Survival of *Pseudomonas aeruginosa* in Fluorescein Solution

Preservative Action of PMN and EDTA

By MICHAEL R. W. BROWN

Colony counts were made for a year on washed and unwashed cells of *Ps. aeruginosa* inoculated into fluorescein sodium solution, 2 percent in water (pH 8.6), into nutrient broth, into tris buffer (pH 8.6), and into water. Broth exerted a protective effect in all storage liquids (22°) and also supported growth, depending on the amount of broth. Water-washed inocula lost viability in less than a day in fluorescein solution. Viability of broth inocula was maintained for more than a year in all vehicles. Fluorescein solution preserved with PMN-sterilized inocula of about 10^6/ml. *Ps. aeruginosa* cells within 5 hr. EDTA in combination with PMN was less effective.

PSEUDOMONAS AERUGINOSA causes general problems of cross infection (1, 2) and is a particular hazard in ophthalmology (3, 4). Dale *et al.* (5) have reviewed many reports of *Ps. aeruginosa* as a contaminant of fluorescein eye drops.

The B.P.C. recommendation of phenylmercuric nitrate (PMN) as an ophthalmic preservative is supported by many studies, nearly all of which

show it to be a relatively slow but effective sterilizing agent (6–9). Other workers have found PMN to be less than effective in the case of fluorescein. Anderson *et al.* (10) found that 0.002% PMN failed to sterilize fluorescein drops after several days contact, but 0.004% PMN achieved sterility within a day. These workers did not use contact times of less than a day and the recovery media did not contain inactivators.

EDTA enhanced the activity of chlorhexidine, benzalkonium, and polymyxin against *Ps. aeruginosa* growing both in serum and broth (11). Furthermore, acquired resistance by this organism to a quaternary ammonium compound was eliminated using EDTA (12, 13).

The present work was done to obtain quantitative information about survival of *Ps. aeruginosa* in fluorescein and other aqueous solutions and to study the preservative properties of 0.1% EDTA (13) used in combination with PMN.

EXPERIMENTAL

Ps. aeruginosa NCTC[1] 6750, NCTC 8203, and NCTC 7244 were used as test bacteria. The growth medium was oxoid[2] nutrient broth No. 1 and incubation was at 37°. B.D.H.[3] fluorescein sodium (microscopical quality) was used. Other chemicals were Analar quality (B.D.H.). Cell numbers in broth cultures were estimated by measuring the absorbance at 420 mμ with a Unicam 600 spectrophotometer and by colony counts using broth as a diluent. Experimental details have been described previously (14).

Survival in Solutions Without Preservative

Survival experiments were made using screw-capped 20-ml. and 100-ml. glass bottles in a water bath at 22°. Inocula were added to fluorescein sodium solution 2% in distilled water (Fig. 1). Colony counts were made at intervals during the first day, then daily, then weekly, until a consistent pattern of results occurred. Representative suspensions were then counted at intervals for about a year. Samples were examined microscopically for cell clumping. An identical control procedure was carried out, adding inocula to distilled water (Fig. 2), to nutrient broth (Fig. 2), and to tris buffer pH 8.6 (pH of fluorescein solution) (Fig. 3). A total of about 50 suspensions was stored.

Preparation of Inocula—A technique similar to that described previously (14) was used to obtain a reproducible growth cycle in nutrient broth. Twenty-four hour cultures were used. The original culture was diluted with fresh broth (culture OR) so that the storage liquids contained initially about 10^3 cells/ml. and duplicates contained 10^6/ml. In addition, the contribution of the original growth medium to survival was assessed. This was done by using inocula washed by centrifugation (3 times) with either fresh broth (culture WB) or 0.2 *M* NaCl then water (culture WW). Preliminary experiments showed that the volume of broth added as part of the cell inoculum contributed to the survival of *Ps. aeruginosa* in the various storage liquids. Preliminary work also suggested that the size of container was significant. Consequently, inocula

consisted of 1 ml. added to 99 ml. storage liquid (*A*); 1 ml. to 9 ml. (*B*), in 20-ml. bottles; 10 ml. to 90 ml. (*C*); 0.5 ml. to 99.5 ml. (*D*). Inoculation was always made to give both 10^3 cells/ml. and 10^6/ml. approximately.

Storage Liquids—*Sodium Fluorescein Solution, 2%*—Inoculum OR was used to give suspensions *B*, *C*, and *D*; WB to give *B*, *C*, and *D*; WW to give *A* and *B* (Fig. 1).

Distilled Water—Inoculum OR gave suspensions *B* and *D*; WB gave *B*, *C*, and *D* (Fig. 2).

Nutrient Broth—Inoculum OR gave suspensions *A* and *D* (Fig. 2).

Tris Buffer—Inoculum OR gave suspensions *B*, *C*, and *D* (Fig. 3). Storage was at 22°.

Survival in Preserved Solutions

One-half milliliter broth inocula of all three test strains to a final concentration of about 10^6 cells/ml. were added to various combinations of fluorescein, EDTA, and PMN in 20-ml. solutions in a water bath at 22° (Table I). One-half milliliter samples were taken at various time intervals, added to 10 ml. recovery broth, and incubated at 37° for 7 days. As a control procedure, samples from all positive tubes were incubated on a milk agar medium (10% dried, defatted milk,[4] and 1.5% agar) and examined for pigment and clearing of the casein.

Recovery Broth—The recovery broth of Kohn *et al.* (9) for *Ps. aeruginosa* after contact with PMN was used, with *M*/372 $CaCl_2 \cdot 6H_2O$ added to inactivate EDTA (0.1% equivalent to *M*/372). The broth was composed of: 0.3 Gm. lecithin, 3 Gm. polysorbate 80,[5] 2.93 Gm. dehydrated thioglycollate medium USP, 59 mg. $CaCl_2 \cdot 6H_2O$ (autoclaved separately), water to 100 ml. This medium was selected after preliminary experiments using colony counts with the basic lecithin–polysorbate–thiogly-

collate medium in the presence and absence of $M/372$, $M/37$, and $M/3.7$ $CaCl_2 \cdot 6H_2O$.

RESULTS AND DISCUSSION

Solutions Without Preservative

Fluorescein Solution—Unwashed broth inocula of *Ps. aeruginosa* added to fluorescein solution rapidly dropped in count when diluted 100-fold or more (Fig. 1, open triangle). The count rose again after this initial drop and remained relatively constant. This pattern was the same for inocula of 10^6/ml. and 10^3/ml. The initial inhibitory effect of fluorescein solution was eliminated when the inoculum was in a sufficiently large volume of broth (Fig. 1, open and closed circles). The larger volume of broth protected the cells from the initial drop in colony count and also allowed the count to rise and be maintained at a higher level for inocula of both 10^6/ml. and 10^3/ml. The results from inocula washed in fresh broth (not illustrated) were similar to those with unwashed cells and showed that the washing process with broth had no significant effect upon subsequent survival in fluorescein solution. Inocula of cells washed in water showed rapid death and were sterile in less than a day.

Water, Broth, and Tris Buffer—The pattern of survival of *Ps. aeruginosa* in water was similar to that in fluorescein and representative results are given in Fig. 2. Inocula with the greater amounts of broth were protected in comparison to those with less, and viability was maintained at higher levels. The effect was similar for both 10^6/ml. and 10^3/ml. inocula. Figure 2, times sign, shows that 0.5 ml. broth inoculum added to 99.5 ml. water retained a relatively constant count for about 6 months; this dropped until the storage liquid was sterile after about 1 year. An inoculum of 10 ml. broth added to 90 ml. water initially showed a rise in count to about 10^8/ml. This dropped for about 2 months when a count of about 4×10^6/ml. was maintained for the rest of the experimental period. A similar pattern occurred with cells washed in fresh broth (Fig. 2, closed circle). The pattern for broth as a storage liquid (Fig. 2, open triangle) was similar to that of water with the high broth inoculum. All inocula into tris buffer showed an initial drop in count (Fig. 3). Inocula with the greater amounts of broth (Fig. 3, open and closed circles) were protected against initial death and ultimately viability was maintained at higher levels when compared to results with small broth inocula.

Broth exerted a protective effect in all the storage liquids and also supported growth. The protection and growth were apparently related to the amount of broth present. The size of cell inoculum and size of storage container apparently had no influence on survival. All three strains gave similar results.

The magnitude of the initial drop in count (about 99.9%) when broth inocula was diluted 100-fold in fluorescein solution, tris buffer (pH 8.6), and water was unexpected. This result, together with that using water-washed inocula (sterilized within a day) shows that the kind of inoculum used in studies with *Ps. aeruginosa* is crucial. It would seem that washing in water has a damaging effect upon *Ps. aeruginosa* and that the use of water-washed cell inocula may give misleading results in antibacterial studies.

In practice it is likely that contamination from *Ps. aeruginosa* would be from cells present with nutrient material. The results from this study show that aqueous vehicles will support viability of large populations of this organism for periods of a year or more. Inocula maintained viability to about the same extent in fluorescein solution, tris buffer, and water.

Preserved Solutions

PMN alone was consistently effective in sterilizing inocula of about 10^6 cells/ml. in fluorescein solution (Table I). There was little difference between the effects of 0.004% and 0.002% PMN, and sterility was achieved with all strains between 1.5 and 5 hr. Kohn *et al.* (9) obtained closely similar results. In the absence of fluorescein, sterility was also achieved within several hours using PMN alone in water. It might be anticipated that a high molecular weight anion such as fluorescein might react with a cation such as the phenylmercuric ion. This possibility is not excluded by the results which, nevertheless, show PMN to be effective within the experimental limits.

In every instance except one (0.004% PMN) solutions with EDTA took longer to achieve sterility than those without it. This apparent antagonism may be due to EDTA chelating the mercury, making it less available for antibacterial action. These results confirm the efficacy of PMN as a relatively slow acting preservative againt *Ps. aeruginosa* and suggest that EDTA exerts a slight antagonistic action in combination with PMN in the test circumstances.

It is questionable whether this preservative effect of PMN is a sufficient protection, especially for drops used with damaged eyes. The difficulty of preserving eye drops against *Ps. aeruginosa* is well known (4) and the present work shows the dangers of long-term contamination of inadequately preserved drops including fluorescein. The use of sterile, single-dose units for damaged eyes or, in the case of fluorescein, sterile, impregnated paper strips would seem to reduce this hazard.

Mechanism of Action of Starch as a Tablet Disintegrant III

Factors Affecting Starch Grain Damage and Their Effect on Swelling of Starch Grains and Disintegration of Tablets at 37°

By JAMES T. INGRAM and WERNER LOWENTHAL

A study was undertaken to determine the effect of the tableting procedure on starch grain swelling and tablet disintegration. The swelling of damaged starch grains in simulated gastric fluid USP is demonstrated. Submersion of starch samples that had been ball milled from 10 to 48 hr. produced increases in grain diameters of 40 to 80 percent. Damage to the grains resulting from compression of pure cornstarch is shown to be insignificant. The effect of compressional force and hardness of tablet ingredients was examined and in each formulation the starch grain damage increased with compressional force. There was no correlation between degree of starch grain damage and hardness of the tablet ingredients. It appeared that the crystalline form of the ingredient may have exerted a greater influence on starch damage than the hardness. There was no correlation between starch damage and stress produced by elastic recovery of the tablet. Contrary to what might be expected, there was an inverse relation between the amount of stress and the degree of starch grain damage for all of the formulations except aspirin. There was no evident relationship demonstrated between disintegration time and starch grain damage. Outside of compressional force, the inherent effect of the tablet ingredient was the only factor that appeared to affect disintegration. The long-accepted swelling mechanism of starch as a tablet disintegrant was not demonstrated in this study. The results of the investigation revealed no measurable correlations between starch grain damage and disintegration or between starch swelling and compressional force.

FROM THE PREVIOUS STUDIES, it does not seem probable that untreated or unmodified starch will swell sufficiently at 37° to cause tablet disintegration (1, 2). If swelling is the primary mechanism whereby starch exerts its disintegrant effect, then this property may be imparted to the starch by the tableting procedure.

Since swelling of the grains may occur reversibly or irreversibly, the effect of each type of swelling on disintegration should be considered. It is known that the starch grains have a limited capacity for absorbing cold water and swelling reversibly (3). When a suspension of starch is subjected to heat or appropriate chemical treatment, the micellar network within the grain is weakened by disruption of hydrogen bonds, and irreversible swelling, or gelatinization, occurs. Irreversible swelling results in partial solubilization of the starch molecules and formation of an adhesive paste. This adhesiveness should tend to hinder rather than promote disintegration. This hindrance was observed by submersing an aspirin tablet containing 10% cornstarch in hot water, which will cause starch to gelatinize. The tablet would not disintegrate and examination of the tablet revealed that the interior was essentially dry. This could indicate formation of a starch paste "sealer" coat around the exterior of the tablet, preventing penetration of water into the tablet.

Cooper and Brecht (4) also suggested starch gelatinization as a possible explanation for the hindrance to disintegration observed when starch is incorporated into a sodium salicylate tablet. Sodium salicylate in aqueous solution causes starch to gelatinize.

The detrimental effect of irreversible swelling on disintegration is further supported by the observation that any substantial amount of pregelatinized starch (*e.g.*, 5%) in the tablet formulation hinders disintegration (5).

From this it would appear that only reversible swelling could exert a favorable effect on disintegration. The literature indicated that reversible swelling results in 5 to 10% increases in grain diameters (5). Assuming that starch grains are spheres, a 10% diameter increase corresponds to a 33.1% volume increase. This volume increase has no relation to tablet disintegration until it can be correlated to the increase it would produce in the tablet volume. The maximum proportion of starch normally used in tablet formulations is 10% by weight. The percent of the total tablet volume occupied by this amount of starch will depend on the density of the other in-

Received July 28, 1967, from the School of Pharmacy, Medical College of Virginia, Richmond, VA 23219

Abstracted in part from the thesis presented by James T. Ingram to the Graduate School, Medical College of Virginia, in partial fulfillment of Master of Science degree requirements.

gredients. The range for densities of tablet formulations is usually from 0.5 to 2.5 Gm./ml. The percent increase in tablet volume (%V) corresponding to a 33.1% starch volume increase may be calculated by:

$$\%V = 0.331 \times 0.1 \times \frac{d_t}{d_s} \times 100$$

where d_t is the density of the tablet formulation, d_s is the density of starch, and the two constants, 0.331 and 0.1, refer to the 33.1% starch volume increase and the 10% by weight starch in the formulation. Based on these conditions, a starch volume increase of 33.1% should produce a tablet volume increase of only 1.1 to 5.5%. Since most tablets probably contain more than 5.5% void space, it seems unlikely that starch grains would produce sufficient strain within the tablet to promote disintegration.

It is known that untreated starch is insoluble in cold water but may absorb 25 to 30% of its weight in water with no appreciable swelling (6). Sjostrom (7) states that if a starch grain is mechanically damaged it will gelatinize in cold water.

A possible explanation for swelling occurring in starch grains incorporated into a tablet is in a report on the compressional behavior of potato starch. Fuhrer (8) reported that the grains are deformed plastically under the pressure and suggested that at a suitable degree of deformation the stability of the grains is lowered so that they may swell in water at room temperature.

EXPERIMENTAL

Since no substantial evidence was found by changing the chemical environment to support the hypothesis that starch effects tablet disintegration through swelling, this study was planned to demonstrate the effect of damage on starch grain swelling and to determine the influence of the tableting procedure and tablet ingredients on starch grain damage and tablet disintegration.

Since the nature of the tablet constituents may affect swelling, the addition of an ingredient to cornstarch was studied. The following general formula was used for the tablet formulations:

Active ingredient	10.00 Gm.
Cornstarch[1]	0.75 Gm.

The materials chosen as the ingredient in the formulations were aspirin, talc, calcium carbonate, calamine, sodium chloride, and sucrose. Aspirin was selected because of its widespread use and because of its use in previous disintegration studies. Talc, calcium carbonate, and calamine were selected to include materials of varying hardness, because hardness may influence the degree of damage imposed on the starch grains during tableting. Mohs' hardness scale values for these three materials are: talc, 1; calcium carbonate, 3; and calamine, 5 (9). Sucrose and sodium chloride were included to determine the effect of water-soluble substances and their crystalline structure on starch damage. Tablets of pure cornstarch were included as controls.

The force of compression used in the tableting procedure influences void space, disintegration time, and may influence starch grain damage. These factors were studied and comparisons among them were made to determine what significance could be attributed to each factor.

The extent of elastic recovery after compression for each of the formulations and for pure cornstarch was investigated. The greater the elastic recovery of the tablet after release of pressure, the greater is the stress within the tablet. This stress might affect starch grain damage.

Procedure for Preparation and Examination of Tablets—The tablet formulations were mixed in a mortar and then compressed as a powder in a Carver laboratory press model B[2] using standard, flat-faced, stainless steel punches and die of $^3/_8$ in. diameter.

The die and lower punch were fixed at a definite position throughout the experiment and the powder was manually placed in the die and leveled with the top. This procedure gave uniform weights for the tablets from a particular formulation.

Tablets of each formulation were prepared using varying compressional forces. The individual tablets were measured for thickness and diameter with a vernier caliper and weighed. Utilizing the tablet dimensions and weights, the percent void space (% e) was calculated by:

$$\%\ e = \left(1 - \frac{d_b}{d_t}\right) \times 100$$

where

$$d_b = \frac{W}{V}$$

and

$$d_t = \frac{10.75\ \text{Gm.}}{10.00\ \text{Gm.}/d_i + 0.75\ \text{Gm.}/d_s}$$

where d_b and d_t are the bulk density and true density of the formulation, d_i is the density of the ingredient (10, 11), d_s is the density of starch, W is the weight of the tablet in Gm., and V is the volume of the tablet in cm.^{3}.

Procedure for Determination of Disintegration Time—The disintegration time for each tablet in simulated gastric fluid USP (SGF) at 37° was determined using a modification of the USP disintegration apparatus, so that only one tablet was disintegrated at a time and the time required for all the granules to pass through the 10-mesh screen determined. The disintegration times reported represent an average of five determinations.

Procedure for Production and Determination of Starch Grain Damage—Sandstedt and Mattern (12) state that starch grains are easily damaged by pressure, shear, or strain such as that applied by grinding procedures. Damage to the grains was effected by ball milling in a 1-quart porcelain ball mill using 0.5-in. diameter porcelain balls and a single tier roller mill.[3] Samples were removed at various time intervals and the extent of damage to the starch grains was determined.

[3] Phipps and Bird, Inc., catalog No. 62-502.

A qualitative method suggested by Schoch (5) consisted of suspending the starch in water and examining the grains under a polarizing microscope. Schoch states that severe damage gives grains which swell in cold water and hence show no polarization cross. Lesser degrees of damage result in a darkened area at the center of the grain when viewed under normal light.

If the damage is severe enough that the paracrystalline structure of the grain is disrupted, the unswollen grain should also lose its polarization cross. Lesser degrees of damage resulting in less disruption of the paracrystalline nature of the grain should allow passage of proportional amounts of polarized light. In order to eliminate the possibility that reversible swelling in water may affect the polarization characteristics of starch, glycerin was used as the slurrying medium, since starch does not swell in glycerin (13).

The percent damage of the various samples removed from the ball mill was calculated from observation of the polarization crosses of 200 grain. Each grain was assigned a weighted degree of damage, dependent on the number of quadrants within the polarization cross which presented a darkened appearance. For example, if the polarization cross contained two quadrants which exhibited a darkened appearance, the grain was assigned a degree of damage of 0.5. Since it was not possible to determine the absolute extent of a darkened area within the cross, these percentages reflect only a relative degree of damage, which is useful for comparison of samples.

The effect of pressure on starch swelling was determined from tablets of pure cornstarch (MJ). The tablets were prepared on a Carver press utilizing various compressional forces. The tablets were slurried in SGF and in glycerin, and swelling was determined on 100 grains' diameters from each sample, using the procedure described previously (1).

Procedure for Determination of Starch Grain Damage in Tablets—The starch grain damage produced by tableting of the different formulations was determined by examination of 200 grains under the polarizing microscope using the procedure described previously. Two tablets of each formulation prepared at each pressure were used for preparation of the slurries. The procedure for preparation of the slurries was modified, because the starch as a tablet constituent was not available for direct slurrying. The aspirin tablets were slurried in absolute ethyl alcohol, which dissolved the aspirin. The alcohol was decanted and the residual starch grains were slurried in glycerin. Talc, calamine, sucrose, and sodium chloride tablets were disrupted in absolute ethyl alcohol to release the starch for preparation of slurries. Glacial acetic acid was used to effect release of starch from calcium carbonate tablets. Glycerin, absolute ethyl alcohol, and glacial acetic acid were used because these liquids have no effect on starch swelling.

Procedure for Determination of Elastic Recovery—The elastic recovery after compression for each formulation was determined on a Carver press. The powder was placed in the die and the distance the upper punch moved to produce each pressure was measured by dial micrometers attached to the upper punch.

After the maximum pressure had been applied and released, the micrometer reading for the tablet at zero was determined. The tablet thickness was measured with a vernier caliper immediately after removal of the tablet from the die in order to exclude any creep recovery. The sum of these two values minus the micrometer reading at each pressure gave the tablet thickness under pressure. By comparison of the final tablet thickness with the tablet thickness while under pressure, the elastic recovery could be determined.

The elastic recovery for the pure cornstarch tablets was determined by the same procedure at each pressure level studied, instead of only at the maximum pressure applied.

