recorded electronically by either isometric or isotonic myographs with 0.5-g. tension. Epinephrine and norepinephrine were used as the agonists. Doses of the antagonists which would block muscle response to the agonists by 50% were determined. The β-receptor action of dichloroisoproterenol against epinephrine- and norepinephrine-induced contractions of the rat vas deferens was also investigated.

In another series of experiments, the protective action of PAI against dibenamine blockade of norepinephrine-induced contractions of rat vas deferens was studied by a method modified from that of Furchgott (7). In protection experiments a Vickers biological assay apparatus was used and muscle responses were recorded electronically by isotonic myographs with 0.5-g. tension.

The test procedure was to first give a series of norepinephrine doses (1.0 mcg./ml.) at 5-min. intervals until the muscle response was quantitated. The muscle strip was then treated with a dose (100 mcg./ml.) of PAI and 5 min. later dibenamine (0.1 mcg./ml.) was added. Following a 5-min. exposure the muscle was washed three times and allowed to rest 10 min. Norepinephrine in the same dose as control was then given at 5-min. intervals for a period of 30–60 min.

The contractile force and coronary flow was tested on four rabbit hearts suspended in an Anderson-Carver perfusion chamber (4). Chenoweth's solution was used as the perfusion fluid (5). Doses of compound PAI were injected directly into the perfusate as it entered the aortic cannula. The heart-muscle response was recorded electronically with an isometric myograph.

RESULTS

In Vivo Preparations of Unanesthetized Animals—When compound PAI was administered orally to renal hypertensive dogs, blood pressure was lowered within 1 hr. of dosing (Table I). The blood pressure returned to near normal 3 hr. following the 5.0-mg./kg. dose. With 7.5 and 10.0 mg./kg., the blood

[a] Vomited. [b] Diarrhea (slight).

pressure was still reduced significantly at 6 hr. However, in dog ZH-120, there was no residual effect 24 hr. following drug administration. The heart rate increased in each instance and appeared to be a function of the dose. The dogs vomited after receiving the drug, and a slight diarrhea was evident with the 7.5-mg./kg. dose. Emesis was a frequent occurrence with the drug when administered orally or i.v. to other dogs, however, there was no apparent relationship to dose or to blood pressure decreases. Emesis generally only occurred once about 1 hr. following treatments. Emetic or other apparent central nervous system activity was not produced in unanesthetized cats.

The rooster combs appeared normal following 21 days of treatment with compound PAI (2.0 mg. b.i.d.) and the general physical condition of the birds was good. During the treatment period, the roosters had an average weight gain of 0.3 kg. All roosters receiving 5.0-mg. b.i.d. doses were also in good condition with normal combs.

Seven of nine roosters dosed only with ergotamine tartrate (1.0 mg.) had definite bluing of the comb followed by dry gangrene on the sixth day of treatment. One rooster died on the seventh day and the remaining bird survived with no bluing of the comb.

In the group of roosters receiving 5.0 mg. of compound PAI 30 min. prior to ergotamine treatment, none of the six surviving birds developed gangrenous combs. One rooster died on the third day, one on the tenth day, and one on the twentieth day following initiation of the regimen. Cause of death was not apparent. There was no weight change in this group.

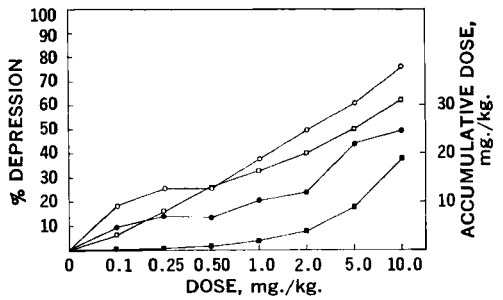

Fig. 1—Four ether–chloralose anesthetized, normotensive cats. Effect of accumulation of larger doses of PAI on blood pressure and nictitating membrane contractile response. Stimulation of nictitating membrane preparation with a square wave (9 v.) stimulation at 2 and 20 c.p.s. following each dose. Key: ○, 2 c.p.s.; ●, 20 c.p.s.; □, B.P.; ■, accumulative dose.

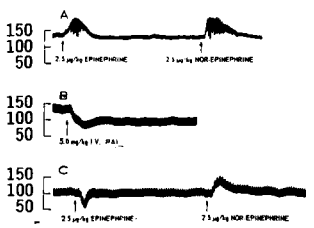

Fig. 2—Example of in vivo *effects of PAI (5.0 mg./kg.) on equal doses of (2.5 mcg./kg. i.v.) of epinephrine and norepinephrine in an ether–chloralose anesthetized cat.*

Anesthetized Animals—The action of compound PAI administered in graded doses of 0.1, 0.25, 0.50, 1.0, 2.0, 5.0, and 10.0 mg./kg. to chloralose anesthetized cats is shown in Fig. 1. A maximum decrease of 62% in blood pressure was produced with 10.0 mg./kg. (accumulated dose = 18.85 mg./kg.). The nictitating membrane was blocked 76% with the 2 c.p.s. stimulation and 50% with the 20 c.p.s. stimulation. "Neural fatigue," defined as a gradual decay of the sustained contractile response, was not observed with any dose of compound PAI.

Following a 5.0 mg./kg. dose of compound PAI to chloralose anesthetized cats, the pressor response to epinephrine was reversed to depressor (Fig. 2). Blood pressure response to norepinephrine was only slightly inhibited.

In Vitro Preparation—Doses of 0.1, 0.2, and 0.3 ml. of a 1-mg./ml. stock solution reduced the isolated heart contractile force by 5.0, 7.0, and 75%, respectively. A dose of 0.5 mg. (0.5 ml.) completely blocked the heart beat with no recovery. The heart rate was not altered nor was the coronary flow changed by smaller doses.

Compound PAI was found to antagonize epinephrine- and norepinephrine-induced spasms of the rat vas deferens. Figure 3 shows a typical response of the muscle to 10 mcg./ml. of the compound. Following matching contractions from doses of 0.3 mcg./ml. of epinephrine, compound PAI (10 mcg./ml.) was injected into the tissue chamber and allowed to act 1 min. Following this procedure, an 0.3-mcg./ml. dose of epinephrine was added to the bath. The stimulating action of epinephrine was reduced 50%. Even with repeated change of bathing fluid and exposure to epinephrine, the muscle failed to recover the pretreatment response after five trials. Thus, compound PAI has a sustained blocking action on epinephrine. The lower tracing on

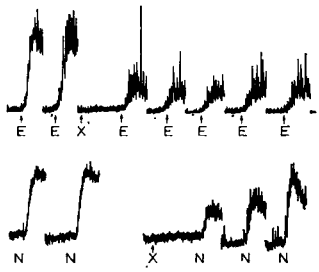

Fig. 3—Comparison of the stimulating action of epinephrine (E) (0.3mcg./ml.) and norepinephrine (N) (0.3 mcg./ml.) on isolated vas deferens of the rat, before and after compound PAI (X) (10 mcg./ml.).

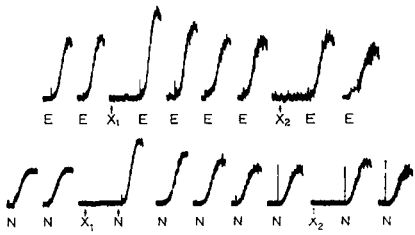

Fig. 4—Potentiation of the spasmogenic activity of epinephrine (E) (0.4 mcg./ml.) and norepinephrine (N) (0.4 mcg./ml.) by DCI (X_1 = 5.0 mcg./ml.) and (X_2 = 10 mcg./ml.) on the isolated vas deferens of the rat.

Fig. 3 shows a similar treatment of the muscle using norepinephrine in doses of 0.25 mcg./ml. Ten mcg./ml. of compound PAI blocked the muscle response to norepinephrine by 50%, but the time of recovery was somewhat less than was required for epinephrine.

In the study with DCI on spasms induced by epinephrine or norepinephrine of the rat vas deferens, it was found that an additive or enhancing action resulted (Fig. 4). DCI was added to the muscle chamber in doses of 5.0 and 10.0 mcg./ml. following matching contractions to 0.4-mcg./ml. doses of epinephrine and norepinephrine. When DCI had been in contact with the tissue for 1 min., a 0.4-mcg/ml. dose of either epinephrine or norepinephrine was added to the chamber. As shown in the tracing, the muscle contracted higher following both catecholamines, indicating an enhancing effect, since DCI in the doses given produced no activity alone.

Although it could be demonstrated in isolated rat vas deferens preparations that compound PAI left in contact with the muscle strip partially blocked norepinephrine-induced contractions (Fig. 3), such was not the case in protection experiments. From control protection tests in which compound PAI alone (100 mcg./ml.) was in contact with the muscle strip 5 min. then washed three times and dosed with norepinephrine (1.0 mcg./ml.), no significant adrenergic receptor blockade was noted. An average of results on three muscle-strip preparations showed response to norepinephrine to be reduced by less than 20%. However, when muscle strips were treated in the same manner with dibenamine (0.1 mcg./ml.), contractile responses to norepinephrine (1.0 mcg./ml.) were reduced by more than 95% through eight doses over a period of 40 min. (Fig. 5).

The protection experiments indicate compound PAI partially protects adrenergic receptors from dibenamine blockade. This confirms the suggestion that PAI reacts with α-adrenergic receptors.

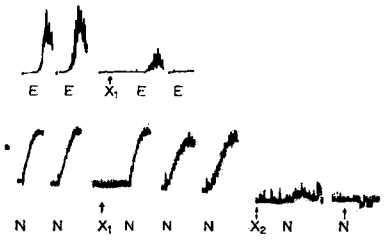

Fig. 5—Antagonism of dibenamine (X_1 = 0.4 mcg./ml.) and (X_2 = 1.0 mcg./ml.) on the stimulation action of epinephrine (E) (0.2 mcg./ml.) and norepinephrine (N) (0.2 mcg./ml.) on the isolated vas deferens of the rat.

DISCUSSION

The *in vivo* and *in vitro* activity of compound PAI suggests that the hypotensive response can be related or ascribed to α-adrenergic blockade. Epinephrine reversal occurs in pithed and decerebrate cats (Fig. 2) and inhibition of epinephrine and norepinephrine contraction of the vas deferens is a prominent feature of the drug (Fig. 3).

It has been clearly demonstrated that compound PAI, when left in contact with rat vas deferens 5 min., protects adrenergic receptors against the contractile action of norepinephrine (Fig. 3). However, when large doses of the compound (100 mcg./ml.) are incubated 5 min. and washed 3 times, most of the blocking action to norepinephrine stimulation disappears. This would indicate the compound does not adhere to the adrenergic receptors as tightly as that of dibenamine. It is well known that dibenamine blockade of epinephrine stimulation of isolated muscle persists up to 2 or more hr. (7). In this study control experiments show dibenamine (0.1 mcg./ml.) to inhibit almost 100% the contractile action of norepinephrine through three initial washes and eight doses of the agonists given at 5-min. intervals (total time 55 min.).

Compound PAI does protect adrenergic receptors against dibenamine blockade of the contractile response of smooth muscle to norepinephrine as demonstrated when compound PAI was incubated with dibenamine and then washed three times. From these experiments it was estimated that PAI protected 38% of the adrenergic receptors from the effectiveness of dibenamine.

The hypotensive response in renal hypertensive dogs was accompanied by an increased heart rate which indicates an attempted compensation by the unblocked β-receptors at the terminals of the cardiac sympathetic nerves (Table I). This response is consistent with the peripheral dilating action of α-blockade (8). Blockade of ergotamine-induced gangrene of rooster combs by PAI further indicates a competitive block at the site of peripheral vasoconstriction. In anesthetized dogs, the heart rate generally decreased. The anesthetic probably depressed the cardiac center and effectively inhibited a compensatory chronotropic response. Compound PAI does produce a blockade of the sympathetic nervous system (Fig. 1). From the data obtained in the above studies, α-receptor blockade probably accounts for a large portion of the hypotensive activity.

SUMMARY

1. Compound PAI produced a significant sustained decrease in blood pressure orally in hypertensive dogs (5.0, 7.5, and 10.0 mg./kg.). Emesis occurred in one hypertensive dog and slight diarrhea in a second.

2. On the rat vas deferens preparation, PAI was observed to block the spasmogenic effect of epinephrine and norepinephrine similar to, but not in the same degree as that observed with dibenamine. Protection experiments show that PAI partially protected the α-receptors from dibenamine blockade of the contractile response to norepinephrine. Thus, compound PAI is primarily an α-blocking agent, since DCI potentiated the spasmogenic effect of epinephrine and norepinephrine. Additional evidence in favor of α-blockade is provided by the fact that epinephrine is reversed in spinal cats by compound PAI.

3. In anesthetized cats, sympathetic block is evidenced following PAI administration. Ergotamine toxicity is inhibited in roosters following prophylactic treatment with PAI.

4. It has been concluded that a primary effect of PAI is interference with sympathetic transmission postsynaptically at the α-receptor which results in peripheral dilatation.

Micellar Solubilization of Testosterone II

In Aqueous Solutions of Some Ionic Surfactants

By ARVIND L. THAKKAR* and NATHAN A. HALL

The solubility of testosterone at 25° was determined in aqueous solutions containing varying concentrations of dodecyltrimethylammonium bromide (DTAB), hexadecyltrimethylammonium bromide (HTAB), and potassium laurate (KL). After the initial stages of solubilization, a linear relationship was observed between the amount of testosterone solubilized and the molar concentration of the surfactant. The order of increasing solubilizing capacity was DTAB < HTAB < KL. The environment of solubilized testosterone, as investigated by the *Z*-value method, was found to be quite polar in all cases. At low concentrations of DTAB and HTAB the *Z* value was similar to that in water. As the concentration of the quaternary ammonium bromides increased, a precipitous drop in *Z* value, corresponding to a sudden decrease in environmental polarity, was observed in the region of the critical micelle concentration. With further increase in the concentration of DTAB and HTAB the *Z* value remained reasonably constant. In low KL concentrations the *Z* value of the testosterone environment was higher (more polar) than in water. With increasing concentrations of KL the *Z* value displayed behavior similar to that in DTAB and HTAB. In general, solutions of ionic surfactants showed higher *Z* values than those of the nonionic surfactants examined previously.

THE MICELLAR solubilization of testosterone by solutions of the nonionic surfactants, polysorbates 20, 40, and 60, was the subject of a prior report from this laboratory (1). The solubilizing capacities of the three polysorbates were determined and the polarity of the chromophore of testosterone examined in these systems. A description of the *Z*-value method for empirically measuring the environmental polarity of the solubilized testosterone was included and the results were discussed in the light of current micellar theories.

In 1949 Ekwall and Sjöblom (2) prepared clear aqueous solutions of testosterone in 10% sodium oleate, 20% sodium myristyl sulfate, and 20% sodium cholate solutions, but they did not study the micellar solubilization of this steroid in detail. Recently Lach and Pauli (3) reported the solubilizing action of aqueous sodium desoxycholate solutions upon this steroid. These workers attributed the solubilizing action of sodium desoxycholate, at least in part, to channel-like inclusion complex formation. Besides these two reports no data regarding the solubilizing action of other anionic or cationic agents for testosterone are available. The investigations reported here include the solubilizing capacities of dodecyltrimethylammonium bromide, hexadecyltrimethylammonium bromide, and potassium laurate, as well as the effect of varying concentrations of these surfactants upon the environmental polarity of solubilized testosterone as determined by the *Z*-value method.

EXPERIMENTAL

Materials—Dodecyltrimethylammonium bromide (DTAB) and hexadecyltrimethylammonium bromide (HTAB) (K and K Laboratories, Plainview, N. Y.) were recrystallized twice before they were used, DTAB from acetone and HTAB from a chloroform–acetone mixture. The critical micelle concentration (CMC) of DTAB at 25° has been reported as 1.6×10^{-2} mole/l. by Scott and Tartar (4). The CMC of HTAB was calculated from the linear plot of log CMC *versus* carbon atom chain length from the data of these authors as 8.4×10^{-4} mole/l. A 0.1 *M* stock solution of DTAB was readily prepared at room temperature. When preparing a 0.01 *M* stock solution of HTAB, however, it was necessary to apply gentle heat. The dissolved HTAB did not precipitate from solution when cooled to room temperature. From the stock solutions a series of solutions were prepared by appropriate volumetric techniques.

The preparation of solutions of potassium laurate (KL) has been described previously (5). The CMC of KL has been reported as 2.34×10^{-2} mole/l. (6).

Testosterone NF,[1] obtained as micronized crystalline powder, was used in this investigation.

Solubility Determinations—The solubility of testosterone in aqueous solutions of DTAB, HTAB, and KL at 25° was determined by the procedure described earlier (1). As in the case of solubilization of testosterone in solutions of nonionic surfactants, initial supersaturation was found to occur in all the cases. Following this supersaturation, equilibrium solubility was attained within 48 hr. All the solutions, however, were equilibrated for 96 hr. The seemingly anomalous phenomenon of initial supersaturation in solubilized systems containing testosterone has been investigated in detail and will be the subject of a future paper (7).

Z-Value Determinations—This method for determining the environmental polarity of solubilized molecules has been described previously (1) and was utilized in this study. In most micellar solutions of DTAB, HTAB, and KL, however, the quantity of testosterone solubilized was so large that it was not possible to carry out spectral measurements using undiluted solutions. The effect of solubilizate concentration upon the wavelength of maximum absorbance ($\lambda_{max.}$) and *Z* value has been investigated before, for testosterone in solutions of a nonionic surfactant (1), and for camphor in solutions of both ionic and nonionic surfactants (8, 9). No significant differences were found in the values of these parameters. In view of these studies and the fact that these parameters reflect the solvent polarity, it seemed reasonable to assume that dilution with the appropriate surfactant solution would not alter the values of $\lambda_{max.}$ and *Z*. Dilutions were kept to a minimum and, even with the largest dilution, the amount of testosterone in solution was well above its aqueous solubility. This would ensure that the testosterone molecules would be associated with surfactant micelles. In all the cases where dilutions were necessitated, cells of shorter (1 mm.) path length were used.

RESULTS AND DISCUSSION

Solubility Determinations—Figures 1, 2, and 3 show the relationship between relative solubility of testosterone and concentration of DTAB, HTAB, and KL, respectively. As in the case of polysorbates,

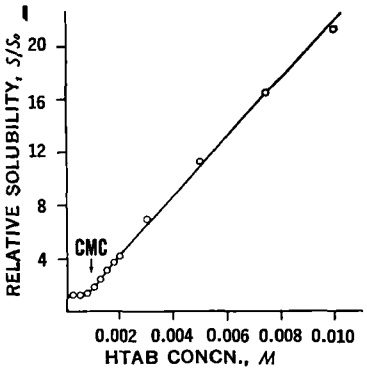

Fig. 2—Relative solubility of testosterone versus *concentration of hexadecyltrimethylammonium bromide. (Relative solubility,* S/S_0 = *solubility in surfactant solution,* S/ *solubility in water,* S_0.) *The CMC indicated is the reported (4) value determined in the absence of any solubilizate.*

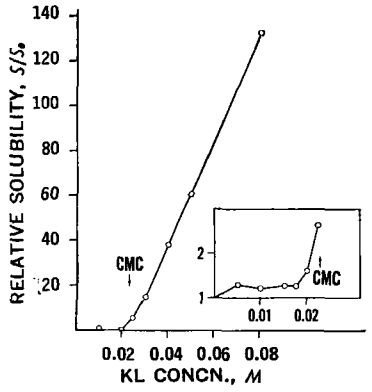

Fig. 3—Relative solubility of testosterone versus *concentration of potassium laurate. (Relative solubility,* S/S_0 = *solubility in surfactant solution,* S/*solubility in water,* S_0.) *The CMC indicated is the reported (6) value determined in the absence of any solubilizate.*

Table I—Solubilizing Capacity of Various Surfactants for Testosterone at 25°

Surfactant	Solubility, Mole Testosterone/Mole Surfactant
Dodecyltrimethylammonium bromide	9.01×10^{-2}
Hexadecyltrimethylammonium bromide	16.26×10^{-2}
Potassium laurate	17.75×10^{-2}
Polysorbate 20	3.529×10^{-2}[a]
Polysorbate 40	3.984×10^{-2}[a]
Polysorbate 60	4.385×10^{-2}[a]

[a] From *Ref. 1.*

the plots are linear after the initial stages of solubilization. The solubilizing capacities were calculated from the slopes of the linear plots and are listed in Table I. In order to facilitate comparison, the previously reported (1) solubilizing capacities of polysorbates 20, 40, and 60 are also listed in Table I.

It may be seen from Table I that among the ionic surfactants the order of increasing solubilizing capacity is DTAB < HTAB < KL. Where surfactant molecules have lipophilic portions of comparable length, the ionic agents are more efficient solubilizers mole for mole than polysorbates, *i.e.*, DTAB and KL are better than polysorbate 20 and HTAB better than polysorbate 60. The anionic KL has the greatest solubilizing capacity of all. Not only is KL more efficient than DTAB and polysorbate 20, but also it is a better solubilizer than HTAB, which is a molecule with a longer lipophilic moiety.

An explanation of the greater efficiency of the fatty acid soap, KL, than that of the quaternary ammonium bromides may lie in the fundamental difference between micelles of the two ionic types. The ions of anionic micelles bear their charges on the exposed oxygen atoms of their polar head groups, the carboxylate groups. For a molecule such as testosterone which has polar–nonpolar characteristics, it is conceivable that hydrogen bonding would be one of the factors in solubilization. The hydroxyl group at C-17 in testosterone would be the site for such bonding. The electron-rich oxygen atoms in the carboxylate ions of KL micelles should be good acceptors for hydrogen. The quaternized nitrogen atom in the polar heads of DTAB and HTAB since it has no unshared electrons would be incapable of hydrogen bonding. The trimethylammonium polar groups will, however, be capable of association with testosterone by ion–dipole and van der Waals type of interactions.

It is interesting to take a closer look at the solubilizing capacities of KL, DTAB, and polysorbate 20. These three surfactants have identical lipophilic moieties within their molecules. In an idealized picture of spherical micelles these lipophilic portions may be considered as forming the relatively nonpolar micellar core which should be similar for micelles of KL, DTAB, and polysorbate 20. If the mechanism of solubilization involved association of testosterone with the nonpolar micellar core, then similar solubilizing capacities would be expected for these three surfactants. However, the solubilizing capacities indicate that KL is about twice as efficient as DTAB and about five times as efficient as polysorbate 20. A similar situation exists for HTAB and polysorbate 60 which have identical lipophilic moieties; HTAB is more than three times as efficient as polysorbate 60. From these differences, it seems logical to believe that solubilization of testosterone may not involve penetration into the micellar interior.

The results of this study and of an earlier one by Bjaastad, Hall, and Thakkar (5) point out that for molecules such as testosterone and camphor which possess a partially polar nature, anionic surfactants are more efficient solubilizers than cationic surfactants. This observation is in apparent disagreement with the generalization that cationic surfactants are better solubilizers than anionic surfactants (6, 10). It is important to take into consideration the nature of the solubilizate and the mode of solubilization before making a generalization regarding the relative solubilizing capacities of different surfactant types. For a nonpolar solubilizate which is solubilized in the lipophilic interior of micelles, for example, cationic agents would be more efficient than anionic agents because the micelles of cationic agents have a greater degree of disorder due to the nature of their ionic head groups (11).

If the concentration of surfactant at which the relative solubility of testosterone begins to increase is considered to be the CMC, then it will be seen from Figs. 1, 2, and 3 (where the CMC's shown are reported values, determined in the absence of any solubilizate) that these values are below the literature values. One might postulate that this early increase in solubility probably results from the formation of mixed micelles between testosterone and surfactant molecules at surfactant concentrations below their usual CMC's and a consequent lowering of the CMC in the ternary system. That such an association between testosterone and the surfactants can occur seems plausible in view of the fact that testosterone also possesses surface activity (12, 13). Wurster and Taylor (14) have shown that the steroid prednisolone is also solubilized in solutions of sodium lauryl sulfate below the binary water-surfactant CMC.

Z-Value Determinations—The relationships among the concentration of DTAB, solubility of testosterone, and *Z* value are shown in Fig. 4. Similar plots for HTAB and KL are shown in Figs. 5 and 6.

In case of the cationic surfactants at low concentrations (up to 0.006 *M* for DTAB, 0.008 *M* for HTAB) in which the solubility of testosterone is not

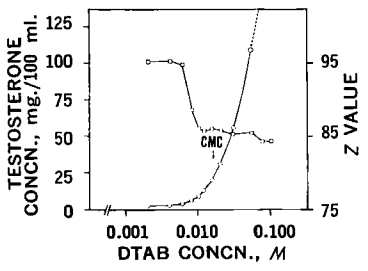

Fig. 4—The relationship between concentration of dodecyltrimethylammonium bromide (logarithm), solubility of testosterone (○), and Z value (□). The CMC indicated is the reported (4) value determined in the absence of any solubilizate.

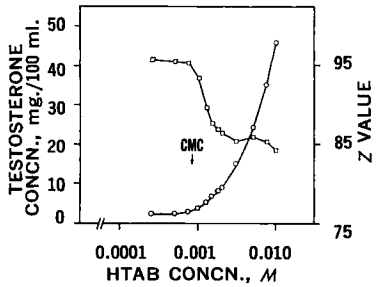

Fig. 5—The relationship between concentration of hexadecyltrimethylammonium bromide (logarithm), solubility of testosterone (○), and Z value (□). The CMC indicated is the reported (4) value determined in the absence of any solubilizate.

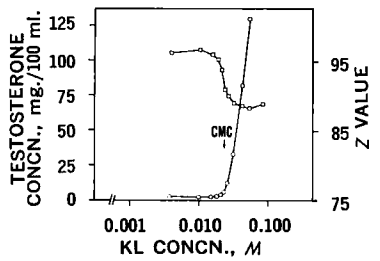

Fig. 6—The relationship between concentration of potassium laurate (logarithm), solubility of testosterone (○), and Z value (□). The CMC indicated is the reported (6) value determined in the absence of any solubilizate.

appreciably greater than in water, the Z value is similar to that in water. However, as the solubility of testosterone begins to increase, the Z value drops sharply over a narrow range of surfactant concentration. After this sudden drop the Z value appears to attain a plateau. It is interesting to note that the relatively precipitous drop in Z value takes place as the solubility of testosterone begins to increase. The solubility of testosterone increases steadily with increasing surfactant concentration in both DTAB and HTAB solutions. Unlike the situation with the polysorbates (1), the increase in the solubility of testosterone does not parallel the change in Z value.

The anionic surfactant, KL, displays a Z-value behavior similar to the cationic surfactants. A sudden drop in Z value takes place in the region of the reported CMC just as the solubility of testosterone begins to increase. The Z value in low concentrations of KL (0.005 M and 0.01 M) is slightly higher than that in water.

As pointed out earlier (1, 8), the decrease in Z values with increase in surfactant concentration may reflect the increase in concentration and organization of the micelles. That this decrease in Z value takes place at or near the CMC is significant. The rather abrupt formation of micelles would indeed lead to an increased structural organization within the solution.

The relative regions of solubilization in or on the micelle may be deduced by a comparison of the changing Z values in the ionic surfactant solutions and in the nonionic polysorbate solutions (1). Higher Z values are attained with all the three ionic surfactant solutions than with polysorbates. The concentrations of ionic surfactants employed in this investigation are much higher on a molar basis than those of the polysorbates used in the previous investigation. The quantity of testosterone solubilized by ionic surfactants is also greater than that solubilized by the polysorbates and yet the solubilized testosterone is in an environment of higher polarity.

The Z value, when it becomes reasonably constant in more concentrated ionic surfactant solutions, compares with the Z value in methanol–water or ethanol–water mixtures. This indicates that the environment of the carbonyl chromophore of the solubilized testosterone is more polar than methanol or ethanol. In view of this high polarity, it seems logical to believe that the carbonyl chromophore is associated with the polar head groups of the surfactant. In the case of the anionic, KL, for which hydrogen bonding between the ionized carboxylate group and the hydroxyl group at the C-17 of testosterone may be postulated, this would mean that the carbonyl chromophore at C-3 is also associated with this polar region of the micelle. If idealized spherical micelles are considered, then this region would be the micellar surface. Such a simplified picture is not easy to visualize for the cationic agents DTAB and HTAB where hydrogen bonding of the hydroxyl group of testosterone cannot take place with the quaternary ammonium polar head groups. From the available Z-value data it can only be concluded that the carbonyl chromophore is in an environment more polar than methanol–water or ethanol–water mixtures. It is not impossible in case of the cationic surfactants that the nonpolar portion of the testosterone molecule could be associated to some extent with the relatively nonpolar palisade region of the micelles. However, as the high Z values indicate the carbonyl chromophore must remain in the polar environment around the polar head groups.

The observation that solutions of KL provide an environment of higher polarity than do the solutions of DTAB and HTAB is in agreement with the findings of Bjaastad and Hall (8) in the case of solubilized camphor and 2-heptanone. An explanation of this observation could lie in the nature of the polar head groups of KL on the one hand and of DTAB and HTAB on the other.

The surface of the KL micelles would be rich in carboxylate ions, and since these ions arise from a weak acid, some hydrolysis would be expected in an aqueous medium. The resulting removal of protons should contribute to the polarization of the environment of the solubilizate (elevated Z value). Hydrogen bonding, possible with KL but not with DTAB or HTAB, may also alter the polarity of the medium at the polar head groups. Furthermore, the carboxylate ions have their charges exposed for direct interaction with the solubilizate chromophore, while the ionic charge on the nitrogen atom of the quaternary ammonium ions is shielded from close contact with the solubilizate by the presence of methyl group substituents. Thus, it appears that these several factors could result in KL solutions producing a more polar environment for the solubilizates than the quaternary ammonium surfactants.

Interaction of NO_2 with Monolayers of Phospholipids Extracted from *E. coli* at 15 and 37°

By N. D. WEINER, M. AMANAT, D. BLONDO, R. CAPRIOLI, N. DINERMAN, and A. FELMEISTER*

Phospholipids were extracted from *E. coli* grown at 15 and 37°. The fatty acid residues of the 15° phospholipids were found to be considerably more unsaturated than the 37° phospholipids. These phospholipids were spread as monomolecular films and exposed to NO_2-containing atmospheres. Whereas the 37° phospholipid films showed no interaction, NO_2 was found to expand considerably the 15° phospholipid films. The results demonstrate that simple changes in environmental conditions may affect markedly the interaction of air pollutants such as NO_2 with biological membranes.

ISOLATION and characterization of membrane components from a wide variety of organisms indicate that the compositions of the membrane phospholipids differ significantly, not only from organism to organism, but even from tissue to tissue within a single organism (1). The phospholipid composition of the membranes of a number of microorganisms has also been shown to vary considerably with varying growth conditions. For example, Engleman, Terry, and Morowitz (2) point out that the fatty acid residues of the membrane phospholipids of *Mycoplasma laidlawii* are a function of the fatty acids included in the growth medium. Marr and Ingraham (3) demonstrated that the degree of unsaturation of membrane fatty acids of *E. coli* is dependent on growth temperature. These latter workers pointed out that the increase in unsaturation of the fatty acids of *E. coli* grown at lower temperatures is part of an expected adaptive process. The degree of fluidity exhibited at low temperatures by these unsaturated acids compares to that of their saturated counterparts at normal growth temperatures. Thus, the organism is able to maintain the level of membrane transport and other essential processes even at temperatures well below the normal optimum level.

In previous studies of the interaction of air pollutants with monomolecular films, it was noted that NO_2 expanded monolayers of egg lecithin (where 50% of the fatty acid groups contain at least one unsaturated bond), but did not affect monolayers of synthetic dipalmitoyl lecithin. The expansion apparently is the result of a chemical interaction of NO_2 with the double bonds of the unsaturated fatty acid groups of egg lecithin rather than a simple physical penetration into the film (4).

In view of these latter results and Marr and Ingraham's report, it was of interest to determine whether the membrane phospholipids extracted from *E. coli* grown at 15 and 37°, respectively, would exhibit similar differences in their interaction with an air pollutant such as NO_2.

EXPERIMENTAL

All inorganic salts were reagent grade; the glucose was USP quality. All organic solvents were spectrograde and distilled prior to use.

The growth media used for both the 15 and 37° studies consisted of: 3 g. glucose; 2 g. NH_4Cl; 6 g. Na_2HPO_4; 3 g. KH_2PO_4; 3 g. NaCl; 85 mg. $MgCl_2 \cdot 6H_2O$; 115 mg. Na_2SO_4; 1,000 ml. distilled water.

E. coli (ASTM No. 9637) was inoculated into a flask containing 1,000 ml. of media and the flask was incubated at 37° until the absorbance of the mixture at 600 mμ was about 0.5. Five-hundred milliliters of the resultant mixture was then added to each of two flasks containing 950 ml. of media. The flasks were then placed in water baths at 15 and 37°, respectively. Incubation was allowed to proceed, in the presence of continuous aeration, until the absorbance of the mixture at 600 mμ was 0.7–0.8. The time required to reach this absorbance was about 72 hr. for the 15° batch and about 24 hr. for the 37° batch.

The cells were harvested by centrifugation at 5,000 r.p.m. at 4° for 30 min. The lipids were extracted from the bacterial cells by a modification of the procedure of Kanfer and Kennedy (5). The cells were added to flasks containing 300 ml. of chloroform–methanol (2:1, v/v), and the contents were stirred with a magnetic stirrer for 24 hr. The mixture was then filtered through a thick plug of glass wool to remove most of the cellular debris. The filtrate was then washed three times with equal volumes of 2 *M* KCl and once with an equal volume of water. The solvent was then evaporated by the use of a flash evaporator until a viscous slurry was obtained. The slurry was then redissolved in a minimum amount of chloroform–methanol (2:1, v/v).

The resultant yellow solution was fractionated by column chromatography using a modification of the method of Huston and Albro (6). A slurry of 60 g. of silicic acid (Mallinckrodt, 100/200 mesh) in *n*-hexane was packed into a 2 × 40 cm. column, and the flow rate was adjusted to 1.5 ml./min. The column was then washed with 50-ml. portions each of acetone, ethyl ether, *n*-hexane, and chloroform. The sample, contained in 2–3 ml. of solvent, was then added to the column.

The crude hydrocarbon fraction was eluted with 150 ml. of *n*-hexane–benzene (49:1, v/v), and the simple lipids were eluted next with 300 ml. of chloroform. The complex lipids were next removed by eluting with 300 ml. of chloroform–methanol (1:1, v/v), followed by 100 ml. of methanol. This complex lipid fraction was collected in increments of 10 ml. Each of these 10-ml. fractions was tested with ninhydrin reagent, and only the first 10 fractions, *i.e.*, the first 100 ml. of chloroform–methanol (1:1, v/v) eluate, yielded positive ninhydrin tests. The next five fractions, when concentrated by partial evaporation, also yielded positive ninhydrin tests, while all the remaining fractions gave negative tests. It was therefore decided to use the first 150 ml. of the chloroform–methanol (1:1, v/v) eluate as the total phospholipid fraction.

The identification and purity of this phospholipid fraction was determined by a modification of the method of Parker and Peterson (7). Both 15 and 37° fractions were spotted on Eastman Chromogram sheets (Silica Gel G) and developed using the Eastman Chromogram developing apparatus.

The solvent system of Parker and Peterson proved unsatisfactory in that the phospholipids traveled with the solvent front. A modified solvent system of chloroform–methanol–acetic acid–water (65:10:4:2) proved quite satisfactory. The samples were spotted 2.5 cm. from the bottom of the sheet and the solvent front was allowed to rise to within 5 cm. from the top of the sheet. The average running time was 4–5 hr.

The 15 and 37° samples, as well as a sample of bovine phosphatidyl ethanolamine (Applied Science Laboratories), gave single spots with identical R_f values as determined by development with ninhydrin reagent. No other spots were detected upon development with iodine vapors and concentrated sulfuric acid spray.

Qualitative iodine determinations of the 15 and 37° phospholipids demonstrated that the 15° samples were significantly more unsaturated than the 37° samples. This was confirmed by the method described by Weiner, Felmeister, and Amanat (8) where the surface-pressure increase of monolayers of phospholipids spread on an iodine solution subphase over that of an aqueous subphase was used to measure the degree of unsaturation.

A phosphorous determination according to the method of King (9) was performed on both the 15 and 37° solutions. On the basis of the molecular weight of phosphatidyl ethanolamine, it was calculated that the authors' extraction procedure yielded approximately 80 mg. of phospholipid per 10 l. of *E. coli*, grown at both 15 and 37°.

Both the 15 and 37° samples were then spread as monolayers and subjected to standard and NO_2-containing atmospheres by the method previously described by Felmeister *et al.* (4). The gases were metered by individual flowmeters into a glass tube equipped with baffles, which served as a premixing tube. Mixing was completed by passing the gases into a 500-ml. round-bottom flask. The gas mixtures were then led through a 0.9-m. length of glass tubing connected to a short length of Teflon tubing. The latter was affixed to the underside of the Lucite trough cover which served to maintain the desired gaseous atmosphere over the film. The Teflon tubing within this enclosure was formed into a loop, and a series of small perforations was made in the wall of the tubing. The shape of the loop and the positions of the perforations gave a uniform flow of the gases over the film surface.

The gas mixtures were permitted to flow through the system for at least 4 hr. before the start of each experiment to ensure steady-state conditions.

A Film Balance (Frater Instrument Co., Corona, N. Y.) was used to study the surface pressure-surface area (π-A) characteristics of the films. The balance consists of a Teflon-coated removable trough, totally free of metal contacts. Two variable-speed reinforced rigid Teflon stirrers are set into the trough to facilitate subphase mixing and temperature control. The temperature of the subphase was maintained at 25 ± 0.1° by circulating water from a constant-temperature bath through the water jacket around the trough. The precision lead screw, which drives the reinforced Teflon barrier, allows for changes in surface area of the

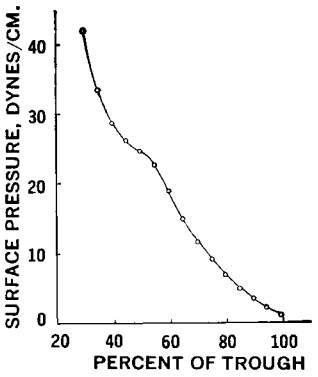

Fig. 1—π-A curve of 37° phospholipid exposed to standard atmosphere (air) and to NO_2-containing test atmosphere.