RESULTS AND DISCUSSION

Investigation of Relationships Among Compressional Force, Starch Grain Damage, and Starch Swelling—Since the compressional force may damage the starch grains, the effect of damage on swelling of starch grains was first studied. Cornstarch (MJ) grains were damaged by ball milling and samples were removed after various time intervals up to 48 hr. and the degree of damage determined by observation of 200 grains under the polarizing microscope. The samples were also examined for the effect of damage on swelling in SGF in a 3 × 12 full factorial experiment. The damage determinations and the mean grain sizes are shown in Table I. The analysis of variance showed that the degree of damage and submersion time both produced significant differences in grain diameters at the 1% level. Duncan's multiple range test (14) for the time effect shows that the grain diameters of unsubmerged starch are significantly different from those of submerged starch, with no difference being demonstrated between the two submersion times. Duncan's multiple range test for the damage effect shows a significant difference between the samples ball

milled for 48 hr. and the samples ball milled for 36 hr. or less. This means more than two-thirds of the starch grains had to be damaged before there was a statistically significant increase in swelling.

To determine the extent of swelling produced by various compressional forces, a 3 × 8 full factorial experiment was designed. Cornstarch (MJ) tablets were prepared on a Carver press using 0.5-in. flat-faced punches and mean grain sizes determined in SGF after 5 and 10 min. submersion. The mean grain sizes of the starch grains were determined from a glycerin slurry to include unsubmerged starch (zero time) as a basis for comparison. Eight pressures between 0 and 5000 psig were investigated. The analysis of variance of the mean grain sizes revealed no significant differences among the variables investigated.

Using 0.5-in. diameter punches, the maximum compressional force used in the previous experiment (5000 psig) corresponds to an actual pressure of 25,480 p.s.i. Because the actual pressures produced in tableting may vary over a wide range depending on the punch sizes that are used, cornstarch samples subjected to an extremely high compressional force were investigated for evidence of damage. Tablets of cornstarch were prepared on a Carver press utilizing $^3/_8$-in. diameter flat-faced punches and compressional forces of 500 and 24,000 psig, which correspond to actual pressures of 4530 and 217,440 p.s.i., respectively. The percent starch grain damage as determined from glycerin slurries, were 7.8% for the tablet prepared at 500 psig and 5.5% for the tablet prepared at 24,000 psig.

The results of the elastic recovery determinations for cornstarch are shown in Fig. 1. Cornstarch exhibited a high degree of elastic recovery when subjected to high compressional forces. The strain produced by this elastic recovery showed no apparent correlation to starch grain damage as indicated by the above data.

From the observations of strain in starch tablets after subjected to pressure and the extent of starch grain damage produced by pressure, along with the observations in the experiment on pressure and swelling, it seems that starch grains are not significantly damaged by the forces involved during and after compression.

Effect of Tableting Procedure on Starch Properties and Tablet Disintegration—Since starch grain damage resulting from compression of cornstarch alone was shown to be insignificant and when a high percent of starch grains are damaged there is an increase in swelling, the combined effect of other tablet ingredients and compression on starch grains was investigated. If these variables could be related to starch grain damage and hence swelling, this could be considered indirect evidence for a swelling mechanism for tablet disintegration.

Effect of the Hardness of an Added Ingredient and Compressional Force on Tablet Properties—To determine how the added ingredient and force of compression affect such properties as disintegration time and void space in the tablet and damage to the starch grains, tablets were compressed over a pressure range of 2000 to 8000 psig. In each formulation the percent void space decreased[4] and the degree of starch grain damage increased with compressional force. The ingredient apparently had no effect on the proportionality of these relationships, but only on the degree to which they occur. Variation in the degree of starch damage among the different formulations is shown in Table II and variation in void space is shown in Table III.

Damage varied from 8.0 to 15.1% for talc to 31.5 to 68.1% for sodium chloride. The ingredients did not produce correspondingly greater degrees of damage as hardness increased. Calamine, with a hardness of 5, produced a maximum starch grain damage of 27.5%; whereas calcium carbonate, with a hardness of 3, produced a maximum damage of 38.1%. The crystalline form or the brittleness of the ingredient may exert a greater influence on starch grain damage than hardness, as illustrated by the damage produced by sodium chloride. The void space percentages in the different formulations ranged from 0 to 2.3% for aspirin tablets to 24.0 to 38.2% for calcium carbonate tablets.

The results of the elastic recovery determinations for the different formulations after compression at 24,000 psig were: sodium chloride, 15.9%; sucrose, 19.5%; aspirin, 34.6%; calcium carbonate, 70.4%; calamine, 76.2%; and talc, 77.7%. There is no apparent correlation between the strain produced

[4] Void space in the sodium chloride and the sucrose tablets decreased with increasing pressure up to 6000 psig and then anomalously increased at 8000 psig. Outside of experimental error, no explanation could be found for this behavior and this increase is disregarded in forming generalizations on compressional effects. Fusion of some of the crystals at the higher pressures and subsequent recrystallization after removal of pressure might effect a void space increase, if expansion of the tablet occurs during recrystallization.

TABLE IV—EFFECT OF PRESSURE ON DISINTEGRATION TIME

Pressure, psig	Ingredient					
	Aspirin	Calcium Carbonate	Calamine	Talc	NaCl	Sucrose

[a] Time in sec. [b] Time in hr.

by elastic recovery and the extent of damage to the starch grains. Surprisingly, the results indicated an inverse relationship between strain and starch grain damage for all of the formulations except aspirin.

The relationship between compressional force and disintegration time varied with the ingredients. Disintegration times for the aspirin, sodium chloride, and sucrose tablets increased with increasing compressional force; whereas disintegration times for the calcium carbonate and the calamine tablets decreased with increasing compressional force. These relationships are shown by the data in Table IV. Since the disintegration times for the talc tablets compressed at all pressures were greater than 8 hr., no correlations for this formulation could be made.

As shown above, the relationships between disintegration time and void space or starch grain damage varied and no correlations could be made. The ingredients appear to be the main source of the variation.

Disintegration times for the aspirin, sodium chloride, and sucrose tablets increased with increasing starch grain damage and decreasing void space. Disintegration times for the calcium carbonate and the calamine tablets decreased with increasing starch grain damage and decreasing void space.

It had been previously demonstrated that the logarithm of disintegration time varies directly with compressional force (15). This study revealed a direct relationship between pressure and dissolution time for the tablet formulations containing sodium chloride and sucrose. It is questionable whether the small decreases in void spaces found justify the large increases in dissolution time. The extensive starch grain damage noted would indicate an increased swelling ability for the starch grains. This was not borne out with the two soluble tablet formulations. The increased damage and hence swelling ability of the starch grains may have actually exerted a detrimental effect on dissolution by formation of a paste which then would hinder penetration of SGF into the tablet.

The tablet formulations containing insoluble ingredients varied in the relationships between pressure and disintegration time. The greatest damage range observed in this group was in the calcium carbonate tablets. Starch grain damage in this formulation ranged from 16.5% to 38.1%. The disintegration times for calcium carbonate tablets decreased from 25.6 to 9.6 sec., indicating that the swelling may have exerted a favorable influence on disintegration. The large void space in this formulation, however, could overshadow any effect on disintegration produced by the increased swelling capability of the damaged starch grains. Also, the results from the ball milling experiment indicated that greater than 67% of the starch grains must be damaged before a significant increase in swelling is observed.

The range of disintegration times for calamine tablets was too small to allow any significant correlations to disintegration time.

The results of this investigation disclosed no correlation between starch grain damage and tablet disintegration. Outside of pressure, the inherent effect of the added ingredient was the only factor that appears to affect tablet disintegration. Starch grain damage, void space, and hardness of the ingredients are at best of secondary importance.

Effect of Compressional Force on Aspirin Tablet Properties—In order to obtain more information on the effect of compressional force, aspirin tablets prepared over a pressure range of 1000 to 24,000 psig were examined for relationships existing among disintegration time, void space, and damage to the starch grains.

The inverse relationship between compressional force and void space observed in the previous study is again obvious over the wider pressure range. Figure 2 shows that void space decreased rapidly with increases in pressure up to 3000 psig. Above 3000 psig the void space decreased slowly up to 7000 psig, at which point zero percent void space was attained.

No relationship between compressional force and degree of starch grain damage was observed over the pressure range studied. Damage varied from 9.4 to 19.2%, but did not consistently increase as the pressure increased.

The increase in disintegration time with increasing

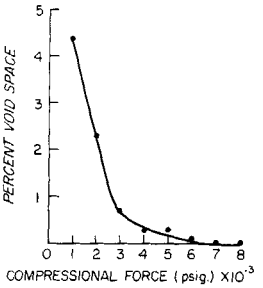

Fig. 2—Influence of compressional force on percent void space in aspirin tablets.

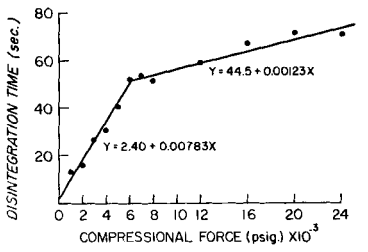

Fig. 3—Influence of compressional force on disintegration time of aspirin tablets.

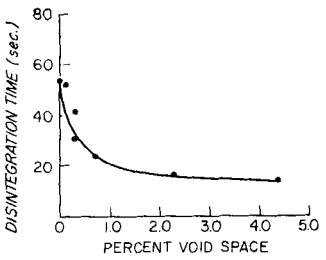

Fig. 4—Relationship between disintegration time and percent void space in aspirin tablets.

compressional force for the aspirin tablets is shown in Fig. 3. Disintegration times increased linearly with compressional forces between 1000 and 6000 psig. Tablets produced with greater than 6000 psig pressure also had disintegration times that were linearly dependent on compressional force; however, the disintegration rate was slower.

Disintegration times increased slowly with decreasing void space until 0.7% void space (3000 psig) was attained. Below 0.7% void space disintegration times increased rapidly until zero percent void space was reached at 6000–7000 psig. After zero percent void space was reached, disintegration times continued to increase with pressure. It appears, at least with aspirin, that the disintegration time is little affected until a certain value at about 0.7% void space is attained, and that further application of pressure affects disintegration greatly. Figure 4 illustrates the relationship between void space and disintegration time in aspirin tablets.

Since there was no correlation between compressional force and degree of damage to the starch grains, the percent damage could not be related to disintegration. Damaged starch grains do not appear to play a significant role in disintegration of aspirin tablets. The tablet that had the shortest disintegration time produced a starch grain damage of only 11.9%.

Since compaction pressure produced by impact due to the rapid action of a tableting machine might effect greater damage than that produced in the slower, hand-operated Carver press, aspirin tablets prepared on a Colton model 321 tablet press[5] were examined for evidence of starch grain damage. Observation of 200 grains showed only 2.6% damage. Disintegration time for these tablets was 15.4 sec. This again indicates that starch grain damage apparently has no significant effect on disintegration.

SUMMARY AND CONCLUSIONS

A procedure for estimation of starch grain damage is described. Swelling of damaged starch grains in SGF at 37° was demonstrated by experiments with cornstarch damaged by ball milling.

Damage to the grains, resulting from compression of pure cornstarch at pressures up to 24,000 psig was shown to be not significant.

The effect of compressional force and hardness of the tablet ingredients on starch grain damage was examined together with the relationships among compressional force, elastic recovery, void space, and disintegration time for the formulations.

In each formulation the starch grain damage increased as the compressional force was increased. The ingredient apparently had no effect on the direct proportionality of this relationship, but only on the degree to which it occurs. There was no correlation between degree of starch grain damage and hardness of the ingredient. The crystalline form of the ingredient may exert a greater influence on starch damage than hardness of the ingredient. This was illustrated by the sodium chloride and sucrose formulations, which produced the greatest degree of starch damage. There was no correlation between starch damage and stress produced by elastic recovery. Contrary to what might be expected, there was an inverse relation between the amount of stress and the degree of starch grain damage for all of the formulations except aspirin.

There was no evident relationship demonstrated between disintegration time and starch grain damage. Dissolution times for sucrose and sodium chloride tablets increased as the degree of starch grain damage increased. Disintegration times for the calcium carbonate tablets decreased with increasing starch damage, but the large void space in this formulation could overshadow any effect of swelling due to damage. Outside of compressional force, the inherent effect of the tablet ingredient was the only factor that appeared to affect disintegration, although starch grain swelling cannot be eliminated as a possible mechanism.

Most compressed tablets are composed of more than one ingredient and require several steps in manufacture. Ingredients commonly used in tablets represent a wide range of chemical and physical properties. Thus, it is possible that disintegration is influenced by a wide variety of factors which are specific for only a given tablet formulation and it is difficult to determine the mechanism of action of starch as a tablet disintegrant. The long-accepted swelling mechanism of action of starch as a tablet disintegrant could not be demonstrated in this study. The results of the investigation revealed no measurable correlations between starch grain damage and disintegration or between starch grain swelling and compressional force.

The proposals of Patel and Hopponen (16) and Nogami *et al.* (17) on the effect of capillaries, starch wettability, and liquid penetration into tablets become more substantial.

Metabolic Fate of Orally Administered 2,3,5-Triiodobenzoic Acid in Lactating Animals

By RODNEY D. ICE*†, JOHN E. CHRISTIAN*, and MILLARD P. PLUMLEE**

The whole body retention, excretion, distribution, thyroid uptake, and metabolism of 2(^{131}I),3,5-triiodobenzoic acid (TI*BA) were studied in goats and a cow. A single oral dose of TIBA exhibited a two-component whole body radioactivity retention curve and was excreted primarily in the urine. TIBA plus nine metabolites, four of which were identified, were found in the urine. The major metabolite was 2,5-diiodobenzoic acid (2,5-DIBA). Trace amounts of 2,3-diiodobenzoic acid (2,3-DIBA), orthoiodobenzoic acid (OIBA), and iodide ion were found. TIBA was metabolized by deiodination. Iodide ion was concentrated in the thyroid and excreted by way of milk and urine.

In soybeans, 2,3,5-triiodobenzoic acid (TIBA) affects plant morphology and flowering response (1, 2). When properly used, soybean production is increased through a better utilization of photosynthate, lodging is decreased, and a more compact plant results (3). Spitznagle (4) has reported a residue in soybeans treated with TIBA. Soybean products are used for animal and human food consumption and the question arises as to the environmental health safety of TIBA. The metabolic fate of TIBA in lactating animals is important to a thorough understanding of the potential hazards.

Ice *et al.* (5) reviewed TIBA and using TIBA labeled with ^{131}I in the two position, orally administered to rats, observed two whole body retention components—one with a biological half-life of 11.8–17.9 hr. and the second of 395–403 hr. Of the administered dose, 70–78% was excreted in the urine, while 3–4% was excreted in the feces over 4 days. Three metabolites plus TIBA and iodide ion were located in the urine. Whole body retention of radioactivity was evident. Distribution studies in rats indicated a marked thyroid uptake of radioactivity.

Ebert and Ware (3) and Barker *et al.* (6) using carboxyl labeled TIBA-^{14}C orally administered to rats, found TIBA and/or its metabolites in all organs analyzed. Seventy-five percent of radioactivity was excreted *via* the urine and 29% *via* the feces. Chromatographic studies indicated two to six metabolites plus TIBA in the urine.

Gutenmann *et al.* (7) found no TIBA in the milk or feces of the dairy cow during a period of 4 days. In urine, 13.5% of the dose excreted was TIBA. A second compound in the urine was identified as 2,5-DIBA and accounted for 53.5% of the TIBA fed.

EXPERIMENTAL

Instrumental Methods—Whole body radioactivity was measured in goats using large volume liquid scintillation counting techniques. The basic mechanisms and characteristics of the 2 π liquid scintillation detector have been previously reported (8). The detector has since been modified by the addition of an upper detecting tank, which allows 4 π geometry. Dosages were adjusted to provide negligible coincidence loss.

A 3-in. diameter standard NaI(Tl) crystal, centrally located in a steel vault, was used for counting liter samples of excreta and tissue. A 3-in. diameter NaI(Tl) well crystal was used to determine the radioactivity in 3-ml. samples of tissue, to count eluent fractions from chromatography columns, to

quantitate metabolites scraped from thick-layer chromatograms, and to count milk samples. Thyroid uptake was determined using a standard 2-in. diameter NaI(Tl) crystal in a collimator, DS-5.[1] Each crystal was connected to appropriate electronics and used in a differential mode. All radioactivity determinations were corrected for background, counter efficiency, and decay as required.

Gel filtration chromatography columns were made by placing a slurry of prewashed 100 Gm. (dry weight) Sephadex G-15[2] into a glass column 122 cm. long and 2.2 cm. i.d. A pledget of glass wool was used at the base and top of the dextran gel bed. Characteristics of the column were: bed length 32 cm.; void volume 135 ml.; and flow rate 0.4 ml./min.; deionized water was the eluent. Five-milliliter fractions were collected in a fractionator[3] with volumetric attachment. Sample size placed on the column was 5 ml.

The thick-layer (1.0-mm.) chromatographic and autoradiographic procedures used were similar to those reported earlier (5). The adsorbent was changed to 85 Gm. of MN-Kieselgel G-HR/UV[4] mixed with 137 ml. of deionized water to form a slurry capable of coating 5 plates each 20 × 20 cm. The solvent systems used were: (*a*) petroleum ether–propionic acid, (10:1, v/v) (3); (*b*) *n*-butanol–acetic acid–water, (4:1:1, v/v) (5); (*c*) ethyl acetate–methanol–2 *N* ammonium hydroxide, (100:40:60, v/v, upper phase) (9); (*d*) ethyl acetate–methanol–0.2 *N* acetic acid (100:40:60, v/v upper phase) (9). Unlabeled standard compounds were detected visually under ultraviolet light (254 mμ).

Radioactive TIBA was synthesized and purified as previously reported (5) immediately prior to experimental use. Radiochemical purity was established by thin-layer chromatography in each solvent system followed by autoradiography.

A precison level of experimental work was established so that an error greater than 5% (at the 95% confidence level) would not be accepted. The mean standard error and the Pearson product-moment correlation coefficient were calculated according to the method outlined by Downie (10).

Whole Body Retention—Five adult female milk goats in the 8–9 month of lactation were used. The average daily milk volume was 300 ml. per goat. The goats weighed 39.5–60.4 Kg. and were maintained on a daily lactation ration consisting of 1.9 Kg. of commercial goat chow and legume hay *ad libitum*.

Prior to dosing, a whole body radioactivity measurement was made on each goat to determine the quantity of natural radioactivity appearing in the differential counting window used. This base level of natural radioactivity was subtracted from whole body determinations made after dosing.

Four of the goats were each given a single dose of 0.1 mg. TI*BA, representing 0.3 μCi. The doses were prepared by pipeting 10 μl. of an alcoholic solution of TI*BA into a No. 000 gelatin capsule and allowing the alcohol to evaporate. Each capsule administered with a balling gun to avoid mastication. Thirty minutes were allowed to elapse before the first whole body radioactivity determination was made. For each determination, the individual goat was immobilized in a steel container (11) without tranquilizers or anesthesia. Twelve 1-min. radioactivity determinations were made on each goat at each time interval. To prevent counting the capsule as a point source, the first net count rate 30 min. after dosing was assigned 100% retention. To measure any possible cross external contamination from excreta, a fifth goat was used as a control. This animal received similar treatment as the four other goats with the exception that a placebo was administered.

Excretion—Five adult goats in the third month of lactation weighing 47.8–62.3 Kg. were acclimatized to metabolism cages (12) for 2 days prior to experimentation. Each goat was catheterized with a Bardex Foley catheter with Bard inflation valve[5] (size 16 French, 5-ml. balloon) and the urinary bladder drained. The goat was milked dry and then given a dose of 5.0 mg. TI*BA representing 5.4 μCi. After dosing, all urine, feces, and milk were recovered at 6 hr., and then at 12-hr. intervals thereafter up to 114 hr. All excreta were weighed and samples 1 L. size taken by weight for radioactivity determinations.

The procedure was repeated using a 3-year old Holstein cow weighing 477 Kg. The cow had calved for the first time 5 months earlier. During the study, the cow was maintained on a daily lactation ration of 18.2 Kg. corn silage, 11.4 Kg. of a 16% protein concentrate, and 2.3 Kg. hay. The single dose to the cow was 1.197 Gm. of TI*BA representing 55.92 mCi. The dose, in a No. 12 veterinary capsule, was administered to the cow with a balling gun. Average daily milk volume was 17.5 Kg. After dosing, all excreta were recovered and weighed at 6 hr. and then at 12-hr. intervals up to 162 hr. One-liter samples by weight were taken for radioactivity determination. Total residue determinations were made on the feces according to "Standard Methods" (13).

Thyroid Uptake—During the excretion study a concomitant determination of thyroid uptake was made on the same five lactating goats dosed with TI*BA. The collimated NaI(Tl) crystal was centered 10 cm. from the thyroid gland of each goat and two radioactivity measurements were made every 12 hr. through 210 hr. after administration of TI*BA. The procedure was repeated on the flank of each goat.

Distribution—Four adult lactating goats weighing 51.4–75.0 Kg. were used. Each goat was milked dry, catheterized, and the urinary bladder drained as in the excretion study. The catheter was then sealed. Each goat was given a single dose of 150 mg. of TI*BA containing 5.0 mCi. Eight hours after dosing, the catheter was reopened, the bladder drained, and the goat milked dry. The goat was stunned by a sharp blow on the head and sacrificed by bleeding from a severed jugular vein. A 1-L. blood sample was collected. The goat was dissected, with the kidneys, thyroid, liver, spleen, brain, heart, and gastrointestinal tract being removed. Lean and fat tissue were obtained from the hind quarter and inner surface of the loin, respectively.

[5] Davol Rubber Company, Providence, R. I.

The gastrointestinal (G.I.) tract was emptied of its contents, weighed, and mixed uniformly. One-liter samples of fat, liver, lean, blood, and G.I. tract were taken by wet weight. The heart, spleen, kidney, and brain were weighed and frozen. Two samples of frozen tissue were removed, weighed, and placed in counting vials. The thyroid gland was weighed, minced, and a 3-Gm. sample taken. Radioactivity measurements were made on all samples and compared to a standard of similar geometry with known specific activity. The percent of the administered dose of TIBA and its metabolites was determined for each organ. Also calculated was the percent of dose per kilogram of organ tissue. A normalized concentration was determined by setting the percent per kilogram of blood equal to 100.0 and correcting all other concentrations to this normalized value.

Metabolism—Accumulated 8-hr. urine, milk, and the thyroid gland from the goats and accumulated 6–18 hr. urine and milk from the cow were analyzed for metabolites. Gel filtration columns and thick (1.0-mm.) layer chromatograms were used. Five-milliliter samples of urine, treated[6-8] urine, skim milk, treated skim milk,[9] and digested thyroid tissue[10] were separated on gel filtration columns.

The identification of TIBA and iodide ion in the column eluent was accomplished by adding TI*BA and iodide-^{131}I ion as internal standards to the urine and milk samples placed on the column. The eluent fractions under each peak and duplicated fractions that had been acidified were forced air evaporated to 0.5 ml. and spotted on thick-layer chromatograms in aliquots of 50 μl. Also chromatographed were treated[6-8] urine samples, skim milk pancreatin,[9] digested thyroid tissue,[10] standard solutions of suspected metabolites, whole urine, and skim milk. A chromatogram was developed in each solvent system. Each chromatogram was autoradiographed 16 days, and the position of metabolites compared to appropriate standards.

Milk Analyses—The skim portion of the milk was obtained by centrifuging 10 ml. of whole milk for 10 min. at 4500 r.p.m. The cream layer was penetrated with a 5-in., 20-gauge needle attached to a syringe and the skim milk portion removed. The partition of radioactivity in cream and skim milk was determined by comparing the relative concentrations of radioactivity in whole milk and skim milk.

Protein bound iodide in milk was determined by adding 5 ml. of 20% trichloroacetic acid (TCA) to 5 ml. of whole milk, stirring, and centrifuging 10 min. at 4500 r.p.m. The nonprotein bound fraction (supernatant) was removed. The protein fraction was treated similarly two more times with 5 ml. of TCA. The nonprotein fractions were combined and the quantity of nonprotein bound radioactivity was compared with the radioactivity of whole milk.

[6] Acidified urine. Urine was acidified to pH 3 using 1 *N* HCl, shaken, and allowed to stand 24 hr.

[7] Alkaline urine. Urine was made alkaline to pH 11 using 1 *N* NaOH, shaken, and allowed to stand 24 hr.

[8] Urine–beta glucuronidase. Ten milliliters of urine and acetate buffer solution pH 4.5 were mixed with 100,000 u. (454 mg.) beta-glucuronidase (Type B-1, Bovine Liver, Sigma Chemical Co., St. Louis, Mo.). The solution was stirred, shaken, and incubated at 37° for 48 hr. The resultant suspension was centrifuged 10 min. at 4500 r.p.m. and 5 ml. of supernatant taken as the sample.

[9] Skim milk–pancreatin. An aliquot of whole milk was added to pancreatin (20 mg./ml.), shaken, and incubated at 37° for 48 hr. The resultant suspension was centrifuged 10 min. at 4500 r.p.m. and a 5-ml. supernatant was taken as the sample.

[10] Digested thyroid tissue. To a cold finger condenser was added 2 Gm. of minced thyroid tissue, 1 ml. of 0.1% thiourea solution, and 10 ml. of 1 *N* NaOH. The condenser was air evacuated, sealed, and heated on a steam bath 4 hr. The digested tissue was centrifuged and 5 ml. of supernatant used for the sample.

RESULTS AND DISCUSSION

The results of the whole body retention study are shown in Table I. The data indicated at least 2 biological half-life components, represented by the equation

$$Y = 19.9e^{(-0.0164)(X \text{ hr.})} + 71.8e^{(-0.0512)(X \text{ hr.})},$$

where Y is the percent retained at X hours. A long biological half-life component of 423 hr. was indicated and had a correlation coefficient of $r = 0.87$. A short biological half-life component of 13.5 hr. was found and had a correlation coefficient of $r = 0.99$. The derived whole body retention equation assumes milk production to be invariant at 300 ml. daily.

The results of the excretion study are shown in Table II. During the acclimatization period prior to experimentation, total excretion records were maintained. Total excreta before and during the study were compared and no significant difference was seen in the quantity of milk, urine, or feces produced due to the TIBA treatment.

Urinary excretion was the primary route of excretion accounting for 76.1% of the administered radioactivity in goats after 114 hr. Milk and fecal excretion accounted for 12 and 2.7%, respectively. Using the derived whole-body retention equation, the accountable dose was 107.4% of the administered dose.

The whole body retention equation was derived from goats with an average daily milk production of 300 ml. In the excretion study, however, the average daily milk production per goat was markedly higher with 1930 ml. With increased milk production during the excretion study, there was increased excretion by the mammary gland at the expense of whole body retention. Weaver (14) has shown that iodide ion excretion in milk varies directly as does the quantity of milk produced. In the cow, 57.5% of the administered dose was excreted in the urine, 12.2% in the milk, and 11.4% in the feces.

Thyroid and flank uptake studies of TIBA

[a] Weighed 47.8–62.3-Kg. dose was 5 mg. TI*BA representing 5.4 μCi. [b] Weighed 477 Kg. dose was 1.197 Gm. TI*BA representing 55.2 mCi. [c] Less than 0.05%.

and/or its metabolites were done concomitantly on the five goats used in the excretion study. Thyroid uptake occurred for 5 days after a single dose before declining in radioactive content. Comparison of the flank uptake curve with the thyroid uptake curve, indicated a definite thyroid involvement in TI*BA metabolism.

The distribution of radioactivity in each goat after 8 hr. is shown in Table III. Of the administered dose, 41% remained in the G.I. tract after 8 hr. TIBA and/or its metabolites were distributed throughout all tissue samples analyzed. The kidney was indicated as the primary organ excreting absorbed TIBA. The thyroid contained 0.19%, of the administered dose and had a relative concentration of radioactivity 28 times the blood concentration after 8 hr. In the organs examined, the lowest level of radioactivity was found in the brain, which accounted for less than 0.01% of the dose administered.

Column chromatographic separation of whole urine produced a pattern typified by Fig. 1. Internal standards of iodide (^{131}I) ion and TI*BA were eluted with peaks 2 and 8, respectively. Column chromatography of acidified urine produced the iodide peak and an enlarged peak 9 at the expense of peaks 3 to 8. The effect may be due to the release of iodinated benzoic acids from conjugation and a change of the iodinated benzoic acids in the ionized form to the molecular form. The urinary metabolites were quantitated by summing the radioactivity associated in each peak and determining the relative percent of each peak contributing to the total radioactivity. The results are shown in Table IV.

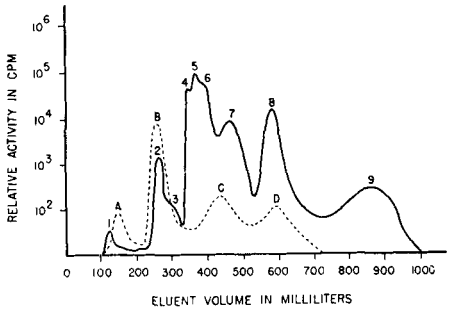

*Fig. 1—Typical column chromatogram of urine (_____) and skim milk (.....) radioactivity after oral TI*BA administration to goats, using a Sephadex G-15 column and deionized water as the eluent.*

TABLE III—TISSUE DISTRIBUTION OF TI*BA AND ITS METABOLITES[a] IN FOUR LACTATING GOATS

	% Dose in Organ		Relative Concentration[b]	
Organ	Mean	S. E.	Mean	S. E.
Kidney	0.72	0.16	270.2	48.5

Brain	0.01	0.00	2.9	0.3

[a] Animals were sacrificed 8 hr. after oral administration of TI*BA. [b] Calculated using the equation: [(% dose in organ/Gm. × 10^3)(100)/(% dose in blood/Gm. × 10^3)]/4 = Relative Concn. [c] Not calculated, as the total organ weights were unknown. [d] Arbitrarily set equal to 100.0.

TABLE IV—RELATIVE PERCENT OF TI*BA AND ITS METABOLITES FOUND IN THE URINE AND SKIM MILK OF LACTATING GOATS[a] AND A COW[a] AFTER ORAL ADMINISTRATION OF TI*BA

Peak No.	Eluent Vol., ml.	Goat No. 11	Goat No. 12	Goat No. 13	Goat Mean	Cow
	Relative % Metabolites in Urine[b]					
1,2,3	0–320	2.4	1.7	0.8	1.6	0.3
4,5,6,7	321–525	39.9	33.5	49.0	40.8	70.0
8,9	526–995	57.7	64.8	50.2	57.6	29.7
	Relative % Metabolites in Skim Milk[b]					
A	0–250	6.6	7.6	5.0	6.4	0.4
B	251–320	76.2	92.4	87.8	85.5	97.8
C	321–525	...	0.0	3.8	...[d]	0.7
D	526–995	17.2[c]	0.0	3.3	...[d]	1.1

[a] Accumulated 8 hr. urine or skim milk sample from goats and accumulated 6–18 hr. urine or skim milk from a cow. [b] Column chromatographic separation using Sephadex G-15 with deionized water as the eluent. [c] Represents combined peaks C and D. [d] Data unavailable.

Components of the urine eluent, acidified urine eluent, and urine eluent peaks acidified after passing through the column were identified using thick-layer chromatography. The eluent of peak 9 from

acidified urine indicated a mixture, primarily of 2,5-DIBA and TIBA with traces of 2,3-DIBA and OIBA. The concentrated eluents of whole urine fractionated into peaks 4, 5, and 6, consisted of predominately 2,5-DIBA with trace quantities of 2,3-DIBA. Peak 7 was seen only as a trace in two of the examined goats but was as shown in the third goat and the cow. When eluent from peak 7 was acidified, it was converted to TIBA.

Column chromatographic separation of skim milk metabolites produced the typical pattern illustrated in Fig. 1. Internal standards of iodide (^{131}I) ion and TI*BA were eluted with peaks B and D, respectively. Peak A may be explained as a physical absorption of radioactivity on some high molecular weight compound in milk as it was eluted with the white color of milk near the void volume. Peak A was seen in all skim milk samples including controls, but was not seen in the pancreatin-treated skim milk. The identity of peak C is unknown. The skim milk metabolites were quantitated by summing the radioactivity associated with each eluted peak. The results are shown in Table IV. While goat 12 showed only iodide ion, peak B, all other goats and the cow examined produced a predominate iodide ion peak and traces of two other radioactive components, peaks C and D.

Digested thyroid tissue from goats was also chromatographed on gel filtration column into two major peaks, one of which appeared at the void volume indicating a high molecular weight compound being passed directly through the column. This peak tailed, giving a positively skewed curve which carried into a second peak consisting of iodide ion. The large amount of peak overlapping prevented any quantitative evaluation of the results. The first peak probably represents the iodine-containing compounds found in the thyroid that result from iodide ion concentration by the thyroid gland.

Thick-layer chromatography in solvent system *a*, separated whole urine into three fractions; origin, TIBA area (R_f 0.37), and 2,5-DIBA area (R_f 0.53). Whole urine eluent from the column chromatogram, representing peaks 4, 5, and 6, was acidified and concentrated. Quantitative evaluation indicated 2,5-DIBA (R_f 0.53) to be the major metabolite. Traces of the metabolite 2,3-DIBA (R_f 0.29) were evident. In goat 13 and the cow a trace metabolite at R_f 0.15 was also seen. Concentrated peak 9 eluent from the column chromatogram of acid hydrolyzed urine consisted of 2,5-DIBA, TIBA, and the metabolite OIBA (R_f 0.41). The three major areas on the chromatogram were quantitated by scraping from the plates and counting the radioactivity associated with each area. The results are shown in Table V. No migration of the metabolites in skim milk or in digested thyroid occurred in this solvent system.

TABLE V—RELATIVE PERCENT OF TIBA AND ITS METABOLITES FOUND IN THE URINE OF LACTATING GOATS AND A COW AFTER ORAL ADMINISTRATION OF TI*BA[a]

Location		Relative % Metabolites in Urine				
		Goat[b] No.				
R_f	Area	11	12	13	14	Cow[b]
0.00–0.29	Base	24.24	23.16	89.98	34.67	28.26
0.30–0.44	TIBA	49.58	59.59	8.63	46.94	27.16
0.45–0.59	2,5-DIBA	26.17	17.25	1.39	18.39	44.58

[a] Thick-layer chromatograms on MN-Kiesel gel and a solvent of petroleum ether (30–60°); propionic acid (10:1 v/v) (16). [b] Accumulated 8-hr. urine sample in goats and accumulated 6–18-hr. urine sample in a cow.

Thick-layer chromatography in solvent system *b* separated urine metabolites into seven positions. Iodide ion (R_f 0.47) and 2,5-DIBA (R_f 0.86) were found along with TIBA (R_f 0.83). The trace at R_f 0.80 was seen in concentrated eluents of peak 9 from the column and gave an R_r of 1.0 with OIBA standard. Three unknown metabolites appeared at R_f 0.54, 0.64, and 0.70.

Chromatograms of skim milk in solvent system *b* showed a major spot corresponding to iodide ion plus a trace of radioactivity at the origin. Pancreatin-treated skim milk contained the iodide ion without the residue at the origin. Digested thyroid supernatant remained at the origin in this solvent system except for a trace at R_f 0.54 and the iodide ion at R_f 0.47. Extraction of digested thyroid with acidified *n*-butanol indicated the presence of iodide ion (R_f 0.47), a metabolite at R_f 0.54, and traces at R_f 0.80 and 0.89.

Thick-layer chromatography using solvent system *c* separated urine metabolites into TIBA (R_f 0.73), 2,5-DIBA (R_f 0.76), iodide ion (R_f 0.30), and six additional metabolites. A ninth metabolite, OIBA (R_f 0.79), was obtained from the concentrated column eluent of peak 9. The six unknown metabolites were located at R_f 0.39, 0.42, 0.44, 0.49, 0.60, and 0.69.

Chromatograms of skim milk in solvent system *c* indicated a predominate iodide ion and trace radioactivity at the origin. Pancreatin-treated skim milk removed the residue at the origin and increased the concentration of the iodide ion. Two other unidentified trace metabolites were seen in the milk of both the cow and the goats (with the exception of goat 12) at R_f 0.44 and 0.76. Digested thyroid produced only iodide ion and a residue at the origin. Digested thyroid tissue extracted with acidified *n*-butanol produced additional metabolites at R_f 0.39, 0.44, 0.73, and 0.76.

Thick-layer chromatography of urine using solvent system *d* indicated TIBA (R_f 0.54), 2,5-DIBA (R_f 0.52), iodide ion (R_f 0.42), three major metabolites at R_f 0.50, 0.46, and 0.38, and three minor metabolites at R_f 0.95, 0.60, and 0.28. The metabolite at R_f 0.95 was only seen in goat 13. A spot at R_f 0.60 was found in the urine of all animals examined and corresponded to an impurity found in the crude synthesis product of TIBA-^{14}C and TI*BA.

Skim milk from the treated animals was separated by solvent system *d* into a major metabolite of iodide ion (R_f 0.42) and a nonmigrating residue. The residue at the origin was not seen in pancreatin-treated skim milk. Except for goat 12, traces of two other metabolites in skim milk at R_f 0.54 and 0.38 were found. Chromatograms of the supernatant of the thyroid digest of goats left a residue at the origin, the iodide ion (R_f 0.42) and traces at R_f 0.52 and 0.54. The spots at R_f 0.52 and 0.54 were also evident in the acidified *n*-butanol extracts of the digested thyroid tissue.

The mean recovered volume of skim milk from whole milk for the four goats was 89.8% (±3.9) and contained 91.0% (±2.3) of the radioactivity of whole milk. Accordingly, the radioactivity was seen to be evenly concentrated in the skim milk and cream portions of goat's milk. A similar relationship was evident in the cow's milk. Protein-bound

radioactivity in whole milk was 19.4% (±10.2) in the goats and 6.2% in the cow of the total radioactivity in whole milk.

SUMMARY AND CONCLUSIONS

1. Whole body retention studies of TI*BA in four adult lactating goats showed a two-component system—one with a biological half-life of 13.5 hr. and the second of 423 hr.

2. Excretion studies in five adult lactating goats and one cow showed that the primary route of excretion was *via* the kidney. For the goats, 76, 12, and 3%, respectively, of the administered dose was excreted in the urine, milk, and feces. Corresponding values for the cow were: 57.5, 12.2, and 11.4%.

3. Distribution studies, 8 hr. after oral administration of TI*BA to goats, indicated TIBA and/or its metabolites were located in the kidney, heart, thyroid, blood, spleen, G.I. tract, liver, fat, lean, and brain. The G.I. tract contained 41% of the administered dose at 8 hr. The average relative concentration of radioactivity in the thyroid was 28 times the average blood concentration. Thyroid uptake occurred for 5 days after oral TIBA administration.

4. Metabolite studies of the urine indicated TIBA and nine metabolites. Four of the metabolites were identified as 2,5-DIBA, 2,3-DIBA, OIBA, and iodide ion. In the 6–18 hr. urine sample of the cow, TIBA accounted for 28% of the radioactivity while the predominate metabolite, 2,5-DIBA, accounted for 45% of the radioactivity. In goats, 21% of the radioactivity in the accumulated 0–8 hr. urine sample was attributable to 2,5-DIBA while 55% was TIBA. The remaining (24%, goat and 27%, cow) metabolites in the urine are explained as representing iodide ion and conjugated forms of OIBA, 2,3-DIBA, 2,5-DIBA, and TIBA.

5. Milk analyses indicated iodide ion as the predominant (82.8–100.0%) metabolite. Eighty-one percent of the radioactivity within the milk was nonprotein bound in the goat while 94% was nonprotein bound in the cow. The two unknowns in skim milk ranged from 0% up to 17.2% of the radioactivity in the milk of goats and was 1.8% of the cow's milk.

radioactivity in whole milk was 19.4% (±10.2) in the goats and 6.2% in the cow of the total radioactivity in whole milk.

SUMMARY AND CONCLUSIONS

1. Whole body retention studies of TI*BA in four adult lactating goats showed a two-component system—one with a biological half-life of 13.5 hr. and the second of 423 hr.

2. Excretion studies in five adult lactating goats and one cow showed that the primary route of excretion was *via* the kidney. For the goats, 76, 12, and 3%, respectively, of the administered dose was excreted in the urine, milk, and feces. Corresponding values for the cow were: 57.5, 12.2, and 11.4%.

3. Distribution studies, 8 hr. after oral administration of TI*BA to goats, indicated TIBA and/or its metabolites were located in the kidney, heart, thyroid, blood, spleen, G.I. tract, liver, fat, lean, and brain. The G.I. tract contained 41% of the administered dose at 8 hr. The average relative concentration of radioactivity in the thyroid was 28 times the average blood concentration. Thyroid uptake occurred for 5 days after oral TIBA administration.

4. Metabolite studies of the urine indicated TIBA and nine metabolites. Four of the metabolites were identified as 2,5-DIBA, 2,3-DIBA, OIBA, and iodide ion. In the 6–18 hr. urine sample of the cow, TIBA accounted for 28% of the radioactivity while the predominate metabolite, 2,5-DIBA, accounted for 45% of the radioactivity. In goats, 21% of the radioactivity in the accumulated 0–8 hr. urine sample was attributable to 2,5-DIBA while 55% was TIBA. The remaining (24%, goat and 27%, cow) metabolites in the urine are explained as representing iodide ion and conjugated forms of OIBA, 2,3-DIBA, 2,5-DIBA, and TIBA.

5. Milk analyses indicated iodide ion as the predominant (82.8–100.0%) metabolite. Eighty-one percent of the radioactivity within the milk was nonprotein bound in the goat while 94% was nonprotein bound in the cow. The two unknowns in skim milk ranged from 0% up to 17.2% of the radioactivity in the milk of goats and was 1.8% of the cow's milk.

Complexing Behavior of Starches with Certain Pharmaceuticals

By ZEYAD MANSOUR and EARL P. GUTH

A study has been made of the complexing behavior of a number of starches and starch fractions with benzoic acid, *p*-hydroxybenzoic acid, sorbic acid, and other selected molecules in aqueous solutions at 30°. By means of the solubility method of analysis it was found that the low molecular weight polymer, amylose, is the main complexing component of starch. The starches showed different affinities for the same drug according to their content of amylose. A correlation of these complexes to those of "starch-alcohols" and "starch-iodine" was made.