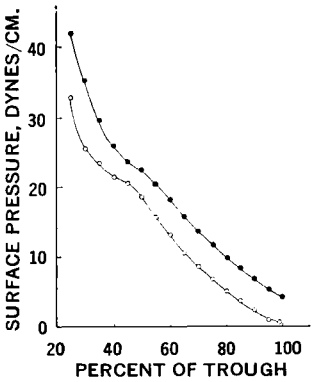

Fig. 2—π-A curves of 15° phospholipid exposed to standard atmosphere (air) (○); and to NO_2-containing test atmosphere (●).

trough as small as 0.0125 cm.^{2}. A quick disengage mechanism permits rapid sweeping of the film for cleaning the surface. The film balance was enclosed in a dust-protective cabinet.

Surface pressures were measured by the Wilhelmy plate method. A thin platinum plate, roughened to ensure complete wetting, was used.

Both the 15 and 37° samples were spread as monolayers from 1:1, v/v, methanol–chloroform solvent mixtures. It was found that when 0.05 ml. of solution was spread onto a subphase containing 0.9% roasted sodium chloride in double-distilled water, a surface pressure of about 1 dyne/cm. was observed, in the case of both the 15 and 37° samples.

These films were studied while exposed to a standard atmosphere (air flowing at the rate of 300 ml./min.) and to a test atmosphere (0.33% nitrogen dioxide in air) flowing at this same rate of 300 ml./min.

In all cases, the films were permitted to stand with the gases flowing for 1 hr. before manual compression of the film was initiated. Surface-pressure readings were then obtained at various film areas.

RESULTS AND DISCUSSION

The surface pressure-surface area (π-A) curve for the 37° phospholipid film exposed to the standard atmosphere is shown in Fig. 1. Exposure of the 37° phospholipid film to the NO_2-containing test atmosphere yielded a π-A curve identical to that of the standard (within ±0.4 dyne/cm. at all areas), indicating no film–NO_2 interaction. Figure 2 shows the π-A curves for the 15° phospholipid films exposed to the standard and test atmospheres. Exposure of 15° phospholipid films to the NO_2 test atmosphere resulted in a π-A curve that was considerably more expanded than that of the standard curve. This interaction, once it occurred, could not be reversed by replacing the NO_2 test atmosphere with the standard atmosphere.

It should be noted that all the curves in Figs. 1 and 2 show a shoulder at π values of about 20–25 dynes/cm. This effect was apparent only at very slow compression rates. Van Deenen *et al.* (10) also reported a shoulder for a synthetic phosphatidyl serine layered on a pH 4 subsolution.

It appears that the 15 and 37° materials differ from one another primarily in the degree of unsaturation of their fatty acid groups. The observed effect of NO_2 on the 15° phospholipid film is most probably the result of the interaction of NO_2 with the double bonds of the unsaturated fatty acid groups.

The results demonstrate that simple changes in environmental conditions may affect markedly the interaction of air pollutants, such as NO_2, with membranes. *In vivo* work now in progress in these laboratories on the effect of NO_2 on *E. coli* grown at different temperatures should serve to determine the relevance of this phenomenon to living systems.

Evaluation, Control, and Prediction of Drug Diffusion Through Polymeric Membranes III

Diffusion of Barbiturates, Phenylalkylamines, Dextromethorphan, Progesterone, and Other Drugs

By EDWARD R. GARRETT and PRAMOD B. CHEMBURKAR

Silastic membrane demonstrated the greatest permeability among the nine polymeric films studied. The apparent diffusion constants through silastic membrane were determined by steady-state studies for a series of barbiturates and phenylalkylamines and correlated with the determined chloroform/acetate buffer partition coefficients in the former case. The apparent diffusion constants did not correlate with the determined solubilities of the barbiturate series in the diffusing solvent since the solubilities within the membrane have to be considered. Only the uncharged species diffuse through the polymeric membrane and half of the maximal diffusion rate occurs at the pKa′. Diffusion rates were proportional to concentrations in all cases up to the solubility of the diffusing species and Fick's law was fully applicable. Diffusion rates can be varied by changing the diffusing and desorbing solvents and membrane thickness and area. Solvent variation (*e.g.*, water, mineral oil, peanut oil, alcohol) affects the apparent diffusion coefficients of dextromethorphan and progesterone. The rates of diffusion of the studied compounds decrease with their increasing solubility in the diffusing solvent which can be assigned to the preferential partitioning in the solvent rather than the membrane. Diffusion from capsules repeats the rates and is dependent on the same factors as diffusion through films. Solid particles in contact with silastic membrane dissolve in and are transported through the membrane. Release rates from the membrane into surrounding solvents should depend on whether these dissolution rates were of higher or lower orders of magnitude than diffusion through the membrane.

THE APPLICABILITY of Fick's law to the transfer of uncharged drugs through polymeric membranes has been substantiated with respect to aminophenones (1, 2). The apparent rates of diffusion, dA/dt, through a typical solid polymeric membrane, the silicone silastic, have been shown to be proportional to the concentration of the uncharged drug concentration in the diffusing solution, C_2, and inversely proportional to the thickness, X, of the membrane in accordance with the steady- and quasi-steady-state expression of Fick's law,

$$dA/dt = V_1 dC_1/dt = D'S(K_2 f_2 C_2 - K_1 f_1 C_1)/X \quad \text{(Eq. 1)}$$

where C_2 and C_1 are the concentrations of the drug in volumes V_2 and V_1 of diffusing and desorbing solutions, respectively; where f_2 and f_1 are the fractions of the drug concentrations, C_2 and C_1, that are uncharged, respectively; where K_2 and K_1 are the respective partition coefficients for the uncharged species between the membrane and solvents; and where S is the area and D' the intrinsic diffusion constant within the membrane. In general the concentration C_1 of the V_1 volume of desorbing solution was monitored as a function of time.

The silastic membranes are impermeable to HCl, phosphate buffer salts, and protonated aminophenones (1, 2). The apparent diffusion constants $D = D'K$ of various aminophenones through silastic membrane from and to equivalent solvents, *i.e.*, $K_1 = K_2 = K$, where, from Eq. 1,

$$dA/dt = V_1 dC_1/dt = D'KS(f_2 C_2 - f_1 C_1)/X \quad \text{(Eq. 2)}$$

appear to be proportional to chloroform/water partition coefficients. The apparent diffusion constants, $D = D'K$, for 4′-aminopropiophenone from and to solvents of the same composition (or when $f_1 = 0$) were inversely proportional to the solubility of the 4′-aminopropiophenone in the diffusing solution.

The purposes of this investigation were to screen various polymeric films for their permeability to various drugs and to investigate in detail the diffusion of barbituric acid derivatives, phenylalkylamine, dextromethorphan, and progesterone through silastic membrane and potential dosage forms based on this principal. The effects of temperature, pH, and variation of diffusing and desorbing solvents were determined. The relations between the apparent

diffusion constants with solubilities and oil/water partition coefficients were also investigated.

EXPERIMENTAL

Chemicals—The following compounds were supplied by Abbott Laboratories, North Chicago, Ill. The molar absorptivities, ϵ, are given for the designated wavelengths at which the absorbances were measured: amobarbital, $C_{11}H_{18}N_2O_3$, eq. wt. 226, 236 found, ϵ = 6,520 (238 mμ), pKa′ 7.40; barbital, $C_8H_{12}N_2O_3$, eq. wt. 184, 197 found, ϵ = 10,310 (238 mμ), pKa′ 7.45 [lit. value 7.91 (3)]; butabarbital, $C_{10}H_{16}N_2O_3$, eq. wt. 212, 215 found, ϵ = 10,410 (238 mμ); cyclobarbital, $C_{12}H_{16}N_2O_3$, eq. wt. 236, 245 found, ϵ = 9,880 (238 mμ), pKa′ 7.27 [lit. value 7.50 (3)]; diallylbarbituric acid, $C_{10}H_{12}N_2O_3$, eq. wt. 208, 202 found, ϵ = 9,690 (238 mμ), pKa′ 7.30 [lit. value 7.79 (3)]; mephobarbital, $C_{13}H_{14}N_2O_3$, eq. wt. 246, 250 found, ϵ = 5,730 (238 mμ), pKa′ 7.45; metharbital, $C_9H_{14}N_2O_3$, eq. wt. 198, 198 found, ϵ = 6,540 (238 mμ), pKa′ 7.90; pentobarbital, $C_{11}H_{18}N_2O_3$, eq. wt. 226, 232 found, ϵ = 11,070 (238 mμ), pKa′ 7.65 [lit. value 8.11 (3)]; phenobarbital, $C_{12}H_{12}N_2O_3$, eq. wt. 232, 257 found, ϵ = 10,880 (238 mμ), pKa′ 7.40 [lit. value 7.41 (3)]; secobarbital, $C_{12}H_{18}N_2O_3$, eq. wt. 238, 230 found, ϵ = 9,860 (238 mμ), pKa′ 7.45 [lit. value 8.08 (3)]; thiamylal, $C_{12}H_{17}N_2O_2S$, eq. wt. 254, 290 found, ϵ = 18,660 (304 mμ), pKa′ 6.80; thiopental, $C_{11}H_{18}N_2O_2S$, eq. wt. 242, 246 found, ϵ = 12,100 (304 mμ), pKa′ 7.12.

The following compounds were supplied by Smith Kline & French Laboratories, Philadelphia, Pa.: α-methylphenethylamine hydrochloride, $C_9H_{13}N \cdot HCl$, eq. wt. 172, 165 found, pKa′ 9.07; α-ethylphenethylamine hydrochloride, $C_{10}H_{15}N \cdot HCl$, eq. wt. 186, 203 found; 2-amino-4-methyl-4-phenylpentane hydrochloride, $C_{12}H_{19}N \cdot HCl$, eq. wt. 214, 205 found, pKa′ 9.42; 3-amino-1-phenylbutane sulfate, $(C_{10}H_{15}N)_4 \cdot H_2SO_4$, eq. wt. 198, 242 found, pKa′ 9.30; 1-methyl-5-phenylpentylamine hydrochloride, $C_{12}H_{19}N \cdot HCl$.

The following compounds were supplied by the Upjohn Company, Kalamazoo, Mich. The molar absorptivities, ϵ, are given for the designated wavelengths at which the absorbances were measured: progesterone, ϵ = 16,470 (248 mμ), m.p. 128–130° [lit. value 127–131° (4)]; cortisone, ϵ = 16,000 (238 mμ), m.p. 230–236° [lit. value 236–240° (4)]; hydrocortisone, ϵ = 16,200 (242 mμ), m.p. 217–220° [lit. value 217–220° (4)]; prednisolone, ϵ = 15,200 (242 mμ), m.p. 239–240° [lit. value 240–241° (4)].

Dextromethorphan, pKa′ 8.25, ϵ = 3,002 (277 mμ) was supplied by Vick Divisions Research and Development, Richardson-Merrell Inc., Mt. Vernon, N. Y.

The following compounds were purchased from National Biochemical Corp., Cleveland, Ohio: sulfathiazole, m.p. 200–203° [lit. value 200–204° (4)]; sulfisoxazole, m.p. 195–198° [lit. value 194° (4)]; sulfadiazine, ϵ = 5,370 in alkaline solution (255 mμ), m.p. 256–257° [lit. value 252–256° (4)]; sulfabenzamide, ϵ = 4,480 in alkaline solution (255 mμ), m.p. 181–183° [lit. value 181.2–183.3° (4)].

The peanut and mineral oil used were USP. All other reagents were of analytical grade. The 4′-aminopropiophenone used has been discussed previously (2).

Polymer films tested were an 11-aminoundecanoic acid polymer[1] (5), a polyamide[2] (6), cellulose acetate,[3] cellulose triacetate,[4] and cellulose acetate butyrate,[5] thermoplastic cellulosic films (7), polyethylene type B (8), and polyethylene terephthalate.[6] Polypropylene (10) was supplied by the Avisun Corp., Philadelphia, Pa.; silastic medical grade sheeting H-0169, HO 293 is a dimethylsiloxane polymer (11) and was supplied by the Dow Corning Center for Aid to Medical Research.

Analytical Methods—Spectrophotometric measurement of absorbances at 24.0 ± 1.0° was used for the quantitative estimation of barbituric acid derivatives, steroids, and dextromethorphan in a Beckman model DU spectrophotometer using 10-mm. cells and 0.1 slit width at the wavelengths stated above. The linear relationship between absorbance and concentration was verified in all cases. The barbituric acids were measured in pH 10.1 borate buffer as the molar absorptivities are much higher than in the uncharged form. The absorbances of dextromethorphan and steroids were measured in pH 6.8 phosphate buffer solutions. The solutions of the sulfonamides were made alkaline with NaOH solution. A Cary recording spectrophotometer model 14 was used in screening.

The phenylalkylamines were analyzed by a modification of the method of Gettler and Sunshine (12). A 1.00-ml. aliquot of 1.5–10 × 10^{-5} *M* solution in pH 6.8 phosphate buffer was made alkaline with 0.1 ml. of 2 *N* NaOH, 5.00 ml. of chloroform added, and the mixture agitated. After centrifugation at 3,200 r.p.m. for 3 min., 4.00 ml. of the chloroform solution was removed and 0.20 ml. of freshly prepared methyl orange reagent (1:1 saturated solution of methyl orange and boric acid) was added to this sample. The mixture was again centrifuged, 3.00 ml. of the chloroform solution was removed, and 0.20 ml. of absolute ethanol containing 2% concentrated sulfuric acid was added to this sample. The absorbance of this solution was read at 520 mμ on a Beckman DU spectrophotometer against a phosphate blank prepared similarly. Calibration curves were prepared daily.

The cited pKa′ values were obtained by potentiometric titration at 24.0 ± 1.0° on a Sargent model D automatic titrator and standardized at pH 4.0, 7.0, and 10.0 and are accurate to ±0.05 pH unit. The difference method of Parke and Davis (13) was used and the pKa′ determined from the half-neutralization value of the difference between the titers of equivalent volumes of sample solution and blank necessary to give the same measured pH value. Alkaline solutions of the barbiturates were titrated with standard $HClO_4$; the acid solutions of the phenylalkylamines and dextromethorphan were titrated with standard NaOH.

Solubility Studies—Saturated solutions of the barbituric acid derivatives in pH 4.7 acetate buffer, ionic strength 0.1, were prepared at 50° and equilibrated at 25° for 48 hr. in a thermostated shaker bath in the presence of excess solids. The solutions were then filtered by suction through electrode isolation tubes, which are fitted with a finely porous fritted-glass membrane (E. H. Sargent and Company, Chicago, Ill.). Aliquots of the filtered solutions were appropriately diluted with pH 10.1 borate buffer and the absorbances measured at the pertinent wavelengths.

Partition Coefficients—Aqueous pH 4.7 acetate buffer and chloroform were saturated with respect to each other. An approximately 5×10^{-4} *M* solution of the barbituric acid derivatives was prepared in the acetate buffer presaturated with chloroform. One milliliter of this solution was appropriately diluted, generally with 10 ml. of pH 10.1 borate buffer, and its absorbance measured at the pertinent wavelength against a blank treated similarly. Five milliliters of the acetate solution and 5.0 ml. of the chloroform presaturated with aqueous acetate buffer in a capped, stoppered vial were mixed on a Vortex Junior mixer for 3 min., centrifuged for 3 min. at 3,200 r.p.m., and 1.00 ml. of the aqueous phase was removed, diluted with 10 ml. of pH 10.1 borate buffer, and spectrophotometrically analyzed against an acetate buffer blank treated similarly. The ratio of the differences in absorbances of the aqueous layer before and after partitioning to the absorbance of the aqueous layer after partitioning was taken as the partition coefficient of the drug in the $CHCl_3$–acetate buffer system.

Screening of Polymer Films for Permeability to Drugs—The cited polymer films in 3 and 5 mil thicknesses were washed with distilled water and dried. Saturated solutions of the cited materials in 0.1 *N* HCl, 0.1 *N* NaOH, pH 6.8 phosphate buffer, propylene glycol, peanut oil, ethanol, mineral oil, ethylene glycol, and polyethylene glycol 200 were prepared. Two milliliters of each saturated solution was put into a serum vial (10-ml. capacity) and the vial stoppered with a holed rubber stopper. A small piece of each membrane was laid upon the stopper and an aluminum cap was then crimped to sandwich the membrane. The serum vial was then inverted and placed into a 60-g. ointment jar containing about 10 ml. of pH 6.8 phosphate buffer. The jars were capped, properly labeled, and set aside for at least 1 week, when the phosphate buffer solutions were analyzed for drug by the methods described. A drug was said to have permeated through a membrane when the peaks at wavelengths corresponding to the $\lambda_{max.}$ values of the drug were observed on the Cary model 15. Experiments with positive results were repeated to avoid erroneous conclusions from leaking vials.

Diffusion Studies—The steady-state diffusions of the barbituric acid derivatives were studied through 3-mil silastic membrane from their solutions in pH 4.7 acetate buffer into pH 10.1 borate buffer at 25 and 37.5°.

Weighed amounts of barbituric acid derivatives were dissolved in small volumes of 1 *N* NaOH and immediately diluted with pH 4.7 acetate buffer solution to 2 l. to obtain solutions which were approximately 5×10^{-3} *M* in barbituric acid derivatives. These were used as reservoir solutions and circulated through the steady-state diffusion cells fitted with 3-mil silastic membranes. The system has been described previously (1). The solutions used on the desorption side of the membrane in the beakers were 200 ml. of pH 10.1 borate buffer. Absorbances of samples were measured as a function of time on the Beckman DU spectrophotometer and the samples were returned to the beakers.

The steady-state diffusion of barbital and pentobarbital through 3-mil silastic membrane from their solutions in acetate, phosphate, and borate buffer solutions of different pH values at 37.5° was also studied.

The steady-state diffusion of the phenylalkylamine salts from borate buffers through 3-mil silastic membrane into 120 ml. of pH 6.8 phosphate buffer was studied at 25°. Samples of the phosphate buffer solutions (1 ml.) were removed every 15 min. and stored in a refrigerator. All the samples were analyzed simultaneously with the standard solutions used to prepare the calibration curve.

The steady-state diffusions of dextromethorphan from peanut oil, mineral oil, and pH 10.1 borate buffer; and progesterone from peanut oil, and a saturated solution in phosphate buffer were studied through 3-mil silastic membrane into pH 6.8 phosphate buffer at 37.5°.

The diffusion of dextromethorphan was also studied from its saturated solutions in peanut oil and mineral oil. The concentration of dextromethorphan in peanut oil was determined by diluting a weighed amount of the filtered solution with chloroform and measuring the absorbance of the solution at 277 mμ against a chloroform blank containing an equivalent amount of peanut oil where the absorbance of a similar solution of a known weight of the drug had been determined. The saturated solution of the dextromethorphan in the mineral oil was filtered and its absorbance was measured against a mineral oil blank. The concentration was calculated from the previously determined absorptivity. The steady-state diffusion apparatus used has been described previously (1).

Silastic capsules (Dow Corning Center for Aid to Medical Research) were small silastic pouches prepared by sealing pieces of tubes (about 6 mm. in diameter and about 2.4 cm. in length) at both ends. These were cleaned externally with water and air dried.

Saturated solutions of 4′-aminopropiophenone in phosphate buffer, solutions of barbital, pentobarbital, and phenobarbital in acetate buffer, and solutions of dextromethorphan in borate buffer, peanut oil, and mineral oil were prepared. The silastic capsules were cut open at one corner and were filled with these saturated solutions. The hole in each of the capsules was sealed by forcing a portion of silastic medical grade adhesive type A (Dow Corning Center for Aid to Medical Research) into and around the hole. The capsules were set aside for 1 day and were tested for leaks by pressing them lightly between fingers. Similarly, capsules containing solvents without drugs were also prepared.

The capsules containing barbital, pentobarbital, and phenobarbital were washed with water and put into 50 ml. of pH 10.1 borate buffer in glass vials. These vials were preequilibrated at 37.5° for about 10 hr. Similarly capsules of 4′-aminopropiophenone and dextromethorphan were put in glass vials containing 50 ml. of 0.12 *N* HCl and pH 6.8 phosphate buffer, respectively. The samples from the vials were assayed spectrophotometrically for the respective compounds.

Diffusion of Solid Progesterone Through Silastic Membrane—One window of the stainless steel steady-state diffusion cell was used. One membrane was placed face down and the available area was covered with powdered, dry progesterone. Another membrane was placed atop and the resultant sandwich was stretched tautly while it was clamped into the window. The cell was immersed in 120 ml. of normal saline and vibrated in the shaker bath at 37.5°. Samples of the solution were removed at intervals and significant absorbance due to progesterone, $\lambda_{max.}$ 248 mμ, was observed on the Cary ultraviolet recording spectrophotometer.

RESULTS

Screening of Polymer Films for Permeability—The spectrophotometric curves of the desorbing solutions were checked for the peaks characterizing the compounds whose diffusion was under test. This method of analysis was sensitive to 10^{-4} *M* concentration in all cases and much more sensitive in the case of steroids. When no drug in the desorbing solution was observed at these sensitivities, the membrane is stated to be impermeable to that drug.

Polyethylene membrane was permeable to 4′-aminoacetophenone in aqueous solutions and in peanut oil and to 4′-aminopropiophenone in ethylene glycol. Both compounds permeated an 11-aminoundecanoic acid polymer membrane[1], from ethanolic solutions. A polymide membrane[2] was permeated by 4′-aminopropiophenone and 3′-aminoacetophenone from 0.1 *N* NaOH and ethanol. Polypropylene was nonpermeable to all the drugs tested.

Substances were leached by phosphate buffer from cellulose triacetate and cellulose butyrate membranes that interfered with the spectrophotometric analyses of the drugs. After compensation for the absorbances of these interfering substances, it was concluded that 4′-aminopropiophenone permeated cellulose triacetate from propylene glycol, ethanol, and polyethylene glycol 200. Positive results were recorded also for barbital in polyethylene glycol 200 and sulfabenzamide in ethanol. Polyethylene terephthalate polyester film[6] was available only in small quantity and was impermeable to all the drugs tested with the available films.

Silastic membrane was permeable to 4′-aminopropiophenone and 3′-aminoacetophenone from all the solvents tested except mineral oil, to progesterone from ethanol, to barbital from ethanol and ethylene glycol, and to phenobarbital from peanut oil, ethanol, polyethylene glycol 200, phosphate buffer, and 0.1 *N* HCl. Silastic membrane allowed permeation of the majority of the compounds screened in measurable quantities and was investigated in further detail.

Steady-State Diffusion Studies—The steady-state diffusion of drugs through silastic membranes was studied with the equipment and by the techniques previously described in detail (1, 2). The concentration, C_2, of the diffusing solution was held constant as was the volume, V_1, of the desorbing solution. The linear slopes, dC_1/dt, of the increase of concentration, C_1, of the desorbing solution with time were determined. The concentrations, f_1C_1, of the uncharged species in the desorbing solution were kept at zero by choosing a pH where the fraction of the drug uncharged, f_1, was effectively zero.

The specific rate of diffusion was obtained by dividing this slope, the rate of increase of total concentration, C_1, of the desorbing solution by the concentration, f_2C_2, of the uncharged species in the diffusing solution. When the slope was obtained from the linear increase in absorbance, A_1, of the desorbing solution with time, this slope, dA_1/dt, was divided by the product of the absorbance, A_2, of the diffusing solution and the fraction, f_2, of the drug uncharged therein since

$$R_S = \text{specific rate of diffusion} = (dA_1/dt)/f_2A_2 = [d(\epsilon C_1)/dt]/f_2\epsilon C_2 = (dC_1/dt)/f_2C_2 \quad \text{(Eq. 3)}$$

Typical plots of the increase of absorbance or concentration with time in the desorbing solutions after diffusion through 3-mil silastic membrane are given in Figs. 1 and 2 for various barbituric

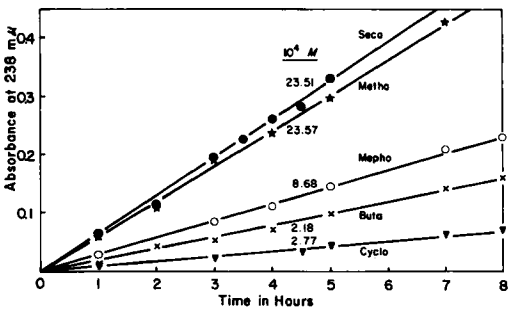

Fig. 1—Absorbance at 238 mμ of 200 ml. of pH 10.1 borate buffer desorbing solution as a function of time on the steady-state diffusion of the stated concentrations of the cited barbitals from pH 4.7 acetate buffer through 3-mil silastic membrane at 37.3°.

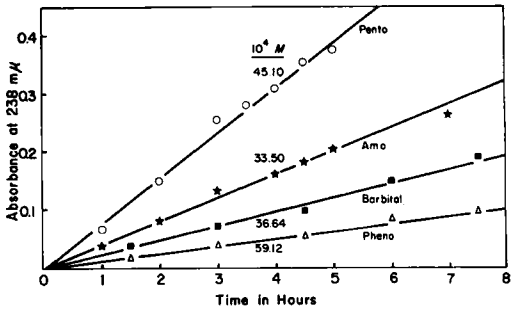

Fig. 2—Absorbance of 238 mμ of 200 ml. of pH 10.1 borate buffer desorbing solution as a function of time on the steady-state diffusion of the stated concentrations of the cited barbitals from pH 4.7 acetate buffer through 3-mil silastic membrane at 37.3°.

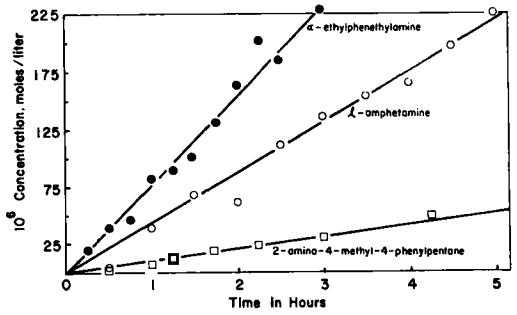

Fig. 3—Concentration of pH 6.8 phosphate buffer desorbing solution as a function of time on the steady-state diffusion of several phenylalkylamines from borate buffer adjusted to the pH corresponding to their pKa' values through 3-mil silastic membrane at 25°. (See Table I.)

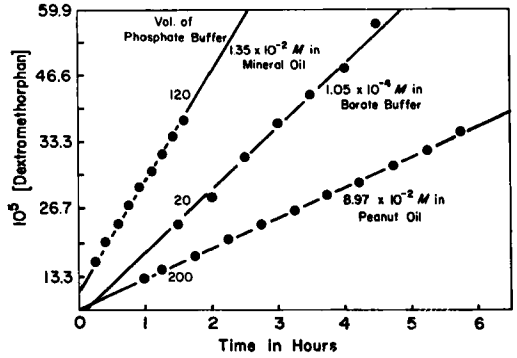

Fig. 4—Concentration of 6.8 phosphate buffer desorbing solution of the stated volumes as a function of time on the steady-state diffusion of dextromethorphan at the cited concentrations from different solutions through 3-mil silastic membrane at 37.5°. The pH of the diffusing solution borate buffer was 10.1.

acid derivatives diffusing from pH 4.7 acetate buffer, where they are unionized, $f_2 = 1$, to pH 10.1 borate buffer where they are ionized, $f_1 = 0$. Typical plots of the diffusion of phenylalkylamines from their partially nonprotonated forms in borate buffers into pH 6.8 phosphate buffers where they are charged, $f_1 = 0$, are given in Fig. 3. Typical plots of the diffusion of dextromethorphan diffusing in its nonprotonated form, $f_2 = 1$, from mineral oil, peanut oil, and pH 10.1 borate buffer into pH 6.8 phosphate buffer, where it would be completely protonated, $f_1 = 0$, are given in Fig. 4.

The apparent diffusion constant, D, was calculated from the rearrangement of Eq. 2 and the determined specific rate of diffusion, $(dC_1/dt)/f_2C_2$ or $(dA_1/dt)/f_2A_2$ as defined in Eq. 3 where $f_1 = 0$,

$$D = XV_1(dC_1/dt)/f_2C_2S \qquad \text{(Eq. 4)}$$

where $X = 7.52 \times 10^{-3}$ cm. for the 3-mil thick silastic membrane, $S = 10.4$ cm.^{2} for the area of the membrane, and V_1 was the maintained volume in liters of the desorbing solution. The fractions of molecules uncharged in the diffusing and desorbing solutions were effectively $f_2 = 1$ and $f_1 = 0$, respectively, for the barbiturates and dextromethorphan. The fraction, f_2, of the phenylalkylamines that were uncharged in the borate buffer diffusing solutions were calculated from the pKa' values of the compounds and the pH values of the borate buffers in accordance with (1),

$$f_2 = [H^+]/([H^+] + K_a) = 10^{-pH}/(10^{-pH} + 10^{-pKa'}) \qquad \text{(Eq. 5)}$$

The concentrations of uncharged phenylalkylamines in the diffusing solutions, their pKa' and pH values, and the observed specific rates of diffusion and apparent diffusion constants are given in Table I.

The determined apparent diffusion constants, solubilities, and partition coefficients for the various barbituric acids are given in Table II. The apparent energies of diffusion, ΔE_a, are calculated from the apparent diffusion constants at the two temperatures studied by

$$\Delta E_a(\text{kcal./mole}) = \frac{10^{-3}(\log D_{37^\circ} - \log D_{24^\circ})2.303R}{(1/T_{24^\circ} - 1/T_{37^\circ})} \qquad \text{(Eq. 6)}$$

where T is the absolute temperature and R is 1.987 cal./degree/mole.

The determined apparent diffusion constants for dextromethorphan from various diffusing solvents are given in Table III.

Further verification of the fact that only nonionized materials diffuse through silastic membranes (1) was obtained from the variation of the apparent diffusion constant, D, on steady-state diffusion into pH 10.1 borate buffer with pH of the diffusing solution on the assumption that $f_2 = 1$ in Eq. 4 (Table IV). The plots of these apparent diffusion constants against pH are shown in Fig. 5. The pKa' values may be considered as the pH values at half the maximum diffusion constant and where dD/dpH is a maximum. These pKa' values for barbital and pentobarbital are 7.50 and 7.72,

TABLE I—APPARENT DIFFUSION CONSTANTS,[a] D, AND SPECIFIC RATES OF DIFFUSION,[b] R_s, OF PHENYLALKYLAMINES THROUGH 3-MIL SILASTIC MEMBRANE AT 25.0° FROM BORATE BUFFER SOLUTIONS INTO pH 6.8 PHOSPHATE BUFFER

Compd.	pKa'	pH	C_2 10^3 M	f_2C_2[c] 10^3 M	R_s[b] 10^2 hr.$^{-1}$	D[a] 10^{10} l./cm.-sec.
α-Methylphenethylamine	9.07	8.93	3.18	1.55	2.84	6.84
3-Amino-1-phenylbutane	9.30	9.40	2.47	1.647	5.00	12.05

[a] Rate of increase per hour of concentration, C_1, of 200 ml. of desorbing solution, pH 10.1 borate buffer, divided by the concentration, C_2, of the diffusing solution of 4.7 pH acetate buffer. This was actually determined from the linear slopes, dA_1/dt, of the plots of absorbance A_1 of the desorbing solution at the wavelengths specified in *Experimental* against time, t, in hours which were divided by the maintained absorbance A_2 of the diffusing solution since $(dA_1/dt)/A_2 = [d(\epsilon C_1)/dt]/\epsilon C_2 = (dC_1/dt)/C_2$ in hr.$^{-1}$. [b] Apparent diffusion constant for the specified barbituric acid derived from steady-state diffusion studies from pH 4.7 acetate buffer diffusing solutions of constant concentrations, C_2 through silastic membrane of thickness $X = 7.52 \times 10^{-3}$ cm. or 3.0 mil and available surface area $S = 10.4$ cm.^{2} into a desorbing pH 10.1 borate buffer solution of volume $V_1 = 0.200$ l. so that D (l./cm. − sec.) = $[(dC_1/dt)/C_2]\ (XV_1)/3600\ S$, where $(dC_1/dt)/C_2$ is given in hr.$^{-1}$. [c] Calculated from $\Delta E_a = [10^{-3}\ (\log D_{37^\circ} - \log D_{24^\circ})\ 2.303R/(1/T_{24^\circ} - 1/T_{37^\circ})]$, where T is the absolute temperature. [d] In pH 4.7 acetate buffer at 25.0°. [e] Parenthetical values are from the literature (14). The acetate buffer was at pH 4.7. [f] These values have large error since the absorbance readings in the acetate buffer were small.

TABLE III—APPARENT DIFFUSION CONSTANTS,[a] D, AND RATES OF DIFFUSION,[b] R, OF DEXTROMETHORPHAN FROM PEANUT OIL, MINERAL OIL, AND pH 10.1 BORATE BUFFER THROUGH 3-MIL SILASTIC MEMBRANE INTO pH 6.8 PHOSPHATE BUFFER AT 37.5°

Dextromethorphan Solution in	Peanut Oil		Mineral Oil	Borate Buffer
	Subsaturated	Saturated	Saturated	Saturated
C_2, 10^2 M	8.97	32.90	1.35	0.0105
R[b], 10^4 M l./hr.	0.6062	2.76	2.10	1.31
V_1, ml.	200	120	120	20
D[a], 10^{11} l./cm.-sec.	2.72	2.02	37.5	501.0

[a] Calculated from $D = XV_1(dC_1/dt)/3600\ f_2C_2S$ since $f_2 = 1$ and $f_1 = 0$, where $S = 7.52 \times 10^{-3}$ cm. and $S = 10.4$ cm.^{2}, where $(dC_1/dt)/f_2C_2$ is in hr.$^{-1}$ and V_1 is the maintained volume of the desorbing solution in liters, and C_1 and C_2 are the total concentrations of the desorbing and diffusing solutions, respectively. [b] dC_1/dt is the linear slope of total concentration in the phosphate buffer solution against time in hours.

respectively, whereas the values from titration were 7.45 and 7.65.

Quasi-Steady-State Diffusion Studies—When nondissociable or nonprotonable compounds such as progesterone are diffused through silastic membrane, there is no way of using buffers to effectively maintain the concentration of the diffusing species as zero in the desorbing solution, *i.e.*, $f_1 = 0$, in the manner that was possible with the previously cited amines and acids. When the same system was used to study the diffusion of progesterone, Eq. 2 is valid where C_2 is maintained constant but C_1 varies with time as $f_2 = f_1 = 1$. Plots of concentration, C_1, of desorbing solution of constant volume, V_1, show decreasing rates of increase with time and approach an asymptotic value as shown in Fig. 6 and the pertinent information is given in Table V.

Diffusion of Drugs from Silastic Capsules—The average area of the silastic membrane in the formulated capsules was 5.58 cm.^{2} with an average membrane thickness of 3.13×10^{-2} cm. However, in this preliminary formulation, the possibilities that some of the silastic adhesive spread over various areas of the capsule modified the thickness and that the capsules were not completely filled must be realized. The observed apparent diffusion constants for various drugs in various solutions from these formulated silastic capsules, on the assumption that the stated available area and thickness are valid, are given in Table VI and compared to those values obtained under the more controlled conditions in all diffusion studies. The comparisons are of the same order of magnitude. When the apparent diffusion constants are related to that of barbital as unity for each method, the

TABLE IV—APPARENT DIFFUSION CONSTANTS,[a] D, OF BARBITAL AND PENTOBARBITAL THROUGH 3.0-MIL SILASTIC MEMBRANE AT 37.3° AS A FUNCTION OF pH

pH	Barbital, D, 10^{13} l./cm.-sec.	pH	Pentobarbital, D, 10^{11} l./cm.-sec.

9.75	2.95	9.05	0.50
10.55	0.65	9.53	0.57

[a] Calculated from $D = XV_1(dC_1/dt)/C_2S$ since $f_1 = 0$, where $X = 7.52 \times 10^{-3}$ cm. and $S = 10.4$ cm.^{2} where V_1 is the maintained volume of the desorbing solution in liters, C_2 is the total concentration of the diffusing solution, and dC_1/dt is the linear slope of total concentration in the desorbing pH 10.1 borate buffer solution against time in seconds.

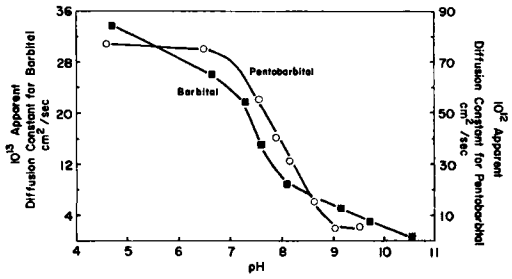

Fig. 5—Apparent diffusion constants of barbital and pentobarbital through 3-mil silastic membranes at 37.3° as a function of pH where no correction has been made for the concentration of uncharged species.

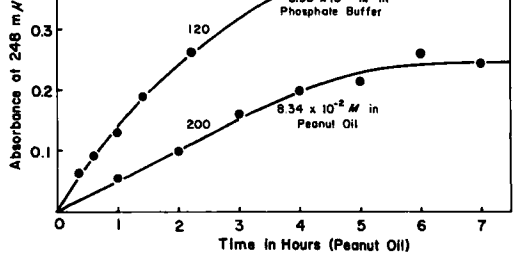

Fig. 6—Absorbance at 248 mμ of the stated volumes of pH 6.8 phosphate buffer desorbing solutions as a function of time on the quasi-steady-state diffusion of progesterone from peanut oil and pH 6.8 phosphate buffer of the stated concentrations through 3-mil silastic membrane at 37.5°.

high degree of correlation of these ratios (Table VI) are truly indicative that the factors affecting diffusion from solution in silastic capsules are the same as those affecting diffusion from solution in the cell.

DISCUSSION

Solid polymeric organic membranes are permeable to uncharged organic molecules which are

Apparent diffusion constant, D, 10^{12} l./cm.-sec.	0.38	630

[a] Estimated from the slope of the plot of log $(C_{eq.} - C_1/C_0)$ against time in accordance with the expression log $(C_{eq.} - C_1/C_0) = \log (V_2/V_1 + V_2) - DSt(V_1 + V_2)/(V_1V_2)/2.303X$, where C_1 is the concentration of the desorbing solution of volume V_1 at any time, t, where $C_{eq.}$ is its concentration after final equilibration, C_0 is the concentration of the diffusing solution of volume V_2, S is the area of the 3-mil silastic membrane, and X is the thickness in cm.

lipophilic. In particular, silastic membrane is permeable to the uncharged species of the aminophenones such as *p*-aminoprophenone (1, 2), phenylalkylamines such as amphetamine, steroids such as progesterone, alkaloids such as dextromethorphan, and the barbiturates. These polymeric membranes are impermeable to the charged organic drug and the inorganic ions studied.

The pKa′ values of protonable or dissociating drugs can be determined from the study of rates of steady-state diffusion as a function of the pH of the diffusing solution where half of the maximum diffusing rate at that total concentration is obtained when pH = pKa′ (Fig. 5).

Water and other solvents such as mineral oil do not appear to be readily transported by silastic, although ethanol is transported without modifying the membrane (2).

The classical laws of diffusion appear to hold for silastic membranes so that transport rates in steady-state and quasi-steady-state diffusion can be predicted for particular diffusing and desorbing solutions, their concentrations and pH values from a knowledge of the thickness and area of the membrane, the pKa′ of the diffusing species, and the apparent diffusion constant, $D = KD'$, of the uncharged species.

The latter have now been determined for the several classes of drugs (Tables I–III, V). Only if studies are conducted on thick membranes to determine the intercept value in nonsteady-state diffusion (2, 15–17) can the intrinsic diffusivity constant, D', within the membrane and the actual partition coefficient, K, be separated.

The fact that the rates of transfer (Eqs. 1 and 2) are directly proportional to the concentrations of the diffusing solution up to the limit of the drug's solubility, implies that there is no selective binding to these membranes, no limitations as to sites, and that at all times the concentration in the monolayer on the diffusing side of the membrane is in instantaneous equilibrium with the solution in contact therewith. It also implies and has been confirmed that saturated solutions of drugs diffuse through the membranes at a constant rate.

The apparent diffusion constant, D, can be formulated as a product of the intrinsic diffusion

[a] Calculated from $D = XV_1 Rs/3600\ S$, where X is the thickness of the membrane in cm. and S is the available surface area in cm.^{2}. [b] The specific rate of diffusion $Rs = (dC_1/dt)/f_2C_2$ is obtained from the slope of the concentration—time in hours plot of the desorbing solution divided by the concentration of the uncharged species in the diffusing solution. [c] Apparent diffusion constant divided by that for barbital from silastic capsules and diffusion cell, respectively.

constant, D', within the membrane, and the operational partition coefficient for the uncharged species between the membrane and the solvent when the diffusing and desorbing solvents are the same (Eq. 2). Another confirmation of this hypothesis is the linear relation between the apparent diffusion constant, D, of a series of barbituric acids for diffusion through silastic membranes and their partition coefficients between acetate buffer solution and chloroform (Fig. 7). Knowledge of rank order of such partition should permit prediction of relative diffusion through such membranes. No significant correlation exists for apparent diffusion constants with solubility or its reciprocal in the diffusing solution for the barbiturate series. This is readily understandable since

$$D = D'K = D'C_m/C_i = D'S_m(1/S_i) \quad \text{(Eq. 7)}$$

where C_m and C_i are the concentrations in the equilibrated monolayer of the membrane and the concentration in the contacting solution, respectively; and where S_m and S_i are the respective solubilities. The apparent diffusion constant would be inversely proportional to the reciprocal of the solubility in the solvent only if the solubility of each drug of a homologous series were the same in the membrane. The fact that the apparent diffusivities, D, are proportional to partition coefficients but not to the solubilities in the case of barbiturates (Table II) denies this assumption.

An interesting result of this analysis is the conclusion that a species in solution can be separated

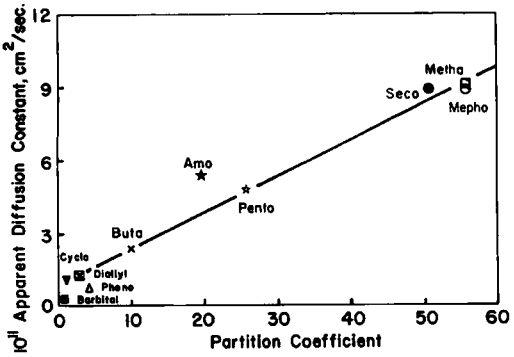

Fig. 7—The apparent diffusion constants of various barbitals diffusing through 3-mil silastic membrane at 25.0° as a function of their partition coefficients between 4.7 pH acetate buffer and chloroform.

from ionic or salt contaminants and concentrated in a desorbing solvent wherein it has a greater activity or solubility than the diffusing solvent. At final equilibrium, the rate of diffusion $dA/dt = 0$ and from Eq. 1.

$$K_2f_2C_2 = K_1f_1C_1 \quad \text{(Eq. 8)}$$

so that, when Eq. 7 is considered,

$$\frac{C_1}{C_2} = \frac{K_2f_2}{K_1f_1} = \frac{f_2}{f_1}\cdot\frac{S_1}{S_2} \quad \text{(Eq. 9)}$$

so that the ratio of the concentrations in both desorbing and diffusing solutions at equilibrium is proportional to the ratio of their solubilities, S_i, in these solutions. In the specific cases of immiscible solvents, these are equivalent to the partition coefficient of the compound in these solvents. In the general case of miscible solvents, such as was shown for ethanol and water (2), these ratios may be considered as hypothetical partition coefficients.

These studies on diffusion through silastic membranes and the fact that solid materials such as progesterone and other steroids in contact with the membrane do permeate (18–21) permits one to conceive of such membranes as isotropic media capable of dissolving drugs in a solid solution with all the operational properties of true solutions. The rates of diffusion within the membrane are dependent on the concentration gradients within them and the distance, X, of traversal. The overall rates of diffusion from solid particles of drug should be dependent on whether or not the rates of dissolution of these particles in contact with the membrane are rate determining. Such particles suspended in a polymer matrix should have rates of dissolution proportional to their surface area in contact. Release rates from the membrane into surrounding solvents would depend on whether these dissolution rates were of higher or lower orders of magnitude than diffusion within the membrane.

SUMMARY

Various polymer films were screened for permeability to various drugs dissolved in several solvents. Detailed attention was placed on the diffusion of a series of barbituric acid and phenylalkylamines, and apparent diffusivities could be correlated with chloroform–acetate buffer partition coefficients. It was ascertained that Fick's law for solid poly-

meric membranes is operative with respect to the concentrations of uncharged organic compounds. Apparent diffusion constants from various solvents were obtained from steady-state and quasi-steady-state studies. Solid materials in contact with such membranes modified to act as potential pharmaceutical dosage forms were studied and demonstrated that basic diffusional information could be used to evaluate, predict, and control such diffusion.

Effect of a Dimethylpolysiloxane Fluid on the Stability of Menadione

By RONALD T. TURNBULL* and KENNETH E. AVIS

The nonaqueous solvents presently in use as parenteral vehicles possess certain disadvantages or have limited application. The silicone fluids have certain physical, chemical, and biological properties which would appear to make them suitable for parenteral formulations. Accelerated thermal and light stability studies were carried out on a dimethyl silicone fluid of 20 centistokes viscosity and corn oil using menadione as the medicinal compound for study. Based on predictions from the accelerated thermal studies, it was found that the dimethyl silicone fluid was superior to corn oil. Corn oil was found to be superior to the dimethyl silicone in retarding photodegradation of menadione at room temperature. Since greater emphasis must be placed on the ability of the vehicle to retard thermal changes in a chemical compound, the experimental results indicate that the dimethyl silicone fluid of 20 centistokes viscosity is superior to corn oil as a vehicle for menadione.

AQUEOUS SYSTEMS are normally preferred for liquid dosage forms intended for parenteral administration because body systems are aqueous and absorption of the drug generally occurs more readily from an aqueous system. However, a number of therapeutic agents, because of their solubility characteristics, can only be formulated in nonaqueous solvent systems. Although the number of such agents is considerably less than those requiring aqueous systems, they are vital to our therapeutic armamentarium.

The nonaqueous vehicles most commonly used are the fixed oils. All of these, however, have disadvantages in use, such as: the development of rancidity with aging, potential allergenic reactions in sensitive individuals and local tissue reac-

tions, including cysts, foreign body granulomas, and occasional nerve injury (1). All of these and other solvents currently in use possess certain disadvantages or have limited applications, therefore, a need exists for other nonaqueous vehicles.

The dimethylpolysiloxane fluids appear to possess most of the characteristics an ideal nonaqueous solvent should have (1), namely, they possess very great chemical and oxidative stability, they have low viscosity-temperature coefficients, their viscosity can be tailored to meet the desired physical needs, their boiling points are high enough to permit heat sterilization, they are nonflammable, and they are very low in toxicity (2–8).

The use of silicone fluids as nonaqueous vehicles for the intramuscular administration of drugs has been reported in the literature (9). This brief account is the only known record of work that has been done in exploring such use for this potentially valuable series of solvents (10).

The objective of this study was to explore the physicochemical effects of dimethylpolysiloxane fluid, 20 centistokes, when utilized as a vehicle for a particular drug, menadione. The observed effects were compared with those obtained using one of the commonly used nonaqueous vehicles, corn oil.

EXPERIMENTAL

Materials—Menadione, USP; silicone fluid[1], 20 centistokes (supplied by Dow Corning Chemical Co., Midland, Mich.); 2,4-dinitrophenylhydrazine; corn oil.

Equipment—Beckman DU spectrophotometer; type I amber glass vials (supplied by Kimble Products, Division of Owens-Illinois, Toledo, Ohio); rubber vial closures, No. 342 Red, P and H coated (supplied by Carron Products Co., Philadelphia, Pa.); Gossen Luna Six light meter; light stability cabinet.

Assay Method—A modified form of the assay procedure official in the NF XII (11) was utilized. The official assay is a colorimetric procedure reacting menadione with 2,4-dinitrophenylhydrazine, and depends on the formation of the 2,4-dinitrophenylhydrazone of the naphthoquinone portion of the molecule, and the interaction of the latter compound with ethanolic ammonia to yield a blue-green colored solution. The concentration is determined spectrophotometrically at a wavelength of 635 mμ. In the official assay, an original sample of approximately 25 mg. in solution is used, the spectrophotometric reading being taken on a 1:100 dilution.

In preliminary trials, it was found that the absorbance of menadione did not conform to Beer's law, when percent transmission was plotted against concentration, throughout the range of concentration tested, *i.e.*, 2.5–25 mg., from either corn oil or silicone fluid, although it did conform to Beer's law from the standard ether–alcohol vehicle. The deviation in the slope occurred at the original concentration of between 12.5 and 15 mg. Since this deviation did exist, had a 25-mg. sample been used, as recommended in the official assay, the assay results would have been unreliable up to a degradation of 50%. Conformity to Beer's law was demonstrated between 2.5 and about 15 mg. in the test sample, therefore, a 10-mg. sample was used in this study.

Thermal Stability—Four temperatures were chosen to study the thermal stability of menadione in each vehicle: room temperature, 35, 55, and 70°. Solutions of menadione in corn oil and the dimethylpolysiloxane fluid, 20 centistokes, were prepared at a concentration of 1 mg./ml. Three samples were assayed for each storage interval and each assay was performed in triplicate. The solutions stored at 55° were assayed every 7 days for 3 weeks. The solutions stored at room temperature, 35, and 70°, were assayed every 14 days for a period of 9 weeks.

Light Stability—A light stability cabinet suggested by Lachman *et al.* (12) for ordinary illumination was used for the light study. From preliminary trial data a light intensity of 750 ftc. was found to be sufficient to cause degradation within a few hours. Solutions of menadione in both vehicles were prepared at a concentration of 1 mg./ml. Ampuls of type I colorless glass containing the solutions were laid horizontally in the center of the shelf in the cabinet to allow for maximum and uniform exposure.

Three samples were tested for each exposure period and assayed in triplicate. The samples were assayed at zero-storage time and after 2, 6, 10, and 12 hr. exposure to light at an intensity of 750 ftc.

RESULTS AND DISCUSSION

Assay Modification—As indicated previously, the absorbance from menadione did obey Beer's law in the standard ether–alcohol vehicle. Figure 1 shows the results of the same assay procedure when menadione was placed in the dimethylpolysiloxane fluid. This curve and the one obtained for menadione in corn oil are essentially identical. As can be seen, a linear relationship occurs only from 25 mcg./50 ml. to a point somewhere between 125 and 150 mcg./50 ml. Therefore, the assay procedure was modified to use an original sample of 10 mg. (100 mcg./50 ml. in dilution) so that degradation at least up to 75% could be measured by this test procedure.

Thermal Stability—The effects of temperature on the degradation of menadione in both vehicles tested

are summarized in Table I. When these data are plotted as in Figs. 2 and 3, the straight lines obtained indicate that the rate of degradation in both vehicles follows that of a first-order reaction. The rate of degradation at a storage temperature of 70° was found to be considerably greater in dimethyl silicone fluid than in corn oil, but at room temperature and 35°, considerably greater in corn oil than in dimethyl silicone fluid. In both fluids, the rate of degradation was greater at higher temperatures.

Utilizing these data to prepare an Arrhenius plot, as proposed by Free and Oyer (13), it is possible to predict the stability of menadione at room temperature. By this method, the times at which the product, stored at selected elevated temperatures, reached 90% of its original concentration was plotted against $1/T$ (absolute temperature). Extending the line to the intercept of $1/T$ equal to room temperature indicated the predicted time of stability to 90% of original concentration. The authors' data for menadione in corn oil and in dimethyl silicone fluid have been plotted in this manner and the results shown in Fig. 4. As can be seen, there is a significant difference in the effects of the two vehicles. The predicted shelf life for menadione in corn oil was about 40 days, while that for menadione in the dimethyl silicone fluid was about 230 days. The experimentally determined value for menadione in corn oil was found to be 45 days. Therefore, the predicted value of 40 days was confirmed quite closely by experimental data.

Light Stability—The experimental results from the light stability study are plotted in Fig. 5. As may be seen, there is a difference in the rate of degradation of menadione in the dimethyl silicone fluid as compared with corn oil. The dimethyl silicone fluid was somewhat less effective than corn oil in retarding the photodegradation of menadione. The rate of degradation in both vehicles was rapid up to about 20% of the original concentration remaining. Subsequently, there was a pronounced reduction in the rate, particularly for the dimethyl silicone fluid. This leveling off of the rate of degradation agreed with the results reported by Collins and Kirch (14).

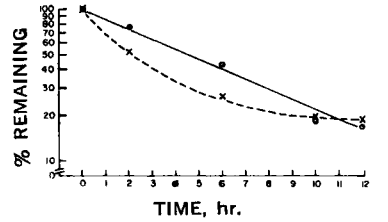

Fig. 5—Effect of light at an intensity of 750 ftc. on the stability of menadione in corn oil and dimethyl silicone fluid. Key: —⊙—, corn oil; --×--, silicone.

SUMMARY

The silicone fluids appear to have certain physical, chemical, and biological properties which would make them useful as nonaqueous solvents for the administration of medicinal agents.

Based upon data from accelerated thermal studies, it was found that the dimethyl silicone fluid was superior to corn oil in preventing the thermal degradation of menadione.

The photodegradation studies indicated that, although corn oil was somewhat superior to the dimethyl silicone fluid in preventing the degradation of menadione, photodegradation was rapid in both vehicles. Since photodegradation can be controlled during normal storage by protective packaging, its practical significance is less than the relatively uncontrollable thermal storage conditions.

In consideration of these findings, it may be concluded that the dimethyl silicone fluid is superior to corn oil as a vehicle for menadione.

Assay of Terpin Hydrate and Codeine Elixir by Gas Chromatography

By HAROLD J. WESSELMAN

Terpin hydrate and codeine after extraction from the elixir are separated and determined with the aid of two internal standards and the use of temperature-programmed gas chromatography. Using the same method, elixir of terpin hydrate can also be determined. A precision and accuracy study for both elixirs is included.

THE QUANTITATIVE determination of terpin hydrate, *cis-p*-menthane-1,8-diol hydrate, has always presented problems. Indeed the National Formulary XII (1) does not include an assay for terpin hydrate or codeine in either the elixir of terpin hydrate or the elixir of terpin hydrate and codeine. In 1921 Murray (2) used a gravimetric method for terpin hydrate. Harrison (3), Carol (4, 5), and Lund and Ameiss (6) improved this method. Later, in 1932, Perelmann (7) proposed a colorimetric method which was modified by Platt and James (8) and Vadodaria, Parikh, and Mukherji (9).

Dembeck (10) described a titrimetric assay for codeine while Stoicheva (11) determined terpin hydrate and codeine by subjecting them to microreactions and examining the results microscopically. Milos (12, 13) developed a spectrophotometric determination for these compounds. Using ion-exchange chromatography and nonaqueous titrimetry, Blake and Carlstedt (14) determined codeine in the elixir, while Mont-

Assay of Terpin Hydrate and Codeine Elixir by Gas Chromatography

By HAROLD J. WESSELMAN

Terpin hydrate and codeine after extraction from the elixir are separated and determined with the aid of two internal standards and the use of temperature-programmed gas chromatography. Using the same method, elixir of terpin hydrate can also be determined. A precision and accuracy study for both elixirs is included.

THE QUANTITATIVE determination of terpin hydrate, *cis-p*-menthane-1,8-diol hydrate, has always presented problems. Indeed the National Formulary XII (1) does not include an assay for terpin hydrate or codeine in either the elixir of terpin hydrate or the elixir of terpin hydrate and codeine. In 1921 Murray (2) used a gravimetric method for terpin hydrate. Harrison (3), Carol (4, 5), and Lund and Ameiss (6) improved this method. Later, in 1932, Perelmann (7) proposed a colorimetric method which was modified by Platt and James (8) and Vadodaria, Parikh, and Mukherji (9).

Dembeck (10) described a titrimetric assay for codeine while Stoicheva (11) determined terpin hydrate and codeine by subjecting them to microreactions and examining the results microscopically. Milos (12, 13) developed a spectrophotometric determination for these compounds. Using ion-exchange chromatography and nonaqueous titrimetry, Blake and Carlstedt (14) determined codeine in the elixir, while Mont-

gomery, Jennings, and Weinswig (15) applied ion-exchange chromatography followed by ultraviolet absorption analysis.

Domange and Longuevalle (16) suggested that terpin hydrate could be determined by gas chromatography but provided no tangible evidence. Recently Kurlansik, Damon, and Salim (17, 18) and Mahn, Viswanathan, and Senkowski (19) devised gas chromatographic methods for terpin hydrate in elixir of terpin hydrate and elixir of terpin hydrate and codeine.

The gas chromatography of codeine was investigated qualitatively by Parker, Fontan, and Kirk (20) and Massingill and Hodgkins (21) and made quantitative by Mule (22) and Schmerzler *et al.* (23).

The literature does not record the use of gas chromatography for the simultaneous determination of terpin hydrate and codeine. These compounds are difficult to separate by isothermal gas chromatography because of their widely spaced boiling points. Another difficulty in the case of the elixir of terpin hydrate and codeine is that terpin hydrate being the more volatile of the two is present in the greatest amount, 17.0 mg./ml., while the higher boiling codeine has only a concentration of 2.0 mg./ml.

The present work overcomes these problems by using a combination of isothermal and temperature-programmed gas chromatography when both compounds are present. By using isothermal gas chromatography, terpin hydrate in elixir of terpin hydrate can be determined easily.

EXPERIMENTAL

Equipment—A linear programmed-temperature gas chromatograph, F & M Scientific Corp., model 402, equipped with a flame-ionization detector, was used for the experimental work. The detector signal was fed to a Honeywell Electronic 16 1-mv. recorder with a chart speed of 15 in./hr. and a 1-sec. full-scale response. Samples were injected with a 10-μl. Hamilton, No. 701, syringe.

Materials—Helium was used as a carrier gas, while electrolytic hydrogen and oxygen were used in the detector. The stationary phase was 3.8% Linde W-98 silicone gum applied by the solution technique of Horning *et al.* (24) to Diatoport S (80–100 mesh) and packed in dual borosilicate glass columns 0.91 m. × 0.64 cm. (3 ft. × 1/4 in. o.d.). A mixture of chloroform and ethanol (1:1) was used to dissolve the analytical reagent grade benzoic acid, terpin hydrate, codeine, and cholestane.

Operating Conditions—For the elixir of terpin hydrate and codeine, the columns were operated isothermally at 140° for 4 min. and then programmed to 275° at a heating rate of 10° per min. At the end of each run, the oven was cooled for exactly 10 min. and then equilibrated at 140° for exactly 10 min. before injecting the next sample. The electrometer range was 1,000 with an attenuation of 64 for terpin hydrate and benzoic acid and 4 for codeine and cholestane. In the case of the elixir of terpin hydrate, the columns were operated isothermally at 135° with an attenuation of 32 on range 1,000.

The helium flow rate was 55 ml./min. with an inlet pressure of 40 psig. Oxygen and hydrogen flow rates were 250 and 35 ml./min., respectively. The sample injection port was maintained at 240° and the detector block at 215°. One-microliter injections of all samples were used throughout.

Quantitative Analysis—This method uses two internal standards—benzoic acid for terpin hydrate and cholestane for codeine.

Elixir of Terpin Hydrate and Codeine—Prepare a standard solution by adding exactly 85.0 mg. benzoic acid, 85.0 mg. terpin hydrate, 10.0 mg. codeine alkaloid, and 10.0 mg. cholestane to a 5-ml. volumetric flask and diluting to volume with a 1:1 mixture of chloroform and ethanol.

Prepare a sample solution by transferring exactly 10.0 ml. of the elixir to a 125-ml. separator and adding 3 ml. sodium hydroxide solution (1:10 distilled water). Extract with four 20-ml. portions of chloroform, collecting the chloroform extracts in a 150-ml. beaker. Carefully evaporate the chloroform, using a stream of dry air and a water bath, to a volume of about 2 ml. Transfer the concentrated extract to a 10-ml. volumetric flask with the aid of chloroform. Carefully evaporate the chloroform to dryness. Dilute to volume with the internal standard solution which is prepared by diluting 850 mg. benzoic acid and 100 mg. cholestane to 50 ml. with a 1:1 mixture of chloroform and ethanol. Chromatograph the standard and the extracted sample solutions and measure the peak height of each component.

Elixir of Terpin Hydrate—Prepare a standard solution by adding exactly 85.0 mg. benzoic acid and 85.0 mg. terpin hydrate to a 5-ml. volumetric flask and diluting to volume with a 1:1 mixture of chloroform and ethanol.

A 10-ml. sample of the elixir is extracted as discussed above. The final dilution is made with an internal standard solution prepared by adding exactly 850.0 mg. benzoic acid to a 50-ml. volumetric flask and diluting to volume with a 1:1 mixture of chloroform and alcohol. Chromatograph the standard and the extracted sample solutions and measure the peak height of each component.

Calculations.

$$\frac{\text{peak height standard benzoic acid}}{\text{peak height standard terpin hydrate}} = A$$

$$\frac{\text{peak height sample benzoic acid}}{\text{peak height sample terpin hydrate}} = B$$

$$A/B \times 17 = \text{mg. terpin hydrate/ml. elixir.}$$

$$\frac{\text{peak height standard cholestane}}{\text{peak height standard codeine}} = C$$

$$\frac{\text{peak height sample cholestane}}{\text{peak height sample codeine}} = D$$

$$C/D \times 2 = \text{mg. codeine/ml. elixir.}$$

Precision and Accuracy—To determine the precision and accuracy of the methods, freshly prepared solutions of terpin hydrate and codeine and terpin hydrate in distilled water were used as standard solutions. The sample solutions were prepared

by dissolving the same components in freshly made elixir blanks. These studies were carried out in accordance with the suggestions of the Advisory Board of Analytical Chemistry (25) and the recommended nomenclature is used. Tables I and II show the results of these studies.

RESULTS AND DISCUSSION

A typical chromatogram of a mixture of terpin hydrate, benzoic acid, codeine, and cholestane is shown in Fig. 1. Table III gives the results of the assays of three production lots of elixir of terpin hydrate and codeine. Table IV shows the results obtained from three production lots of elixir of terpin hydrate. Triplicate assays in each case show good agreement.

CONCLUSION

A new method for determining terpin hydrate and codeine simultaneously using a combination of isothermal and programmed-temperature gas chromatography has been developed. The use of two internal standards permits a high degree of precision and accuracy. The relative standard deviations for terpin hydrate and codeine are ±1.48% and ±0.66%, respectively. The procedure is fast and accurate and easily carried out. The overall time for determining the standard and the sample is approximately 1 hr.

Automated Colorimetric Analysis of Ethinyl Estradiol and Mestranol in Pharmaceutical Tablets

By WILLIAM F. BEYER

An automated colorimetric procedure is described for the determination of ethinyl estradiol and ethinyl estradiol-3-methyl ether in pharmaceutical tablets. Chloroform solutions of the estrogen are automatically extracted with alcohol–sulfuric acid and analyzed at a rate of 20 samples/hr. The relative standard deviation of repetitive sampling of tablet extracts was less than 1 percent, and Beer's law was obeyed over the range of 0.40–8.00 mcg./ml. of sample solution. The procedure is applicable to unit dosage assays and to assays requiring composite samples of pulverized tablets or numerous whole tablets.

NUMEROUS METHODS have been reported for the determination of ethinyl estradiol (EE) or its 3-methyl ether derivative (EE-3ME) from tablets (1–5). The majority of these procedures depends upon the spectrophotometric analysis of sulfuric acid-induced color, and involve somewhat lengthy separative techniques.

A recent publication of Khoury and Cali (6) describes an automated assay for EE and EE-3ME based on the fluorescence exhibited by the estrogens in 90% sulfuric acid. The necessity of assaying large numbers of tablets for EE in combination with nonestrogenic steroids also prompted the investigation of automation in these laboratories. A relatively simple, automated method has been developed with instruments normally found in laboratories employing automatic analysis—sampler, proportioning pump, heating bath, spectrophotometer, and recorder. The procedure is based on a manual method developed in these laboratories (7), a modification and quantitation of the USP XVII sulfuric acid identification test for EE (1). The red color formed when sulfuric acid is added to a chloroform solution of EE is extractable with sulfuric acid and exhibits a maximum absorption at 518 mμ. The color develops rapidly and is

Automated Colorimetric Analysis of Ethinyl Estradiol and Mestranol in Pharmaceutical Tablets

By WILLIAM F. BEYER

An automated colorimetric procedure is described for the determination of ethinyl estradiol and ethinyl estradiol-3-methyl ether in pharmaceutical tablets. Chloroform solutions of the estrogen are automatically extracted with alcohol–sulfuric acid and analyzed at a rate of 20 samples/hr. The relative standard deviation of repetitive sampling of tablet extracts was less than 1 percent, and Beer's law was obeyed over the range of 0.40–8.00 mcg./ml. of sample solution. The procedure is applicable to unit dosage assays and to assays requiring composite samples of pulverized tablets or numerous whole tablets.

NUMEROUS METHODS have been reported for the determination of ethinyl estradiol (EE) or its 3-methyl ether derivative (EE-3ME) from tablets (1–5). The majority of these procedures depends upon the spectrophotometric analysis of sulfuric acid-induced color, and involve somewhat lengthy separative techniques.

A recent publication of Khoury and Cali (6) describes an automated assay for EE and EE-3ME based on the fluorescence exhibited by the estrogens in 90% sulfuric acid. The necessity of assaying large numbers of tablets for EE in combination with nonestrogenic steroids also prompted the investigation of automation in these laboratories. A relatively simple, automated method has been developed with instruments normally found in laboratories employing automatic analysis—sampler, proportioning pump, heating bath, spectrophotometer, and recorder. The procedure is based on a manual method developed in these laboratories (7), a modification and quantitation of the USP XVII sulfuric acid identification test for EE (1). The red color formed when sulfuric acid is added to a chloroform solution of EE is extractable with sulfuric acid and exhibits a maximum absorption at 518 mμ. The color develops rapidly and is

Statistical analyses of data by R. J. Cole and W. D. Frailing, Control Statistical Services, The Upjohn Company, using an IBM 1620 are appreciated. Manual assays, carried out by E. Christensen and P. Dame, Product Control, The Upjohn Company, are acknowledged.

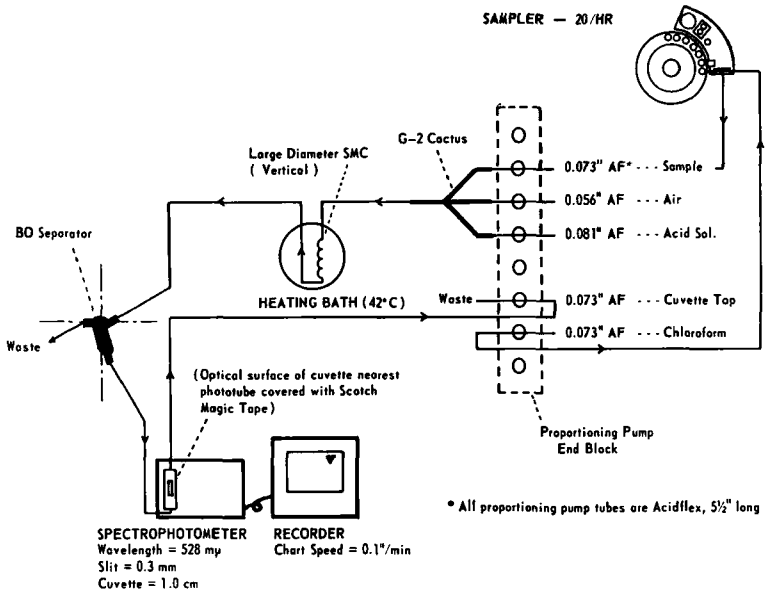

Fig. 1—Flow diagram for the automated determination of ethinyl estradiol and ethinyl estradiol-3-methyl ether, at wavelengths of 528 and 538 mμ, respectively.

stable at room temperature for at least 15 hr. Although the reaction is not influenced by the volume of chloroform, the color is enhanced by the small amount of alcohol used as a preservative in chloroform. The interference of nonestrogenic steroids present in tablets in combination with the estrogen is eliminated by correcting for absorbances due to nonestrogenic steroids.

Details of the automated procedure and a comparison of assay results with the manual procedure are the subject of this report.

EXPERIMENTAL

Equipment—Automatic sampler, proportioning pump, and assorted tubing and glass fittings[1]; heating bath[2]; spectrophotometer[3]; recorder[4]; and 12 × 35-mm. glass shell vials.

Reagents—Chloroform, analytical grade; 10% 3A alcohol[5] in 90% sulfuric acid, analytical grade (v/v).

Standards—Chloroform stock solutions containing 100 mcg./ml. of USP ethinyl estradiol or ethinyl estradiol-3-methyl ether are refrigerated in tightly sealed volumetric flasks. The stock standards are brought to room temperature and diluted with chloroform to approximately 4 mcg./ml. just prior to use.

Interfering Nonestrogenic Steroids—Chloroform stock solutions of steroids present in tablet formulation in combination with EE or EE-3ME are refrigerated in tightly sealed volumetric flasks. Chloroform solutions of nonestrogenic steroids are prepared from the stock solutions, maintaining the ratio of estrogen to nonestrogen that exists in the tablets.

Tablets—Tablets are disintegrated by gentle shaking in polyethylene-stoppered conical flasks, containing a small amount of water and several glass beads. To completely disintegrate the tablets, the stoppers are loosened and the flasks are heated on a steam bath for approximately 15 min. After cooling to room temperature, chloroform is added at a ratio of 10 ml. for each ml. of water so that the final estrogen concentration is similar to that of the standard. For example in the assay of 0.05-mg. EE tablets, eight tablets are disintegrated with 10.0 ml. of water and extracted with 100.0 ml. of chloroform. The flasks are shaken vigorously for approximately 30 min. A portion of the chloroform phase is filtered directly into shell vials using a rapid flow filter paper such as Whatman No. 41. A layer of water (approximately 0.4 ml.) is added to each vial immediately after filtration to suppress evaporation of chloroform.

Procedure—The sampling probe of the automatic sampler is aligned so that satisfactory aspiration from the shell vials and from the rinsing compartment occurs. A zero base line is established with all instruments operating using the flow system of Fig. 1 with sample and rinse lines in chloroform and the remaining line in acidic alcohol. Sampling rate is set at 20/hr. with a sample–rinse ratio of 1:1. Before aspiration of samples, the flow cell is inverted and tapped to release chloroform or water droplets that may be trapped. Vials of the nonestrogenic steroid are sampled first if that particular steroid is present in the tablets in combination with the estrogen. Vials of duplicate EE or EE-3ME standards follow, with approximately 0.4 ml. of water added to vials of both the nonestrogenic steroid and standard. Additional standards are interspaced among test samples to compensate for instrumental variation. EE is measured at a wavelength of 528 mμ, EE-3ME at 538 mμ.

Calculations are based on the relative absorbance of standards and test samples with corrections made for the absorbance of the nonestrogenic steroid present in the tablet formulation.

RESULTS AND DISCUSSION

Virgorous shaking of tablets in chloroform follow-

[1] Technicon, Ardsley, N. Y.
[2] Tamson heating bath, Witt Sales, Cleveland, Ohio

ing disintegration with a small amount of water, gave both a simple and efficient extraction of EE. The use of chloroform samples introduced difficulties; however, satisfactory procedures were developed that permitted their use. An attachment to hold glass shell vials in the sample plate of the automatic sampler and a glass cover plate for the sampler were constructed. Two metal disks were attached to the standard sample plate, below the plastic holder; one with forty 1.3-cm. (0.5-in.) holes to center the shell vials, the other without holes as a support for the containers. An exact duplicate of the original plastic cover plate was made using plate glass, to eliminate the effect of chloroform on the plate. Placing a layer of water on the vials of chloroform, eliminated the problem of chloroform evaporation. In-stream extraction of the estrogen in chloroform with sulfuric acid was aided by adding 10% water and 10% alcohol to the acid and by using a 42° water bath. Alcohol added to diluted sulfuric acid decreased the viscosity of the acid, giving a uniform flow of liquids and a satisfactory separation of acid–chloroform phases. The effect of striations caused by sulfuric acid passing through the flow cell was eliminated by applying Scotch Magic tape[6] to the optical surface of the flow cell nearest the photo tube in the manner described by Anderson *et al.* for the automated assay of vitamin A (8). Maximal absorption of EE and EE-3ME occurred at 528 and 538 mμ, respectively, verified with a recording spectrophotometer[7] after manually collecting acid from the exit port of the flow cell while sampling continuously.

Recordings of repetitive and continuous sampling of chloroform solutions of EE at a concentration of 3.0 mcg./ml. are shown in Fig. 2. A relative standard deviation for the 12 replicate analyses was 0.54% even though peak heights of individual samples did not reach that of continuous sampling and the base line was not reached during the rinse cycle. Recordings of various concentrations of EE (Fig. 3), with duplicate sampling at each level, show minimal interaction between subsequent samples. Beer's law was obeyed and a y intercept of −0.004 was calculated. The values gave a calculated slope of 0.999 when plotted on the ordinate against theoretical values on the abscissa.

The recovery of EE from pooled chloroform extracts of oral contraceptive tablets containing 0.05 mg. EE in combination with 10.0 mg. medroxyprogesterone acetate per tablet was tested. EE standard was added to varying quantities of tablet extracts, giving an average recovery of 100.2% (Table I), with a low of 99.6% and a high of 100.7%. Medroxyprogesterone acetate, the progestin in the tablet, did not interfere with the assay. Recovery studies of EE from tablets containing 0.02 mg. EE and 1.0 mg. fluoxymesterone, in which the anabolic androgen contributed approximately 3% of the absorbance, were carried out. Samples were prepared to contain tablet excipients, varying quantities of EE, and fluoxymesterone at a concentration equivalent to 50 times the level of EE used for assay purposes. Table II shows that it is possible to assay EE at a concentration of 75–125% of the labeled amount in the presence of the nonestrogenic steroid at label strength.

Numerous assays for EE in tablets containing medroxyprogesterone acetate or fluoxymesterone were carried out using automated and manual

procedures. Table III shows that satisfactory agreement occurred for the two methods of assay.

Progestins present in formulations of oral contraceptive tablets, in combination with EE-3ME interfered with the automated assay to varying degrees. The interference, however, was eliminated by correcting for the absorbance at 538 mμ, due to the progestin alone. Table IV gives results of tablet assays from five manufacturers.

SUMMARY

An automated colorimetric method has been described for the assay of ethinyl estradiol and ethinyl estradiol-3-methyl ether in tablets. Interferences due to nonestrogenic steroids also present in the tablets are eliminated by correcting for the absorbance due to the steroids. Following manual extraction of test preparations, chloroform samples are analyzed at a rate of 20/hr. The relative standard deviation is less than 1% and Beer's law is obeyed in the range of 0.4–8.0 mcg./ml. Satisfactory agreement of assay results was obtained for the automated and manual procedures.