STARCH has a multitude of applications in many areas of our life; *e.g.*, foods, drug therapy, and many industries. It has a long history of usefulness in medicine and pharmacy. Its use, however, has been entirely empirical. It is described as a protective, an adsorbent, and as a diluent in texts on pharmacology, with no explanation of the mode of action. Starch appears

to be quite effective in "drying-up" dermatitis lesions where there is a watery exudate; as a consequence, starch is found as a component in such pharmaceuticals as dusting powders, pastes, ointments, emulsions, and aerosols. The importance of starch inclusion in these products has not been questioned. Starch has also been used in the manufacturing of compressed tablets as a disintegrator, as a diluent, and as an excipient.

Although vast numbers of researches have been published on the physical and chemical properties of the various species of starch, very little work has been published regarding the possible involvement of the properties of starch regarding the stability and availability of the drug when included in a pharmaceutical preparation.

Guth and Goudah (1) reported a study of the complexing behavior of potato and arrowroot starches with a number of pharmaceutical compounds most of which are used as preservatives. By means of the solubility method of analysis it was found that starches form complexes in solution with benzoic acid with a number of its derivatives. All the complexing drugs were polar organic molecules, and the mechanism of interaction was believed to be a combination of inclusion formation and attractive forces like hydrogen bonding and dipole–dipole interactions.

In this work further investigation was undertaken to determine the affinities of various starches for a drug molecule, and the affinity of each of the starch fractions, amylose and amylopectin, for the drug. Dry starch adsorption of fatty acids and fatty alcohols from their methanol solutions was also investigated.

Reviews on starch chemistry (2, 3) show that it is now established that starch is a polymolecular system containing two components, amylose and amylopectin. The former is a linear polymer composed of α-D-glucopyranose residues linked by α-D-(1–4) glucosidic bonds. The latter, amylopectin, is the major component (75–85% in most starches) and consists of high molecular weight multibranched polysaccharide composed of α-D-glucopyranose residues linked by α-D-(1–4) glucosidic bonds. The chains normally contain 20–25 D-glucose residues and are interlinked to form a ramified or bush-like structure by means of α-D-(1–6) glucosidic linkages. Evidence regarding the manner in which the glucose units are combined in the two starch components has been obtained from methylation studies (4), from terminal group determination by periodate oxidation (5), and from hydrolysis studies (6). When a suspension of starch in cooled water is heated, the starch granules swell to several hundred times in original volume forming a viscous sol or paste. The swelling occurs at a specific temperature after which the granules undergo a complete rupture. Thus, a starch paste or sol is a collodial system in which there are highly swollen granules, free molecules of the starch, two molecular components, and empty sacs (7). Starch sols are physically unstable and tend to become less soluble on standing. This phenomenon has been termed as "retrogradation" and explained to be caused by aggregation of amylose molecules. Amylose stable form is suggested to be an α-helix (8); in retrogradation aggregates of the α-helical molecules are formed. The properties and behavior of amylose chains have been subjected to extensive investigations (9, 10). The rates of retrogradation in a given starch sol depend on the amylose percentage in the starch, on the size of the amylose molecule, and on the method in which the starch sol is prepared (11). The occurrence of amylopectin aggregates is improbable, since it was shown that amylopectin is physically stable in aqueous solutions (12).

EXPERIMENTAL

Materials—Three amylose starches, designated as amylose-A,[1] amylose-B,[2] and amylose-C,[3] are starches containing varying amounts of amylose (National Starch and Chemical Corp., Chicago). All other starches were commercially available from different sources, potato starch (Mallinckrodt Chemical), corn starch (Argo), arrowroot and rice (S. B. Penick and Co.), pure amylose, and amylopectin (amylose-free) (Calbio Chem. Co.). All other chemicals used were commercially available and of reagent grade.

Procedures—Determinations of the "Weight Average" Molecular Weights of the Starches—Light scattering measurements were applied on dilute solutions of the starches in 0.5 *M* potassium hydroxide solution. The starch solutions were prepared by stirring the starches or starch fractions in the potassium hydroxide solution while nitrogen is bubbled through the system. The turbidities of the solutions (τ) were measured indirectly by measuring the transmitted light at 430 mμ on a Beckman DU spectrophotometer and a Cary 15 recording spectrophotometer, using 1-cm. cells. The turbidity is defined by Debye (13) as the fractional decrease in the transmitted light intensity:

$$I/I_o = e^{-\tau L} \qquad \text{(Eq. 1)}$$

where I_o = the intensity of the incident beam, I = the intensity of the transmitted beam, τ = the turbidity in cm.$^{-1}$, L = the length of the scattering medium (1 cm. in this case).

The following equation was used for molecular weight determinations taken from the theoretical treatment given by Debye.

$$\tau = H \cdot M_w \cdot C \qquad \text{(Eq. 2)}$$

where τ = turbidity, cm.$^{-1}$, M_w = molecular weight

of the solute, C = the concentration of the solute in Gm./cm.^{3}, H = a constant given by the following equation:

$$H = (32\pi^3/3)\,(\gamma^2 \cdot n_o^2/\lambda^4 N) \qquad \text{(Eq. 3)}$$

where γ = the refractive increment which can be considered constant if the dilution is sufficiently great, n_o = the refractive index of the solvent, N = Avogadro's number, λ = the wavelength of light.

Equation 2 is corrected to show the effect of solvent–polymer interaction and is finally written:

$$HC/\tau = \frac{1}{M_w} + 2BC \qquad \text{(Eq. 4)}$$

where B = a constant which depends on the degree of solvent–polymer interaction.

Using Eq. 3 the values of the constant H for three different starches were calculated and averaged into one constant to be used in the study. The only unknown is the refractive index increment γ. A sample determination of that value is shown in Fig. 1. The slope of the line was calculated by the least-squares method to give the value $\gamma = 0.1141$.

The average value of H was calculated to give $H = 3.71 \times 10^{-6}$. This value was used for all subsequent calculations, using Eq. 4. The values HC/τ are plotted against C (Figs. 2–4). The least-squares method was used to calculate the intercepts $(1/M_w)$.

Fractionation of Potato Starch to Obtain Crystalline Amylose—The method based on complexing amylose with *n*-butanol was followed in this work. A starch sol was prepared by autoclaving, as described later in the complexing study. The sol was saturated with *n*-butanol after it was removed from the autoclave. The mixture was stirred while placed in the hood until it was cooled to room temperature. The precipitate of "amylose–butanol" complex was isolated by centrifuging at 7,000 r.p.m. for 20 min. This precipitate was stirred in 500 ml. of *n*-butanol saturated water and recentrifuged as before, the precipitate was resuspended several times in distilled water and centrifuged at 10,000 r.p.m. as recommended for the removal of *n*-butanol from the complex. The amylose, thus obtained, was dried and used for preparation of amylose sols for the complexing study. Although some residual *n*-butanol was left in the amylose crystalline powder, the bubbling of nitrogen through the sols during their preparation was one of the procedures recommended for the removal of the residual *n*-butanol (14).

Complexation in Aqueous Solutions—The starch sols were prepared by autoclaving as described in a previous work (1). The required amount of starch or starch fraction to make 500 ml. of the sol was accurately weighed into a 125-ml. beaker, smoothed into a slurry with distilled water, then poured all at once into a liter beaker containing 400-ml. boiling water. The gelatinized paste was stirred and transferred to an autoclave to be heated at the pressure of 20 p.s.i. for 3 hr. The resulting sol was then stirred until cooled and distilled water added to obtain 500 ml. of the sol.

Excess quantities of the drug were added to various starch sols of different concentrations in stoppered bottles. The bottles were agitated in a constant temperature water bath at 30° until the system reached equilibrium (24–48 hr.). Aliquots of 2–3 ml. were removed from each bottle using 10-ml. hypodermic syringes kept at 30° temperature. The aliquots were filtered through a Swinny filter adapter placed on the tip of the syringe. The adapter was equipped with S&S filter paper. The filtrates were placed in tubes kept in the 30° water bath. The filtered solutions were left 20 min. in the bath. Aliquots of these were removed using pipets kept at 30° temperatures and appropriately diluted for spectrophotometric analysis. Dilution factors varied from 1:100 to 1:1000 depending on the solubility and the molar absorbancy of the drug tested. The wavelengths of maximum absorbance were determined on a Cary 15 recording spectrophotometer. Each drug showed the same wavelength of maximum absorbance in water and in the presence of starch solution. Readings of absorbance were made using proper dilution of a starch sol (without the drug) as a blank in the reference cell.

Determination of the Adsorption of Long Chain Fatty Acids and Fatty Alcohols on Dry Unruptured Potato Starch Granules—Solutions of the fatty materials were prepared in two different solvents, methanol and petroleum ether. All solutions had the same concentration (15 Gm./L.), since it was shown that adsorption of fatty acids on potato starch follows a typical Freundlich isotherm (15). Fifty grams of potato starch was placed in a bottle, 100 ml. of the fatty material solution was added. The bottles were tightly stoppered and agitated in a water bath at 30° for 24 hr. All samples were filtered and the filtrates were tested for the excess of fatty acid or fatty alcohol in solution. The starch collected on the filter papers was washed with 25 ml. of petroleum ether three times. The washed starches were transferred into clean beakers and hydrolyzed with 500 ml. of 1 *N* hydrochloric acid while heated on a steam bath and stirred slowly. A blank sample of potato starch was hydrolyzed in a similar manner. Two hours of hydrolysis showed a complete disappearance of the iodine reaction in the mixture. The mixtures were cooled and placed overnight in the refrigerator. The cold

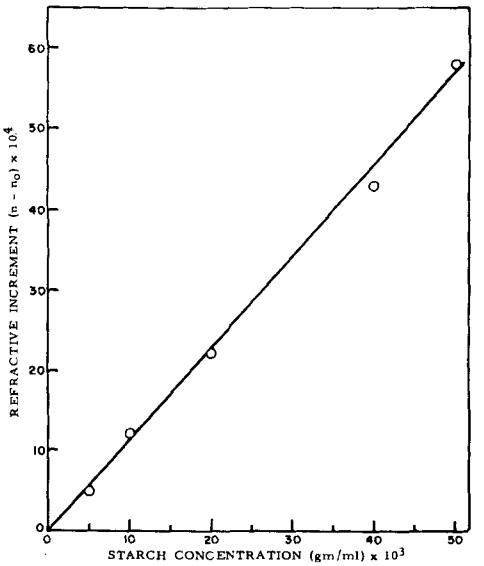

Fig. 1—Refractive index increments of potato starch solutions in 0.5 M KOH.

mixtures were than filtered through a fluted filter paper, and the beakers and the filters were repeatedly washed until the filtrates were free of hydrochloric acid as shown with methyl orange T.S. The inside and the lip of the beakers were scrubbed with small pieces of damp filter paper to pick up adherent fatty materials, and these pieces were placed in the fluted filter of each beaker. The papers were allowed to dry overnight and then were extracted in a Soxhlet extractor with petroleum ether. The solvent was removed and the amount of the fatty material was determined by weighing the dry flask containing the extracted fatty material.

RESULTS

Molecular Weight Determination—Figure 1 shows a sample determination of the refractive index increment for a series of dilute potato starch solutions. The constant γ is the slope of the line of $(n - n_o)$ *versus* (C) where n_o is the refractive index of the solvent (0.5 M KOH), n is the refractive index of the solution using light source of 430-mμ wavelength, and C is the concentration of the starch solution.

Figures 2–4 are those of HC/τ plotted against C as given by Debye (Eq. 4). The least-squares method was used to calculate the intercepts $(1/M_w)$, and Table I shows the values of the molecular weights obtained.

Complexation in aqueous solutions—Figures 5–7 represent the solubility behavior of benzoic acid, *p*-hydroxybenzoic acid, and sorbic acid in the presence of various concentrations of the starches in aqueous solutions at 30°. Figures 8 and 9 represent the solubility behavior of a number of organic molecules in the presence of potato starch aqueous solutions at 30°. Figure 10 shows the same plots on Figs. 8 and 9 plotted on the same ordinate scale to compare the slopes.

Table II shows the unruptured starch granules adsorption of fatty acids and fatty alcohols. Figure 11 shows the amounts of fatty materials adsorbed per 1 Gm. of potato starch plotted against the number of carbons of the fatty chain.

DISCUSSION

Using the light scattering method "weight average" molecular weights of the various starches were obtained. These molecular weights count the various molecules in the polymolecular starch system according to their masses. Each of the starch fractions, amylose and amylopectin, is known to be a polymolecular system consisting of a number of subfractions (16). Thus, the molecular weight of a given starch as obtained in this work can be considered a mean value which accounts for all the polymolecular components of that starch according to their respective masses. The amyloses showed the lowest molecular weights, and amylopectin the highest. As the rest of the starches are heterogeneous systems, the molecular weight values varied according to the starch content of low molecular weight amylose and according to the sizes of the amylose and amylopectin fraction. In each starch the two polymer fractions (and even their subfractions) contributed to the value of (M_w) according to their percentage and weight distribution.

Cetyl alcohol	2.01	...

The solubility method for determining interactions between starch and the selected drugs indicated complex formation evidenced by an increase of the solubility of the drug with the increase of a given starch concentration. The phase diagrams of benzoic acid, *p*-hydroxybenzoic acid, and sorbic acid in the presence of various starches and starch fractions can be explained briefly by (*a*) pure amylopectin showed little or no interaction with the three drugs. (*b*) The various starches showed complexation represented by a linear increase of the solubility of the drug with the increase of a given starch concentration up to a certain limit where no more drug could be detected in the solution. The limit can be called the saturation concentration of the complex (C_S), at which the turbidity of the

solution was notably increased and the "starch-drug" complex precipitated out of the solution. (*c*) Amylose sols showed a high uptake of the complexing drug into solution. In sols containing more than 20 Gm./L. of amylose a cake-like product precipitated out of the solution. This precipitate was successfully centrifuged at 7,000 r.p.m. A similar precipitation occurred in potato starch when the complexing drug was *p*-nitrophenol or *p*-aminobenzoic acid (Fig. 9).

It can be said in summary that when the same solid drug was added to the solutions of the various starches (each being a polymolecular system of its own), the amounts of the drug that entered the solution before precipitating the complex were dependent on the type of the starch. These amounts can be calculated by subtracting the amount of drug in water at 30° (C_o) from the total drug in the system at the plateau region (C_s). It must be noted that these values (C_s-C_o) for the same drug decreased with the increase of the "weight average" molecular weight of the starch.

These values varied from one starch to the other for the same complexing drug. The lower the average molecular weight of the starch the greater the amount of the complexing drug needed to reach the plateau region. Such a relationship can only be explained when one understands that the lower the molecular weight of a starch the richer the starch in amylose, thus the precipitation of an amylose complex from the system at the plateau region is influenced by the average molecular weight of the starch which can be considered related to the amylose content of the starch. (*d*) Finally, one can recognize that the low molecular weight polymer, amylose, is the main complexing component of starch with the drug. The amylose tendency to crystallize in a complex form with the drugs tested is noted to be far stronger than that of amylopectin.

The complexing of potato starch sols with selected molecules occurs with wide variance as seen in Figs. 8–10. It appears at first that the tendency of drugs to complex with the starch matches their solubility, *i.e.*, the higher the solubility of a drug the higher its tendency to complex; however, arranging the tendencies for complexing, as given by the slopes of the lines on Fig. 10, in a decreasing order shows that those tendencies do not match the solubilities in water (Table III). The effect of groups, like nitro or amino, in increasing the tendency to complex is noted. For example, the water solubility of *p*-aminobenzoic acid is higher than that of *o*-nitrobenzoic acid but the latter has a higher tendency to complex with starch than the former.

TABLE III—SOLUBILITY RELATIVE TO COMPLEXING TENDENCY OF DRUG MOLECULES

Decreasing Order of Solubility in Water	Decreasing Order of Tendency to Complex[a]
I	I
II	III
III	V
IV	II
V	IV
VI	VII
VII	VI
VIII	VIII

[a] I = *p*-nitrophenol, II = *p*-aminobenzoic acid, III = *o*-nitrobenzoic acid, IV = benzoic acid, V = *m*-nitrobenzoic acid, VI = methyl-*p*-hydroxybenzoate, VII = *o*-nitrophenol, VIII = *m*-nitroaniline.

Correlations of the complexes reported in this work with those of "amylose-alcohols" used for the fractionation of starch and "amylose-iodine" can be made after extensive X-ray studies as reported in the cases of "amylose-fatty acids" complexes (19). A general similarity is noted in the behavior of the complexes reported in this work with those of "alcohols-amylose," and those reported by Whistler (20) that are obtained with nitrobenzene, pyridine, 2-heptanone, and many other water soluble compounds possessing groups capable of hydrogen bonding and used for the fractionation of starch. Such similarity in the complexing behavior makes one assume that the complexing takes the same route and mechanism as that of "starch-iodine" and "starch *n*-butanol" complexes, which are explained to be consisting of an entrapment of the "guest" molecule in the α-helical structure of amylose with a supplementary stabilization by dipole–dipole interactions (21).

The adsorption affinity of starch is demonstrated in the case of the unruptured starch granules interacting with fatty acids and fatty alcohols. The affinity was decreased with the increase of the hydrophobic chain of the fatty material. Starch affinity for a given fatty material in methanol solution was higher than its affinity for the same material in a petroleum ether solution of the same concentration. This cannot be explained easily. One must notice that the starch used contained 10–12% water. It is conceivable that the fatty acid can be carried into the granule polymers by an exchange process between the water content and the organic solvent; thus, the polarity of the solvent proved to be of value.

It is important to appreciate that the understanding of the many applications of a fundamental phenomenon, like starch complexation can help the pharmaceutial compounder to predict any unfavorable incompatibilities. A drug complexed with starch might differ from the free drug with respect to solubility, diffusivity, partition coefficient, and ability to penetrate biological membranes. A drug pharmacological effectiveness might be altered if the drug is bound in such a complex; when the complex dissociates by the hydrolysis of the macromolecular polysaccharide at some stage in the body, the drug can then be available for its usual absorption and effect. In this respect the availability of a drug for external therapeutic treatment and its effectiveness should be investigated when the drug is included in a starch paste, sol, or any base containing polysaccharides in general.

With the fundamental understanding of the high affinity of starch for molecules varying from phenols and alcohols to weak carboxylic acids, the pharmaceutical compounder should investigate the effects of the complexation of the various drugs introduced in very small quantities in a tablet containing starch, especially when starch paste or polysaccharide excipients increase the magnitude of the complexation in the wet granulation technique. In general, the possible interactions between starch and many organic molecules found in small concentration dosage forms where starch is used as a pharmaceutical adjunct, must be considered carefully. The complexation of the starch with a preservative like benzoic acid, for example, is expected to decrease its preservative activity.

Finally, drug complexation with starch can be a useful method of retarding absorption of a very irritant drug that might complex with starch and thereby reduce its toxicity. Starch has been used in this sense as an antidote for iodine poisoning. In a similar manner, the starch complexing affinity could explain the possible binding to bacterial excretion products in certain dermatitis conditions, thus providing the rationale of the wide use of starch as anti-irritant in dusting powders.

As the precipitation and isolation of "amylose-drug" complex is possible, a highly important question about the stability of a drug enclosed in such a complex form should not remain long unanswered. The nature of these complexes appear to suggest their possible use in a sustained dosage form, since the release of the drug from the complex is possibly caused by the enzymatic hydrolysis of the macromolecule.

SUMMARY AND CONCLUSION

Amylopectin (amylose-free) was found to have very little interaction for benzoic acid, *p*-hydroxybenzoic acid, and sorbic acid, while amylose was found to produce complexes rapidly. Potato starch, arrowroot starch, corn starch, rice starch, and a number of commercial starches rich in amylose were all found to complex with the three drugs tested. A number of selected pharmaceuticals showed interaction with potato starch sols, and in many cases, depending on the solubility of the pharmaceutical, the complex precipitated off the solution after reaching a saturation concentration.

Unruptured potato starch granules were found to adsorb fatty acids and fatty alcohols from methanol or petroleum ether solutions.

A correlation of the appearance and behavior of these complexes with those of "amylose-alcohols" used for the fractionation of starch, and with those of "amylose-iodine" reported in the literature, make one assume that the drug-starch complexing takes the same route and may be the same mechanism as that of "starch-iodine" and "starch-alcohols" complexes.

Kinetics and Mechanism of Degradation of Echothiophate Iodide in Aqueous Solution

By ANWAR HUSSAIN, P. SCHURMAN, V. PETER, and G. MILOSOVICH

The degradation of echothiophate iodide was found to occur by two different mechanisms depending on the pH of the solution. In alkaline media (pH range 9.5–12), the major reaction was S-P bond cleavage to yield (2-mercaptoethyl)trimethylammonium iodide. This reaction was found to be first order with respect to the concentration of the compound and first order with respect to hydroxyl ion concentration. In weakly acidic media (pH range 2.4–5), the loss of 1 mole of ethanol through C—O bond cleavage was the predominant reaction. The rate of this reaction was also found to be first order with respect to the concentration of echothiophate iodide. The reaction rate constants and the energies of activation were determined for the two reactions and the degradation products were isolated and characterized.