Continuous Flow Apparatus for the Determination of the Dissolution Characteristics of Tablets and Capsules

By M. PERNAROWSKI, W. WOO, and R. O. SEARL

The apparatus described in this paper consists of a closed dissolution container, a basket-stirrer assembly, and a variable speed pump. It may be automated by connecting the pump to a flow cell in a suitable spectrophotometer. Two or more test fluids can be used interchangeably for the determination of dissolution characteristics.

THE DISSOLUTION characteristics of a tablet or capsule may be determined by using any one of the many methods described in the literature (1–4). Several different types of dissolution containers, agitation methods, test media, and sampling procedures have been used to determine dissolution profiles or values. However, most methodology is based on either the USP disintegration apparatus (5–7) or on the use of a beaker-stirrer assembly (8–10).

It is now generally accepted that *in vitro* results should be correlated to some physiological parameter. This can only be done if the dissolution method yields results which reflect the physiological differences between chemically similar drug products. This implies that the apparatus should be so designed that its operating characteristics can be easily changed. The apparatus described in this paper is a nodification of the beaker-stirrer method used by Levy (8) and others. A tablet-capsule container has been built into the assembly and provisions have been made for change of test fluids during a dissolution study.

Automated assemblies have been used by several investigators (11–14). The continuous flow apparatus used in this laboratory is easily automated but, at the same time, may be used as a simple flask-stirrer assembly with an auxiliary system for media transfer.

EXPERIMENTAL

Equipment—The continuous flow dissolution apparatus is illustrated in Fig. 1. A diagram of the stainless steel basket-stirrer assembly is shown in Fig. 2. The assembly is connected to a Fisher model 12 Stedi-Speed adjustable stirrer. Ten-mesh stainless steel wire cloth is used in the construction of the main part of the basket.

The dissolution container is a 1-l., three-neck flask. The main neck is 35 mm. in diameter; the secondary necks are 20 mm. in diameter. The total volume of the container is slightly more than 1l.

If fluid flow or changeover is necessary, the container is connected (*via* a suitable filtering device and short lengths of latex tubing) to a Cole-Palmer Series A-76910 pump. The dial readings on this pump are proportional to the pumping rate in ml./min. Flow rates of up to 70 ml./min. have been used in this laboratory. Test fluids may be pumped directly to a collection container. Alternatively, they may be circulated through a 1-cm. flow cell in a Spectronic 505 recording spectrophotometer to the collection flask. Tubing lengths are kept to a minimum.

Dissolution profiles are graphed externally on a previously calibrated Varicord model 43 recorder.

Procedure—Dissolution characteristics may be determined by using exactly 1 l. of fluid or by operating the apparatus as a continuous flow system. If the apparatus is operated continuously, the volume of fluid in the dissolution container is slightly more than 1 l. Dissolution characteristics are based, therefore, on the amount of fluid pumped through the dissolution container.

One of the procedures used in this laboratory for the determination of the dissolution characteristics of phenylbutazone tablets NF is given below and illustrates the continuous flow method of operation with fluid changeover.

Place one phenylbutazone tablet into the basket

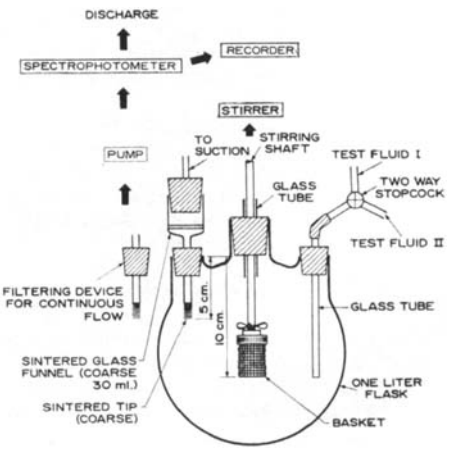

Fig. 1—Continuous flow dissolution apparatus.

Received March 14, 1968, from the Faculty of Pharmacy, University of British Columbia, Vancouver 8, British Columbia, Canada.

Accepted for publication May 27, 1968.

Supported by National Health grant No. 609-7-128 and by the Canadian Foundation for the Advancement of Pharmacy.

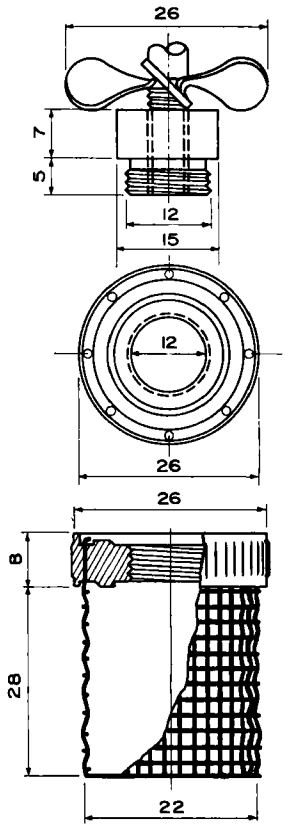

Fig. 2—Specifications (in mm.) for the basket-stirrer assembly used in the dissolution apparatus. The four impeller blades of the stirrer are set at an angle of 45°.

and attach the stirrer. Fill the dissolution container with 1 l. of simulated gastric fluid USP. (The fluid contains no enzyme and is preheated to 37°. Temperature is maintained by immersing the dissolution container in a water bath held at 37°.) Insert the basket-stirrer assembly into the dissolution container and rotate clockwise at 100 r.p.m. Set the pump to deliver 60 ml. of fluid per minute. Allow simulated gastric fluid USP to flow through the container for 30 min. Turn the stopcock connecting the media reservoirs to the dissolution container and allow simulated intestinal fluid USP (no enzyme) to flow through the system for the remainder of the test.

Determine the amount of phenylbutazone in the collection flask at hourly intervals by diluting aliquots with simulated intestinal fluid USP (no enzyme) and reading the absorbance of the solution at 240 mμ (an isosbestic point). Record dissolution profiles on the external recorder.

DISCUSSION

A basket-stirrer assembly similar to that illustrated in Fig. 2 was used to determine the dissolution characteristics of phenylbutazone tablets (15). The apparatus diagrammed in Fig. 1 is currently being used to investigate phenylbutazone tablets using two test media and bishydroxycoumarin tablets using one test fluid.

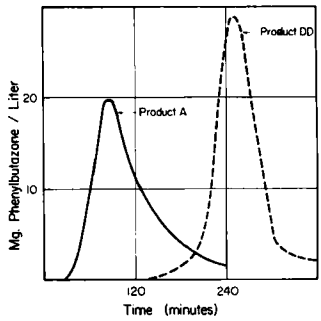

Fig. 3—Dissolution profiles for sugar-coated (Product A) and enteric-coated (Product DD) phenylbutazone tablets.

Dissolution profiles for sugar-coated (Product A) and enteric-coated (Product DD) phenylbutazone tablets are shown in Fig. 3. For the first 30 min., the pH of the fluid is 1.2. Simulated intestinal fluid USP (no enzyme) is then introduced into the flask. At a pumping rate of 60 ml./min., the pH of the fluid changes from that of simulated gastric fluid USP to that of simulated intestinal fluid USP (pH = 7.5) in 30 min.

The dissolution profiles show that both products release drug to a test fluid quickly. However, Product A released most of its phenylbutazone content in 3 hr. Product DD, which failed to comply with the disintegration specification for enteric-coated tablets, released, in 3 hr., only 4.9 (average of three determinations) of the 100 mg. claimed on the label. The apparatus does, therefore, differentiate between two different types of dosage forms. Moreover, these *in vitro* differences appear to be related to physiological availability. Product A was administered to three subjects. The area under the plasma concentration *versus* time curve for Product A was 20 sq. in. units or better. Under the same conditions of administration, the area value for Product DD varied from 4.6 to 11.2 in four subjects.

The basket-stirrer assembly has been used in this laboratory (both in the manner described in this paper and in conjunction with 1, 2, or 3-l. beakers) for approximately 2 years. It is a convenient assembly for tablets but is particularly useful when the dissolution characteristics of a capsule are being determined. Without such a container, capsules tend to float on the surface of the test media. Visual inspection during the test suggests that the tablets and capsules are subjected to much less abrasion than that observed in the USP disintegration test. A 10-mesh wire cloth is used in the construction of the basket and it is possible, therefore, to measure "disintegration" times. Although such values are routinely recorded, no relationship between this time and dissolution characteristics has been established.

This apparatus can be easily adapted to the routine control of tablets and capsules. Although dissolution profiles may be required in certain instances, total amount of drug eluted in a certain period of time would be a satisfactory criterion for many products. For example, the specification for phenylbutazone tablets NF would state that the total quantity of drug eluted from the tablet under specified conditions shall be not less than $x\%$ of that claimed on the label.

Slight changes in pumping rate do not materially change dissolution characteristics. With Product A, the amount of drug in solution at the end of 3 hr. was approximately the same (85 to 90 of the 100 mg. claimed on the label) even though the pumping rate was varied from 50 to 70 ml./min.

The operating characteristics of this apparatus can be easily altered. However, when conditions are fixed, similar dissolution profiles are obtained when drug or tablets from a uniform lot are subjected to the procedure. Repeated tests with Product A[1] produced dissolution profiles similar to that shown in Fig. 3. Moreover, the basket-stirrer assembly positions the tablet in the same way from run to run and helps, therefore, to produce results which are characteristic of the product rather than the apparatus.

Some Measurements of Friction in Simple Powder Beds

By EVERETT N. HIESTAND and CHARLES J. WILCOX

An apparatus and procedure for measuring the static friction coefficient of powders in simple beds are described. The relative merits of three variations of the shear cell are considered. A sandwich of powder between two surfaces covered with sandpaper is satisfactory under most experimental conditions. Examples of the effect of relative humidity, time under load, mechanical vibration of the powder bed, and variations in the experimental procedure are presented. Reproducible values of the friction coefficient can be obtained readily if the experimental and environmental conditions are standardized. The results of the experiments suggest that a single value of the friction coefficient applies only to a specific powder bed. In practical applications the entire range of values that may be encountered must be within acceptable limits.

FRICTION COEFFICIENTS and cohesion values have been used to characterize the flow properties of powders. In a recent review (1), the methods used and the problems encountered have been discussed. In the opinion of the authors, there are limitations on the usefulness of such data because neither the friction coefficient nor the cohesion is a single valued property of the powder. As stated in the review article, "The properties of a powder bed depend on the cumulative effect of the previous history of all the portions of the bulk being considered. Isolated regions of shear, vibration, or compaction may have produced high bulk density regions. These may remain intact in subsequent flow of the powder or may fragment into macroscopic regions mixed throughout the less dense bed. The forces acting on the top of the bed may be quite different from those at the bottom of the bed." In the studies reported here, considerable data have been collected that reveal the large number of factors that cause changes in the properties of powder beds as well as indicating the magnitude of these effects.

The basic measurements of friction coefficient and cohesion may be obtained from a simple shear cell described by Nash *et al.* (2). Though

Some Measurements of Friction in Simple Powder Beds

By EVERETT N. HIESTAND and CHARLES J. WILCOX

An apparatus and procedure for measuring the static friction coefficient of powders in simple beds are described. The relative merits of three variations of the shear cell are considered. A sandwich of powder between two surfaces covered with sandpaper is satisfactory under most experimental conditions. Examples of the effect of relative humidity, time under load, mechanical vibration of the powder bed, and variations in the experimental procedure are presented. Reproducible values of the friction coefficient can be obtained readily if the experimental and environmental conditions are standardized. The results of the experiments suggest that a single value of the friction coefficient applies only to a specific powder bed. In practical applications the entire range of values that may be encountered must be within acceptable limits.

FRICTION COEFFICIENTS and cohesion values have been used to characterize the flow properties of powders. In a recent review (1), the methods used and the problems encountered have been discussed. In the opinion of the authors, there are limitations on the usefulness of such data because neither the friction coefficient nor the cohesion is a single valued property of the powder. As stated in the review article, "The properties of a powder bed depend on the cumulative effect of the previous history of all the portions of the bulk being considered. Isolated regions of shear, vibration, or compaction may have produced high bulk density regions. These may remain intact in subsequent flow of the powder or may fragment into macroscopic regions mixed throughout the less dense bed. The forces acting on the top of the bed may be quite different from those at the bottom of the bed." In the studies reported here, considerable data have been collected that reveal the large number of factors that cause changes in the properties of powder beds as well as indicating the magnitude of these effects.

The basic measurements of friction coefficient and cohesion may be obtained from a simple shear cell described by Nash *et al.* (2). Though

Received March 29, 1968, from the Upjohn Company, Kalamazoo, MI 49001
Accepted for publication June 6, 1968.
The authors wish to thank Mr. B. D. Haffner and Mr. W. E. Painter for making some of the measurements and assisting in the development of the apparatus.

modified in detail, the apparatus used in these studies retains the advantages of simplicity and the use of a thin layer of powder that may be formed by gentle sifting into place. Deep powder beds are not necessary and may be undesirable since uniform bulk density is difficult to maintain in forming deep beds. Other shear cells have been used successfully but some of the observations reported here could not be made using them because of the pretreatment, packing, *etc.*, of the powder bed (3).

FRICTION COEFFICIENT AND COHESION

The friction-cohesion equation used here is basically the same as suggested by Deryagin (4).

$$\tau = \mu (mg + c) \qquad \text{(Eq. 1)}$$

where τ is the force required to shear the powder, μ is the friction coefficient, mg is the load in dynes applied normal to the shear plane, and c is the apparent cohesion force of the powder.

Since friction is said to be the shear strength of the areas of true contact, an increase in friction coefficient should reflect either an increase in true contact area or an increase in force of interaction in the regions of true contact. Either of these should produce a corresponding increase in cohesion. In real cases the cohesion value obtained by applying Eq. 1 often decreases when the friction coefficient increases and vice versa. These experimental values vary in such a way that the authors have been unable to determine their significance. Other workers have observed that values of c based on Eq. 1 are larger than values obtained by direct tensile strength tests (5).

APPARATUS

Shear Cells—The basic shear cell is in the form of a sandwich of powder between upper and lower plates. The powder bed is prepared by sifting it into the 6.2-cm. diameter hole of a thin template placed over the bottom plate. The thickness of the template used varies with the type of upper and lower plates employed. A spatula serves to level the surface by gently scraping away excess powder. Care is taken to accomplish this with minimum disturbance of the powder bed. The template is lifted off and a disk-shaped bed of powder remains. The top plate is gently lowered onto the powder bed to bring its surface into contact with the powder. Additional weights are added to produce the desired applied load. Figures 1 and 2 show the cell in place in the apparatus. Normal loads less than the weight of the top plate are produced by suspending the top plate from one side of the analytical balance holding the desired counterbalance weights (not shown in Figs. 1 and 2). In this case the powder bed is gently raised to meet the top plate and to zero the balance.

Several different designs of top and bottom plates have been used. For some experiments at smaller applied loads, the bottom plate was a rectangular piece of "harrow" assembled from file cards[1] after reducing the bristle length. The top plate was a 5-cm. diameter "harrow" of the same material. This shear cell "sandwich" will be referred to as the HPH cell (harrow-powder-harrow). At higher loads, the harrow teeth may touch during a determination. Consequently, the upper and lower plate materials were changed. The first experiments done in this laboratory used metal disks coated with sandpaper,[2] called the SPS cell. In most of the recent studies the plates have been made from compressed tablets[3] prepared from the same powder used in the shear test, the TPT cell. Figure 3 shows the parts of these three types of cells. The top plate has been removed and placed upside down beside the powder bed.

In a few cases, a direct tablet-to-tablet measurement was made, the TT cell. This would not be a

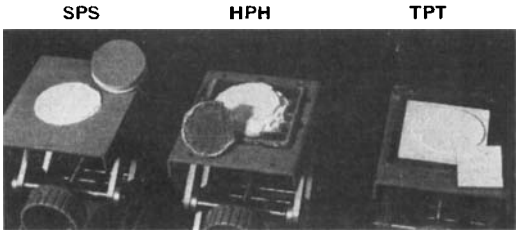

Fig. 3—Three varieties of shear cells used.

[1] Coulton's No. 10 File Cleaner, E. C. Knudson, Mfg., Chicago, Ill. Facing removed and cemented to flat plate. Surface grinder used to reduce length of steel bristles to 0.16 cm.

[2] The grade of sandpaper is not a critical factor. A satisfactory paper is garnet finishing paper, open coat, No. 100, Minnesota Mining and Mfg. Co., St. Paul, Minn.

[3] The top element is a tablet 3.7-cm. square and about 0.64-cm. thick. The bottom element is four of these tablets cemented to a rigid base plate and sanded smooth. Each tablet was made from 10 g. of powder A special die was used with the Carver press to form the tablets. Care was taken to make all tablets in a set as nearly alike as possible.

powder study unless indigenous powder was present. However, a comparison of TPT and TT data was desired.

Force Detector—A cantilever beam strain gauge was connected to a horizontal screw jack. The jack was driven through a gear box by an electronically speed-controlled, reversible electric motor. The upper plate of the shear cell was connected to the strain gauge by a small diameter tow line or wire including a fish-line swivel. The strain gauge output was connected directly to the input of a Sargent model SR recorder and resulted in a sensitivity of 1.315×10^5 dynes/mv. These parts are shown in Fig. 1 and diagrammatically in Fig. 2.

The usual linear speed of the gauge assembly was 4 cm./sec. Only static friction or "breakaway" force values were used. The shear force was insensitive to the rate of application of force in this range of gauge velocities.

The usual operating procedure was to assemble the cell and connect the linkage to the gauge. The screw jack was operated until the top plate moved. Then the direction of the jack was reversed until the tow line became slack. The forward motion of the jack was reestablished and a second pull was made. This sequence was repeated until the same shear force was observed for several sequential pulls. This was called the plateau value of the shear force and the powder bed was considered to have attained a reproducible steady-state condition referred to as the plateau condition.

The frequency of the pulls was arbitrarily selected as approximately 2/min. The loading and unloading times vary with the magnitude of the shear force and therefore with the applied load. The time interval between the "breakaway" peak force and the unloading is determined by the backlash of the jack. The exact magnitude of these factors is not critical but uniformity of practice is desirable to reduce the variability of results.

Environment—The shear cell assembly was contained in a controlled-humidity chamber. The humidity chamber draws from dry and wet air reservoirs to cycle the relative humidity over a range of about ±1% every 2 min. The air in the chamber is circulated rapidly through the chamber and a mixing box beneath it which contains the humidity controller and the dry and wet air-injector systems.

EXPERIMENTAL MATERIALS

With a few exceptions, the materials used were selected from the common chemical entities used in pharmaceutical dosage forms. They were preconditioned in the controlled humidity environment for no less than 24 hr. and usually for more than 80 hr. before use in the shear cell. The dynamic nature of the properties of powders will be illustrated by observations of the changing of a sample over very long periods of time.

CHANGES OF SHEAR STRENGTH IN A SERIES OF PULLS

The series of pulls used to establish the plateau condition will provide a pattern of shear values typical of the powder bed at the applied load. In general, one of three patterns is obtained. These

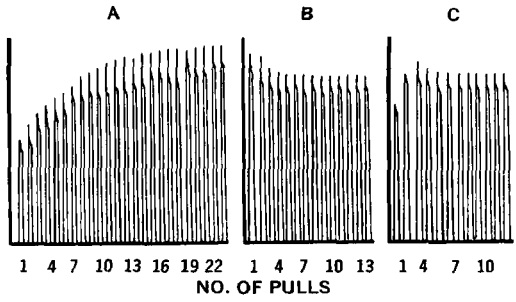

Fig. 4—Recorder chart traces. Patterns developed by peaks prior to reaching plateau condition.

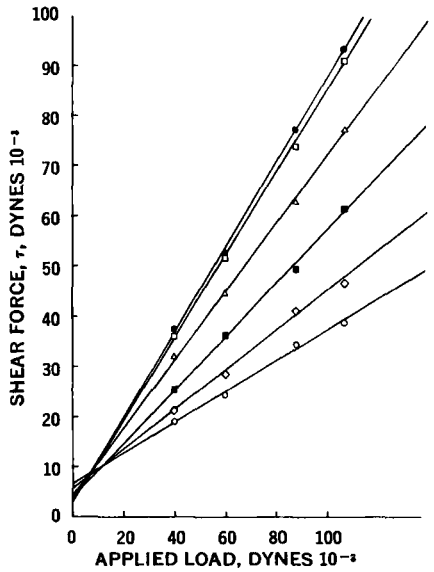

Fig. 5—Repeated shearing of powder bed changing its properties. Each line represents the shear force for a given number of pulls on the top disk obtained at various applied loads. The HPH cell was used in 50% relative humidity environment with calcium acid novobiocin powder. Key: ○, 1st pull; ◇, 2nd pull; ■, 4th pull; △, 8th pull; □, 16th pull; ●, plateau.

are shown in the recorder chart traces in Fig. 4. The peak value of the leading edge of each individual "spike" is the breakaway force. Once shear occurs, the measurement becomes one of dynamic friction and not static friction. The "spike" ends when the force is removed by reversal of the jack. The regular spacing of these spikes shows the uniform schedule of the pull cycles. This is necessary to obtain reproducible results.

One of the patterns shown in Fig. 4 is obtained at each individual applied load. The usual friction plot used in this work is obtained by plotting the plateau values of the shear force against the applied load. Others have preferred to use the first pull data (2). Figure 5 shows both results with calcium acid novobiocin as well as plots obtained by using other selected values, *e.g.*, only second pull values for each series, only fourth pull values, *etc.* At all loads used, the pattern of pulls was like those in Fig. 4A. All strongly cohesive powders produce patterns of the type in Fig. 4A. These

changes with shear may be produced by changes in packing density, changes in bed thickness, or a development of structure that resists particle movement in a given direction. It is not the result of powder piling-up in front of the top element of the cell since removal of the powder in front has negligible effect on the shear force for the following pull. The types of patterns in Figs. 4B and 4C probably result from powders in which particle orientation and/or dialation are dominant factors associated with shearing of the bed. The bed thickness of choice depends on the selection of the shear cell. Obviously the HPH cell must use thicker beds than might be used with the TPT arrangement. Separate studies using beds of different initial thickness gave very similar results, though not always identical values of τ and c. With the HPH cell, the plateau values remained constant until the teeth of the harrow made contact with each other. With the other cells the plateau values remained constant over many pulls. Therefore, changes in bed thickness are not believed to be major factors in these measurements, especially when plateau conditions are used. Probably, the plateau condition is a steady-state situation in which the rate of introduction of new powder at the leading edge remains nearly constant with each successive movement of the top plate (see section on the elasticity of the tow line).

If one concludes that the changes observed in a series of pulls is the result of changes in the bed other than thickness *per se*, then one may conclude that in some applications the friction and cohesion values may vary over at least the range observed in the series of pulls. Certainly a single value of friction and cohesion cannot be characteristic of the powder but only of the specific powder bed. It would be interesting to relate these values to other properties such as bulk density, *etc.* However, it is not simple to obtain both measurements on the powder in the cell under the conditions of each individual pull.

TIME-DEPENDENT EFFECTS

Duration of Application of Static Load—It has been reported that the static friction coefficient between solids varies with the logarithm of the time of contact (6). There is no reason to expect the friction coefficient of powder beds to be independent of time of contact. Lidocaine base illustrates an extreme case as shown in Fig. 6. When the load was placed on the top plate and left for 30 min. before the first pull was made, the static friction force was much larger than when the usual time schedule was followed. However, the next pull, made immediately after the time-delayed pull, is only very slightly different from the first pull made on the usual schedule without the time delay.

Similar results were obtained when the time studies were applied to powder beds brought to the plateau condition. Figure 7 shows data obtained with chlorphenesin carbamate. The plateau condition was established and then the cell was left undisturbed for the chosen time interval. The magnitude of the first pull after the time interval was higher than the plateau value. The lowest line in Fig. 7 shows the magnitude of a second pull made immediately after the time-delayed one for the 30-min. case. Similar results were observed

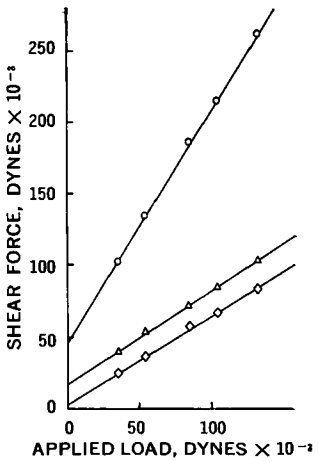

Fig. 6—Lidocaine base, SPS data, 70% relative humidity; influence of time of static loading on magnitude of shear force for first pull. Key: ○, 1st pull after 30 min.; ◇, 2nd pull, immediately after 30-min. delay pull; △, plateau by usual method.

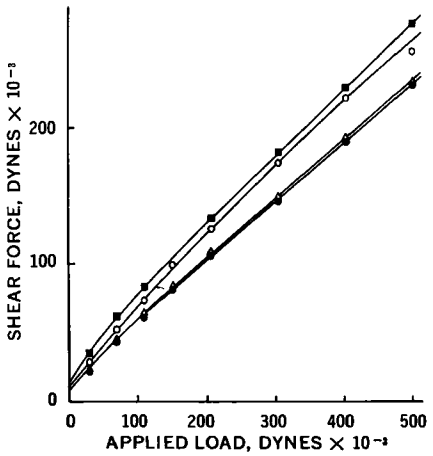

Fig. 7—Chlorphenesin carbamate, TPT data, 50% relative humidity; influence of time of static loading on magnitude of shear forces after plateau condition has been established. Key: ■, 1st pull after 60-min. wait; ○, 1st pull after 30-min. wait; △, plateau; ●, 2nd pull immediately following 1st pull after 30-min. wait.

after each of the time-delay intervals. The shear forces have returned to approximately the same as the plateau condition.[4] This indicates that the changes in shear force with time of static load application are not due to irreversible changes in the power bed.

Figure 8 shows a longer interval of time lapse than shown in Fig. 7 but for only one applied load. Note that changes still are occurring after 30 hr. of standing with the load applied.

Again the conclusion is that a single value of the friction coefficient and the cohesion is not adequate to describe the powder properties.

Effect of Storage Time in the Controlled-Humidity Chamber—Changes in the properties of powders

[4] The fact that this line is slightly below the plateau value in both examples is consistent with an observation made in other cases, *viz.*, whenever a preceding pull results in an unusually high shear force the next pull will be smaller than the average value.

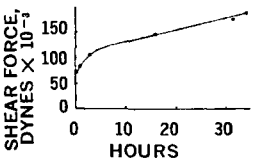

Fig. 8—Chlorphenesin carbamate in the same study as in Fig. 7 but shows extended time scale for the application of a 110-g. applied load.

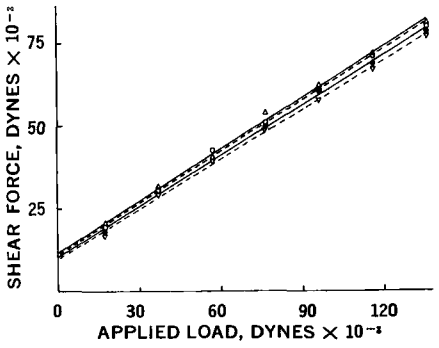

Fig. 9—Changes in the properties of a placebo mixture stored in the controlled-humidity chamber. Key: △, 0 days; ○, 3 days; ●, 14 days; ▽, 25 days.

lengths of time in the controlled-humidity environment. The option of ignoring the effects of time of storage of each material was adopted, obviously to save time. This expediency detracts from the absolute precision of a given value but should not mask the important effects.

Table I shows the differences in plateau values of the friction coefficient obtained in various relative-humidity atmospheres using the TPT cell prepared from β-sitosterol. A minimum value in the 25–65% relative humidity range was expected. The dramatic changes in the shear forces observed in the 30 and 50% relative humidity range were not expected.

EFFECT OF VIBRATION ON SHEAR FORCE

One possible cause of changes of shear force with time is the change in area of true contact induced by the ever present ambient vibrations of the laboratory. If so, an increase of shear force with time should be accelerated by subjecting the shear cell to forced vibration.

An electric vibrator[6] was attached to the lab jack supporting the shear cell. The motion orientation was parallel to the direction of shear. A plateau value was attained in the same manner as before except that the vibrator was turned on for a few seconds between each pull Figure 10 compares the plateau condition results with spray-dried lactose (TPT) subjected to a 4-sec. vibration period with the unvibrated case. On the same graph is shown this same comparison for the TT cell. Figure 11 shows

TABLE I—CHANGES IN THE FRICTION COEFFICIENT OF β-SITOSTEROL POWDER, TPT CELL DATA

Relative humidity, %	30	40	50	72	87	94
Friction coefficient	0.91	0.76	0.87	0.93	0.94	0.89

occur during the storage of the material in the controlled-humidity environment. Figure 9 shows the results of a series of measurements[5] with the HPH cell on a powder mixture. The mixture was used for a placebo tablet preparation and its primary constituent was lactose. The powder was not preconditioned in the controlled-humidity environment. Zero time is taken as the time when the powder was spread on a tray in a layer not in excess of 1.2 cm. thick and was placed in the controlled-humidity chamber for the duration of the experiment. The results of the study indicate that it did not attain an equilibrium with its environment in 25 days.

The controlled environment limits the humidity fluctuations to a range of ±1% relative humidity. Moisture on the surface and especially fluctuations in the amount of moisture could promote surface changes of the solid. However, the environmental changes in relative humidity are rapid enough that one would expect very little effect. Certainly one would not expect all powders to continue to change over such long periods of time but this example illustrates that the possibility must be considered.

EFFECT OF RELATIVE HUMIDITY OF THE ENVIRONMENT

As indicated earlier, most measurements were made after powders had been stored for reasonable

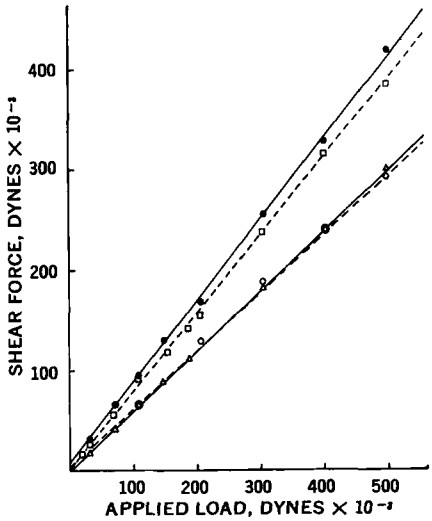

Fig. 10—Lactose, spray dried, 50% relative humidity, TPT and TT data; effects of vibration on the values at plateau conditions. Key: ●—, TPT vibrated 4 sec.; △—, TPT not vibrated; □---, TT vibrated 1 sec.; ⊕---, TT not vibrated.

[5] These data are taken from a study in which all measurements were made using a standard powder bed that reached a plateau condition with 138 g. applied load prior to shearing at the desired load.

Small nylon thread	87.1	1.45
Nylon, No. 15 fish line	92.5	0.53
Wire	93.2	0.44

the analogous case using chlorphenesin carbamate.

TT data for materials such as lactose may be misleading because some powder is formed at the shear plane between the tablets. No evidence of powder was found for the TT case with chlorphenesin carbamate. Forced vibrations produced, in a few seconds, an effect similar to that produced by standing for a much longer time; however, the phenomenon occurring in the powder bed could have been different in the two cases. Possibly the main effect of vibrations is to produce packing changes. Standing for longer periods may permit only the relaxation of elastic stresses at points of true contact. Either could increase the friction force. Again it is difficult to make measurements that would define unequivocally the mechanism producing the effect.

SOME RESULTS RELATED TO EXPERIMENTAL PROCEDURES

Sifting—The same lactose placebo mixture used in the study of changes during storage was used to demonstrate the effects produced by repeated sifting. Figure 12 shows the result; the HPH method was used. Since the sifting to form a shear cell normally is done in the air bath, *i.e.*, the controlled-humidity chamber, in which there is rapid circulation of the air, some fine particles are swept away by the air currents. This is believed to be the cause of the observed changes. These results led to the use of a fresh sample of powder each time a powder bed was formed.

Elasticity of Tow Line—It is obvious that the factors that produce variation in the observed values of the friction coefficient are multitudinous. The influence of the design of the apparatus cannot be eliminated. Table II shows data obtained using three different tow lines between the cell and the strain gauge. The nylon line stretches as tension is applied. When the static friction is overcome, the top plate of the cell will move forward until the tension is reduced to the dynamic force. Obviously this distance of travel depends on the elastic properties of the tow line and the cantilever beam strain gauge assembly. In this study only the tow line was changed. Apparently, the structure of the bed of powder is dependent on the extent of movement of the top plate. Therefore, the plateau value changes. Possibly the differences result from the change in the rate of introduction of new powder at the leading edge.

Differences in Values with Various Shear Cells—It must be noted that the three cells, HPH, TPT, and SPS do not yield identical results in the shear cell studies. The HPH design was developed to assure that the shear was within the powder bed. In concept it is essentially the same as a cell used by Dawes (7) but of a much simpler design. Dawes compared the results obtained using a cell with sandpaper-coated surfaces with those using a cell with vanes extending into the powder bed. The absolute values were found to be significantly different.

The results of these studies confirm this observation. Table III gives examples. Each cell fits a specific need and also has specific limitations. The HPH cell produces shear in the powder bed but cannot be used to obtain plateau conditions if a large applied load is used because the teeth of the harrow-like plates will touch before the plateau

TABLE III—COMPARISON OF VALUES OBTAINED WITH LACTOSE USING DIFFERENT SHEAR CELLS

	HPH	TPT	SPS
Friction coefficient, μ	0.608	0.608	0.602
Cohesion (dynes/cm.²)[a]	+59	−57	+260

[a] These units are obtained by dividing the intercept on the σ axis by (μ × area of top plate).

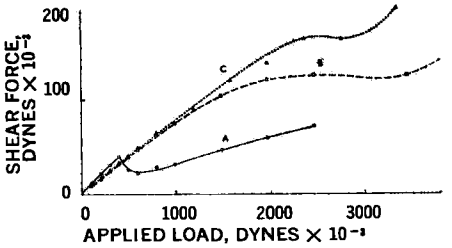

Fig. 13—Anomalous results obtained for plateau conditions with magnesium stearate. TPT and lower SPS data were obtained by pulling top plate in one direction. Top SPS data were obtained by reversing direction of pull each time. Key: A, TPT data for τ_p, all pulls in same direction; B, SPS data for τ_p, all pulls in same direction; C, SPS data for τ_p, pull direction reversed after each pull.

condition is established. The TPT cell is useful with the larger applied loads and does not introduce a foreign material at the interface with the powder. Obviously it cannot be used when the powder will not form a sufficiently strong compact by compression. Sometimes shear may occur at the tablet-powder interface more readily than within the powder bed. With magnesium stearate the surface of the tablet changed during a single run. Reproducible results were obtained by removing the surface layer between each run. Figure 13 shows three friction plots obtained with magnesium stearate. The conditioning of the tablet surface and shifting of the shear plane to the interface is believed to account for the irregular shape of the plot. The SPS cell required larger loads to produce the effect. After shearing to the plateau condition under these larger loads, the sandpaper was plated with magnesium stearate and appeared to be just like the compressed tablet surface. Pulling the top plate alternately in opposite directions diminished this effect and delayed the onset of gross deviations in the plot. The SPS cell seems to be the most versatile assembly.

Differences Produced by Direction of Shear—If after a series of pulls in a given direction the direction of pull is reversed, the observed shear force changes to be more nearly like the first pull, *e.g.*, powders producing patterns like Fig. 4A would require a smaller shear force when the direction of shear is reversed, if like Fig. 4B a larger force would be required. Table IV lists plateau values for several powders. The usual one direction of pull values are given and also the values obtained when the direction of pull is reversed after each individual pull. The magnitude of the plateau values seems to follow the same general rule as for the case of a single pull in the opposite direction.

The failure of these experiments to produce values independent of the detailed design of the apparatus and independent of the procedure followed in its use could prompt extensive criticism of the entire study. However, many of the conclusions have been made using a carefully standardized procedure in which given values may be reproducibly obtained. Therefore, changes in these values produced by humidity, time, vibrations, *etc.*, are believed to be meaningful observations. The discussion of the observations relating to the experimental design or procedure may assist other investigators interested in conducting similar experiments.

TABLE IV—COMPARISON OF PLATEAU VALUES OF SHEAR FORCE BETWEEN CASE OF ALL PULLS IN SAME DIRECTION, τ_p, AND CASE OF PULL DIRECTION REVERSED AFTER EACH PULL, $\tau_p \rightleftharpoons a$ (SPS CELL, 50% RELATIVE HUMIDITY)

Material	Plateau Value of Shear Force τ_p	$\tau_p \rightleftharpoons a$
β-Sitosterol[a]	0.90	0.79
Lactose (spray dried)	0.63	0.65
Erythromycin base	0.82	0.72

[a] Different lots of drugs were used than for studies reported in Tables I and II.

CONCLUSIONS

A relative simple apparatus and procedure are described for obtaining reproducible powder bed conditions. Experimental results have been obtained that indicate some of the factors in the environmental history of a powder bed that produce changes in the friction and cohesion within the bed. In practical applications, the entire range of values of friction coefficients and cohesion should be within acceptable limits. The experimental design used to establish the significant range of values must include the use of powders subjected to the environmental variations that will be encountered by the powder in actual use.

Effect of Chronic Poisoning by Emetine on Oxidative Process in Rat Heart III. Effects on Oxidation of Pyruvate and Lactate

By GLENN D. APPELT and HAROLD C. HEIM*

The effect of chronic emetine poisoning on the oxidation of pyruvate and lactate by rat heart and liver homogenates was investigated. Oxygen consumption by heart homogenates was lower in the emetine-poisoned animals when compared to sham-injected controls. No significant difference was noted in liver homogenates. Heart slices from emetine-poisoned rats consumed less oxygen than slices from sham-injected controls. When diaphragm sections were employed, this difference was not noted.