ALTHOUGH ECHOTHIOPHATE IODIDE (I), a potent long-acting cholinesterase inhibitor, has been recognized in the USP (1) to be unstable in aqueous solution, the chemical degradation of the compound has not been thoroughly investigated. However, it is known that I

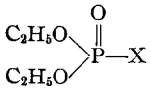
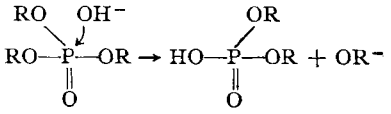
hydrolyzes quantitatively in alkaline media to (2-mercaptoethyl)trimethylammonium iodide and diethylphosphoric acid (1, 2).

Most of the past studies on the degradation of organophosphorus compounds related to I have dealt with the effect of substituents on their alkaline rates of hydrolysis (2, 3). Heath (3) found that the rate of alkaline hydrolysis of the X group from compounds of the type $RR'P(O)X$, where R and R' are alkoxy or alkylamine groups and X is an acidic group, is influenced greatly by the nature of the X group. Thus, the second-order rate constant for the hydrolysis of

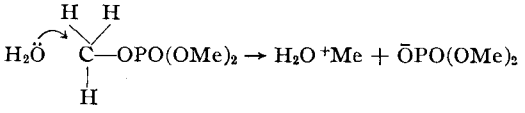


where X is OC_2H_5 is 4.86×10^{-2} M^{-1} min.$^{-1}$ at 25° compared to 81 M^{-1} min.$^{-1}$ where X is $S—C_2H_4S—C_2H_5$.

Trialkylphosphoric acid esters, however, have been thoroughly investigated by many workers (4–6). Barnard *et al.* (4) stated that in a trisubstituted phosphate ester, in which both carbon and phosphorus centers are subject to attack, hydroxide and water will tend to be selective for phosphorus and carbon, respectively. From their isotope experiments using water enriched in oxygen-18, they concluded that trimethylphosphate undergoes hydrolysis in alkaline medium with phosphorus-oxygen fission. There action was postulated as a simple nucleophilic displacement at the phosphorus atom:



In neutral and acidic media, however, the hydrolysis proceeded with carbon-oxygen bond fission. Since the reaction rate in water was not significantly changed by the presence of up to 3 M perchloric acid, it was presumed by these authors that this reaction proceeded *via* an S_{N2}-type displacement on carbon with water as the attacking species:



On the basis of the above information and the structure of (I), with both phosphorus and carbon centers open to attack, similar reactions may be anticipated, as shown in the following scheme. It was the primary purpose of this investigation to determine the mechanism of degradation of echothiophate iodide in neutral and weakly acidic media. A further objective was the determination of reaction rate constants and activation energies over a wide pH range.

RESULTS AND DISCUSSION

Order and Nature of the Degradative Steps—The results of this study indicated that in aqueous buffered solutions, the degradation of echothiophate iodide was first order with respect to the compound over a broad pH and temperature range.

In alkaline media, above pH 9, the reaction was followed measuring (2-mercaptoethyl)trimethylammonium iodide (II) formation by iodometric and spectrophotometric determinations, and by measuring consumption of hydroxyl ion on a pH stat. These results are shown in Figs. 1–3. As expected, from the ionic character of the reactant species (Scheme I), a negative primary salt effect was observed in the alkaline pH range. This is evident in Fig. 4, where the logarithm of the observed pseudo first-order rate constant, k_1 [OH^-], determined at pH 11.5, was plotted against the

square root of ionic strength according to the Brönsted-Bjerum equation. Since this relationship was derived on the assumption of low ionic strength, the experimental values deviate rapidly from linearity. The initial slope, however, has a value of 0.9, close to the theoretically predicted value of 0.98 for sodium chloride. Since the rate of degradation at these hydroxyl ion concentrations was not influenced by changes in concentration or species of buffer, as shown in Figs. 5 and 8, the hydrolysis appears to be a specific hydroxide ion catalyzed reaction.

In acidic media, pH range 2.4–4.6, there was no detectable free thiol in degraded echothiophate iodide solutions, although solutions of thiol alone are stable under these conditions (less than 1% lost in 24 hr. at 70°). It was found, however, that in this pH range 1 mole of ethanol was formed for every

mole of I lost. Furthermore, the rate of loss of I from solution and the rate of appearance of ethanol were essentially the same. As shown in Fig. 6, the residual concentrations of I obtained by direct analysis are the same as those calculated from the concentrations of ethanol liberated. It is evident that for all practical purposes the reaction involving ethanol formation was responsible for the entire observed loss of I.

A slight influence of buffer concentration on the rate of ethanol formation determined at different hydroxyl ion concentration is seen in Fig. 7. At pH's below 5, the buffer effect was minimal. Since the rate constants were determined at low buffer concentration below pH 5, the contribution of buffer to the overall degradation was insignificant.

Thus, it appeared on the basis of these results that echothiophate iodide degrades in aqueous solution by at least two different mechanisms, depending upon the pH.

Variation of Reaction Rate Constants with pH—The pseudo first-order rate constants for formation of thiol and ethanol are shown as a function of pH in Fig. 8. These rate constants were determined directly from first-order concentration–time plots at pH's greater than 9 for thiol formation and pH's less than 5 for ethanol formation. It is seen from Fig. 8 that the plot has a zero slope at low pH and slope of unity at high pH.

In the intermediate pH range of 5–9, where both reactions contribute to the overall degradation, the individual rate constants were calculated from the overall rate of degradation of (I) and the final concentration of ethanol.

A rate equation for loss of I, based on Scheme I and Fig. 8, can be written:

$$-\frac{d[I]}{dt} = k_1[I]\,[OH^-] + k_2[I] = k_{obs.}[I] \quad \text{(Eq. 1)}$$

and

$$k_{obs.} = k_1[OH^-] + k_2$$

where [I] is the concentration of echothiophate iodide, k_1 is the rate constant for formation of thiol

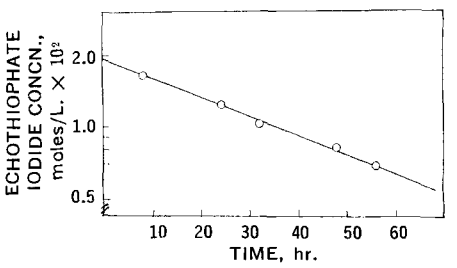

Fig. 9—Plot showing the disappearance of echothiophate iodide as a function of time at pH 6.3 and 60°.

TABLE I—FINAL CONCENTRATION OF ETHANOL AS A FUNCTION OF pH AT 60°, $[I]_o = 2.4 \times 10^{-2}$ *M*

pH	Ethanol Concentration × 10²
2.4	2.4
4.6	2.4
6.3	1.2
8.1	0.24
9.5	0.0

(II), k_2 is the rate constant for formation of ethanol and $k_{obs.}$ is the observed rate constant for loss of echothiophate iodide.

Since pH was maintained constant during an experiment, Eq. 1 can be integrated to give,

$$\log [I]_t = \log [I]_o - \frac{(k_1[OH^-] + k_2)t}{2.303} \quad \text{(Eq. 2)}$$

It can be shown (7) that for the case $[E_o] = 0$ at $t = 0$, the formation of ethanol with time may be described by,

$$[E]_t = \frac{k_2[I]_o}{(k_1[OH^-] + k_2)}\,(1 - e^{-(k_1[OH^-] + k_2)t}) \quad \text{(Eq. 3)}$$

where $[E]_t$ is the concentration of ethanol at time t. At $t = \infty$ Eq. 3 becomes,

$$[E]_\infty = \frac{k_2[I]_o}{(k_1[OH^-] + k_2)} \quad \text{(Eq. 4)}$$

$(k_1\,[OH^-] + k_2)$ can be obtained from the slope of log $[I]_t$ *versus* t plots, Fig. 9, according to Eq. 2. Since $[I]_o$ is known, and $[E]_\infty$ can be measured after $[I]_t = 0$, $k_1\,[OH^-]$ and k_2[1] can be calculated for the intermediate pH range.

According to Eq. 4, the final concentration of ethanol will be a function of pH. At high pH, k_1 $[OH^-]$ is large compared to k_2 and $[E]_\infty$ is very small, while at low pH, k_1 $[OH^-]$ is small compared to k_2 and $[E]_\infty$ approaches $[I]_o$. This is shown in Table I.

In the above scheme and equations, it was assumed that ethanol production was due solely to direct hydrolysis of echothiophate iodide as caused by Reaction 2, and the formation of ethanol from diethylphosphoric acid (III) was negligible. This assumption seems entirely valid in view of the much slower rate of hydrolysis of dialkylphosphates under these conditions (8, 9).

Both the USP assay method and the method used in this study for echothiophate iodide are based upon alkaline hydrolysis followed by iodometric determination of the liberated thiol. Although one might

[1] k_2 at pH 6.3 was determined by extrapolation of the data shown in Fig. 8 to zero buffer concentration.

expect that the degradation product (IV) produced by Reaction 2 would behave similarly, it appears that IV is not readily hydrolyzed to thiol under these basic conditions, probably because the negative charge acquired in basic solution serves to hinder attack by the negatively charged hydroxyl ion. It is known, for example, that subsequent stages of alkaline hydrolysis of triethylphosphoric acid are extremely slow after the first ethanol group is cleaved (10).

Temperature Dependency—Since the hydrolysis reaction may proceed by either of the two pathways, Reactions 1 and 2, it was necessary to determine the temperature dependency for each. The effect of temperature on Reaction 1 was determined iodometrically at pH 10.85 and on a pH stat at pH 10.5, since at these pH's, Reaction 2 was negligible. Arrhenius-type plots of log k_1 OH^- *versus* $1/T$ were observed to give straight lines, as shown in Fig. 10. The apparent activation energy was calculated from the slopes and found to be 22 Kcal./mole with a standard error of 1 Kcal./mole. Since this apparent energy of activation includes the heat of ionization of water (approximately 12 Kcal./mole), the energy of activation for the hydroxyl reaction would be 10 Kcal./mole.

The effect of temperature on Reaction 2 was determined at pH 2.4 and pH 4.6, since at these pH's Reaction 1 was negligible. The results obtained are shown in Fig. 11 where the log k_2, the observed first-order rate constant, was plotted against $1/T$. The heat of activation calculated from the slope of these lines is 23 Kcal./mole. The activation energy of the hydrolysis of trimethylphosphate in neutral and acidic solution was found to be 22.7 Kcal./mole (4).

The observed overall first-order rate constants for the degradation of echothiophate iodide, calculated at 25°, are shown as a function of pH in Table II.

In Fig. 12, the observed overall first-order rate constant $k_{obs.}$ was plotted against the pH of the solution. The line was calculated from Eq. 1 using $k_1 = 59.7\ M^{-1}$ min.$^{-1}$ and $k_2 = 2.3 \times 10^{-6}$ min.$^{-1}$ determined at pH 12 and pH 2.4, respectively, and the points were experimentally determined.

Degradation Products in Acidic Media—The degradation products in solutions at pH 4.6 were identified as ethanol and the monoethylester (IV).

The ethanol was determined quantitatively by gas chromatography. The monoethylester (IV) was isolated as the sodium salt (Na IV), and found to possess no cholinesterase inhibitor properties (11). Thin-layer chromatographic analysis of (Na IV)

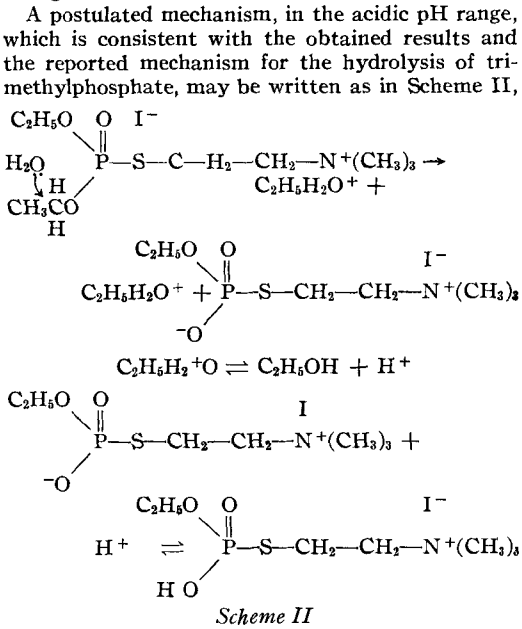
showed one spot with R_f value 0.7. The NMR spectra in D_2O was consistent with the structure of the monoethylester (12). Molecular weight determinations using perchloric acid as a titrant, according to the method described by Pifer *et al.* (13), gave a value of 377.3, corresponding to that of Na IV.

Elemental analysis of the sodium content corresponded to the theoretical value calculated for (Na IV) and the X-ray diffraction pattern showed no sodium iodide, indicating existence of Na IV, as such, in the solid state. A solution of Na IV was degraded at 121° in 3 *N* HCl, and the presence of free thiol (II) was detected by thin-layer chro matography.

Mechanism of Degradation in Weakly Acidic Media—The observed rate of formation of ethanol from echothiophate iodide was not influenced by changes in concentration of hydroxyl ion. The slight buffer catalysis observed was considered insignificant in the overall reaction.

The rate of hydrolysis of triethylphosphate (5) and trimethylphosphate (4) were also investigated in neutral and acidic media. The reported values for the observed first-order rate constants for formation of ethanol from triethylphosphate at 101° at pH 1.0 and 4.9 were 3.85×10^{-3} min.$^{-1}$ and 4.2×10^{-3} min.$^{-1}$, respectively. The observed first-order rate constants for formation of methanol from trimethylphosphate at 101° in water and in 3 *M* perchloric acid were reported to be 2.2×10^{-3} min.$^{-1}$ and 2.0×10^{-3} min.$^{-1}$, respectively. The observed first-order rate constant for the formation of ethanol from echothiophate iodide at pH 2.6 and 101° calculated by extrapolation from data shown in Fig. 11 was found to be 6.1×10^{-3} min.$^{-1}$.

A postulated mechanism, in the acidic pH range, which is consistent with the obtained results and the reported mechanism for the hydrolysis of trimethylphosphate, may be written as in Scheme II,



Scheme II

where the rate determining step would be the initial attack by H_2O on echothiophate iodide.

EXPERIMENTAL

Reagents and Apparatus—Echothiophate iodide (98% potency) and (2-mercaptoethyl)trimethylammonium iodide were obtained from the Research Department, Ayerst Laboratories, Division of Ayerst, McKenna and Harrison Ltd., Montreal.

Buffer, standard sodium hydroxide, iodine, and perchloric acid solutions were prepared using reagent grade materials.

Water used in the studies was prepared by distilling tap distilled water from an acidic permanganate solution.

The instruments used in this study were a Cary model 14 spectrophotometer, a pH stat, catalog No. S-30240, an Aerograph 204B gas chromatograph, and a Beckman pH meter.

Kinetic Procedures—The hydroxyl and hydrogen ion concentrations of the system were maintained by using buffer solutions or excess base. Buffer systems used in the study were: phosphate, pH's 2.4, 6.3, 10.8–11; acetate, pH 4.6; glycine, pH 8.1; borate, 9.5–10; and dilute NaOH (carbonate free) for pH's above 11.

The ionic strength of the solutions was adjusted to the desired value by the addition of sodium chloride. Most of the determinations were run at a total ionic strength of 0.5 unless otherwise specified.

Rate of Formation of (2-Mercaptoethyl)trimethylammonium Iodide—The rate of degradation of echothiophate iodide in alkaline pH range was determined by measuring the rate of formation of (2-mercaptoethyl)trimethylammonium iodide by three independent methods: iodometrically, spectrophotometrically, and on a pH stat.

When the reaction was followed iodometrically, solutions of 0.200 Gm. of the compound in 50 ml. of water and 50 ml. of 0.20 *M* buffer of the desired pH were equilibrated in separate flasks in a constant-temperature bath and then mixed. Periodically, 5-ml. samples (2 mg./ml.) were quickly discharged into a 50-ml. conical flask containing 5 ml. of 0.1 *M* phosphoric acid in order to quench the reaction. The thiol was then titrated with 1×10^{-3} *M* iodine solution under a blanket of nitrogen using starch as an indicator to obtain V_t (ml. of iodine solution at time t). A final titration was performed to obtain V_∞ (ml. of iodine solution at infinite time which corresponds to essentially complete hydrolysis).

Spectrophotometric determinations were made at 226 mμ. Although the ultraviolet absorption spectra of echothiophate iodine and its hydrolytic product, the thiol (pKa 7.6 determined spectrophotometrically), are practically identical in acid media (molar absorptivity values for echothiophate iodide and the thiol at pH 4.2 are 1.3×10^4 and 1.4×10^4 M^{-1} cm.$^{-1}$, respectively), the salt form of the thiol has sufficiently higher molar absorptivity that it can be differentiated in alkaline media (2×10^4 M^{-1} cm.$^{-1}$ at pH 9.1). A fresh 2.6×10^3 *M* solution of echothiophate iodide was prepared in water and a 0.1-ml. portion was transferred to a 1.0-cm. light path silica cell. Three milliliters of 0.1 *M* phosphate buffer of the desired pH was injected into the cell, and the change in absorbance at 226 mμ was followed in the Cary model 14 recording spectrophotometer. After the run was completed, the pH of the reaction mixture was determined to be unchanged.

The rate of the alkaline hydrolysis was also determined from data obtained on a pH stat. In 50 ml. of water 0.200 Gm. of the compound was dis-

solved and the consumption of hydroxyl ion, under nitrogen, was followed at constant temperatures and fixed pH. Not more than 1 ml. of 1.0 N sodium hydroxide was added totally to maintain the pH throughout the reaction.

The effect of buffer concentration upon the alkaline rate of hydrolysis was studied iodometrically at pH 10.85 using 0.1 and 0.2 M phosphate buffers and total ionic strength of 1.0.

The effect of ionic strength upon the rates of hydrolysis was studied in 3.5×10^{-3} N sodium hydroxide containing sodium chloride to give the desired ionic strength. The reaction was followed spectrophotometrically by adding the sodium hydroxide solutions to the echothiophate iodide as described above.

The effect of temperature on the rate of the alkaline hydrolysis was determined iodometrically at pH 10.85, 0.1 M phosphate buffer, and on a pH stat at pH 10.5 as described above.

Rate of Loss of Echothiophate Iodide and Rate of Formation of Ethanol—The degradation of echothiophate iodide below pH 9 was determined following the rate of loss of the compound and the rate of formation of ethanol.

Echothiophate iodide solutions, of concentration 2.4×10^{-2} M were prepared using phosphate, acetate, and glycine buffers of the desired pH and ionic strength of 0.5. The solutions were filled into hard glass ampuls and saturated with nitrogen before sealing. The ampuls were then placed in a constant-temperature bath which was maintained at the desired temperature ±0.05°. After allowing 15 min. for temperature equilibration, the 0-hr. samples were removed and further samples were withdrawn at time intervals suitable to the nature of the system. The reaction was quenched by immersion of the samples in ice water. The samples were then frozen till the end of each experiment.

The residual concentration of echothiophate iodide in the ampuls was determined using a modified USP method, in which potassium iodate as a titrant was replaced by standard iodine solution. A sample containing approximately 10 mg./ml. of echothiophate iodide was transferred into a conical flask. Two milliliters of 1.0 N sodium hydroxide was added, the flask was flushed with nitrogen, and stoppered. The solution was allowed to stand for 10 min. at room temperature. Two milliliters of 1 M phosphoric acid was then added, and the liberated thiol was titrated with 2×10^{-3} moles/L. standard iodine solution using starch as indicator. A residual blank titration for the thiol in solution was performed using the same procedure except the alkaline hydrolysis was omitted. The difference between the volume of iodine solution consumed in the two determinations is equivalent to the amount of thiol literated from the intact molecule. The concentration of echothiophate iodide can then be calculated as follows:

$$\text{moles/L. echothiophate iodide} = \frac{\text{ml. } I_2 \times 2 \times 10^{-3}}{\text{ml. sample size}}$$

The concentrations of ethanol in the ampuls were determined by gas chromatography using a 5-ft., 1/8-in. o.d. stainless steel column packed with 8% w/w didecylphthalate on 80/100 mesh Gas-chrom Z.

The following instrument parameters were used. Nitrogen carrier, 40 ml./min., column temperature 80°, sample size, 3 μl.

The amount of ethanol in the sample was determined by comparison with a standard aqueous ethanol solution.

The effect of buffer concentration on the rate of hydrolysis in the acidic pH range was determined at pH's 2.4, 6.3 phosphate and pH's 4.6 and 5.2 acetate, and ionic strength of 0.5.

The effect of temperature on the acid rate of hydrolysis was determined at elevated temperatures at pH's 2.4 and 4.6. Samples were also left at room temperature, pH 2.4, and the reaction was followed over a 1-year period.

Stability of (2-Mercaptoethyl)trimethylammonium Iodide—The stability of (2-mercaptoethyl)-trimethylammonium iodide was determined at 70° at pH's 2.4, 4.6, 6.3, and 8.1. Fresh 2.4×10^{-2} M solutions were stored in ampuls under nitrogen. The concentration of thiol was determined periodically by titrating with 2×10^{-3} M iodine to the blue starch end point.

Isolation and Characterization of Trimethyl (2-hydroxyethyl) Ammonium Iodide, S-ester with Phosphorothioic Acid, O-ether Ester (Na IV)—Three grams of echothiophate iodide was dissolved in 30 ml. of 1 M acetate buffer pH 4.6. The solution was transferred into a 50-ml. ampul and saturated with nitrogen before sealing. The ampul was kept for 4 days at 80° to ensure complete degradation. The solution was then transferred into a round-bottom flask and evaporated to dryness under vacuum at 80°. The solid residue was extracted with hot isopropanol (3 × 30 ml.), and the extracts were left at refrigerator temperature overnight. The separated crystalline compound had an m.p. 119°.

Thin-layer Chromatographic Analysis—Alcoholic solutions of (Na IV) and echothiophate iodide were prepared by dissolving 10 mg. in 1 ml. of methanol. Ten microliters of each solution was spotted directly on a chromatographic plate prepared with Silica Gel G. The plate was developed using a solvent mixture of two parts methanol, two parts water, and one part ammonium hydroxide. When placed in an iodine chamber, two spots were visible, one with R_f 0.7 corresponding to that of (Na IV), and the other of R_f 0.48 corresponding to echothiophate iodide. Twenty milligrams of (Na IV) was hydrolyzed with 3.0 N HCl at 121° and the hydrolytic product was identified using the above chromatographic procedure, as (2-mercaptoethyl)trimethylammonium iodide.

Sodium Analysis—The sodium content of the compound was determined by flame photometric analysis. Sodium calculated for $C_7H_{14}INO_3PSNa$, 6.1, found 6.2.

Resistance to Mild Alkaline Hydrolysis—To 20 mg. of (Na IV) in 3 ml. of water, 2 ml. of 1.0 N sodium hydroxide was added. No thiol was detected after 10 min. at room temperature as determined iodometrically with 2×10^{-3} M iodine solution.

SUMMARY

1. The overall degradation rate of echothiophate iodide in aqueous solution has been shown to be first order with respect to the compound over a wide pH and temperature range.

2. In alkaline media above pH 9, the main degradative pathway was the hydrolytic cleavage at

the sulfur–phosphorus bonds for form (2-mercaptoethyl) ammonium iodide. The rate of this reaction was found to be first order with respect to hydroxyl ion. The second-order rate constant at 25° was calculated to be 59.7 M^{-1} min.$^{-1}$. The apparent activation energy was determined to be 22 Kcal./mole with a standard error of 1 Kcal./mole. Since this energy of activation includes the heat of ionization of water, the energy of activation for the hydroxyl reaction would be 10 Kcal./mole.

3. Below pH 5 the main degradative route was the hydrolytic cleavage at the carbon oxygen bonds to form ethanol and trimethyl (2-hydroxylethyl) ammonium iodide, *S*-ester with phosphorothionic and *O*-ethyl ester. The rate of this reaction was not influenced by changes in concentration of hydroxyl ion but was increased slightly by increased buffer concentration. The attacking species were postulated to be a water molecule and the activation energy was determined to be 23 Kcal./mole.

4. The overall first-order rate constant for echothiophate iodide in aqueous solution was presented at 25° as a function of pH.

Inhibition of Acetylcholinesterase by Chelates III

By ERNEST MARIO* and SANFORD BOLTON†

Inhibition of acetylcholinesterase by 1–1 cupric chelates of 1,3-diaminopropanol-2 and 1,3-diaminopropane is analyzed in the pH range of 8.0–9.0. The terdentate chelate of 1,3-diaminopropanol-2 exhibits weak inhibitory activity at pH values below 8.5 and increased activity at pH values above 8.5. The bidentate chelate of 1,3-diaminopropane exerts significant inhibition at pH 8.0. The bidentate system exhibits essentially noncompetitive inhibition while the terdentate system appears to be essentially competitive. Increased inhibition at elevated pH in the terdentate system is further evidence that the chelate is interacting with an ionizing group(s) on the enzyme surface, as previously reported.

As PART of a continuing study to investigate metal chelate inhibition of the acetylcholinesterase–acetylcholine enzyme reaction system, copper chelates of 1,3-diaminopropanol-2 (AOH) and 1,3-diaminopropane (AH) were prepared. These two structurally similar ligands were chosen because (*a*) the cupric chelates of AOH and AH had been clearly elucidated in an earlier investigation (1) and (*b*) it was of interest to examine the comparative effects of the two ligands, one of which is capable of forming both a 1–1 and 2–1 and the other only a 1–1 chelate.

In the first papers of this series, Bolton (2, 3) described some of the problems which are incurred in a study of this type. Since the chelate solutions contain an equilibrium mixture of several species, it is necessary to monitor closely the absolute concentrations of free ligand, free metal, 1–1 chelate, and 2–1 chelate under specific experimental conditions to determine which specie(s) is responsible for enzyme inhibition. The information obtained from the first two papers in this series may be briefly summarized as follows: (*a*) metal chelates inhibit the acetylcholinesterase–acetylcholine interaction; (*b*) in general, free ligand does not inhibit the interaction; (*c*) cupric

ion alone is an inhibitor above concentrations of approximately $3 \times 10^{-5} M$ (the inhibitory effects of free metal ion may be eliminated if the chelate stability constant is large, or high pH values are used); (*d*) available coordination sites on the metal ion appear to be necessary prerequisites for inhibition; (*e*) overall chelate charge has a significant increasing effect on enzyme inhibition at elevated pH values; and (*f*) the 1–1[1] chelate species of Cu^{2+} appears to inhibit the enzyme system in a primarily "noncompetitive" manner.

The concentrations of individual species in an equilibrium mixture of ligand and metal under fixed conditions of concentration and pH may be calculated with a knowledge of the total metal, total ligand, chelate formation constants, ligand dissociation constants, and (H^+). The equations used to calculate the individual species in cupric chelate mixtures have been described (2). The values for free ligand (L) and free metal (M) can be solved from these equations by a method of successive approximations.[2] The values of (L) and (M) may then be used to calculate the concentrations of the chelate species present. In the case of the AOH-cupric interaction, a very strong 1–1 terdentate chelate is formed (1) with no discernible amount of 2–1 chelate species present. In the AH-cupric interaction, both a 1–1 bidentate chelate and a 2–1 tetradentate chelate are formed. The 1-1 AOH-Cu chelate carries a net (+1) charge while the 1–1 AH-Cu chelate carries a net (+2) charge. Thus, the two systems present an opportunity to compare the effects of metal coordination vacancies and overall chelate charge on enzyme inhibition.

EXPERIMENTAL

Reagents—AOH and AH (Aldrich Chemical Corp.) were obtained in the impure, free amine form. The di-HCl salts of these two ligands were prepared by dissolving the appropriate diamine species in excess concentrated hydrochloric acid (analytical reagent grade), flash evaporating to dryness and recrystallizing several times from methanol–ethanol mixtures (for AOH) and methanol–ethanol–water mixtures (for AH). Salt purity was checked by titration with standard base and the pKa values were compared to literature values, where available. Acetylcholine iodide and acetylcholinesterase (Nutritional Biochemicals Corp.) were used. Sodium chloride, magnesium chloride, and cupric nitrate, all analytical reagent grade, were also employed. The cupric nitrate solutions prepared were standardized according to the chelatometric titration method described by Wilson and Wilson (4) using murexide as an indicator. The diluent in all studies was prepared as previously reported (2).

[1] The 1–1 and 2–1 chelate species refer to (ligand–metal) and (ligand$_2$–metal) complexes, respectively.

[2] An IBM 7094 computer was used to solve the equations. The solution yielded values so that (MT) and (M) + (ML) + (ML_2) agreed to 10 decimal places.

Procedure—The experimental conditions and procedures were essentially the same as previously described (2). The values of V_0/V, (velocity with no inhibitor/velocity with inhibitor), and the values of $1/V$ were taken as the relative time necessary to consume 0.30 ml. of approximately 0.005 *N* base if the hydrolysis was linear as a function of time. The data were analyzed using the Michaelis-Menten theory of enzyme kinetics as extended by Friedenwald and Maengwyn-Davies to the case of a dissociable inhibitor (3, 8).

RESULTS AND DISCUSSION

Acid Dissociation and Chelate Stability Constants—The values of the constants required to determine the concentrations of species present in the chelate equilibrium mixtures are shown in Table I. Literature values are included where available.

Inhibition by Chelate Mixtures—Ligand-metal mixtures of different ratios[3] were used to inhibit the enzyme-substrate reaction at various pH values in the range of 8.0–9.0. The selection of pH values and chelate mixture ratios was governed by the desire to obtain one chelate species in predominance to all other species and the necessity of keeping the free metal concentration below approximately 3×10^{-5} *M* to prevent free metal initiated enzyme inhibition. Typical results of enzyme inhibition by solutions containing a 2.1–1 ligand–metal ratio of AOH-Cu at several pH values are shown in Table II. The concentration of 1–1 chelate is directly related to V_0/V. The choice of chelate mixture ratios with this system was not critical; the formation constant of the terdentate chelate attachment being very large, results in constant molar values for the 1–1 chelate species and extremely minute quantities of free metal. The values for V_0/V shown in Table II indicate a decrease in inhibition from pH 8.0 to pH 8.5 and then an increase in inhibition in the pH range of 8.5 to 9.0. Since the 1–1 chelate species formed has been shown to be stable up to pH 10, the increased inhibition cannot be due to chelate dissociation and may therefore be attributed to charge changes on the enzyme surface. The strong possibility exists that the pKa of the group(s) on the enzyme surface directly responsible for chelate attachment or proximal to the point of attachment has been reached in the pH range of 8.5–9.0. That the anionic site of the enzyme or some other negatively charged site is probably involved, was the hypothesis Bolton offered in the first paper of this series (2), and the data shown in Table II appears to support this proposed mechanism of inhibition.

The results of enzyme inhibition by several ligand-metal ratio solutions of AH–Cu^{2+} at pH 8.0 are shown in Fig. 1. The concentration of 1–1 chelate species is seen to be directly related to V_0/V. It was not possible to obtain meaningful data at pH values above 8.0 using the above-mentioned chelate mixture ratios. There was no apparent linear relationship between any of the species present and V_0/V. Some possible explanations for this behavior are: (*a*) the double plus charge in Cu^{2+} chelates of AH changes either the site or mechanism of binding on the enzyme surface and/or (*b*) the concentration of 1–1 chelate species was so small compared to 2–1 chelate species (at pH values above 8.0) that a

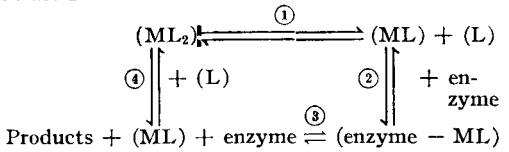
rate-determining equilibrium was achieved between the enzyme and the chelate solution according to Scheme I.



Scheme I

Analysis of Inhibition—The inhibition of acetylcholinesterase by the 1–1 cupric chelate of AOH at pH 8.5 was analyzed according to the methods suggested by Friedenwald and Maengwyn-Davies (8). The results of this study are tabulated in Table III and shown graphically in Fig. 2. The inhibition by the AOH chelate appeared to be essentially competitive at pH 8.5 with a small, noncompetitive component. This small noncompetitive component may in fact be the result of experimental error since the inhibitory properties of the 1–1 AO-Cu^+ chelate were relatively weak. The inhibition of acetylcholinesterase by the 1–1 cupric chelate of AH at pH 8.0 was analyzed by the same method, and the results of this study are tabulated in Table IV and shown graphically in Fig. 3. The inhibition by the 1-1 AH-Cu^{2+} chelate appeared to be essentially

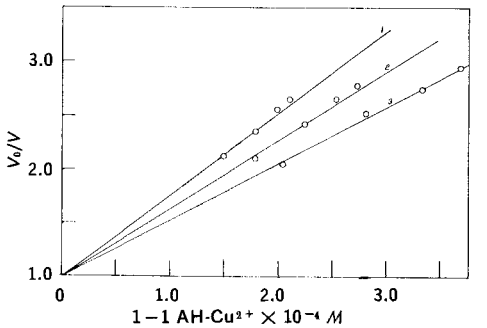


Fig. 1—Inhibition by 1–1 AH–Cu^{2+} chelate in several ligand–metal ratios at pH 8.0. Key: 1, ligand-metal ratio = 2.3–1; 2, ligand–metal ratio = 2.2–1; 3, ligand–metal ratio = 2.1–1.

pH 8.0 and 9.0, the inhibition of the enzyme system increased when the pH exceeded 8.5 (see Table II). Since there is only one available coordination vacancy in the terdentate 1–1 AOH chelate, the increased inhibition may be attributed to the net +1 charge on the chelate being attracted to some negatively charged site on the enzyme surface with a pKa value between 8.5 and 9.0. At pH values below 8.5 the inhibition was slight. This may be expected considering the assumption that metal coordination vacancies are necessary at low pH values for inhibition to occur (the 1–1 AOH chelate having only one available coordination site, access to which is spacially hindered by the strong terdentate attachment). The results of studies with the AH system lend support to this hypothesis. The 1–1 AH chelate has two coordination vacancies and

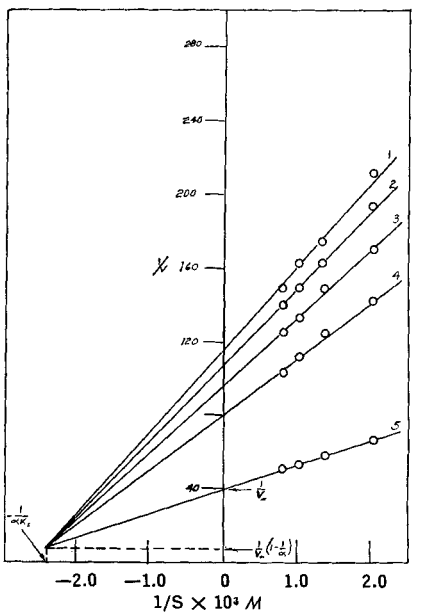

Fig. 3—Analysis of inhibition by 1–1 AH–Cu²⁺ chelate at pH 8.0 using 1/S values. Key: 1, (I) = 3.73 × 10⁻⁴ M; 2, (I) = 3.34 × 10⁻⁴ M; 3, (I) = 2.82 × 10⁻⁴ M; 4, (I) = 2.06 × 10⁻⁴ M; 5, (I) = 0.

is a stronger inhibitor than the 1–1 AOH chelate at pH 8.0 (see Fig. 1). At elevated pH values it was not possible to correlate inhibition with any individual species concentration present. This was of particular interest since the 1–1 AH chelate carries a net +2 charge and would probably be attracted to a negatively charged site on the enzyme surface more strongly than the single +1 charge of the AO–Cu⁺ chelate.

SUMMARY

Previous analyses of enzyme-chelate interactions have shown that 1–1 chelate species of ethylenediamine and glycine yield noncompetitive enzyme inhibition at pH 8.0 (see *Reference 3*). This study has shown that the 1–1 chelate species of AH also inhibits acetylcholinesterase in an essentially noncompetitive manner at pH 8.0. This was not unexpected since all of the above-mentioned chelate species are similar in that they have two metal coordination vacancies. The 1–1 chelate species of AOH was found to inhibit the enzyme weakly in an essentially competitive manner that may be attributed to the single, hindered, metal coordination vacancy present in the terdentate chelate attachment. At pH values above 8.5, the 1–1 chelate species of AOH exhibited stronger inhibitory properties. This can be explained on the basis of the predominance of a charge attraction between the chelate and the enzyme surface compared to a purely metal–enzyme attachment *via* the coordination vacancy. At pH values above 8.0, the 1-1 chelate species of AH was no longer linearly related to inhibition. Since this chelate carries a doubly positive net charge, the magnitude of any charge affinity between the chelate and a negatively charged

site on the enzyme surface would be large. If in fact, the mechanism of chelate–enzyme interaction changes from metal coordination attachment to charge attraction at elevated pH values, as the data would appear to indicate, it may be possible to identify the specific amino acid(s) responsible for the charge attraction from the estimated pKa. Further investigations are being contemplated to pursue these avenues.

Comparison of the Absorption and Excretion of Calcium from Precipitated Calcium Carbonate USP XVII and Egg Shells

By ARMEN H. MIRZAIAN and E. BLANCHE SOMMERS

Experiments were conducted to evaluate relative absorption and excretion of calcium from precipitated calcium carbonate USP and powdered egg shells (93.7 percent). Samples from 24-hr. specimens of urine and feces were collected after the fourth day of a repeated daily diet of the same food containing approximately 1 Gm. of calcium. The subjects were continued on the same regimen and samples were collected for 10 consecutive days from each person tested. The calcium content of the samples was determined by means of a flame photometer and a spectrophotometer. This procedure was repeated with addition of 2.5 Gm. of the official precipitated $CaCO_3$ and again with 2.6 Gm. of powdered egg shells to each daily diet. The calcium balance, that is, the difference between the quantity of calcium ingested and the total amount excreted, was positive for each type of experiment. When the diet was supplemented with the precipitated $CaCO_3$ and egg shells, calcium retention was increased 86.3 and 97.9 percent, respectively. Increased calcium absorption was reflected in increased urinary calcium. Egg shells compared favorably with the precipitated calcium carbonate as a source of absorbed calcium.

EXTENSIVE STUDIES have been concerned with nutritional standards for calcium. The National Research Council recommends a daily dietary allowance of 0.8 Gm. of calcium for an adult (1). Goodman and Gilman state that the average adult's daily requirement is about 10 mg./Kg. of body weight (2).

Calcium is the fifth most abundant element in the body, and the major fraction is in the bony structure (99%). It is present in small quantities in the extracellular fluid and to a minor extent in the structure and cytoplasm of cells of soft tissue. In the instance of hypocalcia, daily intake is frequently supplemented with a calcium salt. Wohl (3) prescribed the clinical use of calcium carbonate in preference to other calcium salts since it has a higher percentage of available calcium (40%).

The high calcium content of egg shells—*Gallus domesticus* Temminck (family, *Phasianidae*): calcium carbonate, 93.7%; magnesium carbonate, 1.3%; phosphorus pentoxide, 0.76%; and organic matter, 4.15% (4)—prompted investigation in regard to their value as a source of calcium. Limited studies of this nature have been done. However, they were primarily concerned with the palatability of foods containing powdered egg shells.

The studies presented here are concerned with comparison of calcium balances when the diet is

supplemented first with precipitated calcium carbonate USP XVII and then with egg shells containing an equivalent amount of calcium.

ABSORPTION AND EXCRETION OF CALCIUM

The problem of defining in a precise manner the relationship between the quantity of calcium ingested and that which is excreted in the stool in terms of absorption alone is exceedingly difficult, owing to the fact that calcium is not only absorbed from the gut lumen but secreted into the luminal contents as well. Therefore, the quantity of fecal calcium represents the net effects of the amounts ingested, absorbed, and secreted. Although considerable progress has been made in understanding some of these interrelations with the use of isotopes of calcium, much remains to be elucidated.

The urinary excretion of calcium appears to be the net effect of the quantity filtered and the amount reabsorbed. There is no evidence of renal tubular secretion of calcium. The mechanisms for the renal absorption of calcium are unknown (5).

According to Best and Taylor (6), the calcium of the feces amounts daily to from 0.4 to 0.8 Gm.; this, though a considerable amount is endogenous, is mainly the unabsorbable calcium of the food. About 150 mg. is excreted daily in the urine. An increase or decrease in the absorption of calcium is reflected in parallel changes in the urinary excretion. The urinary calcium constitutes, therefore, a convenient index of calcium absorption.

Krantz and Carr (7) state that about 30% of the calcium ingested by man is absorbed and that the remainder is excreted in the feces. The excess of the absorbed calcium is excreted in the urine, mainly as calcium phosphate. From 0.1 to 0.4 Gm. of calcium is excreted daily in the urine, dependent upon the dietary intake.

Grollman (8) reports that approximately 80% of ingested calcium is excreted in the feces. The remaining 20% of the ingested calcium in an individual, in calcium equilibrium, is excreted in the urine. With low and moderate levels of intake, 0.1–0.5 Gm. daily, approximately 30–50% is eliminated in the urine, while with high levels, 1 Gm. daily, approximately 25% is excreted. However, considerable deviations from these values occur, dependent upon variable dietary, metabolic, and gastrointestinal factors (8).

EXPERIMENTAL

Ten men ranging from 20 to 25 years of age served as the test subjects. All had normal renal function and no evidence of malabsorption.

Representative samples from pooled 24-hr. specimens of urine and of feces were obtained from each individual. This procedure was initiated after the fourth day of a repeated daily diet of the same food containing approximately 1 Gm. of calcium. The subjects were continued on the same regimen and samples were collected for 10 consecutive days thereafter. After intervals of 10 days, this procedure was repeated first with the addition of 2.5 Gm. of the official precipitated calcium carbonate and then with the addition of 2.6 Gm. of powdered egg shells to each daily diet. Preliminary studies indicated that pretreatment levels of excreted calcium were regained within 10 days after discontinuation of calcium therapy. Accordingly, a 10-day interval before the administration of each of the supplemented diets was allowed. Samples were refrigerated in tightly closed containers until they were assayed for calcium content.

The *Heinz Handbook of Nutrition* (9) was used in the selection of the basic unsupplemented diet which contained approximately 1 Gm. of calcium. Considerations other than calcium content were caloric content, balance of food elements, and food preferences of the 10 subjects. Food portions were weighed and each meal was prepared in the same manner by the same personnel.

This basic diet (Table I) was used for each of the 10 subjects in each of the three phases of the study. During the first phase of the study, it was administered without supplementation. In the second and the third phases of the study, it was supplemented with calcium carbonate and egg shells, respectively. The daily dose of each of these substances was administered in a portion of the milk consumed at breakfast. All of the 10 subjects first received the basic diet, then the calcium carbonate supplemented diet, and finally the egg shell supplemented diet.