MUCH EVIDENCE has been accumulated to show that the myocardium utilizes, as a source of energy, a variety of substrates including glucose, lactate, pyruvate, and fatty acids. In earlier communications, data were presented which described an inhibitory effect elicited by chronic emetine poisoning on the oxidation of fatty acids (1), and of certain citric acid intermediates (2) by rat heart homogenates. These inhibitory effects were not noted in the oxidation of these substrates by rat liver homogenates from emetine-poisoned animals. The heart contains a small amount of emetine after intraperitoneal injection, although a relatively high concentration of the drug is found in the liver (3). Cardiotoxicity, however, has been observed with emetine (4–6), and this effect may be related to a rather specific aberration of biochemical processes in the myocardium.

Since pyruvate and lactate may be utilized by the myocardium, and apparently represent substrates for the heart (7–9), it appeared of interest to study the effect of chronic emetine poisoning on the oxidation of these compounds by rat heart and liver homogenates. In addition, oxygen consumption by heart slices and diaphragm sections from emetine-poisoned rats in the presence of pyruvate was measured.

EXPERIMENTAL

To study the effects of chronic poisoning by emetine on the oxidation of pyruvate and lactate by heart and liver homogenates, young adult Sprague-Dawley rats of both sexes were employed as test animals. The animals weighed approximately 150 g. at the beginning of the experiment. The animals were separated into two groups of six animals each and given intraperitoneal injections daily for 14 days as follows: Group A, 0.2 mg. emetine HCl in 0.1 ml. water; Group B, 0.1 ml. water. Food and water were allowed *ad libitum*. After 14 days, the animals were decapitated, the heart or liver tissue immediately removed, washed quickly in cold water, blotted dry, and weighed. The tissue was then transferred to a chilled Ten Broek tissue grinder containing sufficient cold 0.1 *M* potassium phosphate buffer, pH 7.4, so that the homogenates contained 80 mg. of fresh tissue per milliliter. The homogenates were pipeted into chilled Warburg vessels containing substrates and cofactors listed below.

When diaphragm sections were employed, the animals were treated for 14 days in the same manner as above, sacrificed, and the diaphragm removed rapidly and cut into segments of approximately 100 mg. each. Ventricle slices were prepared using the tissue slicer described by Stadie and Riggs (10). The individual slices or sections were quickly transferred to a torsion balance, the exact weight determined, and one slice or section placed in each iced Warburg vessel containing the reaction medium.

The main compartment of each flask contained 0.5 ml. of homogenate or a tissue slice, 0.1 ml. of 5×10^{-4} *M* cytochrome c; 0.1 ml. of 1.5×10^{-2}*M* malate; 0.1 ml. of 2×10^{-2}*M* $MgCl_2$; 0.1 ml. of 2×10^{-2}*M* ATP; 0.1 ml. of 1.5×10^{-2}*M* nicotinamide; 0.3 ml. of 0.1 *M* pyruvate or lactate; 1.2 ml. of 0.1 *M* potassium phosphate buffer, pH 7.4, in flasks which contained homogenates, or 1.7 ml. in flasks which contained a diaphragm section or heart slice; and 0.3 ml. of distilled water. In all experiments the center well of each flask contained 0.2 ml. of 10% potassium hydroxide solution. The total volume of the flask contents was 3 ml. in all the oxidative studies. After a 10-min. equilibration period, oxygen consumption was measured according to conventional manometric techniques (11).

Oxygen uptake readings were taken at 15-min. intervals for 90 min. All values represent the average of data obtained with at least six animals, and each determination was performed in duplicate. The vertical line through each point designates the standard error of the mean for each set of values.

RESULTS AND DISCUSSION

Figures 1 and 2 illustrate the effect of chronic poisoning by emetine on the oxygen uptake by rat heart homogenates in the presence of pyruvate and lactate, respectively. The total oxygen consumption at the end of 90 min. was significantly lower ($p < 0.001$) in the preparations from emetine-poisoned rats when compared to values obtained from sham-

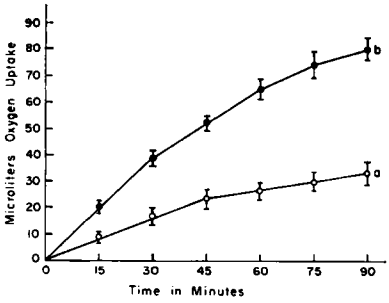

Fig. 2—Oxidation of lactate by heart homogenates from sham-injected and emetine-treated rats. Key: Curve a, emetine-treated animals, Curve b, sham-injected animals.

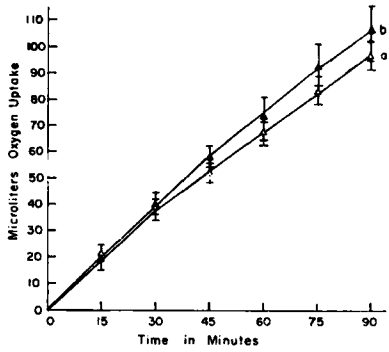

Fig. 3—Oxidation of pyruvate by liver homogenates from sham-injected and emetine-treated rats. Key: Curve a, emetine-injected animals; Curve b, sham-injected animals.

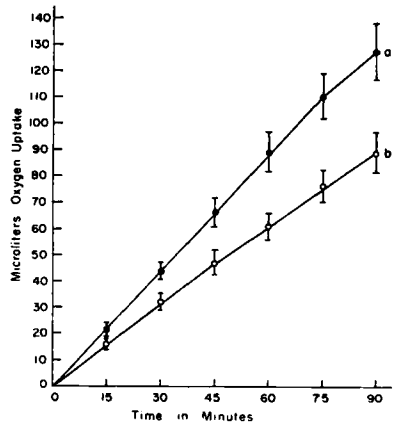

Fig. 4—Oxidation of lactate by liver homogenates from sham-injected and emetine-treated rats. Key: Curve a, sham-injected animals; Curve b, emetine-treated animals.

injected animals. This inhibitory effect represents a 48% decrease for pyruvate and a 59% reduction when lactate was the substrate.

Figures 3 and 4 depict oxygen consumption by rat liver homogenates when pyruvate and lactate were utilized as substrates. The 90-min. *r* readings from emetine-poisoned animals in this instance, however, were not significantly lower than the values from the sham-injected animals.

These data indicate that heart homogenates from emetine-poisoned rats were less efficient in the oxidation of these substrates than homogenates from control animals. Such a difference, however, was not noted in liver homogenates from emetine-poisoned rats.

Figure 5 shows a comparison of the respiration by diaphragm sections from emetine-poisoned rats with that of the sham-injected controls. Pyruvate was the substrate and, under the conditions of the experiment, no significant difference was observed between the test groups. Figure 6 illustrates that the total oxygen consumption of ventricle slices from emetine-poisoned rats was about 40% lower than that obtained with ventricle slices from the sham-injected controls. These results extend the idea that this inhibitory effect may be fairly specific for the myocardium, by including a muscle preparation for comparison.

It has been reported that pyruvate and lactate are utilized less efficiently in certain thiamine-deficient situations (12–14). Thiamine pyrophosphate is necessary in the biotransformation of pyruvate to acetyl-coenzyme A which represents a pathway whereby these substrates may be metabolized *via* the citric acid cycle. Diamant and associates (15) have reported that emetine-treated rats stored smaller amounts of thiamine in the liver than did control animals. It is conceivable that a similar situation exists in cardiac muscle resulting in a diminished utilization of pyruvate and lactate.

Nicotinamide adenine dinucleotide (NAD) functions as a coenzyme in the lactic dehydrogenase system, as well as a cofactor in the conversion of pyruvate to acetyl-coenzyme A. Deitrich and Heim (16) have noted that emetine decreased the oxygen uptake of rat heart homogenates in the presence of pyruvate and malate, however, an enhancement of the oxidation of succinate, an FAD-linked sub-

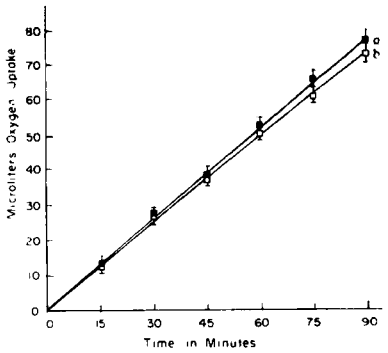

Fig. 5—Oxidation of pyruvate by diaphragm slices rom sham-injected and emetine-treated rats. Key: Curve a, sham-injected animals; Curve b, emetine-treated animals.

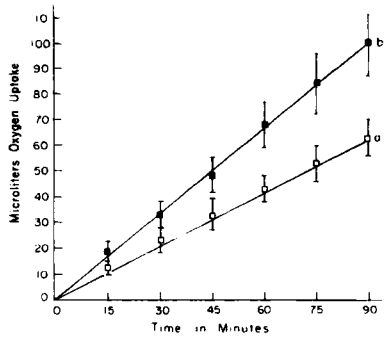

Fig. 6—Oxidation of pyruvate by heart slices from sham-injected and emetine-treated rats. Key: Curve a, emetine-treated animals; Curve b, sham-injected animals.

strate, was observed. A similar inhibitory activity of the oxidation of NAD-linked substrates in emetine-poisoned rats has previously been reported, although no alteration in NAD metabolism was noted (2).

At least one investigator (17) has suggested that emetine is most toxic to those tissues which involve contractility as the principal function. One might expect, therefore, that metabolic processes in tissue such as diaphragm would be altered by emetine. However, it was found that pyruvate was oxidized as rapidly by diaphragm sections from the emetine-poisoned animals as from the sham-injected animals. With heart slices it was found that chronic poisoning by emetine elicited an impaired ability to oxidize pyruvate. Such evidence tends to indicate that the effect of emetine, as far as oxidative processes are concerned, is not common only to those tissues in which contractility is the principal function, and further supports the view that the toxic effect of emetine is rather specific to the heart.

SUMMARY

1. The effects of chronic poisoning by emetine on the oxidation of pyruvate and lactate by various tissue preparations was studied.

2. Oxygen consumption by heart homogenates prepared from emetine-poisoned rats was lower than that observed with homogenates prepared from sham-injected controls.

3. The oxygen uptake by liver homogenates prepared from emetine-poisoned rats did not differ significantly from that observed with homogenates prepared from sham-injected controls with pyruvate and lactate as substrates.

4. Heart slices prepared from emetine-poisoned rats consumed less oxygen in the presence of pyruvate than did slices from the sham-injected controls. With diaphragm sections this difference was not observed.

Synthesis, Purification, and Influence of Chain Length on Toxicity of Two Quaternary Ammonium Compounds

By THEODORE H. EICKHOLT, GARY K. BRASHIER*, MICHAEL D. HIGGINS, and U. B. MARTINEZ

The synthesis and purification of two quaternary ammonium compounds was accomplished. The influence of chain length upon toxicity of the two compounds was determined using oral LD_{50} values, in fasted animals, and intraperitoneal LD_{50} values in male Swiss-Webster mice and male Wistar rats except where limited by the critical micelle concentration and the volume required for administration. The larger molecular weight compound was more toxic i.p. in rats than mice while the lower molecular weight compound was more toxic orally in mice than rats. The i.p. LD_{50} values in mice for both compounds were nearly identical and these values in both rats and mice after 24 hr. for the larger weight compound were practically the same. The usual greater toxicity with i.p. administration *versus* oral was not seen with these compounds in mice but was observed in rats.

QUATERNARY AMMONIUM COMPOUNDS are capable of a variety of pharmacologic activities, from antihypertensive to antiseptic. Many surface-active agents are quaternary ammonium compounds and have received considerable investigation as bactericidal agents (1, 2). Cetylpyridinium chloride and benzalkonium chloride are common examples, the latter of which is not a pure, single compound. The LD_{50} of cetylpyridinium chloride i.p. in the mouse is stated to be 10 mg./kg. (3). The LD_{50} in the rat orally is 200 mg./kg., subcutaneously 250 mg./kg., intraperitoneally 6 mg./kg., and intravenously 30 mg./kg. (3). The LD_{50} of benzalkonium chloride, calculated as commercial solution, in the mouse i.p. is 10 mg./kg., and i.v. 10 mg./kg. (3). For none of these figures are times of death indicated.

A mixture of triethyl ammonium bromide homologs[1] is commercially available.

It was, therefore, the purpose of this study to synthesize in a pure form dodecatriethylammonium bromide (DTEAB) and tetradecatriethylammonium bromide (TTEAB) and to determine the influence of chain length on the toxicity of these two compounds, for which little work on the pure systems has been done.

EXPERIMENTAL

The quaternary ammonium bromides were prepared by a method similar to that of Scott and Tartar (4), an established synthesis procedure for making surfactants of the cationic type. The essential differences were ones of degree, *e.g.*, (*a*) reflux times were longer, up to 3 days, (*b*) solvents were not exclusively ethanol, (*c*) surfactants were not limited to only trimethyl head groups on the monomer. Varying the conditions in *a* and *b* the extent of reaction was controlled, thereby producing more surfactant by shifting the equilibrium to the right. The position of equilibrium is most certainly affected by the nature of the monomer formed (*c* above) consequently the reflux conditions were improved as dictated by the specific synthesis.

The long-chain alkyl bromide was mixed with a 35–40% excess of the appropriate trialkylamine and this solution was added to a particular volume of the reaction solvent (CH_3OH or CH_3CH_2OH). The resulting solution was heated under total reflux from 7 hr. to 3 days as, in general, reaction time increases as molecular weight of the quaternary increases.

After the reaction mixture cooled, most of the alcohol and excess amine were boiled off, in some cases, under reduced pressure. Ethyl ether was added to precipitate the quaternary crystals.

Purification was effected by (*a*) repeated recrystallization from alcohol (CH_3OH) by adding ether, (*b*) Soxhlet extraction using ether for as long as 20 hr., or (*c*) a combination of the first two methods. The ether was then filtered from the crystals. The last traces of ether were removed by heating under vacuum for about 24 hr. at approximately 35° (5).

When ethanol was substituted for methanol as the reaction solvent, the reflux temperature was increased sufficiently to enhance the quaternary yield, in some cases by as much as 100%.

Starting materials were reagent grade products of either Eastman Organic Chemicals or Matheson, Coleman, and Bell. In those cases in which the gas chromatogram of the alkyl bromide showed more than one large peak, the compound was purified by vacuum distillation.

The primary criterion for purity of the quaternary compounds was the absence of a minimum in the surface tension-concentration curve as reported by Miles and Shedlovsky (6, 7) and verified by others (8, 9).

Stoichiometric equation:

$$RBr + R_3'N \xrightarrow[\text{reflux}]{\text{alcohol}} R\overset{+}{N}R_3'\overset{-}{Br}$$

$(R = C_{12}, C_{14})$ $(R' = Me, Et, Pr, Bu)$

Example:

$$C_{12}H_{25}Br + Et_3N \rightarrow C_{12}H_{25}\overset{+}{N}Et_3\overset{-}{Br}$$
(DTEAB)

To determine the influence of chain length on the toxicity of the two pure compounds, animals were treated as follows.

Male mice of the Swiss-Webster strain received 7.5, 15, and 30 mg./kg. of DTEAB and TTEAB i.p. Thirty animals were used at each dosage and the LD_{50} after 24, 48, and 72 hr. was determined using the Reed-Muench method (10).

Male rats of the Wistar strain received 30, 60, and

120 mg./kg. of DTEAB and 7.5, 15, and 30 mg./kg. of TTEAB i.p.

Ten animals were used at each dosage and the LD_{50} after 24, 48, and 72 hr. was determined where possible using the Reed-Muench method (10).

Male mice, Swiss-Webster strain, were fasted at least 20 hr. but not longer than 24 hr., water was given *ad libitum*. The animals were fasted in screen-bottom cages such that there was no access to feces or litter.

The fasted mice in groups of 30–40 received 5, 10, and 20 mg./kg. of DTEAB and 12.5, 25, and 50 mg./kg. of TTEAB orally by means of stomach intubation. The oral LD_{50} was calculated where possible after 24, 48, and 72 hr. using the Reed-Muench method (10).

Male rats, Wistar strain, were fasted similarly to the mice with water *ad libitum* in screen-bottom cages such that there was no access to feces or litter.

The fasted rats in groups of 16 or 20 received 62.5, 125, and 250 mg./kg. of DTEAB and 10, 20, and 40 mg./kg. of TTEAB orally by stomach intubation similarly to obtain the oral LD_{50}.

The doses in all animals were calculated on a mg./kg. basis and all animals used were approximately 10–12 weeks of age with average weights for mice and rats 19 and 128 g., respectively. All surviving animals were observed for a period of 30 days to include any possibility of latent effects.

RESULTS AND DISCUSSION

The synthesis of the expected products was indicated by elemental analysis. Similar confirmation was reported by Venable (11) on related compounds made by this method.

Anal.[2]—Calcd. for (DTEAB) $C_{18}H_{40}BrN$: C, 61.94; H, 11.50; N, 3.99. Found: C, 61.40; H, 11.73; N, 3.97.

Anal.[2]—Calcd. for (TTEAB) $C_{20}H_{44}BrN$: C, 63.46; H, 11.71; N, 3.70. Found: C, 61.81; H, 11.67; N, 3.86.

The possibility of isomers still exists; however, based on studies of organic syntheses of this nature and on the surface and micellar properties of aqueous solutions of these compounds, it would appear identity of the products was established.

The synthesis of the pure quaternary compounds was shown by the lack of a minimum in the surface-tension concentration curve. A purity of 99% plus was obtained. The absence of minima in these curves reflected a high degree of purity and agrees with earlier reports (6, 9)

The critical micelle concentration (CMC) in water at 30° for DTEAB was 5×10^{-3} g./ml. and for TTEAB was 1.06×10^{-3} g./ml.

No particular observance of any autonomic effects typical of other quaternary ammonium compounds was made. A few of the mice injected i.p. with DTEAB first appeared hyperexcitable but soon returned, as were all other animals, to their normal, grouped together, daytime positions.

The results of the LD_{50} studies of DTEAB i.p. and p.o. in mice and rats are listed in Table I. The LD_{50} values of DTEAB i.p. in mice calculated from the results in Table I using death after 24, 48, and 72 hr. as the end points are 19.60 ± 2.07, 11.25 ± 1.58, and 8.38 ± 1.16 mg./kg., respectively. Similarly, the LD_{50} values of DTEAB orally in mice

[2]Analyses performed by Schwarzkopf Microanalytical Laboratory, Woodside, N. Y.

are 12.84 ± 1.42, 7.95 ± 0.82, and 7.03 ± 0.61 mg./kg. after 24, 48, and 72 hr., respectively.

In the rats, only the i.p. LD_{50} for DTEAB after 24 hr. could be calculated and was found to be 30.00 ± 6.28 mg./kg.

In the mice with DTEAB the i.p. and p.o. LD_{50} values were reversed from what is normally expected when comparing toxicities with these two routes of administration. Orally, DTEAB appeared more toxic than i.p.

In the rats, comparing the i.p. and p.o. DTEAB doses administered, the normal toxicity relationship between the routes of administration was seen. In preliminary work no deaths i.p. were obtained below 30 mg./kg., 50% mortality at 30 mg., and 100% mortality above this, making further calculations impossible. Orally, larger doses were prevented due to the CMC and the maximal volume allowable which could be intubated. In preliminary work, larger doses and volumes, were attempted with no greater mortality rate resulting.

Larger doses of DTEAB were required for toxicity in rats than in mice by either route of administration, being less toxic in the rat and especially appearing much less toxic orally.

The results of the LD_{50} studies of TTEAB i.p. and p.o. in mice and rats are listed in Table I. The LD_{50} values of TTEAB i.p. in mice calculated from the results in Table I using death after 24, 48, and 72 hr. as the end points are 20.07 ± 2.17, 11.14 ± 1.61, and 8.45 ± 1.26 mg./kg., respectively. Only the 24-hr. p.o. LD_{50} for TTEAB in mice could be calculated and was found to be 15.63 ± 1.83 mg./kg.

In the rats, the i.p. LD_{50} for TTEAB was found to be 21.67 ± 3.49, 20.83 ± 3.35, and 20.83 ± 3.35 after 24, 48, and 72 hr., respectively. No p.o. LD_{50} for TTEAB in rats could be obtained again due to CMC and volume limitations.

Comparing i.p. LD_{50} values in mice for DTEAB and TTEAB, the two-carbon increase in chain length and the resulting increase in molecular weight with TTEAB influenced the LD_{50} values obtained very little.

In mice with TTEAB the i.p. and p.o. LD_{50} values were again reversed from what is normally expected when comparing toxicities *via* these two routes of administration; oral administration being more toxic than i.p.

The oral LD_{50} in mice for TTEAB was larger than the oral LD_{50} for DTEAB indicating lesser toxicity for the larger molecular weight compound.

In rats, the i.p. LD_{50} for TTEAB did not change much over 24, 48, or 72 hr., whereas, in mice the i.p. LD_{50} for TTEAB changed considerably. However, the 24-hr. LD_{50} values for both rats and mice for TTEAB were nearly the same.

The i.p. LD_{50} for TTEAB in rats was smaller than the i.p. LD_{50} for DTEAB in rats indicating greater toxicity for the larger molecular weight compound.

The larger oral dose of TTEAB in rats indicates lesser toxicity than i.p. The variations observed in this study again demonstrate the problem of species variation although the data from the rats correlate with increase in molecular weight and toxicity increases. The lesser toxicity of these compounds i.p. than orally in mice is interesting to note as oral absorption of quaternary ammonium compounds is usually stated as difficult, only up to 15% of an oral dose being absorbed due possibly to formation of nonabsorbable complexes (12).

The surviving animals after the 30-day observation period appeared in good health and without deleterious effects.

SUMMARY AND CONCLUSIONS

Synthesis of very pure DTEAB and TTEAB was accomplished.

The influence of chain length or increase in molecular weight of the compounds on toxicity proved to be species variable.

The i.p. LD_{50} values of DTEAB in mice were found to be 19.60 ± 2.07, 11.25 ± 1.58, and 8.38 ± 1.16 mg./kg. after 24, 48, and 72 hr., respectively. The oral LD_{50} values of DTEAB in mice were 12.84 ± 1.42, 7.95 ± 0.82, and 7.03 ± 0.61 mg./kg. after 24, 48, and 72 hr., respectively. Only the 24-hr. i.p. LD_{50} value of DTEAB in rats could be determined and was found to be 30.00 ± 6.28 mg./kg. The usual greater toxicity from i.p. administration *versus* p.o. was not seen with DTEAB in mice but was in rats. DTEAB appeared more toxic in mice than rats, particularly orally.

The i.p. LD_{50} values of TTEAB in mice were found to be 20.07 ± 2.17, 11.14 ± 1.61, and 8.45 ± 1.26 mg./kg., after 24, 48, and 72 hr., respectively. Only the 24-hr. p.o. LD_{50} value of TTEAB in mice could be determined and was found to be 15.63 ± 1.83 mg./kg. The i.p. LD_{50} values of TTEAB in rats were found to be 21.67 ± 3.49, 20.83 ± 3.35, and 20.83 ± 3.35 mg./kg., after 24, 48, and 72 hr., respectively. No. p.o. LD_{50} of TTEAB in rats could be obtained due to limitations of critical micelle concentration and volumes required for administration. The usual greater toxicity from i.p. administration *versus* p.o. was again not seen with TTEAB in mice.

The i.p. LD_{50} values in mice for DTEAB and TTEAB were nearly identical. Chain length appeared to have little influence on toxicity in mice i.p. Orally, the LD_{50} values in mice indicated DTEAB was more toxic than TTEAB, the lesser molecular weight compound being the more toxic. The i.p. LD_{50} values in rats and mice after 24 hr. for TTEAB were practically the same. However, the i.p. LD_{50} values indicated that the higher molecular weight compound, TTEAB, in rats was more toxic than DTEAB which is what usually would be expected. TTEAB was less toxic p.o. than i.p. in rats again demonstrating the variability of absorption seen with quaternary compounds.

General comparisons of the LD_{50} values for DTEAB and TTEAB with those of cetylpyridinium chloride and benzalkonium chloride indicated lesser toxicity for the pure DTEAB and TTEAB compounds.

Determination of the pKa′ Value for 5,5-Diphenylhydantoin

By SURAJ P. AGARWAL and MARTIN I. BLAKE

The pKa′ value for diphenylhydantoin was found to be 8.31 by ultraviolet spectrophotometry and 8.33 by potentiometric titration.

A NONAQUEOUS titrimetric procedure for determining combinations of phenobarbital and sodium diphenylhydantoin was recently reported by Agarwal and Blake (1). In considering the feasibility of a differentiating titration for mixtures of phenobarbital and diphenylhydantoin, it was apparent that the pKa value for the latter component had not been reported in the literature. Preliminary studies (2) with a variety of solvents, titrants, and electrode systems indicated that a differentiating titration was not possible. It was concluded that the pKa values for the two components were probably too close together to permit an effective differentiating nonaqueous titration. This study was undertaken for the purpose of establishing the pKa′ for diphenylhydantoin. The spectrophotometric procedure described by Albert and Sergeant (3) was applied in this investigation. The pKa′ was also determined potentiometrically.

EXPERIMENTAL

Apparatus—All spectrophotometric measurements were made with a Carl Zeiss model PMQII spectrophotometer, equipped with matched 1.0-cm. silica cells. Potentiometric titrations were performed with a Beckman pH meter (Expandomatic) model 76A equipped with a glass electrode (Beckman No. 41263) and a calomel electrode (Beckman No. 39170). A 5-ml. buret (Kimax) graduated in 0.01 ml. was used for delivery of the titrant.

Reagents and Solutions—Reference standard diphenylhydantoin and sodium diphenylhydantoin were supplied by Parke-Davis and Co. Tris-(hydroxymethyl)aminomethane (THAM), primary standard grade, was obtained from Fisher Scientific Co. Buffer solutions were prepared by combining appropriate volumes of 1.0 *N* HCl and 0.01 *M* THAM solution to give the desired pH. All other chemicals were reagent grade.

Received March 18, 1968, from the Department of Pharmacy, University of Illinois at the Medical Center, Chicago, IL 60612
Accepted for publication May 31, 1968.

Spectrophotometric Procedure—The absorption spectra of diphenylhydantoin were obtained in 0.01 *N* sodium hydroxide and in 0.01 *N* hydrochloric acid. Since the maximum difference in absorption for the ionized and unionized species occurs at 236 mμ, this was the wavelength selected for all absorbance measurements. The spectra are shown in Fig. 1.

A stock solution of diphenylhydantoin (0.01 *M*) in alcohol was prepared. One milliliter of this solution was transferred by pipet to each of seven 100-ml. volumetric flasks and the volume was brought to the mark with THAM buffer solutions having pH values of 7.7, 7.9, 8.1, 8.3, 8.5, 8.7, and 8.9, respectively. A similar series of solutions was prepared which contained 1 ml. of alcohol and the corresponding buffer solution. These served as blanks for the absorbance measurements. The average ionic strength was 0.005 (0.002–0.008).

Potentiometric Procedure—A series of stock solutions, 0.01 *M* in sodium diphenylhydantoin, was prepared in aqueous alcohol solution containing 20, 30, 40, and 50% alcohol by volume, respectively. Fifty milliliters of each solution was titrated potentiometrically with 1 *N* hydrochloric acid. The ionic strength was 0.01.

DISCUSSION

The pKa′ of diphenylhydantoin was determined spectrophotometrically by the procedure described by Albert and Sergeant (3). The absorbance of the

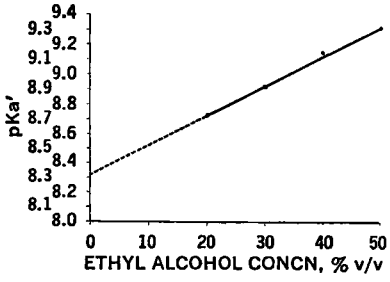

Fig. 2—The pKa' of 5,5-diphenylhydantoin in hydroalcoholic medium plotted against the concentration of ethyl alcohol.

ionized and unionized forms of diphenylhydantoin was determined. The absorbance values were also obtained for a series of solutions varying in pH, but still in the general region where the pH approximates the pKa' value, at which point the ionized and unionized species are equal in concentration. The pKa' was calculated by the expression,

$$pKa' = pH + \log \frac{A - B}{B - C}$$

where A = absorbance of diphenylhydantoin in 0.01 N NaOH, B = absorbance of diphenylhydantoin in buffered solution, C = absorbance of diphenylhydantoin in 0.01 N HCl. For the 7 buffers used in this study an average pKa' of 8.31 ± 0.04 (SD) was obtained.

The pKa' was also determined potentiometrically by titrating sodium diphenylhydantoin with standard hydrochloric acid. Since diphenylhydantoin is soluble in alcohol but not in water, and the reverse is true for the sodium salt, a series of titrations was performed in solvent mixtures containing varying concentrations of alcohol in water. The average pKa' value was determined at each alcohol level from the data obtained for at least five points in each titration curve using the expression,

$$pKa' = pH - \log \frac{(salt)}{(acid)}$$

The pKa' in water (0% alcohol) was obtained by plotting the average pKa' values *versus* alcohol concentration. This procedure was first reported by Mizutani (4). Figure 2 shows a plot of pKa' *versus* alcohol concentration. Extrapolation to 0% alcohol content yields a pKa' value of 8.33 which is in good agreement with the spectrophotometric value.

The pKa' values for hydantoin and 5,5-dimethylhydantoin have been reported (5) as 9.12 and 9.19, respectively. Butler (6) reported a pKa' value of 8.5 for 5-ethyl-5-phenylhydantoin. One would expect the 5,5-diphenyl derivative to be more acidic (lower pKa) than the 5-ethyl-5-phenyl derivative. This was demonstrated in the present report by spectrophotometric and potentiometric methods.

Chemistry and Biochemistry of Polyvalent Iodine Compounds VII. The ARP (Apparent Reduction Potential) of 1,3-Dihydro-1-hydroxo-3-oxo-1,2-benziodoxole

By A. EISENMANN* and W. WOLF

Iodoso compounds are strong oxidizing agents. In order to define an order of magnitude for this oxidizing action, the ARP (apparent reduction potential) of 1,3-dihydro-1-hydroxy-3-oxo-1,2-benziodoxole has been measured using the method of Conant and Lutz. At pH 7.4, the ARP of benziodoxole was 0.327 ± 0.005 v., indicating that this heterocyclic iodine derivative, under the conditions used, is approximately as strong an oxidizing agent as ceric ion. The usefulness of this technique is discussed.

THE KINETICS (1) and the mechanism (2) of the reduction of 1,3-dihydro-1-hydroxy-3-oxo-1,2-benziodoxole (I) to *o*-iodobenzoic acid have been studied in this laboratory. This process is irreversible, and thus, a normal oxidation-reduction potential cannot be measured. As it had been suggested that the difference between the two classes of trivalent iodine (iodoso, iodonium) is more one of degree and rate of reaction than of nature (3), it was of

interest to see if a value could be assigned to the "oxidizing power" of such compounds.

One method that is appropriate for a study of irreversible systems is that of Conant and Lutz (4). Instead of a normal potential, Conant (5) has defined an "apparent reduction potential" (ARP) as a pseudo-redox potential. The ARP is the potential of a reversible redox system which will cause 20–30% reduction within 30 min. of the oxidized form of the irreversible system. A more precise definition is derived from the use of the rate equation for a monomolecular reaction:

$$\frac{ds}{dt} = kx(c - s) \qquad \text{(Eq. 1)}$$

where c is the initial concentration of the compound studied, s is the amount which has been irreversibly reduced at any given time, and $x(c - s)$ is the concentration of the substance undergoing the irreversible change. If the system contains a large excess of a reversible redox system, with an equimolar amount in the reduced and oxidized form, x (fraction of compound reduced irreversibly by the reaction) will be essentially constant during the reaction. Then, integration of Eq. 1 yields Eq. 2:

$$k_1 = kx = \frac{2.3}{t} \log \frac{1}{1 - s} \qquad \text{(Eq. 2)}$$

where t is the time in min. for the reaction and s is the fraction which has been reduced of the irreversible substance. If, according to Conant, t is set at 30 min., use a $k_1 = 0.01$, then, by inserting these values of t and k_1 in Eq. 2 one defines a value of 25.9% reduction for s, instead of the vague 20–30% previously suggested. Using this value, a more accurate ARP could be determined; as shown by Conant (4), the ARP is a general concept and is not restricted to monomolecular reactions.

EXPERIMENTAL METHOD

The apparatus consisted of a glass cell with an i.d. of 65 mm. and a capacity of 125 ml., closed with a loose-fitting rubber top with openings for two electrodes, a gas bubbler, and admittance of the irreversible agent. A platinum electrode and a saturated calomel reference electrode (both Beckman) formed the cell circuit; both were located a few centimeters above the bottom of the cell. Nitrogen gas from a commercial tank was bubbled through using a Corning gas-dispersion fixture. The entire cell was mounted on a magnetic stirrer with adjustable rotational speeds. The potential was measured by a Corning 10 pH meter and also recorded constantly on a Texas Instruments recorder.

A solution of 0.05 M phosphate buffer (pH = 7.4 ± 0.1), 90 ml., was placed in the glass cell at the beginning of each trial. Equimolar amounts of the reducing agent and its oxidized form (each being about 0.001 M in the buffer solution) were then added, thus forming the reversible reference system. The stirring speed was adjusted and nitrogen bubbled in. When a steady potential had been recorded for about 5 min., 10.5 ml. of a solution of I was rapidly introduced into the redox cell. This solution was prepared by dissolving the weighed sample of I in 0.6 M NaOH with 10.0 ml. distilled water. The change in potential was followed for 30 min. As I was approximately 0.002 M in the buffer solution, it was in about 100% excess of the reducing agent.

Not all reversible systems are equally well suited for these experiments. The systems used formed a graded series of potentials, going in steps of about 50 mv. or so. This gave a good range for a quick determination of an approximate ARP. Since the measured change in cell potential was really the change in potential of the reversible redox system, these systems also had to come quickly to equilibrium. A sluggish system would not accurately reflect the amount of reduction which had taken place at any given moment. However, the 30-min. observation period compensated for this, as well as for the different rates of reaction.

RESULTS AND DISCUSSION

The data obtained are summarized in Table I.

The E.M.F. values of the reference systems used ranged from 77.2–599 mv. A redox system with a normal potential higher than the ARP did not appreciably reduce I, while one with a lower potential reduced it almost completely and very rapidly.

After the cell E.M.F. values were corrected for the calomel electrode to a hydrogen standard (E_h), a plot of these E_h values against the change in cell potential after 30 min. showed a linear relationship (Fig. 1). Points 1 and 4 represent two trials of the

[a] Experimental value. The experimental E.M.F. values for mixtures of the same ions are not exactly identical, since no system was exactly equimolar. [b] As calculated graphically.

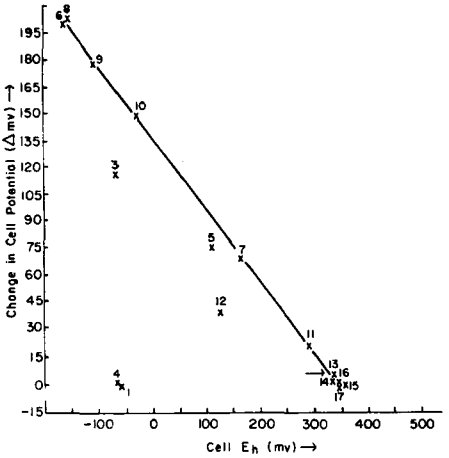

Fig. 1—Change in cell potential (Δmv.) as a function of the corrected E.M.F. (E_h).

ferricyanide/ferrocyanide system; the values are seen to agree well with each other. This apparently anomalous result suggests that the ferricyanide ion is somehow hindered in reacting with *I*, and raises the interesting possibility that *I* may be a sterically selective oxidizing agent.

Some systems were used in one ratio, and the ceric/cerous system was used in different ratios (runs 8, 9, 12). Using a linear least-squares program on a Mathatron 848 computer, the equation of this line was found to be:

$$Y = 136.79 - 0.397X$$

where *Y* is the change in potential and *X* is E_h. Using a theoretical Δmv. of 6.85 for 25.9% reduction, the apparent reduction potential of 1,3-dihydro-1-hydroxy-3-oxo-1,2-benziodoxole under the conditions of these experiments was found to be 327 ± 5 mv. (Room temperature, pH 7.4, concentrations given.)

The linear relation shows that the amount of benziodoxole which is irreversibly reduced is a function of the electromotive force of the reversible system tested. This, of course, is the basis for the quantitative study employed here. The graph of percentage reduction *versus* E_h (Fig. 2) shows resemblance to a log curve, which is not surprising since the change of cell potential is logarithmically related to the percentage reduction. Values of E_h much greater than the ARP would show a 0% reduction on Fig. 2.

Extension of this method to other iodoso and

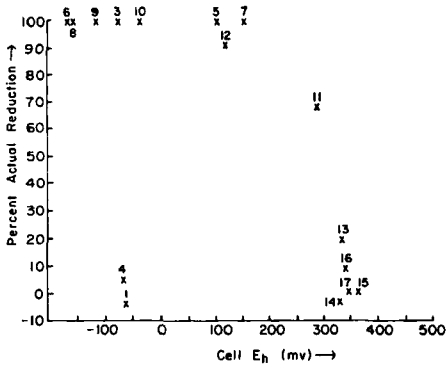

Fig. 2—Percent reduction of 1,3-dihydro-1-hydroxy-3-oxo-1,2-benziodoxole as a function of cell E_h.

iodonium compounds is indicated, in order to verify Beringer's suggestions and to determine if a real difference exists or not between these two types of polyvalent iodine compounds.

It would also be advantageous to devise some new method for the determination of the ARP. Although this method has been updated and is relatively simple, a faster method is desirable. Polarography shows some hints of being applicable to the problem, but potentiometric titration seems to be possibly the most promising direction.

The authors consider that the present modification of the method of Conant and Lutz allows for an easy and accurate determination of the ARP of organic compounds suffering irreversible reduction. This method should also be adequate for the determination of the apparent oxidation potential.

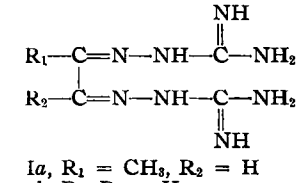
Methylglyoxal Bis(guanylhydrazone) Analogs VI. Methylglyoxal Bis(guanylhydrazone) Pamoate

By EUGENE G. PODREBARAC and C. C. CHENG

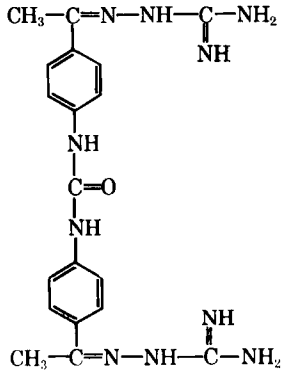
The pamoate of methylglyoxal bis(guanylhydrazone) was prepared. This compound, on a molar basis, is more active and less toxic than the corresponding dihydrochloride salt against leukemia L-1210.

THE ANTITUMOR ACTIVITY of methylglyoxal bis(guanylhydrazone),[1] [methyl-GAG, *Ia*], against leukemia L-1210 in mice and adult acute myelocytic leukemia (1, 2) in man is now well known. This drug, however, was found to be quite toxic (3, 4).



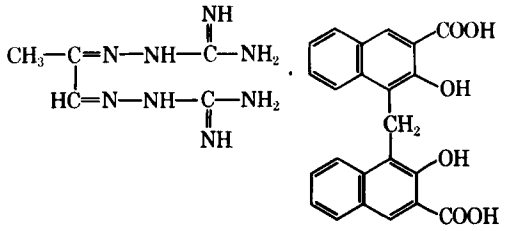
Ia, $R_1 = CH_3$, $R_2 = H$
b, R_1, $R_2 = H$
c, $R_1 = CH_2OH$, $R_2 = H$
d, R_1, $R_2 = CH_3$

Subsequent work revealed that, except for the unmethylated compound *Ib* which is almost as active (1) as *Ia*, other modifications of the basic structure failed to yield compounds active against leukemia L-1210 (5–9). The reported activity of hydroxymethyl-GAG (*Ic*) was proved to be erroneous since the originally synthesized *Ic* (10) was found to be actually hydrated methyl-GAG (11–13). The authentic hydroxymethyl-GAG did not show the expected activity (11–13). Although the compound 4,4′-diacetyldiphenylurea bis(guanylhydrazone) [DDUG, II], was found to have marked activity against leukemia L-1210 (14), no cross-resistance between methyl-GAG and DDUG was observed (14–16). In addition, a structurally related compound, dimethyl-GAG (*Id*), is entirely devoid of antileukemia activity (6). Compound II is believed to be an analog of the terephthalanilide-type (15).



II

In view of the aforementioned information, an attempt was made to modify the absorption and excretion pattern, rather than the basic structure, of *Ia*. Since salts of pamoic acid, due to their very limited solubility, are known to provide slow release of basic drugs and thus maintain a low level of drug in the blood stream,[2] the pamoate salt of methyl-GAG (III) was prepared in this laboratory.



III

The title compound was readily obtained by the reaction of methylglyoxal bis(guanylhydrazone) dihydrochloride and the disodium salt of pamoic acid. Equivalent amounts of pure starting materials gave desired product of analytical purity in 91% yield.

Preliminary tests of III indicated activity in the 9KB primary screen. Tests in the leukemia L-1210 system revealed that, on a molar basis, compound III is much more active and less toxic than the corresponding dihydrochloride salt (see Table I). For comparison, pamoic acid or its sodium salt possessed no anticancer activity against either sarcoma 180, carcinoma 755, or leukemia L-1210 in mice (21).

That compound III is more than a simple acid-base compound was demonstrated by titration studies. The addition of two equivalents of base to an aqueous suspension of the compound, even after prolonged stirring, failed to yield a solution (a solution was obtained after the addition of four equivalents of base). Since these conditions should give freely water-soluble materials—the free base of methyl-GAG and the disodium salt of pamoic acid—it appears that the phenolic functions of the pamoic acid may play an important role in the composition of III. As such, the pamoic acid salt of methyl-GAG is very different from the simple methyl-GAG salts.

EXPERIMENTAL

One mole (257 g.) of the purified dihydrochloride

Received May 5, 1968, from the Midwest Research Institute, Kansas City, MO 64110
Accepted for publication June 5, 1968.
This investigation was supported by the Cancer Chemotherapy National Service Center (CCNSC), National Cancer Institute, of the National Institutes of Health, Public Health Service, contract PH-43-65-94.

[1] According to *Chemical Abstracts*, the name for this compound is 1,1′-[(methyl)ethanediylidenedinitrilo]diguanidine.

[2] In the treatment of malaria, intramuscular injection of an oil suspension of cycloguanil pamoate was found to curtail the effects of malaria in man for extended periods (17–19). In cancer chemotherapy study, it was reported that the pamoates of various alkylating agents had significantly better actions in prolonging the survival time of mice with ascites tumors than their corresponding hydrochloride salts (20).

[a] Biological testing was performed by contract screeners of CCNSC. [b] T/C = survival time: test/control.

salt of methyl-GAG was dissolved in 2,500 ml. of distilled water and the solution warmed to 80°. A disodium pamoate solution was prepared by dissolving 1 mole of disodium pamoate monohydrate (450 g.) in 2,800 ml. of distilled water. The solution was warmed to 70°, treated with Norite, then filtered (still had red-brown color).

The Me-GAG·2HCl solution was stirred vigorously at 80–90° while the disodium pamoate solution at 70° was added portionwise during approximately 45 min. A solid began to separate immediately. The reaction mixture was stirred at 90° for 1 hr. then filtered. The filter cake was washed well with hot water then dried in a vacuum oven at 80–85° at approximately 20 mm. for 20 hr. to give 536 g. (91% yield) of the pamoate salt of methylglyoxal bis(guanylhydrazone), m.p. 262–263° dec.; $\lambda_{max.}^{pH\ 1}$ 282 mμ (ε 61,800); 273 mμ (ε 63,600). $\lambda_{max.}^{pH\ 11}$ 327 mμ (ε 34,100); 235 mμ (ε 94,200). Minor absorption peaks at 300 and 288 mμ and a shoulder at 277 mμ were noted in pH 11.

Anal.—Calcd. for $C_{23}H_{28}N_8O_6 \cdot H_2O$ (mol. wt. 590.6): C, 56.94; H, 5.12; N, 18.97; H_2O, 3.05. Found: C, 56.98; H, 4.71; N, 19.27; H_2O, 3.00.

Monomolecular Film Properties of Protective and Enteric Film Formers I. Effect of Polymer Side Chain on Surface Pressure-Area Isotherms

By JOEL L. ZATZ*, NORMAN D. WEINER, and MILO GIBALDI†

Polymeric film formers of pharmaceutical interest have been investigated using surface monolayer techniques. Surface pressure-area curves were obtained and evaluated for monomolecular films of several half-esters of poly (methyl vinyl ether/maleic anhydride) at the air-water interface. The ester side chain was found to contribute significantly to the surface properties of the polymer.

FILM COATINGS are widely used on pharmaceutical dosage forms as protectives and as diffusion barriers to control drug release. A number of studies has been reported on the physical-chemical properties of free polymeric films (1–7). Although free films represent a useful model for evaluating the gross properties of applied films, they provide limited information of molecular interactions which in fact dictate the properties of the film.

An interesting approach to the study of polymeric films is the use of techniques devised for investigation of insoluble monomolecular films at the air-water surface. Monomolecular films or monolayers have been used as models for a number of biologic and physical-chemical processes. Goddard and Schulman (8) studied the penetration of cholesetrol films by surface-active agents and were able to relate their data to the ability of these surfactants to hemolyze red blood cells. More recently Schaubman and Felmeister (9) discussed the biologic significance of the penetration of monolayers of lecithin by chlorpromazine, and Torosion and Lemberger (10) considered the physical-chemical interactions between lecithin and lipids in mixed monolayers.

Crisp (11) studied a number of synthetic polymers on a surface balance and concluded that many polymers are spread completely at the air-water surface, a condition which must be met if the experimental results are to be properly interpreted (11–13). It would appear that the polymer molecule must have a degree of hydrophilic character but possess very limited solubility to form a stable monolayer (13). The applicability of monolayer techniques for studying polymeric material has been confirmed by a number of other workers (14–20). The polymer is applied to the aqueous surface or substrate in the usual fashion by dissolving it in a suitable solvent which can spread over the surface and subsequently evaporate or dissolve.

However, the area per chemical segment or monomeric unit, rather than the area per molecule, is the preferred parameter to characterize the system since the force-area curves of polymers have been shown to be independent of the degree of polymerization (11, 14).

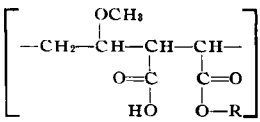
Monolayers of film-forming polymers may provide a useful model for the investigation of polymer structure and orientation, as well as the effect of pH and additives, on the properties of the polymer. The present report concerns the determination and evaluation of surface pressure-area curves for several half-esters of poly (methyl vinyl ether/maleic anhydride). These polymers have been evaluated previously as sustained-action coatings and appear to have potential for controlling drug release (5, 21). The structure of these polymers may be represented by



where R is the hydrocarbon side chain.

EXPERIMENTAL

Preparation of Polymer Derivatives—The various half-esters used in this study were prepared from the same lot of poly (methyl vinyl ether/maleic anhydride)[1] (designated as PVM/MA) by slurrying the polymer in the appropriate organic alcohol (previously purified by repeated passage through an alumina-silica gel column), adding 0.1% HCl, and allowing the mixture to reflux at its boiling point for a specified period of time, as indicated in Table I. The resulting half-esters were purified by precipitation from ethyl ether or *n*-hexane and repeated washings with these solvents, and subsequently dried at 30° *in vacuo* to constant weight. The degree of esterification was confirmed by titrating free acid groups with NaOH. All acid value determinations agreed within 6% of the theoretical values.

TABLE I—PREPARATION OF POLY (METHYL VINYL ETHER/MALEIC ANHYDRIDE) HALF-ESTERS

Derivative	Segment Formula Weight	Reflux Time, hr.
Ethyl	202	4
n-Propyl	216	6
n-Butyl	230	7.25
n-Pentyl	244	8
n-Hexyl	258	9

Determination of Surface Pressure-Area (π-A) Curves—The surface balance employed was made of Teflon and has been described in a previous report (22). Water was triple distilled in a glass still from an alkaline permanganate solution.

[1] Gantrez AN 119, General Aniline and Film Corp., New York, N. Y.

The half-esters were dissolved in a mixture of isopropanol and hexane and spread on the aqueous subphase by means of an Agla micrometer syringe. Preliminary experiments indicated that the addition of 10^{-3} *M* HCl to the subphase was sufficient to suppress ionization of the free carboxyl groups of the polymer derivatives. Surface pressure was determined at room temperature (24.0° ± 0.5°) as a function of area using the Wilhelmy plate method (23, 24).

RESULTS AND DISCUSSION

The surface pressure-area (π-A) isotherms determined with each half-ester are shown in Fig. 1. Each curve represents the average of three determinations. Data points have been eliminated to attain clarity. When the films were spread with other spreading solvents, *e.g.*, ethanol–chloroform–hexane, 1:1:3, or at different initial surface areas, curves identical to those in Fig. 1 were obtained indicating complete spreading (13).

The π-A isotherm obtained with the hexyl half-ester of PVM/MA is presented in Fig. 2 to depict the various regions of the curve which may be defined. In the expanded region (α) the molecules are relatively far apart and do not interact. Compression (*i.e.*, decreasing the surface area occupied by the film) produces a "squeezing out" of water molecules and the segments approach each other. This phenomenon is reflected by the transition region (β) in the π-A curve. In the condensed region (γ) the segments are in close contact. In this region of the curve, a small change in area results in a comparatively large change in surface pressure. The marked increase in π in the condensed region probably reflects changes in orientation or configuration of the polymer. Crisp (11) has suggested that, in the condensed region, there is a gradual expulsion of hydrophobic groups from the surface into an "overfilm" above the monolayer. The polymer molecule, however, remains anchored to the surface probably because of hydrogen bonding between hydrophilic groups and the water molecules.

As compression is continued, a point is reached where the film can no longer be accommodated as a monomolecular layer and the film collapses to form a three-dimensional bulk phase. The surface pressure at which this phenomenon occurs is termed the collapse pressure (Point A in Fig. 2). The collapse pressure is a function of both cohesional forces between polymer segments and adhesional forces between the polar groups of the polymer and the subphase (15).

Point B in Fig. 2 represents the limiting area per molecular segment at zero surface pressure. It is obtained, as indicated, by extrapolating the condensed region of the curve to the abscissa. At the limiting area the film is in a hypothetical state in which it is condensed under no external pressure.

Examination of the π-A isotherms in Fig. 1 indicates a number of interesting relationships. For example, the collapse pressure is found to increase with increasing chain length of the ester. This suggests that cohesional forces, due to van der Waals' interactions between the ester chains, contribute significantly to the physical-chemical properties of the polymer.

Previous workers (16, 17) have reported that ester groups of polymers are oriented in the *cis*-configuration at the air-water surface. Hence, the ester chain protrudes through the surface toward the gas phase. It is likely that the side chains of the PVM/MA half-esters are oriented in a similar fashion since the limiting area for all five derivatives is 48–50 Å.²/segment. This observation implies identical configuration in the limiting case and thereby, the lack of contribution of the ester side chain to the limiting area. If the ester chain were oriented in the plane of the surface, then a direct relation between limiting area and the length of the ester chain would be apparent.

The interactions between polymers and plasticizers, as well as the relationships between polymer chain length, plasticizer, and water vapor transmission are presently under investigation in an effort to elucidate the molecular considerations which control the properties of polymeric films. Finally, the results obtained using monomolecular

Lipids from the Seeds of *Abrus precatorius*

By MORTON S. LEFAR, DAVID FIRESTONE, EUGENE C. COLEMAN, NATHAN BROWN, and DONALD W. SHAW

The lipids obtained from *Abrus precatorius* were separated into a saponifiable and unsaponifiable fraction. Analysis of the saponifiable fraction by gas-liquid chromatography (GLC) showed the presence of a series of C-8 to C-24 saturated and C-16 to C-24 unsaturated acids. Column chromatography of the unsaponifiable material yielded a hydrocarbon, alcohol–methyl sterol, and sterol fraction. GLC showed that the hydrocarbon fraction contained squalene, a homologous series of C-16 to C-35 normal, iso and/or anteiso, and possibly multibranched compounds. The alcohol–methyl sterol fraction contained a series of C-14 to C-28 normal alcohols in addition to β-amyrin and cycloartenol. Stigmasterol, β-sitosterol, and campesterol were the major sterol constituents identified by GLC.

Abrus precatorius (also called Jequirity, Gunja, Kunch, and Rati) is a perennial twiner belonging to the family *Leguminosae* that grows throughout India and other tropical countries (1). It contains some of the most lethal plant poisons in the tropics. Many children have been attracted to its color and have accidentally swallowed the seed. Jequirity beans are frequently used as eyes in dolls, toys, necklace beads, and clothing ornaments. Some of the preparations from this plant induced severe cytotoxicity in concentrations of less than 0.01 mcg./ml. of solid material. Extracts of *Abrus precatorius* initially suppressed the growth of cancer cells and prolonged the survival of laboratory animals (2).

The biological effects of extracts of the seed have stimulated the need for further information concerning the identity of the compounds contained in *Abrus precatorius*.

EXPERIMENTAL

Source and Preparation of Material—Ripe seeds of *Abrus precatorius* were obtained from Herbst Brothers, Seedsmen, Inc., Brewster, N. Y. Approximately 65 g. of seeds dispersed in powdered dry ice were ground to a powder in a Wiley mill.

Extraction of Seeds—The powdered seeds were extracted successively with two 200-ml. portions of *n*-hexane, ethyl ether,[1] and distilled water at room temperature, and finally with two 500-ml. portions of 95% ethyl alcohol in a Soxhlet for 6 hr. Evaporation of 250 ml. of the hexane and ether fractions yielded, respectively, 372 and 177 mg. of yellow oils.

Saponifiable and Unsaponifiable Fractions—The saponifiable and unsaponifiable fractions were extracted (3). The alkaline soaps obtained were acidified with 1 + 1 HCl, extracted three times with petroleum ether, and then converted to the methyl esters (4).

Gas-Liquid Chromatography of Methyl Esters[2]—The mixture of methyl esters was subjected to GLC, using a Wilkins Aerograph model 1520 instrument fitted with a flame-ionization detector. The 2.7 m. × 0.6 cm. i.d. (9 ft. × 1/4 in.) aluminum column was packed with 20% polydiethylene glycol

Received March 11, 1968, from Bureau of Science, Food and Drug Administration, U. S. Department of Health, Education, and Welfare, Washington, DC 20204
Accepted for publication May 15, 1968.
Presented to the American Chemical Society, Third Middle Atlantic Regional meeting, Philadelphia, Pa., February 1968.

[1] The ether and hexane extracted residues did not inhibit the growth of diploid cells (Hayflick strain, Wistar 138; obtained from Baltimore Biological Laboratories, Cockeysville, Md.).

[2] Stationary phases, packings, and standards were obtained from Applied Science Laboratories, State College, Pa.

films will be compared with literature data on free films in order to evaluate the utility of the model.

Stigmasterol, β-sitosterol, and campesterol were the major sterol constituents identified by GLC.

Abrus precatorius (also called Jequirity, Gunja, Kunch, and Rati) is a perennial twiner belonging to the family *Leguminosae* that grows throughout India and other tropical countries (1). It contains some of the most lethal plant poisons in the tropics. Many children have been attracted to its color and have accidentally swallowed the seed. Jequirity beans are frequently used as eyes in dolls, toys, necklace beads, and clothing ornaments. Some of the preparations from this plant induced severe cytotoxicity in concentrations of less than 0.01 mcg./ml. of solid material. Extracts of *Abrus precatorius* initially suppressed the growth of cancer cells and prolonged the survival of laboratory animals (2).

The biological effects of extracts of the seed have stimulated the need for further information concerning the identity of the compounds contained in *Abrus precatorius*.

EXPERIMENTAL

Source and Preparation of Material—Ripe seeds of *Abrus precatorius* were obtained from Herbst Brothers, Seedsmen, Inc., Brewster, N. Y. Approximately 65 g. of seeds dispersed in powdered dry ice were ground to a powder in a Wiley mill.

Extraction of Seeds—The powdered seeds were extracted successively with two 200-ml. portions of *n*-hexane, ethyl ether,[1] and distilled water at room temperature, and finally with two 500-ml. portions of 95% ethyl alcohol in a Soxhlet for 6 hr. Evaporation of 250 ml. of the hexane and ether fractions yielded, respectively, 372 and 177 mg. of yellow oils.

Saponifiable and Unsaponifiable Fractions—The saponifiable and unsaponifiable fractions were extracted (3). The alkaline soaps obtained were acidified with 1 + 1 HCl, extracted three times with petroleum ether, and then converted to the methyl esters (4).

Gas-Liquid Chromatography of Methyl Esters[2]—The mixture of methyl esters was subjected to GLC, using a Wilkins Aerograph model 1520 instrument fitted with a flame-ionization detector. The 2.7 m. × 0.6 cm. i.d. (9 ft. × 1/4 in.) aluminum column was packed with 20% polydiethylene glycol

Received March 11, 1968, from Bureau of Science, Food and Drug Administration, U. S. Department of Health, Education, and Welfare, Washington, DC 20204
Accepted for publication May 15, 1968.
Presented to the American Chemical Society, Third Middle Atlantic Regional meeting, Philadelphia, Pa., February 1968.

[1] The ether and hexane extracted residues did not inhibit the growth of diploid cells (Hayflick strain, Wistar 138; obtained from Baltimore Biological Laboratories, Cockeysville, Md.).

[2] Stationary phases, packings, and standards were obtained from Applied Science Laboratories, State College, Pa.

TABLE I—UNSAPONIFIABLE COMPONENTS OF *Abrus precatorius*

Fraction	Ethyl Ether Extract 2.2 mg.	Hexane Extract 18.4 mg.

TABLE II—PERCENT OF TOTAL FATTY ACIDS[a] EXTRACTED FROM *Abrus precatorius*

Fatty Acid	Hexane Fraction, %	Ether Fraction, %
Octanoic (8:0)	trace	—
Dodecanoic (12:0)	trace	0.2
Tetradecanoic (14:0)	0.1	0.7
Hexadecanoic (16:0)	4.0	10.5
9-Hexadecenoic	0.2	1.3
Unidentified[b]	0.2	0.7
Octadecanoic (18:0)	1.0	1.9
9-Octadenenoic (18:1)	23.0	22.3
9,12-Octadecadienoic (18:2)	7.7	30.7
Eicosanoic (20:0)	0.6	—
11-Eicosenoic (20:1)	5.2	16.8
9,12,15-Octadecatrienoic (18:3)	10.6	
Docosanoic (22:0)	3.9	2.2
13-Docosenoic (22:1)	33.6	3.4
Tetracosanoic (24:0)	1.9	9.4
15-Tetracosenoic (24:1)	2.9	—
Unidentified[c]	4.8	—

[a] As methyl esters; not corrected for detector response. [b] Retention time *versus* 16:0 = 1.47. [c] Retention time *versus* 16:0 = 9.07.

succinate (DEGS) on 60–80 mesh Chromosorb W. The gas chromatographic conditions were as follows: helium gas flow 70 ml./min.; column temperature 207°; injection port 253°; cell temperature 268°.

Identification of Esters—The retention times of the sample components were compared with that of highly purified esters on polar (DEGS) and nonpolar columns (2.7 m. × 0.6 cm. i.d.; 3% SE-30 on 60–89 mesh Chromosorb W). Semilogarithmic plots of retention times *versus* carbon number were used to identify 15-tetracosenoic acid and to confirm assignments.

Column Chromatography of Unsaponifiables—Magnesium silicate[3] was heated to 260° for 2 hr., then deactivated with 10 g. of water per 100 g. of magnesium silicate and allowed to equilibrate overnight. The 18.4 mg. and 2.2 mg. of unsapouifiable material from the hexane and ether fractions, respectively, were chromatographed on a 2.5 × 30 cm. column containing 20 g. of the prepared magnesium silicate. The hydrocarbons were eluted with 40 ml. of 10% anhydrous ethyl ether in hexane and the alcohol-methyl sterols with an additional 140 ml. of the same mixture. The sterols were then eluted with 150 ml. of 50% ether in hexane.

Gas-Liquid Chromatography of the Hydrocarbon, Alcohol-Methyl Sterol, and Sterol Fraction—The three fractions eluted from the column were subjected to GLC on a Barber-Colman model 5000 instrument utilizing the hydrogen-flame detector. The instrument was fitted with a 1.8 m. × 0.6 cm. i.d. (6 ft. × 1/4 in.) glass column filled with 3% JXR on 100–120 mesh Gas Chrom Q. Nitrogen was used as the carrier gas at 30 p.s.i. Detector and sample temperatures were maintained at 262°. The column temperatures were controlled at 180° and 240° (see Table I). For quantitative estimation of various components, areas beneath gas chromatographic peaks were determined by the peak height retention time method (5).

RESULTS AND DISCUSSION

The fatty acids detected in *Abrus precatorius* in this study differ from an earlier chemical investigation (1) of the lipid fraction which did not report the presence of trace amounts of octanoic (8:0), dodecanoic (12:0), or tetradecanoic (14:0) acids, in addition to larger amounts of 9-hexadecenoic (16:1) acid (see Table II).

GLC revealed that 13-docosenoic (22:1) acid was the third most prevalent component in this preparation. However, Mandiratta and Dutt (1) did not indicate the presence of this lipid.

Examination of the chromatogram of the hydrocarbon fraction and plots of retention time *versus* carbon number (Fig. 1) indicate the presence of three homologous series in addition to squalene. The first series consists of normal straight chain hydrocarbons in the range C_{16}–C_{26}. The second series consists of iso and/or anteiso hydrocarbons (*e.g.*, iso = 2-methyl; anteiso = 3-methyl). Pre-

TABLE III—PERCENT[a] OF TOTAL STEROLS EXTRACTED FROM *Abrus precatorius*

Sterol	Hexane Fraction, %	Ether Fraction, %
Cholesterol	1.3	2.3
Brassicasterol	2.8	1.7
Campesterol	21.0	16.5
Stigmasterol	46.8	50.8
β-Sitosterol	24.8	26.9
Unidentified[b]	2.4	1.8
Unidentified[c]	0.9	—

[a] Not corrected for detector response. [b] Retention time *versus* cholesterol = 1.84. [c] Retention time *versus* cholesterol = 2.22.

vious examination of standards indicated that iso and anteiso hydrocarbons with the same molecular weights could not be resolved. Iso and anteiso compounds have been reported to be present in vegetable and animals oils (6–9). The third series probably consists of multiple-branched hydrocarbons, which Mold *et al.* (6) have reported to be present in tobacco leaf wax.

The alcohol–methyl sterol fraction contained mainly a series of C_{10}–C_{28} normal alcohols, β-amyrin, and cycloartenol (Table I and Fig. 2). Campesterol and the C_{29} and C_{33} alcohols may be present as minor components.

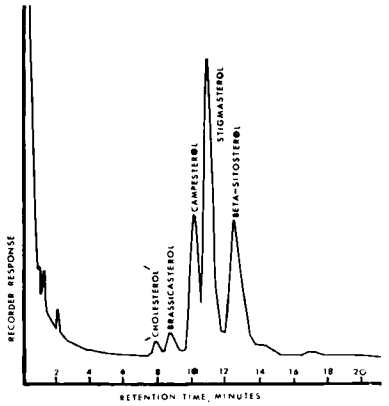

Fig. 3—Chromatogram of sterols from hexane extract.

GLC of the sterol fraction (Table III and Fig. 3) indicated the presence of at least seven components, which were identified by comparison with retention times of standards. Stigmasterol was the most prevalent sterol; Mandiratta and Dutt (1) reported only the presence of sitosterol.

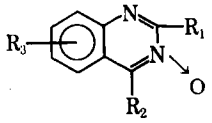
Reaction of 2-Chlorobenzoxazole with Anthranilic Acids and 2-Amino-1-naphthalenesulfonic Acid

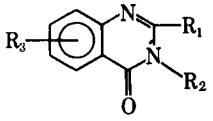
By JOSEPH SAM, J. L. VALENTINE, and C. W. RICHMOND

The preparation of 1-carboxy-12-benzo(*d*)quinazo(2,3-*b*)oxazole-12-one and 2-chloro-12-benzo(*d*)quinazo(2,3-*b*)oxazole-12-one are reported. The reaction of 2-chlorobenzoxazole with 2-amino-1-naphthalenesulfonic acid gave 2-(2-naphthylamino)benzoxazole. Preliminary pharmacological screening indicates mild sedative properties for the described compounds.

NUMEROUS CNS properties have been attributed to quinazoline-3-oxides (I) (1) and quinazolones (II) (2). The incorporation of the latter moiety into a tetraheterocyclic system (*e.g.*, VII)



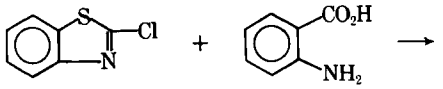
I



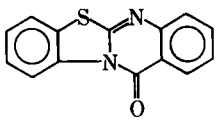
II

which also includes the benzoxazole nucleus was undertaken in order to obtain compounds which might exhibit interesting CNS properties. Benzoxazole derivatives are known to exhibit CNS effects (3).

The preparation of 12-benzo(*d*)quinazo(2,3-*b*)-thiazole-12-one (V) from 2-chlorobenzothiazole (III) and anthranilic acid (IV) has been described by Katz (4); Katz also mentioned 12-benzo(*d*)quinazo-(2,3-*b*)-oxazole-12-one (VII*a*) but did not describe

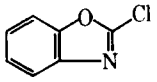


III IV

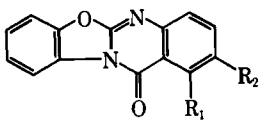


V

its preparation. More recently Sam and Plampin (5) described the preparation of VII*a* *via* condensation of 2-chlorobenzoxazole (VI) and IV. Two related substances, *viz.*, VII*b* and VII*c*, have been



VI

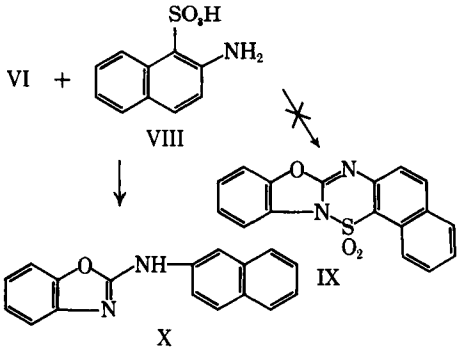


VII

a, $R_1 = R_2 = H$
b, $R_1 = CO_2H, R_2 = H$
c, $R_1 = H, R_2 = Cl$

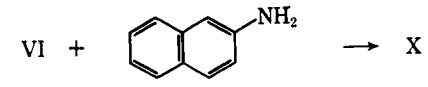
prepared from VI and an appropriately substituted anthranilic acid.

The above results prompted the investigation of the preparation of 12-benzo(*d*)naphtha(*a*)thiadiazo-(2,3-*b*)oxazole-12,12-dioxide (IX) by the condensation of VI with 2-amino-1-naphthalenesulfonic acid (VIII). However, the condensation of VI and VIII



VIII IX X

in either acidic, basic, or neutral medium resulted in either starting materials or intractable residues. The fusion of VI and VIII resulted in 2-(2-amino-naphthyl)benzoxazole (X) which was identified on the basis of physical data and unequivocal synthesis from VI and 2-naphthalamine (XI). The desulfonation inherent in this fusion reaction has not been



XI

previously observed for VIII although the related *1*-naphthalenesulfonic acid is known to undergo desulfonation under acid conditions at 140° (6).

Pharmacological Results[1]—Fasted male albino mice (25–50 g.) were used. The animals were observed closely for signs of pharmacological and toxic effects during the first 2 hr. following intraperitoneal injection. Posttreatment observations were made at 4, 6, 18, 24, and 72 hr. The vehicle for all compounds was a 10% suspension of the respective compound in a 5% acacia solution.

Compound VII*b* exhibited sedation and analgesia at 500 mg./kg. The same effects were noted at 1,000 mg./kg. and 2,000 mg./kg. in addition to ataxia, hypothermia, and opaque clouding of the eyes.

Received April 29, 1968, from the Department of Pharmaceutical Chemistry, The University of Mississippi, University, MS 38677

Accepted for publication May 20, 1968.

[1] The authors are grateful to Dr. W. M. Davis, Department of Pharmacology, School of Pharmacy, The University of Mississippi for pharmacological data.

Compound VII*c* produced writhing, sedation, and diarrhea at 1,000 mg./kg. Compound X exhibited sedation at 500 mg./kg. and 1,000 mg./kg. Sedation was apparent at 2,000 mg./kg. along with writhing and ataxia.

EXPERIMENTAL[2]

1 - Carboxy - 12 - benzo(d)quinazo(2,3 - b)oxazole-12-one (VIIb)—The procedure described by Sam and Plampin (5) for the preparation of VII*a* was followed using 21.7 g. (0.1 mole) of 3-aminophthalic acid and 15.4 g. (0.1 mole) of 2-chlorobenzoxazole. Recrystallization from acetone gave 23.8 g. (85%) of product, m.p. 293–294°; $\nu_{max.}^{KBr}$ 1725 cm.$^{-1}$ (C=O), 1650 (CO_2H); NMR (in d_2-DMSO), 7 proton multiplet at 7.43–8.43 (aromatic), 1 proton broad singlet at 13.0–13.3 (carboxyl hydrogen); upon D_2O exchange the absorption at 13.0–13.3 was absent.

Anal.—Calcd. for $C_{15}H_8N_2O_4$: C, 64.29; H, 2.88; N, 10.00. Found: C, 64.41; H, 2.96; N, 9.82.

2 - Chloro - 12 - benzo(d)quinazo(2,3-b)oxazole-12-one (VIIc)—The procedure described above was followed using 17.1 g. (0.1 mole) of 5-chloroanthranilic acid and 15.4 g. (0.1 mole) of 2-chlorobenzoxazole. Recrystallization from isoamyl alcohol gave 21.6 g. (80%) of product, m.p. 228–229°; $\nu_{max.}^{KBr}$ 1700 cm.$^{-1}$ (C=O); NMR (in d_2-DMSO) 7 proton multiplet at 7.43–8.43 (aromatic).

Anal.—Calcd. for $C_{14}H_7ClN_2O_2$: C, 62.12; H, 2.61; N, 10.35. Found: C, 62.18; H, 2.80; N, 10.38.

2-(2-Naphthylamino)benzoxazole (X)—*Method A*—A mixture of 15.4 g. (0.1 mole) of 2-chlorobenzoxazole and 23.1 g. (0.1 mole) of 2-amino-1-naphthalene-sulfonic acid was fused in a preheated oil bath at 180–190° for 3 hr. The crude product was washed with 5% aqueous NaOH, then recrystallized from cellosolve–water and subsequently from benzene to give 9.5 g. (62%) of product, m.p. 245–245.5°; $\nu_{max.}^{KBr}$ 3300 cm.$^{-1}$ (NH); NMR (in d_2-DMSO), 11 proton multiplet at 7.08–7.3 (aromatic), one proton singlet at 12.5 (NH); upon D_2O exchange the absorption at 12.5 was absent.

Anal.—Calcd. for $C_{17}H_{12}N_2O$: C, 78.44; H, 4.65; N, 10.76. Found: C, 78.45; H, 4.57; N, 10.66.

Method B—A mixture of 15.4 g. (0.1 mole) of 2-chlorobenzoxazole and 14.3 g. (0.1 mole) of 2-naphthylamine was fused in a preheated oil bath at 130–140° for 4 hr. The crude product was treated as in Method A to give 9.5 g. (62%) of product, m.p. 245–245.5°. A mixture melting point with the product from Method A showed no depression. The infrared as well as the NMR spectra were identical.

[2] Melting points were determined on a Fisher-Johns melting apparatus and are corrected. Infrared spectra were obtained on a Perkin-Elmer 137B Infracord spectrophotometer using KBr pellets. The NMR spectra were determined on a Varian A-60A spectrometer using Me_4Si as internal standard; chemical shifts are recorded as δ values.

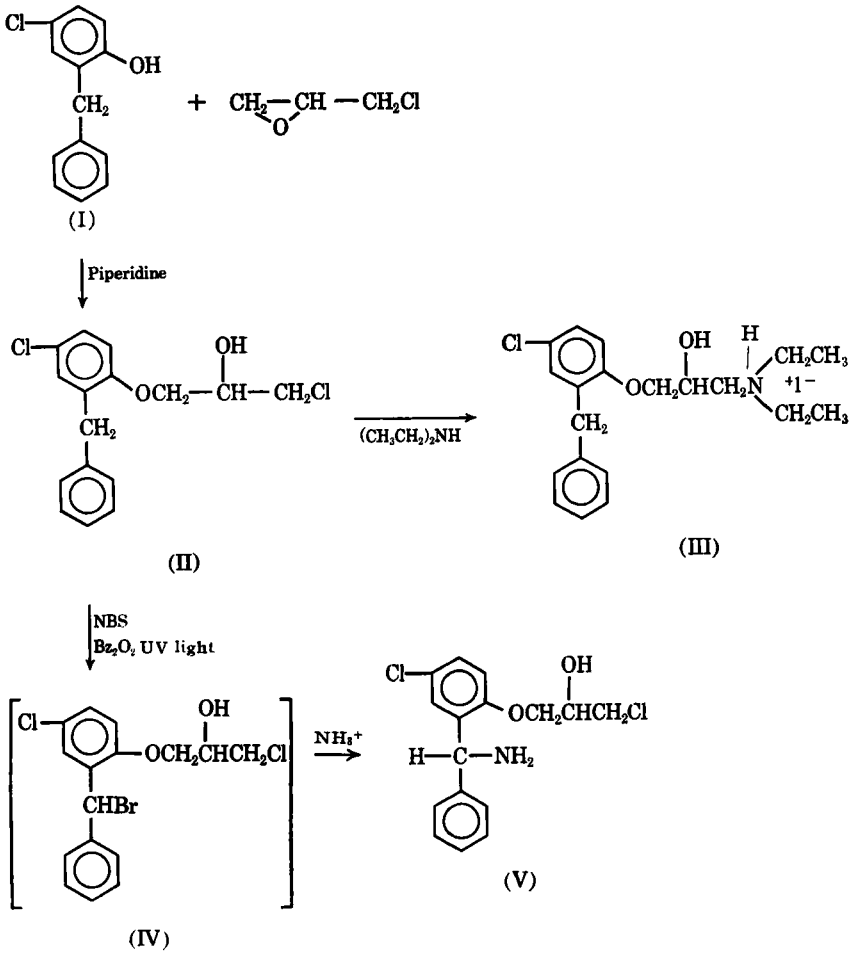
New Compounds: 5-Chloro-2-(3-chloro-2-hydroxypropoxy)-benzhydrylamine and Related Compounds

By HEINO A. LUTS*, and D. YAMASHIRO†

In connection with the chemical-medicinal work 5-chloro-2-(3-chloro-2-hydroxypropoxy)-benzhydrylamine was prepared by a three-step synthesis. Compound I was reacted with epichlorohydrin and the formed 3-(2-benzyl 4-chlorophenoxy)-2-hydroxypropylchloride (II) was then converted to III by free-radical bromination, which was not isolated, but converted to compound V by amination.