A search of the literature concerned with experiments in regard to calcium balance did not reveal control of water intake. Accordingly, this study was not concerned with this aspect. However, total daily urine and feces for each subject were collected and tested for calcium content.

Egg shells used for the experiment were washed and their membranes were removed. The shells after being air dried were reduced to the consistency of the official calcium carbonate, and the powder thus obtained was thoroughly mixed. The official assay specified for calcium carbonate was used to determine the total calcium content of this powder

which proved to be 94.1% when calculated as calcium carbonate. The egg shell and calcium carbonate powders were stored in tightly closed containers.

Determination of Calcium—Even though various methods are available for the determination of calcium from organic sources, the assay of some of these compounds is difficult. Urine and feces present difficulties due to the presence of phosphates and coloring matter.

In this study, the determination of calcium in urine was first attempted according to the official direct EDTA titration method specified for calcium carbonate. Interfering phosphate ions of the urine were previously removed by elution of the samples through anion-exchange resin columns containing an exchanger with a high capacity for phosphates. Satisfactory end points could not be obtained so hydroxy naphthol blue, "Indicator of Choice," according to Butler *et al.* (10), was unsuccessfully substituted for the naphthol green screened murexide. Eriochrome black T was also tried as an indicator; however, due to the interference of the coloring matter of the urine, reliable end points were not obtainable.

Flame photometry proved to be a more rapid and accurate method for the determination of the calcium content of urine and feces. The samples were assayed by means of a Coleman model 21 flame photometer and a Coleman model 6D junior spectrophotometer according to the directions of the Coleman operating manual for urinary and fecal calcium (11). Results are shown in Table II.

The calcium retention that occurred when the diet was supplemented first with the official calcium carbonate and then with egg shells was compared with the calcium retention from the basic diet. Results are shown in Table III. The average daily

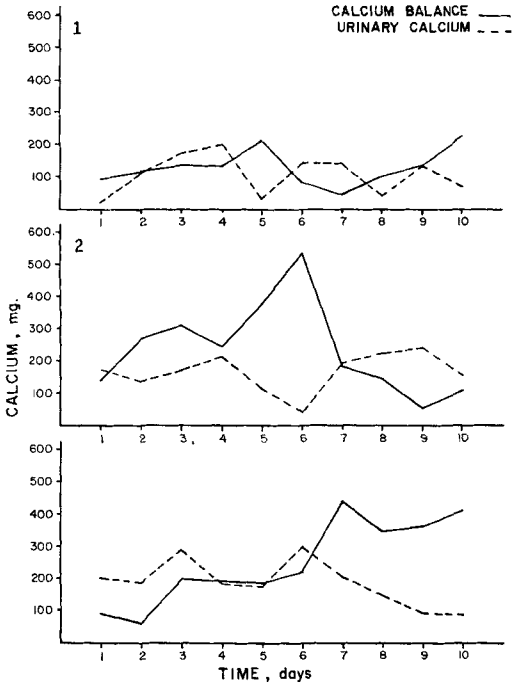

Fig. 1—Comparison of calcium balance with urinary calcium for each of 10 days. amounts of urinary calcium and daily calcium

balance for the 10 subjects studied are shown for the three types of experiments in Fig. 1.

DISCUSSION AND CONCLUSION

Calcium Balance—Based upon the limited number of subjects and the observed values, one cannot definitely say which source of calcium is superior. However, it is obvious that calcium from egg shells is assimilated to approximately the same extent as calcium from the official calcium carbonate. The use of egg shells as a source of dietary and therapeutic calcium warrants further investigation.

Absorption—According to Best and Taylor (6), urinary calcium constitutes a convenient index of calcium absorption. In agreement with their statement, calcium carbonate and egg shell supplemented diets, when compared to the unsupplemented diet, provide greater calcium content in excreted urine.

Some investigations, such as that of Briscoe and Ragan (12), indicate that increased calcium absorption occurs in the instance of increased calcium retention. Briscoe and Ragan also stated, "In studies of calcium balance, if maintained calcium balance is observed, it is assumed that the retained calcium is used for bone mineralization" (13).

Daily Comparison of Calcium Balance with Urinary Calcium—Since Best and Taylor consider urinary calcium a convenient index of calcium absorption (6), the purpose of this phase of the study was to determine if calcium excreted in the urine could also be used as an index of calcium balance.

The experiment concerned with the unsupplemented diet revealed that on days 4, 5, 6, 8, and 10 of the 10-day study increased calcium balances varied indirectly with urinary calcium values. In the instance of the calcium carbonate supplemented diet, this same relationship existed for 8 days of the 10-day period. The diet supplemented with egg shells, except for days 7, 9, and 10, demonstrated direct variation of calcium balance and urinary calcium. The daily calcium balance for this third type of experiment showed an irregular but overall continued increase of calcium balance during the 10-day period.

Little, if any, correlation can be derived for the three types of experiments in regard to the daily averages of calcium balances and calcium excreted in the urine. However, according to Table II, the averages for the total of each of the 10 days for the three types of experiments indicated that calcium balance does vary directly with urinary calcium. According to this study, the average urinary calcium value for a period of time can be used as an index for calcium balance. However, periodic 1-day urinary calcium values can be misleading as a clinically acceptable diagnostic index for calcium balance.

The validity of data obtained in human metabolism studies depends on the constancy of the regimen, an adequate number of subjects, and the length of time covered by the study. These studies were of short but of sufficient duration in order to substantiate the value of egg shells as a source of dietary and/or therapeutic calcium.

Determination of Phenaglycodol in Biologic Specimens by Ultraviolet Spectrophotometry

By JACK E. WALLACE

A rapid spectrophotometric method for the determination of phenaglycodol in body fluids and tissues is presented. Separation from other drugs is not required. The substituted glycol is oxidized by means of acid dichromate to a carbonyl derivative which has a high molar absorptivity in the ultraviolet region. The carbonyl product is converted to a semicarbazone which exhibits an even greater sensitivity to the absorption of ultraviolet radiations. The spectra of the phenaglycodol derivatives permit enough specificity for use of the procedure in forensic chemistry. The method is sufficiently sensitive for determination of phenaglycodol in urine 5 days after the ingestion of a single therapeutic dose. The distribution pattern of phenaglycodol in the rat and the nature of its excretion in man are presented.

PHENAGLYCODOL[1] (2-*p*-chlorophenyl-3-methyl-2, 3-butanediol) is claimed to have a distinct tranquilizing effect. Its calming and muscle relaxing properties are probably comparable to that of meprobamate (1, 2). The literature contains few methods for the analysis of this drug. Rose (3) described a technique for determining phenaglycodol by electrolytic cleavage of the glycol group to yield *p*-chloroacetophenone, which has a sensitive ultraviolet absorption spectrum. The procedure, however, is not applicable to determination of the drug in biologic specimens. Cima and Fassina (4) have published a method that utilizes both chromatographic and colorimetric techniques for determining phenaglycodol in urine. However, the method is applicable only to urine and the colorimetric assay, which utilizes a phosphomolybdic reagent, is subject to interference by many carbohydrates and polyphenols. Goldbaum (5) determined neutral drugs by gas chromatography, but his procedure does not provide positive identification nor does it afford routine application in the analysis of biologic specimens. In addition, no mention of phenaglycodol is made. In hexane, phenaglycodol absorbs radiation strongly at 222 mμ; therefore, small amounts of the drug in pure solution can be determined by spectrophotometric analysis (6). In biologic extracts, however, the ultraviolet spectral curve of the drug at 222 mμ is so affected by background absorption that direct analysis of unconverted drug, even in high concentrations, is not feasible. In addition, the solubility characteristics of this drug make difficult any procedure for obtaining it in an environment suitable for direct spectrophotometric assay. The need for a specific quantitative method for determining phenaglycodol in body fluids and tissues is apparent.

This report describes a rapid and specific method for the quantitative determination of phenaglycodol. Separation of phenaglycodol from other neutral drugs is not required. The method permits a reliable evaluation of the drug intake by patients receiving treatment with phenaglycodol.

EXPERIMENTAL

Instrumentation—A Beckman DK-2A ratio-recording spectrophotometer with linear presentation was used for the ultraviolet absorption measurements. A sample path length of 10 mm. was used throughout the study. Infrared functional group assignments were made with a Beckman IR 4 spectrophotometer.

Method—At any pH phenaglycodol is extracted from blood, urine, and tissues into most organic solvents. In this procedure 10 ml. of whole oxalated blood or serum or 10 Gm. of homogenized tissue is shaken vigorously for 3 to 5 min. with 100 ml. of chloroform. For urine, 10 ml. of specimen is refluxed for 10 min. with 1 ml. of concentrated hydrochloric acid prior to chloroform extraction. After the two phases have separated, the chloroform layer is removed and filtered through Whatman No. 41 or equivalent filter paper. The filtrate is subsequently washed with 10 ml. of 1 *N* sodium hydroxide solution and then with 10 ml. of 1 *N* hydrochloric acid solution. The volume of washed chloroform is recorded and the amount lost is considered in the final calculations. The chloroform is subsequently evaporated to dryness at 50° under vacuum. To the residue are added 20 ml. of 0.1 *N* potassium dichromate in 10 *N* sulfuric acid and 50 ml. of spectroquality hexane. The contents are refluxed for 30 min. with constant mechanical stirring, after which the hexane layer is cooled, separated, and read in a spectrophotometer against a hexane blank. When moderate or low levels of the drug are indicated, conversion of the reaction product to a semicarbazone derivative is desirable. This is accomplished by reacting 4–40 ml. of the hexane containing reaction product with 4 ml. of 0.5 *M* semicarbazide hydrochloride buffered to pH 3.5 with sodium acetate. The reaction is done conveniently at room temperature in a suitable size flask connected to a vacuum

rotary evaporator. Semicarbazone formation is complete when all the hexane has been removed. The remaining aqueous layer is read at 273 mμ against a 0.5 *M* semicarbazide blank.

The amount of phenaglycodol in the original sample is calculated from a standard curve prepared from aqueous solutions of the drug in appropriate concentrations, which have been carried through the procedure described, including the concentration technique for solutions containing small amounts of the drug.

RESULTS AND DISCUSSION

The ultraviolet absorption curve of the reaction product of phenaglycodol is well defined. It has an absorption maximum at 247 mμ in hexane and at 254 mμ in water. The unconverted drug absorbs maximally at 222 mμ. The high absorbance at 247 mμ for the reaction product and at 273 mμ for the semicarbazone of the product (Fig. 1), provides increased sensitivity and specificity over that of techniques which rely on direct spectrophotometric analysis of unconverted phenaglycodol. At 247 mμ a linear relationship exists between the absorbance of the reaction product and the concentration of the drug in the original sample. At 273 mμ a similar relationship exists for the semicarbazone of the product (Table I). Phenaglycodol extracted from urine of man and from tissues of animals that have received the drug yields reaction products that have identical ultraviolet absorption spectra to that obtained from the pure drug.

Infrared spectra of phenaglycodol (Fig. 2) and its reaction product (Fig. 3) show several distinct differences, of which the most significant is a band at 1692 cm.$^{-1}$ in the spectrum of the product. Absorption at this wavelength is entirely absent in the infrared spectrum of phenaglycodol. This band is believed to be the result of a carbonyl group formed by dichromate oxidation of the glycol group in the parent compound. The conversion of the

[a] Determined from semicarbazone of reaction product.

(Fig. 5) indicate that approximately 100% of the phenaglycodol is converted to *p*-chloroacetophenone.

Several drugs were investigated for interference with the determination of phenaglycodol. None produced a reaction product or semicarbazone which absorbed significantly throughout the range 220–360 mμ. The results of the study for interfering substances are presented in Table II. Standard alcoholic solutions of phenaglycodol were added to biologic material to provide concentrations from 0.50 to 5.0 mg. %. Ten milliliters of blood or hydrolyzed urine with added drug was then examined by the above method. Since phenaglycodol is predominantly conjugated in urine specimens (Table VII), hydrolysis provides a better appraisal of the method's ability to recover the drug from that specimen. Average recovery from blood was approximately 94% and from urine 96% (Table III).

To determine the tissue distribution pattern of the drug, rats were fed, *via* stomach tube, 104 mg. of phenaglycodol per kilogram of body weight. Blood and tissue levels after 3, 6, 12, and 24 hr. are shown in Table IV. Levels of the drug found in blood and tissues are given in decreasing order: liver, brain, kidney, muscle, and blood. Average distribution ratios for 15 rats are given in Table V.

Each of four adult human males who had fasted for 12 hr. received 800 mg. of phenaglycodol by mouth. Thereafter, phenaglycodol concentrations were determined in venous blood specimens drawn at predetermined intervals. The highest concentration of drug in the blood occurred 2–3 hr. after ingestion (Table VI). Phenaglycodol in the urine was predominantly excreted in the conjugated form (Table VII). Urine analysis without prior hydrolysis of the conjugated derivative indicates that less than 0.5% of the administered drug is eliminated unchanged in man during the first 120 hr. Five to 8% of the drug, however, was found in the urine during the first 24 hr. as the conjugated form. The concentration of conjugated drug measured in the urine over a 120-hr. period varied from one subject to another, but the total amount excreted in the urine by the four subjects was less variable: 178.6–275.5 mg. Cima and Fassina (4) found in their study with rabbits that in 4 days about 3% of the unchanged drug is excreted in the urine and an additional 31% is found as conjugated products, one of which they claim to be a glucuronide. Their report gives no tissue or blood levels of the drug.

The method described distinguishes between phenaglycodol and its conjugated metabolites, and affords the only available spectrophotometric analysis of the drug in blood and tissues. The sensitivity of the method permits the analyst to detect the drug in blood and urine after an individual has taken a therapeutic amount of the drug. The drug and its metabolites can be detected in the urine of adult humans for at least 5 days after the ingestion of a single 800-mg. dose.

Allenic Amines: A New Class of Nonhydrazine MAO Inhibitors

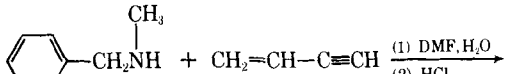
By R. P. HALLIDAY, C. S. DAVIS, J. P. HEOTIS, D. T. PALS, E. J. WATSON*, and R. K. BICKERTON

N-2,3-Butadienyl-*N*-methylbenzylamine HCl (U-1247) and *N*-2,3-butadienyl-*N*-methyl-*o*-chlorobenzylamine HCl (U-1379) have been synthesized and potent *in vivo* monoamine oxidase inhibition demonstrated. Antihypertensive activity comparable to that produced by pargyline was demonstrated in hypertensive rats with U-1247. When administered to mice, U-1247 and U-1379 produced initial stimulation of motor activity in contrast with pargyline which produced initial depression.

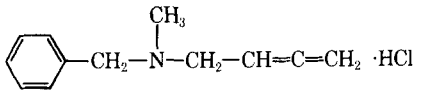
Swett *et al.* (1) in 1963 described the structural requirements necessary for monoamine oxidase inhibitory (MAOI) activity within the pargyline series. These workers indicated that a triple bond was essential for MAOI activity. It was the purpose of this study to synthesize and evaluate the activity of two allenic derivatives of pargyline which contained no triple bond.

N-2,3-Butadienyl-*N*-methylbenzylamine hydrochloride (U-1247) was prepared by a modification of the general method reported by Engelhardt (2). Engelhardt condensed water-soluble amines with vinylacetylene (I) in water to produce allenic amines. Since methylbenzylamine (II) is only slightly soluble in water, a mixture of *N*,*N*-dimethylformamide and water was used as the reaction solvent.

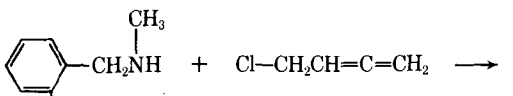
N - 2,3 - Butadienyl - *N* - methyl - *o* - chlorobenzylamine hydrochloride (U-1379) was prepared by the method of Vartanian and Badanian (3). *o*-Chloro-*N*-methylbenzylamine (II*a*) was alkylated with 4-chloro-1,2-butadiene (III) to give U-1379. U-1247 may be prepared by alkylation of *N*-methylbenzylamine (II) with III.



(II) (I)



U-1247



(II or II*a*) (III)

EXPERIMENTAL

N-2,3-Butadienyl-N-methylbenzylamine Hydrochloride (U-1247)—Into a 1-L. Parr bomb (capacity about 854 ml.) was placed a mixture of benzylmethylamine (121 Gm., 1.0 mole), 130 ml. of water, and 170 ml. of *N*,*N*-dimethylformamide. The homogeneous mixture was cooled by placing the bomb in a dry ice–acetone bath while nitrogen was bubbled through the mixture. After the mixture had cooled to −30°, vinylacetylene (52 Gm., 1.0 mole) was condensed into the bomb. The bomb was closed, pressurized to 150 p.s.i. with nitrogen, and heated to 70–98° for 20 hr. with shaking.

The bomb was allowed to cool for 1 day before venting and purging with nitrogen. The contents of the bomb were removed and steam distilled immediately. The steam distillate was transferred to a separator and extracted with two 1-L. portions of ether. The ethereal extracts were dried over anhydrous sodium sulfate and then concentrated under vacuum. The residue was distilled, b.p. 85–94°/2.0 mm., yield 21 Gm. (12%). The infrared spectrum indicated a strong band at 5.10 μ which is characteristic of the allene group. No absorption bands characteristic of acetylenic compounds were observed. Vapor-phase chromatography indicated the product consisted of a single material.

One gram of distilled material was treated with an ethereal solution of hydrogen chloride. An oil separated which crystallized with rubbing. The solid was recrystallized from ethyl acetate to give a material with a melting point of 118–120°.

Anal.—Calcd. for $C_{13}H_{16}ClN$: C, 68.72; H, 7.69; Cl, 16.91; N, 6.68. Found: C, 68.70, 68.70; H, 7.54, 7.63, 6.12; Cl, 17.21, 17.08; N, 6.11.

N-2,3-Butadienyl-N-methyl-o-chlorobenzylamine Hydrochloride (U-1379)—*o*-Chloro-*N*-methylbenzylamine (Sapon Labs.) (122 Gm., 0.8 mole), 5 ml. of water, and 4-chloro-1,2-butadiene (3) (75 Gm., 0.85 mole) were allowed to stand for 5 days at room temperature. To the mixture was added, with vigorous shaking, 200 ml. of a saturated solution of sodium carbonate. The organic layer was extracted with two 150-ml. portions of ether. The

Received September 8, 1967 from the Research and Development Department, The Norwich Pharmacal Company, Norwich, NY 13815

Accepted for publication November 13, 1967.

* Present address: Chemical Development Department, Wyeth Laboratories, Inc., West Chester, PA 19101

ethereal extracts were dried over anhydrous sodium sulfate and then concentrated under vacuum. The residue was distilled, b.p. (1st fraction) 45–78°/1 mm.; (2nd fraction) 79–105°/1 mm. There was about 80 Gm. in the second fraction which was redistilled. The material boiling at 81–91°/0.2 mm. was taken as product, yield 45 Gm. (27%). The infrared spectrum showed a strong allenic band and no acetylenic band.

A small amount of the free base was dissolved in dry ether and treated with an ethereal solution of hydrogen chloride. An oil separated that crystallized with rubbing. The solid was recrystallized from benzene to give a material with a melting point of 121–122°.

Anal.—Calcd. for $C_{12}H_{15}Cl_2N$: C, 59.03; H, 6.19; N, 5.74. Found: C, 58.72, 58.79; H, 6.19, 6.32; N, 5.68, 5.67.

N-2,3-Butadienyl-*N*-methylbenzylamine hydrochloride (U-1247) may be prepared by the above method, yield 9%.

Monoamine Oxidase Inhibition—The colorimetric method of Stern *et al.* (4) was used to determine monoamine oxidase activity. MAO in the presence of oxygen catalyzes the conversion of tyramine to *p*-hydroxyphenylacetaldehyde (*p*HPA) which is trapped as the semicarbazone in the incubation mixture. Thus, inhibition of MAO activity by a drug results in a decrease in the production of *p*HPA. Potassium cyanide is added to the incubation mixture to inhibit competing oxidative reactions.

For *in vitro* studies, stock solutions (6×10^{-3} or 6×10^{-4} *M*) of pargyline, U-1247, and U-1379 prepared in 0.2 *M* phosphate buffer (pH 7.4) were serially diluted with buffer. Half-milliliter aliquots of the drug in buffer were added to 2.0-ml. aliquots of a 2.5% rat liver homogenate. Control mixtures were prepared by adding 0.5-ml. aliquots of phosphate buffer without drug to 2.0-ml. aliquots of the same rat liver homogenate. The mixtures were preincubated for 10 min. before the addition of 0.5 ml. of 0.06 *M* semicarbazide–0.006 *M* KCN solution containing 30 μM of tyramine. The reaction mixtures were shaken at 37° in an O_2 atmosphere for 10 min. At the end of the incubation period, 0.5 ml. of a 50% trichloroacetic (TCA) solution in water was added to each homogenate to stop the reaction.

For the *in vivo* study, rats ranging in weight from 250 to 300 Gm. were given a single oral dose of either pargyline, U-1247, or U-1379 in water. Each drug was administered to rats at various dosages using three rats per level of drug. Control rats were dosed with water. After 4 hr. the rats were sacrificed and their livers and brains removed to determine monoamine oxidase activity. Liver and brain homogenates, 2.5% (w/v), were prepared in 0.2 *M* phosphate buffer (pH 7.4); 2.0 ml. of homogenate was added to an additional 0.5 ml. of the phosphate buffer and treated as described for the *in vitro* studies.