EXPERIMENTAL[1]—SCHEME I

3-(2-Benzyl-4-chlorophenoxy)-2-hydroxypropyl chloride (II)—A solution of 21.65 g. (0.100 mole) of 2-benzyl-4-chlorophenol (I) (Dow Santophen), 24.8 g. (0.269 mole) of epichlorohydrin, and 2.0 ml. of piperidine was heated at 90–95° for 4.5 hr. with stirring. Occasional cooling of the exothermic reaction was required during the initial stages. The excess epichlorohydrin was removed by distillation of all material boiling to 40°/0.7 mm. The residual oil was dissolved in an equal volume of chloroform, then shaken for 10 min. with 35 ml. of concentrated hydrochloric acid. The lower chloroform phase was separated and washed with four 30-ml. portions of water. The chloroform solution was steam distilled. The oily, nondistillable residue was extracted with 50 ml. of benzene. The benzene solution was washed with two 30-ml. portions of water, dried over anhydrous calcium sulfate, and evaporated *in vacuo* to remove the solvent. The crude oil was distilled under vacuum twice to yield 8.5 g. (27% yield) of pure 3-(2-benzyl-4-chlorophenoxy)-2-hydroxypropylchloride, b.p. 188–190°/0.6 mm.



Scheme I

Received February 28, 1968, from Horizons Inc., Cleveland, Ohio, and Bristol Laboratories Inc., Syracuse, NY 13201
Accepted for publication April 10, 1968.

† Stanford Research Institute, Menlo Park, Calif.

[1] All melting points are uncorrected. Microanalyses were performed by G. Robertson, Jr., Florham Park, N. J.

Anal.—Calcd. for $C_{16}H_{16}Cl_2O_2$: C, 61.75; H, 5.18; Cl, 22.79. Found: C, 61.49; H, 5.13; Cl, 22.71.

5-Chloro-2-(3-chloro-2-hydroxypropoxy)benzhydrylamine Hydrochloride (V)—A solution of 44 g. (0.142 mole) of 3-(2-benzyl-4-chlorophenoxy)-2-hydroxypropyl chloride in 150 ml. of carbon tetrachloride was brought to reflux. The solution was exposed to 275-w., 110–125 v., 60-cycle AC General Electric sunlamp held at a distance of 8 in. While stirring the refluxing solution there was added 5.7 g. (0.032 mole) of *N*-bromosuccinimide and 0.31 g. (0.00128 mole) of benzoyl peroxide. The initial dark red solution disappeared in 10 min. The process was repeated three more times until a total of 22.8 g. (0.128 mole) of *N*-bromosuccinimide and 1.24 g. (0.0051 mole) of benzoyl peroxide had been reacted. An additional 1.5 hr. of refluxing under irradiation was permitted. The mixture was filtered to remove the succinimide, and the filtrate was evaporated *in vacuo* to an oil. The crude oil (IV) was dissolved in a mixture of 300 ml. of dimethylformamide and 175 ml. of concentrated ammonium hydroxide with vigorous stirring at room temperature. The solution was allowed to stand overnight and then diluted with 1,600 ml. of water. The crude mixture was extracted with two 300-ml. portions of chloroform. The combined chloroform solutions were washed with two 200-ml. portions of water, dried over anhydrous calcium sulfate, and evaporated *in vacuo* to an oil. The oil was shaken with 800 ml. of ether and 500 ml. of water. The aqueous phase was separated, made basic with 80 ml. of 10% sodium hydroxide, and extracted with two 200-ml. portions of ether. The three ether solutions were combined, washed with two 100-ml. portions of water, dried over anhydrous calcium sulfate, and saturated with dry hydrogen chloride. A total of 7.5 g. (15% yield) of crude salt was obtained. Trituration with chloroform–petroleum ether (75:100 ml.) did not improve the purity of the product, which is somewhat hygroscopic. It was dissolved in 50 ml. of chloroform, treated with charcoal, and the solution evaporated *in vacuo* to an oil. Trituration with anhydrous ether gave 4.87 g. of 5-chloro-2-(3-chloro-2-hydroxypropoxy)-benzhydrylamine hydrochloride, m.p. 97–100°.

Anal.—Calcd. for $C_{16}H_{13}Cl_3NO_2$: C, 52.98; H, 5.00; Cl, 29.33; N, 3.86. Found: C, 53.21; H, 5.24; Cl, 29.21; N, 3.71.

N,N-Diethyl-3-(2-benzyl-4-chlorophenoxy)-2-hydroxypropylamine Hydrochloride (III)—A solution of 31.1 g. (0.100 mole) of 3-(2-benzyl-4-chlorophenoxy)2-hydroxypropyl chloride in 14.6 g. (0.200 mole) of diethylamine was refluxed for 5.5 hr. with stirring. The excess of amine was removed by distillation. The oily residue was dissolved in 250 ml. of ether and extracted with two 100-ml. portions of 10% hydrochloric acid. The combined aqueous acid solutions were washed with 100 ml. of ether and then made basic with 200 ml. of 10% sodium hydroxide. The mixture was extracted with three 100-ml. portions of ether. The combined ether solutions were washed with two 50-ml. portions of water, dried over anhydrous calcium sulfate, and saturated with dry hydrogen chloride. The crude salt was collected and triturated with absolute ethanol–absolute ether (50:250 ml.) to give 16.3 g. (42% yield) of product, m.p. 128–131°. Recrystallization from methanol–ether (75:300 ml.) gave 14.4 g. of pure *N,N*-diethyl-3-(2-benzyl-4-chlorophenoxy)-2-hydroxypropylamine hydrochloride, m.p. 131–133°.

Anal.—Calcd. for $C_{20}H_{27}Cl_2NO_2$: C, 62.50; H, 7.08; Cl, 18.45; N, 3.65. Found: C, 62.53; H, 7.08; Cl, 18.48; N, 3.84.

Hydrolysis of Aspirin by Rat Small Intestine

Sir:

A recent study of the effect of certain antirheumatic drugs on active amino acid transport across the small intestine revealed that the hamster small intestine is able to hydrolyze aspirin at an appreciable rate (1). This was considered to be due to the presence of esterase(s) in the intestinal epithelium which are known to occur also in all regions of the human gastrointestinal tract (2). It was suggested on this basis that appreciable hydrolysis of aspirin may take place during the absorption of this drug from the gastrointestinal tract (1). A subsequent report by Rowland and co-workers on the kinetics of aspirin disposition in man provided further evidence suggesting aspirin hydrolysis in the gut wall (3). In view of the apparent enzymic nature of the hydrolytic process it was of interest to determine its dependence on aspirin concentration.

Five-centimeter segments of everted small intestine were obtained from male Sprague-Dawley rats as described previously (1). Individual segments were placed in 50-ml. capacity conical flasks containing 15 ml. of 0–120 m*M* aspirin in Krebs-Ringer bicarbonate solution (final pH 7.4). Other segments of small intestine were first immersed in boiling water for 5 min. and then placed in aspirin solutions (controls). Flasks with drug solution but without an intestine segment were also prepared. All flasks were flushed with 95% oxygen–5% carbon dioxide mixture, sealed, and agitated mildly at 37° in a water bath. An aliquot of solution was removed after 1-hr., placed in a chilled test tube containing 1 *N* hydrochloric acid, diluted if necessary, and then extracted immediately with carbon tetrachloride and assayed colorimetrically for salicylic acid by the method of Brodie and co-workers (4).

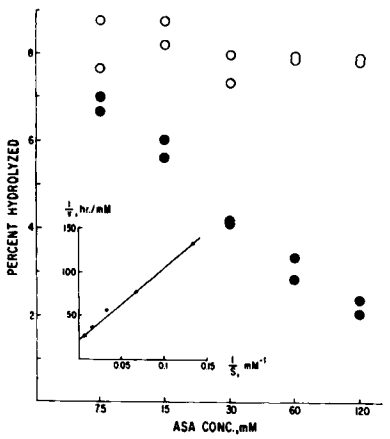

Fig. 1—Hydrolysis of aspirin by rat small intestine as a function of aspirin concentration. Key: ○, *percent hydrolyzed in 1 hr. in the presence of intestine segments inactivated by 5-min. immersion in boiling water (controls);* ●, *percent hydrolyzed in excess of control values by active intestine segments. Inset: Lineweaver-Burk-type plot of the average data.*

The hydrolysis of aspirin by everted intestine segments of rats as a function of aspirin concentration is shown in Fig. 1. The percent hydrolysis decreased markedly with increasing aspirin concentration. A double reciprocal plot of the Lineweaver-Burk-type yielded a linear relationship between the reciprocal of hydrolysis rate and the reciprocal of the initial aspirin concentration (inset of Fig. 1). The percent hydrolysis of aspirin in solutions containing boiled intestine segments was concentration independent and did not differ measurably from that in solutions without intestine.[1] These properties (saturability and heat inactivation) are characteristic of enzymic processes and suggest that aspirin hydrolysis by intestinal tissue is due to esterase(s). The presence of esterases in the human gastrointestinal tract is well established (2) and it is likely that the activity of nonspecific esterase differs in different regions of the gastrointestinal tract. The saturability of aspirin-hydrolyzing activity in the rat intestine is readily apparent at reasonable concentrations of aspirin under the conditions of the present study. It can be expected that this limited capacity of esterase activity will be reflected by a concentration and dose dependence in the extent of aspirin hydrolysis during absorption. Rapid absorption, with high concentrations of aspirin at sites of hydrolysis in the intestinal wall, is likely to result in less extensive hydrolysis of the drug than would be encountered when the same amount of drug is absorbed more slowly. Dosage-form characteristics, inasmuch as they affect the site and rate of release of aspirin in the gastrointestinal tract, may therefore be expected to influence the extent of hydrolysis of aspirin during absorption. The

[1] These control data reflect the extent of hydrolysis of aspirin during the preparation and incubation of the solutions.

magnitude of this effect in man must remain speculative pending appropriately designed clinical trials.

A Cardioactive Steroidal Iodoacetate

Sir:

Empirical relationships between the chemical constitution and biological activity of cardiac glycosides and aglycones, *e.g.*, I, have been tabulated (1), and the unsaturated lactone at C-17 appears essential for activity. Moreover, it seems likely that these cardiotonic substances act through inhibition of enzyme systems involved in ion transport (2).

The chemical basis for the essentiality of the lactone is unknown. Portius and Repke (3) have proposed that the α,β-unsaturated carbonyl *Wirkguppierung* is a proton acceptor in hydrogen bonding, whereas Glynn (4) has postulated that addition of essential sulfhydryl groups to the unsaturated center may be involved. We have evaluated the last suggestion by the preparation of analogs.

The reaction of II with chloroacetic anhydride at 55° produced the corresponding 21-chloroacetate ester m.p. 109–111°, $[\alpha]_D$ + 51°[1] which on treatment with sodium iodide in acetone solution gave the iodoacetate III, m.p. 150–155°, $[\alpha]^{20}$ + 49°.

Biological evaluation was performed in the usual way (6) in cats under chloralose-urethan anesthesia. A volume of 1 ml. of 47.5% alcohol containing 0.4 mg. of drug was injected at 3-min. intervals into the femoral vein. The effect of the drug was observed by EKG and blood-pressure readings recorded on a Grass polygraph. The following lethal doses were determined (LD ± SE in mg./kg.): III (1.37 ± 0.26), IV (7) (15.59 ± 2.28). The high activity of III indicates that the lactone ring is not an essential feature for a cardioactive compound.

Iodoacetates are known to react with nucleophiles, such as sulfhydryl groups. Thus a reasonable explanation for the great difference in potency of the iodoacetate III relative to the acetate IV is that alkylation of an essential nucleophilic

reactions between unsaturated lactones and reagents containing sulfhydryl groups. On the other hand, the difference in activity of the iodoacetate III and the acetate IV argues against a hydrogen bonding role for the lacetone carbonyl group.

The cardiotonic activity of cassaine V (9) (LD 1.15 mg./kg.), may be explained in a similar manner, as the α,β-unsaturated ester in this material is also a potential electrophilic reagent. In both cases, the function of the polycyclic portion of the molecule is presumably to induce an inhibitory specific conformational perturbation (10) in the enzyme. This is indicated by the known biological consequences of structural variations in this part of the molecule (1), as well as by the fact that simple unsaturated lactones (11) and simple sulfhydryl reagents (12) are dissimilar from cardiac glycosides in their effects.

The extension of these studies to other electrophilic analogs is in progress.

REVIEWS

Treatise on Analytical Chemistry. Part III: *Analytical Chemistry in Industry.* Vol. 1. Edited by I. M. KOLTHOFF, P. J. ELVING, and F. H. STROSS. Interscience Publishers, Inc., 605 Third Ave., New York, NY 10016, 1967. xxiv + 455 pp. 17 × 24.5 cm. Price $17.50.

The well-known and respected "Treatise on Analytical Chemistry" series edited by Kolthoff and Elving by now has reached encyclopedic proportions. However, when it came to Part III "Analytical Chemistry in Industry" the editors, as they state in the Preface, deferred for industrially important analytical methods and procedures to Snell and Hilton's even larger "Encyclopedia of Industrial Chemical Analysis" by the same publishers. Therefore, the first volume of Part III with F. Stross as co-editor addresses selected topics to the organization builder, the laboratory designer, the production controller, and the safety conscious among others. The pharmaceutical analyst should approach this volume forewarned that there are few specific references to the pharmaceutical industry. The student eager to explore the attractiveness of industrial employment should be told that the treatise is a "comprehensive account" but comprehensiveness is not apt to stimulate the imagination or inspire enthusiasm. Where is the analytical Watson to write "The Double Focus?"

About individual contributions the following should be briefly reported: In "Analytical Chemistry and the Analytical Chemist in Industry" Royer and Maricle are of the opinion that "analytical chemistry, without doubt, entered industry through the Control Laboratory." In "Methodology of Industrial Analysis" Spauschus makes the excellent point that "the contributions of the analytical chemist to a research program will be most effective if he is given the opportunity to participate while the program is being planned." In "Organization of Analytical Chemistry in the Industrial Research Laboratory" Kirklin makes very cogent comments on the controversial question whether to submit samples for reanalysis "openly" or "blindly." Kirklin also presents a plethora of organization charts but wisely states that "changes in details of organization are made frequently in accordance with the demands of the work." He should have added "and of problems of personality." In "Organization for Analytical Chemistry in Production Control" the same

reactions between unsaturated lactones and reagents containing sulfhydryl groups. On the other hand, the difference in activity of the iodoacetate III and the acetate IV argues against a hydrogen bonding role for the lacetone carbonyl group.

The well-known and respected "Treatise on Analytical Chemistry" series edited by Kolthoff and Elving by now has reached encyclopedic proportions. However, when it came to Part III "Analytical Chemistry in Industry" the editors, as they state in the Preface, deferred for industrially important analytical methods and procedures to Snell and Hilton's even larger "Encyclopedia of Industrial Chemical Analysis" by the same publishers. Therefore, the first volume of Part III with F. Stross as co-editor addresses selected topics to the organization builder, the laboratory designer, the production controller, and the safety conscious among others. The pharmaceutical analyst should approach this volume forewarned that there are few specific references to the pharmaceutical industry. The student eager to explore the attractiveness of industrial employment should be told that the treatise is a "comprehensive account" but comprehensiveness is not apt to stimulate the imagination or inspire enthusiasm. Where is the analytical Watson to write "The Double Focus?"

About individual contributions the following should be briefly reported: In "Analytical Chemistry and the Analytical Chemist in Industry" Royer and Maricle are of the opinion that "analytical chemistry, without doubt, entered industry through the Control Laboratory." In "Methodology of Industrial Analysis" Spauschus makes the excellent point that "the contributions of the analytical chemist to a research program will be most effective if he is given the opportunity to participate while the program is being planned." In "Organization of Analytical Chemistry in the Industrial Research Laboratory" Kirklin makes very cogent comments on the controversial question whether to submit samples for reanalysis "openly" or "blindly." Kirklin also presents a plethora of organization charts but wisely states that "changes in details of organization are made frequently in accordance with the demands of the work." He should have added "and of problems of personality." In "Organization for Analytical Chemistry in Production Control" the same

author has the control laboratories report to the plant manager, "Verboten" in the pharmaceutical industry! Kehoe in "Automation in Industrial Analytical Chemistry" gives five excellent theses which should be recommended reading for anybody considering or working on laboratory automation. Thesis number four states: "The best automatic analyzer still requires intelligent supervision to detect subtle errors and to recognize gradual decay of accuracy."

I hope that the instructive and well-written chapters on "Design of Laboratories for Analytical Chemistry" by Mellon, "Design of Laboratories for Radiochemical Work" by Fenninger and Hale and "Safety in the Analytical Laboratory" by Stalzer, Martin, and Railing find a wide readership since the information presented reaches beyond the confines of the analytical laboratory.

"Development of Raw Material and Product Specifications" should be required reading for all purchasing agents. Patek makes the memorable point that "it is almost impossible to develop a good purchase specification without the assistance of an analytical chemist." In the final chapter on "Testing of Consumer Products" by Schwartz and Gaffney the reader not only is treated to the cigarette puffing machine but also will learn that there is a gadget called the Handle-O-Meter to measure the fluffiness of towels.

The print of the book is readable and the drawings are clear. However, the paper used does not lend itself too well to photographic reproduction. This particularly detracts from the nice gesture of presenting the authors' portraits.

The book then contains an abundance of information over a wide range of subjects. I can visualize that a future historian might use the volume as a rich source to study the role and organization of analytical chemistry in the chemical process industry in the mid-20th century. To the contemporary pharmaceutical analyst the book offers a broad view of the adjoining pasture.

Fractional Solidification. Vol. I. Edited by M. ZIEF and W. R. WILCOX. Marcel Dekker, Inc., 95 Madison Ave., New York, NY 10019 1967. xvi + 714 pp. 16 × 23.5 cm. Price $28.75.

Fractional Solidification is the first of two volumes. Twenty-two authors from England and the United States have contributed to the text. The contributions of Paul Jannke are of special interest to the pharmaceutical scientist. Each chapter is well documented with references—a majority being recent.

The book is divided into six parts. Part I is devoted to basic principles with contributions dealing with phase diagrams, mass transfer in fractional solidification, constitutional supercooling and microsegregation, polyphase solidification, and heat transfer in fractional solidification. Part II deals with laboratory scale apparatus used in fractional solidification with specifics that deal with batch zone and continuous zone melting, progressive freezing and column crystallization, and zone precipitation and allied techniques. Part III deals with industrial scale equipment. Different authors discuss the Proabd Refiner, Newton Chambers' Process, Rotary-Drum Techniques, Phillips Fractional-Solidification Process, and desalination by freezing. Part IV deals with applications of fractional solidification. Ultrapurification and its relation to pharmaceuticals are discussed by Jannke *et al.* Chapters are devoted to ultrapurity in crystal growth and to bulk purification. Part V is devoted to the economics of fractional solidification, and Part VI contains tables listing the purification and operating parameters for zone melting of inorganic and organic compounds. A great many of the organic compounds are important pharmaceuticals.

This book is of value because the basic knowledge and methods used to produce chemicals of ultrapurity are presented. The processes required to produce ultrapurity are examined in detail. The material should be valuable to those in pharmaceutical and other industries in order to develop and maintain strict specifications on raw materials. This book should prove to be valuable to the researcher in producing ultra-pure crystals in either very small or large scale batches.

The book is printed on paper which provides easy reading, and the print is of adequate size. The authors have used many figures to illustrate their concepts and discussions.

I recommend this book as a reference to the scientist in research, teaching, and industry.

Take as Directed. Edited by F. E. SHIDEMAN and written by JOHN P. RUSSO. The Chemical Rubber Company Press, 18901 Cranwood Parkway, Cleveland, OH 44128, 1967. xiv + 457 pp. 16 × 23.5 cm. Price $14.75.

The editor has fulfilled the objective given on the book cover, "Our modern medicines explained for the layman." Diseases and physiological conditions have been described clearly in terms the layman will understand. The fundamental information given about the drugs is presented in a sound, reasonable way that is a pleasant contrast to the dramatic presentations that frequently are offered to the lay public. This book is an excellent, simplified discussion of drugs and their use in medical treatment today. Pharmacists and pharmaceutical scientists can confidently suggest this book in response to requests from laymen to recommend a simplified—yet authoritative—text discussing drugs in current use.

The contributions of Paul Jannke are of special interest to the pharmaceutical scientist. Each chapter is well documented with references—a majority being recent.

The book is divided into six parts. Part I is devoted to basic principles with contributions dealing with phase diagrams, mass transfer in fractional solidification, constitutional supercooling and microsegregation, polyphase solidification, and heat transfer in fractional solidification. Part II deals with laboratory scale apparatus used in fractional solidification with specifics that deal with batch zone and continuous zone melting, progressive freezing and column crystallization, and zone precipitation and allied techniques. Part III deals with industrial scale equipment. Different authors discuss the Proabd Refiner, Newton Chambers' Process, Rotary-Drum Techniques, Phillips Fractional-Solidification Process, and desalination by freezing. Part IV deals with applications of fractional solidification. Ultrapurification and its relation to pharmaceuticals are discussed by Jannke *et al.* Chapters are devoted to ultrapurity in crystal growth and to bulk purification. Part V is devoted to the economics of fractional solidification, and Part VI contains tables listing the purification and operating parameters for zone melting of inorganic and organic compounds. A great many of the organic compounds are important pharmaceuticals.

This book is of value because the basic knowledge and methods used to produce chemicals of ultrapurity are presented. The processes required to produce ultrapurity are examined in detail. The material should be valuable to those in pharmaceutical and other industries in order to develop and maintain strict specifications on raw materials. This book should prove to be valuable to the researcher in producing ultra-pure crystals in either very small or large scale batches.

The book is printed on paper which provides easy reading, and the print is of adequate size. The authors have used many figures to illustrate their concepts and discussions.

I recommend this book as a reference to the scientist in research, teaching, and industry.

Take as Directed. Edited by F. E. SHIDEMAN and written by JOHN P. RUSSO. The Chemical Rubber Company Press, 18901 Cranwood Parkway, Cleveland, OH 44128, 1967. xiv + 457 pp. 16 × 23.5 cm. Price $14.75.

The editor has fulfilled the objective given on the book cover, "Our modern medicines explained for the layman." Diseases and physiological conditions have been described clearly in terms the layman will understand. The fundamental information given about the drugs is presented in a sound, reasonable way that is a pleasant contrast to the dramatic presentations that frequently are offered to the lay public. This book is an excellent, simplified discussion of drugs and their use in medical treatment today. Pharmacists and pharmaceutical scientists can confidently suggest this book in response to requests from laymen to recommend a simplified—yet authoritative—text discussing drugs in current use.

Aromatic Amine Oxides. By EIJI OCHIAI. Translated by Dorothy U. Mizoguchi. Elsevier Publishing Company, 52 Vanderbilt Ave., New York, NY 10017, 1967. ix + 456 pp. 15 × 23 cm. Price $30.00.

In view of the frequently predictable chemical

author has the control laboratories report to the plant manager, "Verboten" in the pharmaceutical industry! Kehoe in "Automation in Industrial Analytical Chemistry" gives five excellent theses which should be recommended reading for anybody considering or working on laboratory automation. Thesis number four states: "The best automatic analyzer still requires intelligent supervision to detect subtle errors and to recognize gradual decay of accuracy."

I hope that the instructive and well-written chapters on "Design of Laboratories for Analytical Chemistry" by Mellon, "Design of Laboratories for Radiochemical Work" by Fenninger and Hale and "Safety in the Analytical Laboratory" by Stalzer, Martin, and Railing find a wide readership since the information presented reaches beyond the confines of the analytical laboratory.

"Development of Raw Material and Product Specifications" should be required reading for all purchasing agents. Patek makes the memorable point that "it is almost impossible to develop a good purchase specification without the assistance of an analytical chemist." In the final chapter on "Testing of Consumer Products" by Schwartz and Gaffney the reader not only is treated to the cigarette puffing machine but also will learn that there is a gadget called the Handle-O-Meter to measure the fluffiness of towels.

The print of the book is readable and the drawings are clear. However, the paper used does not lend itself too well to photographic reproduction. This particularly detracts from the nice gesture of presenting the authors' portraits.

The book then contains an abundance of information over a wide range of subjects. I can visualize that a future historian might use the volume as a rich source to study the role and organization of analytical chemistry in the chemical process industry in the mid-20th century. To the contemporary pharmaceutical analyst the book offers a broad view of the adjoining pasture.

Aromatic Amine Oxides. By EIJI OCHIAI. Translated by Dorothy U. Mizoguchi. Elsevier Publishing Company, 52 Vanderbilt Ave., New York, NY 10017, 1967. ix + 456 pp. 15 × 23 cm. Price $30.00.

In view of the frequently predictable chemical

effect of the introduction of an *N*-oxide function into a compound, it is disappointing that so few biologically useful *N*-oxides have been found. The two amine oxides having the most widespread use, chlordiazepoxide and 2-mercaptopyridine 1-oxide, are not aromatic *N*-oxides despite the nomenclature of the latter. One of the chapters of Professor Eiji Ochiai's "Aromatic Amine Oxides," reviews in detail the attempts to employ *N*-oxidation in favorably altering biological properties.

Other chapters of this comprehensive and informative treatise cover the history, the preparation, and the reactions of the aromatic heterocyclic *N*-oxides. Electrophilic and nucleophilic substitution of compounds containing *N*-oxides and the effects of an *N*-oxide function upon other substituents are reviewed.

As befits a true expert, Professor Ochiai has called upon another, Dr. C. Kaneko, to provide a chapter on the physicochemical properties of the amine oxides. The book is limited to the aromatic *N*-oxides as its title indicates, but aliphatic *N*-oxides receive some attention for the purposes of differentiation.

It is a tribute to Professor Ochiai's 1953 article in the *Journal of Organic Chemistry* (**18**, 534) that so much of the western synthetic work recorded here was stimulated by that seminal review. Nevertheless, a large part of the original work on *N*-oxides has been published in Japan, and it is helpful that experimental details for many syntheses are provided in this volume.

The personal identification of Professor Ochiai with this segment of organic chemistry—an identification of a type that is rare nowadays—makes this an especially attractive book. Its long-term usefulness makes it well worth owning.

The translation is serviceable but is not always idiomatic and better editorial work by the publisher might have changed such awkward usage as "active to substitution." A grossly incomplete author index is included. The literature has been reviewed through 1963.

Fundamentals of Immunology. 4th ed. By WILLIAM C. BOYD. Interscience Publishers, Inc., 605 Third Ave., New York, NY 10016, 1966. xvii + 773 pp. 15.5 × 23 cm. Price $14.95.

"Fundamentals of Immunology" continues to be an excellent text for the beginning student and as indicated in the title, does not require previous knowledge of the subject. Exception must be taken to the phrase on the fly-leaf, "completely rewritten." Although there has been updating in some chapters, it might be more accurate to state that the book has been reprinted. It is difficult to know just how much material on laboratory and clinical techniques should be included in a book of this type, but it is this reviewer's opinion that more techniques should have been added rather than deleted in this issue. This reviewer also feels that development of fluorescent antibody techniques and applications would have been advantageous to the reader.

As in previous editions, all phases of immunology are developed or at least mentioned. The book includes chapters on: Immunity and Immunology, Antibiotics and Antibody Specificity, Antigens, Cell Antigens, Blood Groups, Antibody-Antigen Reactions, Complement and Complement Fixation, Immediate Hypersensitivity, Delayed Hypersensitivity, Non-Immunological Equivalents of Hypersensitivity Reactions, Hypersensitivity and Immunity, Immunological Tolerance and Intolerance, Autoimmunization and Disease, Immunity in Action, Practical Use of Immunity and Hypersensitivity, Laboratory and Clinical Technic, and Quantitation and Statistical Methods in Immunology. Comprehensive references are provided at the end of each chapter for those individuals who wish to delve more deeply into the text material.

Peptides. Edited by H. C. BEYERMAN, A. VAN DE LINDE, and W. M. VAN DEN BRINK. North-Holland Publishing Co., Amsterdam, Holland. Available in the U. S. from John Wiley & Sons, Inc., 605 Third Ave., New York, NY 10016, 1967. xii + 292 pp. 15.5 × 23 cm. Price $14.50

This book, the latest in the series of publications of the Proceedings of annual European Peptide Symposiums, is a welcome addition to the desk of researchers interested in peptide work. There are eight sections and each section contains the presentations by authors intimately associated with the material presented. Bibliography of most of the articles in this book is most up-to-date and is intended to familiarize the reader with pertinent information concerning various aspects of peptide chemistry.

While the sections of this book devoted to coupling methods, protecting groups, synthesis of peptides with polymeric supports, and mass spectroscopy in peptide chemistry, are of general interest, the medicinal chemists, however, will benefit most from sections on sequential polymers, racemization, and biologically active peptides. Among the peptides with biological activity, a very interesting discussion is focused on the recent developments in the synthesis of biologically active corticotropin fragments. Several peptides with biological activity, such as human gastrin, glucagon, secretin, melittin, and others, have also been discussed from a synthetic and biological activity point of view.

The only improvement in this book would have been the inclusion of subject index.

Emulsion Science. Edited by PHILIP SHERMAN. Academic Press, Inc., Ltd., Berkeley Square House, Berkeley Square, London, W.1. U. S. Academic Press, Inc., 111 Fifth Avenue, New

York, NY 10003, 1968. 16 × 23.5 cm. x + 496 pp. Price 115s $21.00.

Emulsion Science is divided into five sections or chapters as follows: (1) Principles of Emulsion Formation, by E. S. R. Gopal; (2) The Theory of Stability of Emulsions, by J. A. Kitchener and P. R. Mussellwhite; (3) General Properties of Emulsions and their Constituents, by Philip Sherman; (4) Rheology of Emulsions, by Philip Sherman; (5) Electrical Properties of Emulsions, by Tetsuya Hanai.

The author-editor has done an excellent job in correlating and unifying the contributions of the other authors. The text is well organized and comprehensive with good continuity and a minimum of overlap. The first three sections are primarily descriptive, but sufficiently quantitative to give adequate depth to the subjects covered. While some differences in style and organization may be expected, only a minimum is actually encountered. For example, demulsification is discussed in Section 1 while Section 2 is devoted entirely to emulsion stability. Section 1 includes a discussion on choice of emulsifying agents while Section 3 includes a detailed discussion of the HLB system. Careful attention has been given to minimizing repetition in such instances.

The first three sections cover about 217 pages of the text, while the latter two sections are more theoretical and quantitative, occupying about 260 pages of the text. The section on rheology is rather unique in its approach to rheological properties. Much of the discussion is based on structural effects within the emulsion, not merely on measurement data.

Each section of the text is well documented and contains sufficient breadth and depth to maintain the interest of a broad cross-section of readers.

Drugs Affecting the Central Nervous System. Vol. 2 of the *Medicinal Research Series.* Edited by ALFRED BURGER. Marcel Dekker, Inc., 95 Madison Ave., New York, NY 10016, 1968. xv + 437 pp. 16 × 24 cm. Price $19.75.

This second volume of a series continues the structural approach to drugs affecting the central nervous system. Eight chapters cover the general topics of narcosis, morphine-like analgesics, antidepressants, psychotomimetic agents, 1,4-benzodiazepine derivatives, centrally acting muscle relaxants, and substituted phenothiazines. The chapter on psychotomimetic agents by Albert Hofmann is of considerable interest. It covers not only his personal discovery of the effects of LSD, but is an excellent review of the naturally occurring psychomimetic drugs. As would be expected, the relationship between chemical structure and clinical action, value, or use is not a major contribution of this volume. There is evidence that the familiar nonagreements as to the meaning of words such as tranquilizer, relaxant, antidepressant are present between the various authors. This, however, should not detract from the main value of the series: the presentation in one place of large numbers of chemically related compounds with many of their comparative pharmacologic effects. The chapter on morphine-like analgesics is outstanding. The chemical anatomy of the many compounds is clearly described. There is a precise definition of the meaning of "morphine-like action." There is no attempt made to describe the morphine-like compounds clinically. This volume, like the first, is recommended for all serious students of pharmacology and pharmaceutical chemistry.

Characterisation and Manipulation of Powders. The Pharmaceutical Press, 17 Bloomsbury Square, London, W.C.1., England, 1967. viii + 180 pp. 14 × 22 cm. Price 50s. (1s. 6d. p/p).

This book is a copy of the handbook prepared for a one-week postgraduate course in Powder Technology. The course was organized by the Pharmaceutical Society of Great Britain and directed by Professor E. Shotten of the School of Pharmacy, University of London in April 1966. The book contains outlines of the lectures given by ten recognized authorities in the field of powder technology, plus 37 experiments and three demonstrations. The experiments and demonstrations were written by thirteen scientists, most of whom are well-known in the pharmaceutical field.

The book is intended to be a practical manual for industrial pharmacists and others who are interested in the characterization and manipulation of powders. The lectures and experiments cover a broad area including particle size analysis, surface area measurement, particle cohesion, size reduction, mixing, granulation, fluidization, classification, crystallization, *etc.* Unfortunately, as noted in its Introduction, this book does lack balance, polish, and accurate syntax. The reader will find some of the experiments confusing, especially those describing operation of apparatus which is not named or described. There is also a lack of continuity which is not helped by placing the lecture outlines in the back of the book. The brevity of the course and size of the book also results in the omission of much important technology.

Despite these shortcomings, this book does provide an assemblage of information which should be useful to teachers and other workers in this field.

Emulsion Science is divided into five sections or chapters as follows: (1) Principles of Emulsion Formation, by E. S. R. Gopal; (2) The Theory of Stability of Emulsions, by J. A. Kitchener and P. R. Mussellwhite; (3) General Properties of Emulsions and their Constituents, by Philip Sherman; (4) Rheology of Emulsions, by Philip Sherman; (5) Electrical Properties of Emulsions, by Tetsuya Hanai.

The author-editor has done an excellent job in correlating and unifying the contributions of the other authors. The text is well organized and comprehensive with good continuity and a minimum of overlap. The first three sections are primarily descriptive, but sufficiently quantitative to give adequate depth to the subjects covered. While some differences in style and organization may be expected, only a minimum is actually encountered. For example, demulsification is discussed in Section 1 while Section 2 is devoted entirely to emulsion stability. Section 1 includes a discussion on choice of emulsifying agents while Section 3 includes a detailed discussion of the HLB system. Careful attention has been given to minimizing repetition in such instances.

The first three sections cover about 217 pages of the text, while the latter two sections are more theoretical and quantitative, occupying about 260 pages of the text. The section on rheology is rather unique in its approach to rheological properties. Much of the discussion is based on structural effects within the emulsion, not merely on measurement data.

Each section of the text is well documented and contains sufficient breadth and depth to maintain the interest of a broad cross-section of readers.

Drugs Affecting the Central Nervous System. Vol. 2 of the *Medicinal Research Series.* Edited by ALFRED BURGER. Marcel Dekker, Inc., 95 Madison Ave., New York, NY 10016, 1968. xv + 437 pp. 16 × 24 cm. Price $19.75.

This second volume of a series continues the structural approach to drugs affecting the central nervous system. Eight chapters cover the general topics of narcosis, morphine-like analgesics, antidepressants, psychotomimetic agents, 1,4-benzodiazepine derivatives, centrally acting muscle relaxants, and substituted phenothiazines. The chapter on psychotomimetic agents by Albert Hofmann is of considerable interest. It covers not only his personal discovery of the effects of LSD, but is an excellent review of the naturally occurring psychomimetic drugs. As would be expected, the relationship between chemical structure and clinical action, value, or use is not a major contribution of this volume. There is evidence that the familiar nonagreements as to the meaning of words such as tranquilizer, relaxant, antidepressant are present between the various authors. This, however, should not detract from the main value of the series: the presentation in one place of large numbers of chemically related compounds with many of their comparative pharmacologic effects. The chapter on morphine-like analgesics is outstanding. The chemical anatomy of the many compounds is clearly described. There is a precise definition of the meaning of "morphine-like action." There is no attempt made to describe the morphine-like compounds clinically. This volume, like the first, is recommended for all serious students of pharmacology and pharmaceutical chemistry.

THIS ARTICLE attempts to review the current knowledge of sulfonamides (SNS),[1] their structure-activity relations, and the mode of action involved. The problem of the mode of action and the relationship between structure and biological and antibacterial action of SNS, which was detected in 1933, are still not completely elucidated. Therefore, it would appear necessary to discuss all important experimental results concerning these problems. However, this is impossible considering that Northey (1) (review, 1948) required 200 pages to discuss the results that were available. Hundreds of publications about the synthesis of new compounds, their chemotherapeutic activity, their biological properties, and their kinetic and enzymatic approaches have been published since then to give an insight into the mode of action. This demonstrates the importance of SNS, which have revolutionized the treatment of bacterial infections. Only some of the important facts can be discussed in this paper, which includes a subjective selection.

There are several statements of many authors concerning the problem of structure-activity rela-

Received from the Borstel Research Institute, Institute for Experimental Biology and Medicine, 2061 Borstel, Hamburg, West Germany.

[1] In this review SNS is used as abbreviation for N^1-substituted sulfanilamides.

tionships of different chemotherapeutics, but among these statements, none has general validity. Definite results and answers to this question can be expected only if one restricts his attention to a very closely related group of chemical substances. SNS belong to such a group and have been studied in great detail. Setting up an extensive theory of the mode of action of chemotherapeutic agents is not only an academic problem, it should also give quantitative meaning to the chemical, physicochemical, and biological properties of the compound for the therapeutic effects. This can serve not only as a basis for the development of new drugs, but also for the evaluation of different drugs. The increasing difficulties in clinical screening tests (2) necessitate exact experimental standards.

The mode of action of chemotherapeutics, including all chemical, physicochemical, and biochemical reactions involved, can be divided into the pharmacodynamic, toxicological, and the antibacterial mode of action. The antibacterial mode of action consists of (*a*) the transport mechanism to the place of bacterial infection (pharmacokinetic) and through the bacterial membrane and (*b*) the chemical reaction which causes bacterial death or inhibition of growth. The reaction may induce sequential biochemical reactions in bacterial metabolism.

The classification of chemotherapeutics by their mode of action can be based only on the chemistry of the chemical reactions involved in the antibacterial action. As long as the chemistry of the responsible reaction is not clarified, the classification of the chemotherapeutic is doubtful. What are the criteria which decide if an antibacterial compound belongs to the group of SNS? There are substituted SNS, the substituents of which have an antibacterial activity by themselves, for instance sulfanilthiocarbamide (3), some sulfathiazoles, sulfathiadiazoles, and sulfapyridine (4–7), sulfa-3,5-dibromobenzene (8), and some sulfapyrimidine derivatives (9, 10).

If the antibacterial activity of the substituents gets the upper hand, the compound does not belong to the group of SNS with respect to the mode of action. Two criteria which are not identical can be used for classification: the

TABLE I—CLASSIFICATION OF 4-AMINOBENZOIC ACID ANTAGONISTS AND OTHER SULFONAMIDES WITH ANTIBACTERIAL ACTIVITY

4-Aminobenzoic acid antagonists (4-substituted aniline derivatives)		4-Aminobenzoyl[a] derivatives
		4-Aminosalicylic acid[a]
		Other ring substituted[a] 4-aminobenzoic acid derivatives
		4-Aminophenylarsonic acid
		Other 4-substituted aniline derivatives, not sulfone derivatives
		Sulfanilic anilines ("sulfones," DDS derivatives)[b]
		Other sulfanilic acid derivatives (not sulfonamides)[b]

antagonism of PABA against the antibacterial activity of SNS (11, 12) and the cross-resistance against sulfanilamide (13). By testing the cross-resistance of sulfanilamide and PAS resistant strains, it is possible to obtain a differentiation of the group of PABA antagonists (Table I).

CHEMICAL STRUCTURE AS REASON FOR BIOLOGICAL ACTION

Structure Specificity of the Activity of PABA and PAS—If the antagonistic action of PABA is used as a criterion for the activity of one group of compounds, knowledge is needed of the structure specificity of the action. In the following the rules of Johnson, Green, and Pauli (14), Zetterberg (15), Hossack (16), and others—completed with some additional facts—are given.

1. The antagonistic action against SNS is afforded by the amino group in the 4 position of the carboxyl group (17, 18).

2. Exchange of the amino group for other substituents with the exception of the nitro or acetyl amino group results in ineffective compounds (18).

3. Exchange of the benzene ring for other ring systems causes loss of activity (19).

4. Monosubstitution in the 3 or 2 position of the PABA molecule by halogen, alkyl, and alkoxy substituents results either in bacteriostatic compounds (20–22) or compounds with antagonistic action against SNS. There are completely different statements about the activity of these compounds in the literature; PAS belongs in this group of compounds.

5. Variation in the carboxyl group by exchange or substitution results in compounds which may possess either antagonistic properties (local anesthetics) (23–25), antibacterial, or no activity (26–30).

6. Simultaneous variation at the amino group and substitution at the benzene ring results in inactive compounds.

As previously stated, among the PABA derivatives are compounds which may act as antagonists against SNS, others which have antibacterial properties, and others which are inactive. Some of these compounds are judged differently by different authors, using different concentrations of the drug or different strains. These results are explainable according to Ariens *et al.* (31, 32) by two independent qualities of PABA, PABA derivatives, and SNS, the so-called "affinity" (reciprocal of the dissociation constant of the compound-receptor complex), and the "intrinsic" activity (metabolic activity).

Structure Specificity of the Activity of SNS—Northey (1) developed the following rules about the structure specificity of SNS. These rules are based on a tremendous mass of literature available from several large chemical companies and have been completed by the addition of some new results. The sequence used is the same which is used for PABA and its derivatives.

1. SNS antagonized by PABA possess an amino group in the 4 position of the sulfone group.

2. Exchange of the amino group by H—, HO—, RO—, HOOC—, $H_2N—SO_2—$, alkyl, or halogen substituents causes loss of activity or results in compounds which are not antagonized by PABA (homosulfanilamide). N^4-derivatives are active if the free amino group is obtainable either hydrolytically or enzymatically.

3. Exchange of the benzene ring for other ring systems decreases the activity of SNS.

4. SNS substituted in the benzene ring are mostly inactive; however, there are exceptions (33, 34).

5. Exchange of the SO_2NH group for NH_2—, —CN, $—SO_3H$ (see, however, 35), $—AsO_3H_2$, —NH—CO—CH_3, or $—NO_2$ results in inactive compounds. The activity maintains—in some cases, however, it decreases—if the sulfonamide group is exchanged for $—SO_2H$, $—SO_2C_6H_4—R$, $—SO—C_6H_4—NH_2$, —S—S—$C_6H_4—NH_2$, —SO —SO—$C_6H_4—NH_2$, $—S—(CH_3)_2$, —SO—CH_2 —$C_6H_4—NH_2$, —CO—NH_2, $—CO—C_6H_4—R$, or $—PO(OH)_2$ (28, 36–38).

Monosubstitution in the N^1 position results in essentially more active compounds as compared to the action of sulfanilamide. The most active compounds were obtained with substituents belonging to a heterocyclic system. Acylderivatives at the N^1-nitrogen atom are active in most cases (39). The rule that disubstitution at the N^1-nitrogen decreases the activity (40, 41) corresponds to the hypothesis of Bell and Roblin (41, 42). However there are some exceptions (41, 43–45). One of the most active SNS *in vitro* is sulfanil-(3,4-dimethyl-isoxazole-5-)-acetamide (see Table II).

6. Simultaneous variation at the amino and sulfonamido group performing Assumptions 2 and 5 results in *in vivo* active compounds.

Table I shows some chemotherapeutics and their classification using the given rules. The structure specificity of the antibacterial action of SNS is not easily seen; the same holds true for the structure specificity of the antagonistic action of PABA and its derivatives. The only rule that can be accepted with certainty is that the benzene

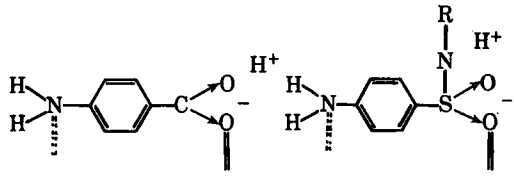
ring and the primary aromatic amino group are essential for the biological action. The same is valid for some other PABA antagonists as for instance 4-aminobenzene-arsenic-acid (27, 46), diaminobenzil (36). Obviously the aromatic amino group in the 4 position in SNS is an important or decisive factor for the antibacterial action. Other conclusions are uncertain, for instance, the necessity of an electronegatively charged substituent (but not ionized) in the *para*-position of the amino group, and the distance of the charge from the amino group must be the same as that of the amino group in PABA (41).

There is no doubt that the aromatic amino group of PABA antagonists is involved in a chemical reaction at the site of action (35). Until now the assumption was made that sulfanilamide and PABA have the same partner in reaction. It has been reported that a twofold binding according to Scheme I takes place:



Scheme I

This picture of the geometrical similarity of PABA and sulfonamide molecules obviously was influenced by the ideas of Bell and Roblin (41), see however Alléaume (47, 48).

There is no experimental proof for such a twofold binding. It is better not to call the amino group "haptophore" according to Ehrlich (49) or "toxophile" according to Albert (50), but preferably it should be called the reactive group of the molecule. An explanation will be attempted for the different antibacterial activities of SNS by the different reactivities of their primary aromatic amino groups. A criterion for the reactivity is the "affinity constant" according to Ariens (31). The affinity constant of the amino group in a certain chemical reaction is influenced by intramolecular forces of the molecule. Therefore, it is not necessary to look for a special name for the rest of the molecule as long as the mode of action is discussed. Another question is the meaning of the rest of the molecule for transport mechanism (see protein binding, lipid partition, and ionization).

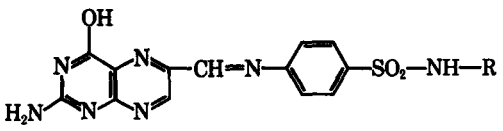
If the structure specificity of SNS is considered from this point of view it is unlikely that structural formulas written in the normal one-dimensional form can contribute to the solution of the question. Even a qualitative grouping of substituents in electropositive and electronegative properties is not sufficient (50). Physical and chemical parameters are needed which describe the condition of the amino group under the influence of certain substituents, for instance, σ-functions according to Hammett (51), rate constants according to Hirsch (52), Kohn and Harris (53), Seydel (43, 54), Brown *et al.* (55), Garrett (56), or optical data for electronic distribution from UV spectra (57–59), IR and NMR spectra (43, 44, 60–62), crystal optical measurements (47), and LCAO calculations (63–67). In considering this question, only a few of Northey's (1) critically discussed mode of action "theories" are of interest. A hypothesis may keep its value if the above-mentioned criteria about the membership of a compound to the group of SNS are considered and correct assumptions are made about the reaction mechanism.

Independent from the metabolic reactions in which SNS may be involved, the question of whether there are any physical or chemical properties of SNS which correlate with the observed antibacterial activity *in vitro* will be discussed. The problem is answered if the minimum inhibitory concentration (MIC) can be calculated by physical or chemical parameters without exception. Bell and Roblin (41) have tried to solve this problem.

CHEMICAL REACTIVITY OF THE PABA ANTAGONISTS

First, some hypotheses and experimental results concerning the reactivity of the primary aromatic amino group will be discussed. In contradiction to the statement of Bell and Roblin (41), there exists a different chemical reactivity of the primary aromatic amino group of different SNS. This can be expressed in reaction rates, pKa values, or electron-density measurements.

Tschesche (68) has developed a hypothesis that SNS are competing with PABA by forming a Schiff base with a pteridinealdehyde. The degree of displacement is a function of concentration; the involved reaction was not considered to be enzymatic but chemical, delivering the following compound:



This compound was considered to be insoluble, thus crystallizing and accumulating within the bacterial cells. In 1950 Tschesche (69) was able to show, that 2-amino-6,9-dioxy-pteridinealdehyde (8) and other pteridines can antagonize the inhibition caused by sulfathiazole. The hydrolysis of the Schiff base is very slow according to Tschesche. From experiments of Wacker, Trebst, and Simon (70) with radioactive SNS, it was not possible to make certain that a Schiff base of that type was formed. This does not mean, however, that the reaction postulated by Tschesche is not possible. It is very likely that under the conditions of the wash process used by Wacker *et al.* (70) a Schiff base could be hydrolyzed. That is even more likely because the action of SNS is considered to be of the bacteriostatic type, which means the bacteria can be liberated from the drug by washing the cells. If the hypothesis is correct, then the sequence of the reactivity of SNS with the pteridinealdehyde should be the same as the sequence of their minimum inhibitory concentration *in vitro*.

A very similar hypothesis was formulated by O'Meara, McNally, and Nelson (71), Bell, Cocker, and O'Meara (72, 73), and Forrest and Walker (74, 75) based on the assumption that SNS was reacting with reductone—an assumed precursor in pteridinealdehyde synthesis—to form a Schiff base. Forrest and Walker (75) were able to support the assumption that the Schiff base from reductone and PABA is a precursor of folic acid by synthesizing pteridine carboxylic acid from 2,4,5-triamino-6-hydroxypyrimidine and reductone. Bell (72) suggested that this reaction was not only blocking folic acid synthesis but also several other reactions where reductone was involved as metabolic compound.

According to O'Meara *et al.* (71) the chemotherapeutic activity of SNS and its susceptibility to the antagonistic action of PABA runs parallel with the stability of the Schiff base formed with glucoreductone. Only qualitative data about the stability are given including a statement that the Schiff base of sulfathiazole is about two times more stable than the Schiff base of PABA.

Bell *et al.* (73), however, obtained the opposite result. They heated a mixture of the Schiff base of sulfathiazole and reductone in sodium acetate with PABA. After 5 min. they obtained crystals which were identified as the Schiff base of PABA and reductone. This result was taken as evidence that SNS can be displaced in Schiff base by PABA in the physiological pH range and therefore would be a chemical explanation of the antagonism. However, there are some objections against this experiment. Reductones were easily oxidized, no exclusion of nitrogen was reported, and the reaction was carried out in heterogeneous mixture. Therefore, the results obtained not only include stability but also solubility constants. The solubility of the Schiff base is very low and differs with different SNS components.

Schiff base formation proceeds in a step reaction, mainly catalyzed by hydroxonium and other oxonium ions (76–78). It is a complex reaction mechanism strongly dependent on pH and changing type of mechanism as a function of pH (79). Therefore, it is more convenient to follow the rate of hydrolysis. Rate constants from such kinetic studies of the hydrolysis of Schiff bases from PABA and SNS with 3-methylreductone were obtained by Seydel *et al.* (44, 54). The sequence of rate constants is similar to the semiquantitative data of O'Meara *et al.* (71); an example is given in Fig. 1. For all studied compounds a minimum of hydrolysis was observed

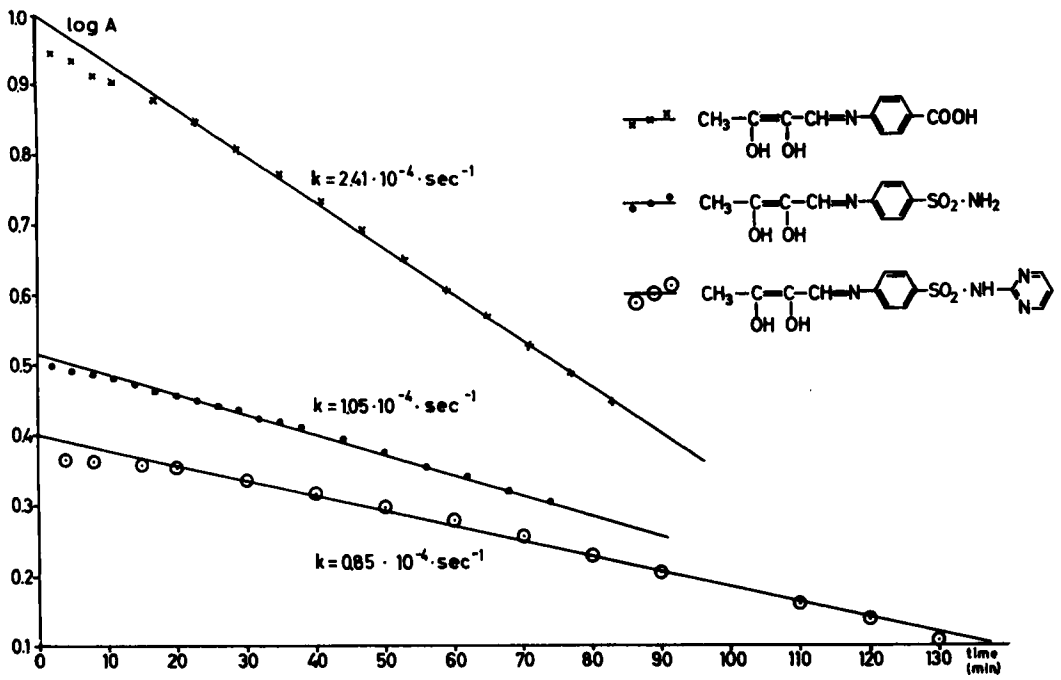


Fig. 1—Apparent first-order plots of Schiff base solvolysis of some sulfonamides, 40°, pH 6.0 phosphate buffer.

between pH 5 and 7. Most of the Schiff bases of SNS studied were more stable than the Schiff base of PABA, but this does not mean that a chemical antagonism of PABA and SNS is not possible. The PABA-reductone compound may be metabolized under *in vivo* conditions thus changing the equilibrium of hydrolysis in favor of the formation of the Schiff base. The antagonism of PABA and SNS may have a metabolic kinetic character in contradiction to the assumption of a more static equilibrium (31, 80, 81). It was not possible, however, to isolate reductone from bacteria (82), and it is known from studies of Brown (83) and Jaenicke and Chan (84) that the biosynthesis of folic acid does not include Schiff base formation, followed by hydration of the double bond. Even *in vivo*, it was not possible to hydrate the double bond of the Schiff base (85). Whatever the reliability of these results may be—with respect to the mode of action—they show that the amino groups of SNS are the reactive groups and that there is a differentiation of the reactivity by the structure of the rest of the molecule. The inductive or conjugative effect of different substituents on the N^1-nitrogen atom of SNS on the primary amino group is shown by some other parameters. Jacobson (86) has studied the effect of substrate structure on the activity of pigeon liver acetyl transferase and compared the effectiveness of several aniline derivatives as acetyl acceptors and donators. The rate of acetyl transfer was seen to decrease as the electronegativity of the *para* substituent decreased; the relative rate of the acceptors was vice versa. Among the compounds studied were sulfanilamide and PABA, with a rate of 6:1 (see Table III).

IONIZATION AND DIPOLE

Ionization of the Amino Group—Although not all of the bacteriostatic acting PABA antagonists possess an ionizing group with a negative charge (—SO_2—NH—), all of them have a primary amino group with a basic character. Tolstoouhov (87) reported that the basic pK_a' values of all active sulfonamides are in the range

Table III—Comparison of Various Derivatives as Acetyl Acceptors[a]

Acetyl Acceptor	Relative Rate
Aniline	0.70
p-Methylaniline	1.00
p-Chloroaniline	1.09
p-Bromoaniline	1.12
p-Nitroaniline	0.34
p-Aminohippuric acid	0.25
Sulfanilamide	0.18
p-Aminosalicylic acid	0.15
p-Aminobenzoic acid	0.03
Sulfanilic acid	0.01

[a] Reaction conditions were as follows: 0.1 *M* Tris pH 8.1; 0.01 *M* EDTA pH 8; 0.03 *M* cysteine HCl(neutralized); 5×10^{-5} *M* acetyl-AABS, A-60 enzyme; and 1×10^{-4} *M* acetyl acceptor amine and temperature 29°. Reaction was followed at 460 mμ. [Reproduced with permission from *J. Biol. Chem.*, **236**, 343 (1961).]

of 1.64–2.34, the most active compounds having a basic pKa_1' in the narrow range of 1.91–2.34. Most emphasis was put on the different pKa_1' values of *p*-, *m*-, and *o*-sulfanilamide (pKa_1' 2.16, 2.89, 1.80), which would explain quite simply the differences in therapeutic activity. The best correlation to activity was obtained by $pH_i = (pKa_1 + pKa_2)/2$.

The earlier results of Bell and Roblin (41), obtained with a larger number of SNS, do not confirm the results of Tolstoouhov (87). This however may be due to insufficient data. In an excellent paper Yoshioka (88) reported the basic pKa_1' values of a homologous series of N^1-arylsulfanilamides. The same compounds were used by Seydel (45, 54, 62) for structure-activity studies. Thus, it was possible to correlate the basic pKa_1' values reported by Yoshioka (88) with the minimum inhibition concentrations reported by Seydel. Figure 2 gives the relationship between those parameters. There is an approximate linear relationship between the MIC and the basic pKa_1' of the N^1-arylsulfonamides. The pKa_1' values of the homologous series of compounds were found to have a linear relationship to the σ-Hammett values of the substituents:

$$\log K_{NH_3}{}^{+} = 0.212\ (\sigma + 0.48\Delta\sigma^{-}R) - 1.815$$

The transmission of the additional resonance effect was considered to be of the cross-conjugation type rather than by a function of —NH—SO_2— like —C=C— (66, 88).

Ionization of the Sulfonamido Group—Bell and Roblin (41, 42) were the first to look for an explanation for the different activity of SNS. The theory of Bell and Roblin published in 1942 is the most important and stimulating one for investigations of structure-activity correlations of SNS. The theory was modified and differentiated by Cowles (89), Fox and Rose (90), Schmelkes *et al.* (91), Brueckner (92), and Klotz (93). The authors stated a functional connection between the acid dissociation constant (pKa_2') and the MIC of SNS. Since then this connection has not been questioned (Fig. 3).

Different hypotheses were developed to explain the observed relation between the acid pKa_2' values and the *in vitro* MIC of SNS. Attention was paid to a possible connection between pKa_2' and the MIC of SNS by the observation of the pH dependency of the inhibitory activity (94) and the antagonizing effect of PABA.

Fox and Rose (90) discovered that the ratio of the MIC of sulfanilamide, sulfathiazole, and sulfapyridine to the antagonistic concentration of PABA varied in the range of 5,000:1–8:1.

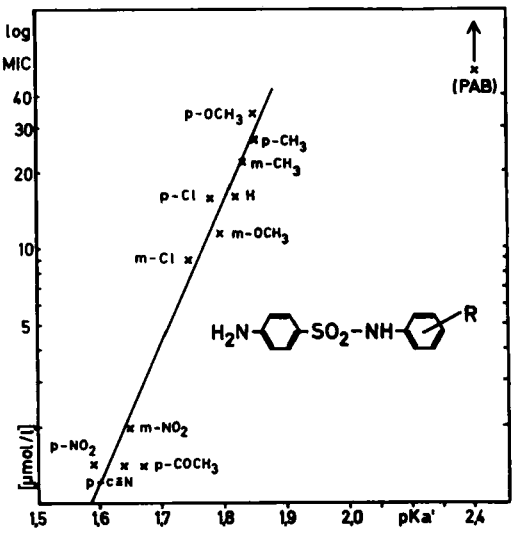

Fig. 2—Correlation between the basic dissociation constant (pKa_1) (88) of some N^1-benzenesulfonamides and their minimum inhibition concentration (MIC) against E. coli.

However, if only the ionized fraction at pH 7 was considered instead of the total concentration, the scattering of the ratio was limited to 1.4:1 up to 6.4:1. The conclusion was derived that only the ionized fraction of the MIC is responsible for the antibacterial action. Schmelkes *et al.* (91) reported that the MIC of sulfanilamide decreased with increasing pH of the culture medium, whereas the activity of sulfadiazine decreased with increasing pH. Cowles (89) considered only the negatively charged form of SNS as active and only the neutral form as able to penetrate the bacterial cell wall. Brueckner (92) differentiated this hypothesis by the assumption of different intra- and extracellular pH values. The results of his experiments only indicate that the molecular fraction of a sulfonamide solution may play an important role in determining the intracellular concentration of the active fraction and that the influence of pH must have a more complex basis than a simple change in the concentration of SNS ions in culture media. To interpret these results, knowledge is needed of the intracellular pH of the bacterial cell and its change as a function of extracellular pH.

Bell and Roblin (41, 42) explained the dependency between pKa_2' and the MIC by the assumption that "the more negative the SO_2 group of N^1-substituted sulfonamide derivatives the more bacteriostatic the compound will be." The acid dissociation constants were shown to furnish an indirect measure of the negative character of the SO_2 group. The hypothesis of Bell and Roblin stated that the unionized molecules

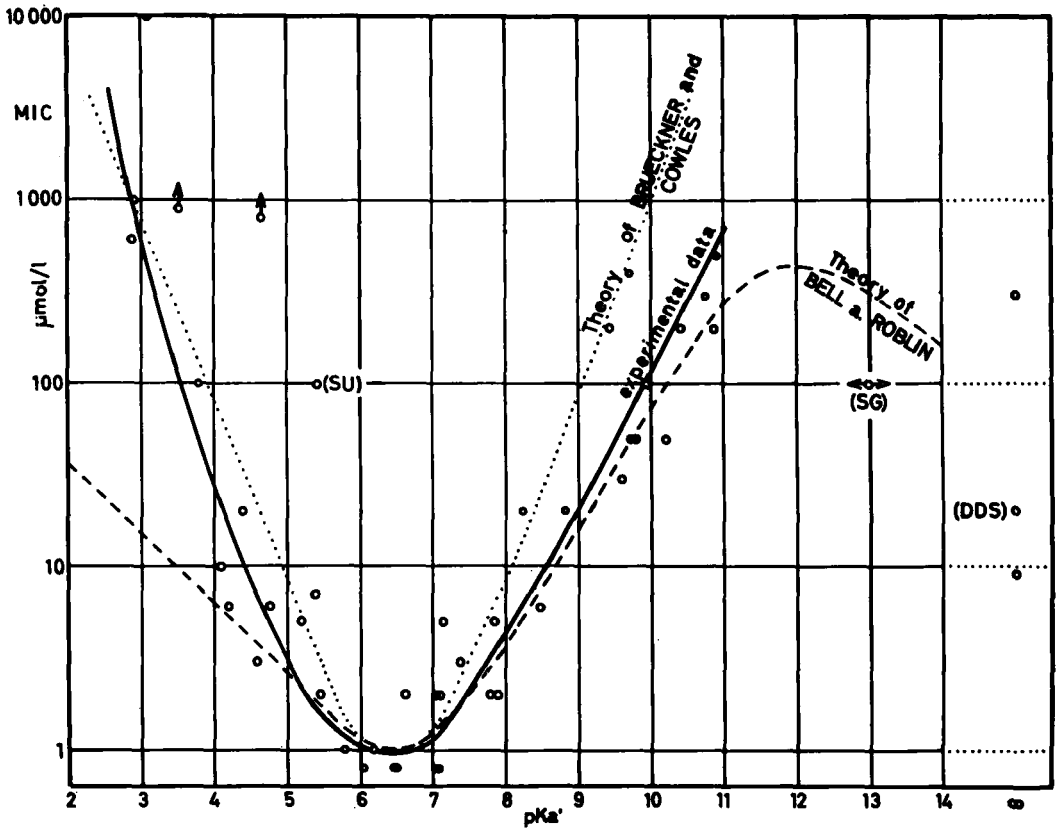

Fig. 3—Plot of the minimum inhibition concentration (MIC, µmole/l.) against the acid dissociation constant (pKa_2) of sulfonamides compared with the theoretical curves of Cowles (89) and Brueckner (92) (···), and of Bell and Roblin (41) (- - -). [Reproduced with permission from Z. Naturforsch., 15b, *628(1960).]*

had a bacteriostatic activity too, however essentially weaker than the ionized form. Further it was supposed that increasing acidity of a compound decreased the negativity of the sulfone group, thus decreasing the bacteriostatic activity of the charged and uncharged molecules. Plotting the MIC against the pKa_2' values of several sulfonamides, Bell and Roblin found a bell-shaped curve with a minimum for the MIC at pKa_2' 6.7. This relationship was used to predict the MIC of a sulfonamide by measuring its pKa_2' value (Fig. 3). There are, however, several exceptions to this hypothesis in addition to the exceptions, sulfaguanidine and sulfanilurea, already stated by Bell and Roblin.

1. There are SNS with pKa_2' values as low as 5.0 or more and still as active as those with pKa values of 6–7. There are SNS with the same pKa_2' but different MIC (44) (see Fig. 4). A striking example is N^1-(3,4-dimethylbenzoyl)-sulfanilamide which has a MIC of 2–4 µmoles/1., the pKa_2' being 4.52 (4.86), and the 2,5- and 2,4-isomers which have a MIC of 22.5 µmoles/1., the pKa_2' being 4.7 [5.1] and 4.6 [5.05], respectively (1, 61). The pKa_2' values in brackets are determined according to Bell and Roblin (41),

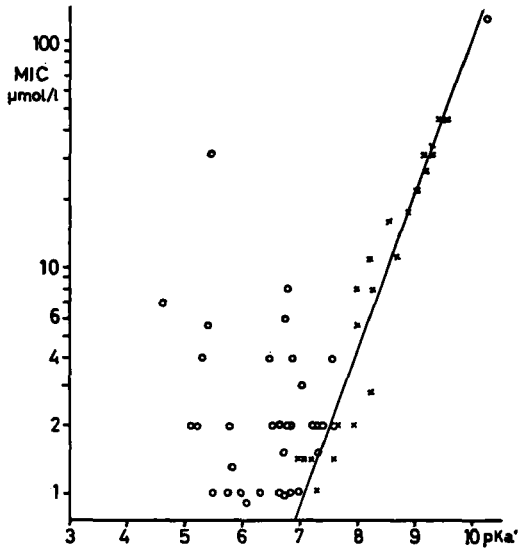

Fig. 4—Relation between the acid dissocation (pKa_2') and the in vitro activity against E. coli *of different sulfonamides* (○) *and of benzenesulfonamides* (×).

for the others a photometric titration method was applied.

It is possible to show in a very homologous series of SNS that there is a *linear* relationship of the pKa_2' and the MIC (45, 54) (see Fig. 4). Using pKa_2' values and MIC data obtained by Bell and Roblin (41), Seydel *et al.* (43), and Seydel and Wempe (61), the bell-shaped curve for the pKa_2'-MIC relation can be separated into linear functions with different slopes (positive and negative) for certain series of substituents (95) (Fig. 5). This provides little evidence in support of a definite pKa_2' which a sulfonamide must possess in order to exhibit maximum activity.

2. N^1-dimethylsulfanilamide is as active as sulfanilamide.

3. N^1-acetylated SNS are as active or even more active than the unacetylated derivatives (Table II) (45). This type of compound has no acidic dissociation constant. The polarization of the SO_2 group should be less in the case of the N^1-acetylated derivatives.

4. There are compounds with a sulfonamide mode of action which do not possess a sulfonamido group, *i.e.*, aminophenylsulfones (96), sulfanilic acid (35), and amino benzil (36), or aminophenyl ketones (37, 28).

5. Furthermore there is no experimental proof that there is a correlation between the degree of polarization of the SO_2 group and the antibacterial activity of SNS (see 32, 34, 35). Therefore it is suggested that the hypothesis of Bell and Roblin fulfills only a minimum condition for the MIC. It is possible to predict from the pKa_2' the MIC of SNS within certain limits of accuracy, but there is no proof for the mode of action theory involved.

Although the relation of ionization to the antibacterial activity and to the mode of action of SNS is very complex, there is no question about the importance of ionization to the physicochemical properties of SNS. The pKa_2' of SNS is directly related to the solubility, the distribution, the partition coefficient and the reabsorption in the kidneys, the permeability of membranes, and the protein binding, to mention only some of the important factors. The solubility is of interest with respect to the toxicologic (crystalluria) (97–100) and the pharmaceutical (absorption) properties of SNS. Therefore the solubilities of SNS have been studied very often (97–104); the functional dependency of pH, pKa_2', the solubility(s), and the base solubility(s_o) is given by the following equation:

$$s = s_o(1 + 10^{pH - pK_a})$$

The distribution has an important influence on the therapeutic effect of SNS; the time needed to reach equilibrium is a function of pH. Sulfathiazole, with pKa_2' of 7, established its equilibrium between blood plasma and erythrocytes *in vitro* in about 4 min., whereas sulfanilacetamide with a pKa_2' of 5.3 needs about 1 hr. (105, 106).

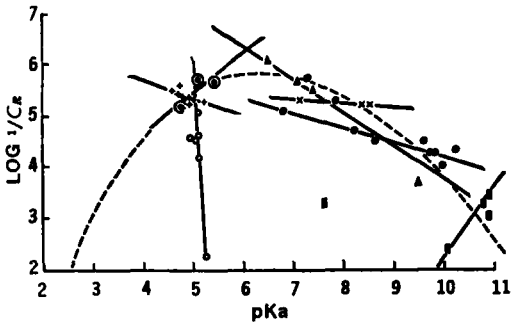

Fig. 5—Correlation between the acid dissociation (pKa_2') and the minimum inhibition concentration (MIC), Key: ⊙, sulfanilamido (substituted) thiazoles, +meta and/or parasubstituted N^1-benzoylsulfanilamides, ○, orthosubstituted N^1-benzoylsulfanilamides; ▲, 2-sulfanilamido (substituted) pyrimidines; ×, 2-sulfanilamido (substituted) pyridines; ●, N^1-(substituted) phenylsulfanilamides; ■ N^1-(substituted) methylsulfanilamides [Reproduced with permission from J. Pharm. Sci., **56**, *640(1967).]*

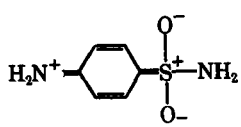
The partition coefficient plays an important role in the reabsorption of SNS in the kidneys (107). Dependency of the partition coefficient (Q) on the pKa_2' is given by the following equation:

$$Q = \frac{m_o - m_1}{m_1}(1 + 10^{pH - pK_a})$$

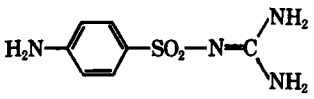
In a detailed study Dettli *et al.* (108) and Portnoff *et al.* (109) were able to demonstrate the change of the excretion rate of SNS by acidifying or alkalizing the urine. The importance of the dissociation constant for the transport of chemotherapeutic agents through membranes is known from several studies (92, 110) and is discussed for SNS by Brueckner (92), and Brown (35), and many other authors.

Dipole Moment of SNS—Kumler and Halverstadt (111) published a paper about the dipole moment of sulfanilamide and related compounds. They stated that there is a contribution of about 3% of the resonance structure in sulfanilamide. Later, Kumler and Daniels (112) and Kumler and Strait (113) proposed a theory that a coplanar amino group resulting from a resonance form



is the main factor effecting activity (see also 114,

115). According to this hypothesis 3-aminobenzene-sulfonamide is inactive because of the inability to build a resonating form; 2-aminobenzene-sulfonamide is inactive in spite of the ability to form a resonance structure, but a hydrogen bond is established between the amino group and the SO_2 group with the consequence of reduction of the active resonance form. Kumler and Daniels (112) explained the low activity of sulfanilurea and the very high activity of sulfaguanidine, which are exceptions of the theory of Bell and Roblin (41) by a resonance form of the ion in which the charge goes mainly to the oxygen rather than to the SO_2 group in case of the sulfanilurea, and by a negative charge appearing on the amide nitrogen in case of the sulfaguanidine. This increases the negativity of the SO_2 group which in turn enhances the coplanar amino resonance form of sulfaguanidine. Since publication of these papers, the resonance hypothesis has been disproved by the papers of Bell, Bone and Roblin (116), Quan *et al.* (33), Quan *et al.* (34), and by NMR measurements, showing that in the case of sulfaguanidine the following form exists (117):



From the paper of Yoshioka *et al.* (88), however, it appears very likely that there is a resonance effect of the R group through the entire molecule and that substituents with a large effect increase the activity of SNS (45). The resonance however is not performed by a SO_2 group acting like

but by cross-conjugation (88).

SPECTRAL DATA AND LCAO PARAMETERS OF SULFONAMIDES AND THEIR PRECURSOR SUBSTANCES IN SYNTHESIS

UV Optical Properties and Structure of SNS—The reactivity of a functional group in a molecule depends on the total structure of the molecule which determines the properties of the compound, for instance, the absorption spectra. UV, IR, and NMR spectra are of special interest because of the relation to the properties of the nucleus and electron density; this again is related to the reactivity of a functional group. Kimmig (57) was the first to study the UV spectra of SNS. He noted that the absorption maxima of active SNS were in the range of 33,000–40,000 cm.$^{-1}$ (300–250 mμ); with increasing activity the maxima shifted toward 33,000 cm.$^{-1}$. The UV absorption spectra of SNS have been studied by several authors (34, 58, 59, 118–123). It was not possible, however, to deduce a general rule for the relation between the position of maximum absorbance and the activity. This is based partly on the fact that the absorbance of the heterocyclic substituents is stronger and shifted toward longer wavelengths (124) in contrast to the absorbance of the important sulfanilamide moiety which is shifted to 38,000 or 40,000 cm.$^{-1}$ and is weak in most cases. The group of interest, the amino group, has no absorbance in the UV range; there is only a certain influence of the primary amino group on the benzene ring absorbance.

IR Data of the Sulfone Group and the Aromatic Amino Group—Therefore it is much more promising to study the IR spectra of SNS. Vibration frequencies in the infrared characterize the relation between two or three adjacent nuclei in a molecule influenced by other nuclei of the molecule. It is known from several IR-relationship studies that the stretching frequencies arising from vibrations localized in functional groups attached to an aromatic ring can be related to the electronic nature of the ring substituent constant (125).

Many IR measurements of SNS were done for assay methods of drug analysis (126, 127). Other IR measurements were performed to study the imido–amido tautomerism (128) or to see if there is any change of the electronegativity of the SO_2 group (43, 44, 60), which may be correlated to the *in vitro* activity of SNS according to the hypothesis of Bell and Roblin. IR vibrations are suitable for the study of the physical properties of the SO_2 group because of the absence of mass and coupling effects (129). There are two IR absorption frequencies of the SO_2 group, the symmetrical stretching frequency (130) which is little affected by changes in the molecule (1,128–1,665 cm.$^{-1}$ in studied SNS), and the asymmetrical frequency (131), which is in the range of 1,360–1,260 cm.$^{-1}$ in SNS. The exact position of these two frequencies is determined by the electrical character of the substituents adjacent to the sulfur atom. From the position of the IR frequencies it is possible to calculate two parameters with a descriptive physical meaning, the force constant k and the bond angle θ. For both parameters no correlation with the *in vitro* activity of the corresponding sulfonamide was obtained (43, 44, 60, 61). Some of the most active sulfonamides have force constants for the S=O bond of $9.8 \cdot 10^5$ dyne/cm., *i.e.*, the degree of polarization is small.

These data are limited by the fact that these measurements must be performed principally in

solid state. Therefore, the data include association effects. The same is true for the IR data obtained from the vibration frequencies of the primary aromatic amino group, which show some correlation to the activity of SNS (43, 44). However, data obtained from an additional sequence of SNS (61) and data obtained by Brandmüller (60) did not support these findings.

IR and NMR Data of the Aromatic Amino Group of the Precursor Substances in Synthesis (Amines)—To avoid the difficulties arising from the insolubility of SNS in nonpolar solvents, it seems better to study the substituents rather than the complete sulfa drug (45, 62, 132). For this purpose one may split the sulfonamide molecule according to the dotted line B, studying for example substituted chlorobenzene, which may be used for the synthesis of sulfa drugs. Since it is known for sulfathiazole and sulfapyridines (40, 124) and for some 4-sulfapyrimidines and sulfaphenazole (133, 134) that the substituents may be bound to the N^1-nitrogen atom by a double bond, it seems to be more appropriate to split the sulfa drug molecule according to the dotted line A, thus studying the substituted anilines.