Colorimetric analysis of *p*HPA in the TCA treated supernatant solution was made by diluting 0.5 ml. of the solution to 3.0 ml. with water and adding 1.0 ml. of 1.5% 4-nitrophenylhydrazine hydrochloride in 1.0 *N* HCl. After extraction of the 4-nitrophenylhydrazone of *p*HPA into 2.0 ml. of chloroform, re-extraction of 1.0 ml. chloroform with 5 ml. of 0.1 *N* NaOH, and dilution of 3.0 ml. of this basic solution to 8.0 ml. with water, the absorbances were determined in a colorimeter at 420 mμ. Percent of inhibition of MAO activity by pargyline, U-1247, and U-1379 *in vivo* and *in vitro* was calculated by comparing the absorbance of the inhibited MAO samples with the appropriate control absorbance.

Comparative Acute Toxicity in Mice—LD_{50} values were determined in CFW male mice with U-1247, U-1379, and pargyline by three routes of administration. Groups of 5 mice received graded doses of drug, and the LD_{50} value was based on deaths which were observed within a 48-hr. period. These animals were also observed for gross pharmacologic effects of the compounds.

Hypotensive and Antihypertensive Activity—The hypotensive and antihypertensive activity of U-1247 and pargyline was investigated in unanesthetized rats.

Thirty rats were divided into six groups of five rats each. Three of these groups consisted of rats made hypertensive by the method of Grollman (5). Systolic blood pressures were recorded twice daily from the tail using a pneumatic pulse pickup and an electrosphygmograph (E & M instruments).

The animals were arranged so that each testing unit consisted of five normotensive and five hypertensive rats. The following procedure was adopted: Days 1 and 4. Control blood pressures were recorded from each animal twice a day. Days 5 through 11. During this, the treatment period, the animals received daily the following: Unit 1—saline 1 ml./Kg., i.p. Unit 2—pargyline 20 mg./Kg., i.p. Unit 3—U-1247 20 mg./Kg., i.p. Days 12 through 15. This was the postdrug observation period.

Effect of U-1247 and Pargyline on the Pressor Effects of Tyramine—Rats were anesthetized with urethan (1.25 Gm./Kg., i.p.) a tracheotomy performed, and polyethylene tubing inserted. A glass cannula was inserted into one of the carotid arteries for direct blood pressure recording through a Statham pressure transducer onto a Grass polygraph. A femoral vein was cannulated for injection of drugs. Two groups of five animals each were pretreated 48, 24, and 2 hr. before i.v. tyramine (0.01 mg./Kg.) challenge with either U-1247 (100 mg./Kg. *per os*) or pargyline HCl (100 mg./Kg. *per os*). Control responses to tyramine (0.01 mg./Kg., i.v.) were obtained using seven animals.

In a second study, the protocol of Tedeschi and Fellows (6) for demonstrating augmentation of peroral tyramine by monoamine oxidase inhibition was followed, with the exception that anesthesia was accomplished with intraperitoneal urethan (1.25 Gm./Kg.) instead of intravenous pentobarbital. The treated rats were given 100 mg./Kg. of U-1247 or pargyline orally 72, 48, and 24 hr. prior to challenge with orally administered tyramine.

RESULTS

MAO Inhibition—*In vitro* U-1247, U-1379, and pargyline greatly inhibited rat liver homogenate MAO activity (Table I). Fifty percent inhibition (IC_{50}) of the MAO activity in liver homogenate was elicited by these drugs at the following molar concentrations: 9.5×10^{-7} *M* for U-1247, 2.3×10^{-7} *M* for U-1379, and 4.0×10^{-8} *M* for pargyline. The IC_{50} values for liver MAO activity must be

interpreted with caution, however, since the length of the preincubation period of MAO with these inhibitors, before the addition of substrate, may affect the degree of inhibition obtained (7).

In vivo peroral administration of U-1247, U-1379, and pargyline resulted in approximately the same magnitude of inhibition of both rat liver and brain MAO (Table I). Graphs of the percent inhibition of rat liver MAO activity by U-1247, U-1379, and pargyline *versus* the logarithms of the doses resulted in the classic sigmoid curves usually obtained in this type of study. The ID_{50} values obtained from these curves were: 0.13 mg./Kg. for pargyline, 0.24 mg./Kg. for U-1247, and 0.51 mg./Kg. for U-1379. The difference between these ID_{50} values is not considered significant. Construction of the same type of graph for the *in vivo* brain data resulted in curves which were too variable to be clearly defined as sigmoid curves. U-1247, U-1379, and pargyline produced a 50% inhibition of rat brain MAO within a 1–3 mg./Kg. dose range.

Acute Toxicity in Mice—The comparative LD_{50} values and 95% confidence limits obtained in CFW mice with U-1247, U-1379, and pargyline by three routes of administration are presented in Table II.

These LD_{50} values were based on deaths which were observed within 48 hr. following drug administration.

The gross observable effects of these three drugs also differed. Deaths among the U-1247 treated mice occurred within 2–15 min. of drug administration and no delayed deaths were observed. The toxic signs observed were: clonic convulsions, dyspnea, cyanosis, and exophthalmus. Sublethal doses produced hyperexcitability which lasted approximately 1 hr.

Pargyline, by contrast, caused little excitability at sublethal doses while minimal lethal doses produced a 1–2 hr. depression followed in 3–4 hr. by marked hyperexcitability. When large lethal doses were given death occurred in 3–10 min. with accompanying cyanosis, dyspnea, and weak (cyanotic) clonic convulsions. Deaths following oral administration were delayed as long as 48 hr.

The gross and toxic effects of U-1379 resembled those observed following either pargyline or U-1247 treatment. Marked initial stimulation, which resembled the effects of U-1247, and latent stimulation and delayed deaths as were seen following pargyline, were observed with this compound.

Hypotensive and Antihypertensive Activity—The effect of U-1247 and pargyline on the systolic blood pressure of normotensive and hypertensive rats is summarized in Table III. The control animals, both normotensive and hypertensive, maintained a steady level of systolic blood pressure over the 16-day period. The systolic blood pressure of the hypertensive animals receiving pargyline or U-1247 decreased over the 7-day treatment period. This decrease in systolic pressure was approximately equal in the two groups and no difference in potency of the two drugs could be demonstrated. At the termination of treatment, the blood pressure rose to predrug levels in approximately 3 days. The normotensive animals which received either U-1247 or pargyline did not appear to demonstrate as marked a hypotensive effect; however, there was a

TABLE IV—EFFECT OF U-1247 AND PARGYLINE ON TYRAMINE BLOOD PRESSURE RESPONSES

Treatment[a]	Tyramine Dose, mg./Kg.	ΔxBP, mm. Hg	±S.E.	No. Rats in Group
Control	Saline	12.0	2.16	6
Control	12.5	16.2	4.00	6
Control	50	38.5	5.35	6
Pargyline	12.5	37.0	11.05	6
U-1247	12.5	33.8	10.80	6

[a] Rats pretreated with U-1247 or pargyline (100 mg./Kg. p.o.) 72, 48, and 24 hr. prior to tyramine challenge (p.o.).

significant blood pressure reduction in both groups.

Effect of U-1247 and Pargyline on the Pressor Response to Tyramine—The mean blood pressure response to 0.01 mg./Kg. i.v. of tyramine in 7 rats was 7.7 (±2.5). After pretreatment with pargyline or U-1247, the mean response to tyramine in 5 rats was increased to 24.4 (±10.4) and 32.6 (±8.5), respectively. These differences from control were significant at the 0.1 level for pargyline and the 0.01 level for U-1247.

The effect of U-1247 and pargyline on perorally administered tyramine is summarized in Table IV.

In control rats there was a significant difference in the blood pressure response between 12.5 mg./Kg. and 50 mg./Kg. of tyramine. After pretreatment with either pargyline or U-1247, the response to 12.5 mg./Kg. of tyramine was increased, and no longer was significantly different from the response to the 50 mg./Kg. dose.

These data indicate that U-1247 and pargyline are capable of potentiating both intravenous and peroral tyramine.

DISCUSSION

This study indicates that within the pargyline series a triple bond is not essential for *in vitro* or *in vivo* MAOI activity. The *in vitro* data suggest that U-1247 is approximately 25 times less active than pargyline, while *in vivo* the two compounds are approximately equal in potency. The *in vivo* conversion of U-1247 to a more active form is one possible explanation of these results. The bioconversion of the allenic compounds to acetylenic derivatives, however, is unlikely as Swett (1) has indicated both the *N*-2 and *N*-3 butynyl-*N*-methylbenzylamine are inactive *in vivo*. The possibility of U-1247 and pargyline being converted to a common active form cannot be discounted from the data and is worthy of further study.

Influence of Various Pretreatments (Carriers, Desiccation, and Relative Cleanliness) on the Destruction of *Bacillus subtilis* var. *niger* Spores with Gaseous Ethylene Oxide

By JOHN E. DOYLE and ROBERT R. ERNST

The ethylene oxide resistance of *Bacillus subtilis* var. *niger* spores inoculated on a variety of carriers was determined. After initial experiments indicated that cleanliness of the spores was important, desiccated and undesiccated spores of varying degrees of cleanliness on aluminum foil and chromatography paper were studied. Under the experimental conditions, desiccation of the spore population had no influence on susceptibility to ethylene oxide. The degree of cleanliness of the spore preparation was the significant factor in excessive resistance. The bacteriological controls used for testing ethylene oxide sterilization processes should be adequately cleaned so that they may accurately monitor the process.

GASEOUS ETHYLENE OXIDE is used for the sterilization of materials which cannot be sterilized by steam. As the utilization of heat- and moisture-sensitive materials increases, the importance of ethylene oxide sterilization increases for the hospital and pharmaceutical related fields.

Essential to an ethylene oxide process is proper monitoring. The USP XVII, page 811 states: "The efficacy of any procedure for the sterilization of pharmaceutical products by ethylene oxide should be tested thoroughly by inclusion of items contaminated with spores of known microorganisms in representative locations in typical sterilizer loads and by subsequent demonstration that these microorganisms have not survived the treatment."

Since the evaluation of the efficiency of an ethylene oxide process depends a great deal on the bacteriological controls, the controls chosen should be uniform as regards to resistance to the sterilant. This paper deals with the effect of cleanliness and desiccation on the resistance of spores to ethylene oxide.

METHODS

Bacillus subtilis var. *niger* 356 S. C. No. 4 (1) was used in this study. The culturing methods have been described previously (2). Washing the spores was accomplished by centrifugation at 20,500 × g for 10 min., decanting the supernate, followed by resuspension in sterile distilled water. This procedure was repeated for further washings when indicated. Dilutions were made in sterile distilled water to produce the desired inoculum. Inoculums were 0.01 ml. per carrier materials.

The procedures similar to those used by Ernst and Shull (3) were used in this study for determination of ethylene oxide resistance.

RESULTS

Initially in the investigation, it was of interest to determine the resistance of *Bacillus subtilis* var. *niger* on a variety of carrier materials. However, a spore suspension was used that had been washed only two times. Table I describes the variety of resistances obtained. There appeared to be little effect due to absorbency or nonabsorbency of the carrier. No consistent difference of resistance between hard and porous surfaces was observed

[a] Spore suspension (10^8 spores/carrier) washed eight times in distilled water. Ethylene oxide concentration, 1,200 mg./L.; relative humidity, 40%; temperature, 130°F.

However, a large zone of partial survivors and high resistance was observed. This may have been due to the fact the spore suspension was only washed twice. A synergistic effect of the carrier material and the residual media may have produced high ethylene oxide resistance.

Therefore, a new suspension of *Bacillus subtilis* var. *niger* was prepared as before. However, this suspension was washed eight times. As shown in Table II, once again there appeared to be little effect on the resistance regardless of whether the carrier was absorbent or nonabsorbent. High resistance due to any carrier effect was not observed. The high degree of cleanliness appeared to reduce the relative resistance of the spores.

Since the cleanliness of a spore suspension appeared to be an important aspect of its relative resistance, the effect of the relative degree of cleanliness on the resistance of spores to ethylene oxide with respect to both nonabsorbent and porous carriers was investigated. Since hard surfaces have been reported to produce a greater resistance than porous surfaces, an aluminum foil carrier was compared with a porous paper carrier. Also because desiccation (4, 5) has been reported to increase the resistance of spores, this aspect was investigated as well.

A new suspension of *Bacillus subtilis* var. *niger* was prepared as before. Equal aliquots of the spore culture broth were separated into five groups. Washing was accomplished as described previously. One suspension was not cleaned, one was cleaned once, *etc.* Then the aluminum foil and chromatography paper strips were inoculated with the five suspensions. A portion of each was allowed to dry and equilibrate at room temperature. The other portion was placed in a desiccator and dried over calcium sulfate desiccant at room temperature in excess of 1 month. Hence there were "normal" dried and desiccant dried aluminum foil and paper carriers of varying degrees of cleanliness as shown by the number of resuspensions in distilled water.

Figure 1 compares the relative resistance of spores with relative degrees of cleanliness when placed upon aluminum foil carriers. If the suspension is not washed at all, a high resistance (over 48 hr.) to sterilization is obtained, probably due to the occlusion of the spores in the media. With one resuspension a broad partial survival region was observed,

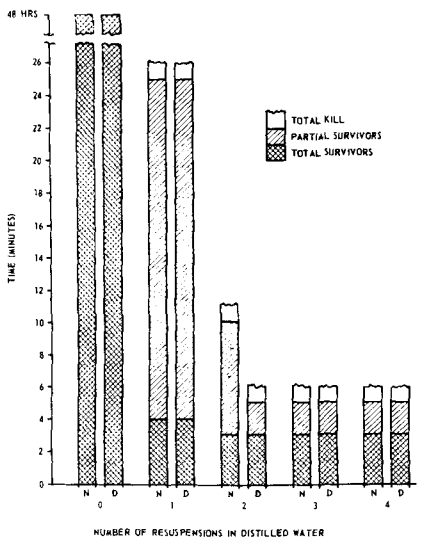

Fig. 1—Effect of relative cleanliness and desiccation on the ethylene oxide resistance of Bacillus subtilis *var.* niger *spores (10^6 spores/carrier) on aluminum foil. N = not desiccated, D = desiccated. Ethylene oxide concentration, 1,200 mg./L.; relative humidity, 40%; temperature, 130° F.*

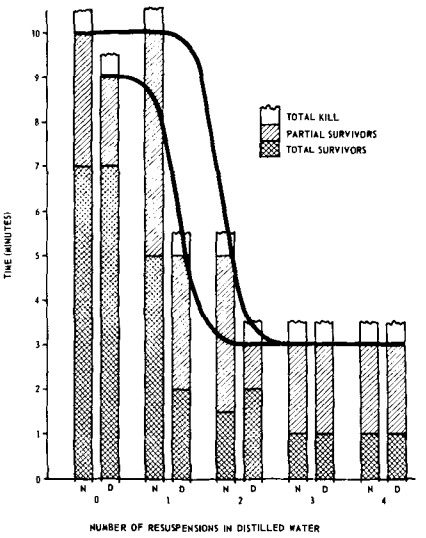

Fig. 2—Effect of relative cleanliness and desiccation on the ethylene oxide resistance of Bacillus subtilis *var.* niger *spores (10^6 spores/carrier) on porous paper. N = not desiccated, D = desiccated. Ethylene oxide concentration, 1,200 mg./L.; relative humidity, 40%; temperature, 130° F.*

indicating that some spores were being randomly protected. However, sterility was obtained in 25 min. With a second resuspension there was still some effect due to the relative uncleanliness of the suspension, except in the case of the desiccated carriers. After the third resuspension, the resistance dropped to 3 min. total survival, requiring only 5 min. for total kill. The partial survival region is approximately 2 min. Desiccation appeared to have little effect on the resistance of the spores.

Figure 2 compares the resistance of spores of relative degrees of cleanliness when placed upon a porous paper carrier. Complete resistance to ethylene oxide with the porous paper was never obtained under these conditions, even when the suspension was not washed at all. It appeared that the desiccated carriers were less resistant than the undesiccated carriers when the spore inoculum was washed less than three times. Upon further washing, undesiccated and desiccated strips had equal resistances.

Some experiments were performed with the spore preparation which was not washed, at 10^7 spores per paper carrier, and an even greater partial survival region was observed. One would expect more resistance with carriers contaminated with a greater number of spores. However, the larger region of partial survival shows the greater likelihood of protection by occlusion due to the larger amount of media as well as the larger number of spores.

When one compares the degrees of cleanliness of spores on the aluminum foil and paper carriers, it is evident that the cleanliness of the spore suspension used determines great differences in relative susceptibility. In every degree of cleanliness the aluminum foil carrier resulted in a greater resistance than the porous paper with a comparative difference in resistance becoming quite small with three washings.

The small difference of greater resistance imparted by a hard surface over a porous one is easy to understand, since diffusion is impossible or hindered through a hard surface carrier material, whereas the gases can diffuse in all directions through a porous one. Also the spores would tend to protect each other for they tend to ball up on a hard surface material whereas the spores become somewhat separated when inoculated on a porous paper or any porous material.

Desiccation of spores did not appear to play a large role in the experimental conditions. Even at 10% RH, 130°F., and 1,200 mg./L. ethylene oxide, little differences in resistance between clean desiccated and undesiccated spores of *Bacillus subtilis* var. *niger* were observed. The sterilization time for both, however, was extended to 1 hr.

Since calcium sulfate desiccation had no effect on ethylene oxide resistance, spores were dried in the following manner: (*a*) Acetone drying of spores prior to inoculation on chromatography paper. (*b*) Vacuum drying of cleaned spores on chromatography paper at 100μ for 24 hr. (*c*) Chromatography paper carriers were inoculated with clean spores at 10^7 spores/carrier. Then the carriers were exposed to 100°C. in an oven for 12 hr., reducing the spore population per carrier to 10^6. These remaining viable spores should have been extremely dry. None of these means of drying clean spore preparations produced any difference in resistance to ethylene oxide. The uncleanliness of a spore preparation seems to be the major reason for unusual resistance.

If the spore crop is clean, the region of partial survivors is narrow. However, if the spore crop is not thoroughly washed, the region of partial survivors is broad. Materials inoculated with the spore suspension are randomly protected by occlusion in crystals, encapsulation in organic debris, or both. The broader the region of partial survivors, the more unreliable the sterility monitor becomes.

One can artificially produce conditions in which microorganisms become extremely resistant to ethylene oxide. When *Staphylococcus aureus* or *Bacillus subtilis* var. *niger* were suspended in blood

and then inoculated on aluminum foil, they failed to be sterilized with ethylene oxide. Likewise, *Bacillus subtilis* var. *niger* spores suspended in peptone and dried on aluminum foil with a contamination level of only 10 spores/carrier were very difficult to sterilize with ethylene oxide. This would be similar to the protective effect found by previous investigators (6), *i.e.*, occlusion of the spores in crystals.

It is also possible to produce artificial conditions which would seem to make the organisms extremely susceptible to ethylene oxide. Spores suspended in 2% glycerin and then dried on polystyrene were less resistant to ethylene oxide than spores suspended in distilled water (7). *Bacillus subtilis* var. *niger* spores were suspended in 10% glycerin, inoculated on chromatography paper strips, and dried at room temperature. After drying at room conditions, the glycerin will contain a certain amount of water depending on the room relative humidity, for it will gain or lose moisture depending on its surroundings. At 130°F., 1,200 mg./L. ethylene oxide, these strips showed the same resistance (3 min. for inactivation) at 40% RH as at 10% RH even though the strips at 40% RH would contain a greater amount of moisture after equilibration. A similar situation would indicate to the unwary that no optimum RH was required. However, clean spores inoculated from distilled water required 1 hr. at 10% RH and 3 min. at 40% RH for inactivation.

SUMMARY

The evaluation of the efficiency of an ethylene oxide process depends a great deal on the type of bacteriological control used. It is therefore recommended that an evaluation be made of the type of load to be sterilized, so that the bacteriological controls chosen will accurately monitor the process. If one uses unwashed spores for preparation of sterility monitors when sterilizing clean materials, then he will likely obtain erratic indications of nonsterility rather than sterility. If, however, one does attempt to sterilize dirty materials, contaminated with dirt, blood, feces, *etc.*, he must realize that the process at its best will sterilize occasionally and should only be considered a decontamination procedure. The only dependable method of testing a sterilization process is to determine if it kills living microorganisms. The microbial control chosen should simulate actual conditions of the materials being sterilized.

Preferential Aggregation and Coalescence in Heterodispersed Systems

By NORMAN F. H. HO and W. I. HIGUCHI

A theoretical study of preferential coalescence and aggregation of small particles in heterodispersed systems has been carried out where moderate electrical barriers exist between the particles. Equations based on the concepts of Derjaguin, Verwey, and Overbeek were employed. Computation over a wide range of conditions has shown that small particles may aggregate (or coalesce) with themselves or with larger particles at rates that are 10 to 50 orders of magnitude faster than particles 10 times larger. These findings may explain (*a*) the relatively narrow particle size distributions observed in certain emulsions and flocculated suspensions and (*b*) the limited flocculation and coalescence behavior observed in certain instances.

THERE ARE many situations involving suspensions and emulsions where with time the particles or droplets of the dispersed phase simultaneously increase in size and narrow in their relative size distributions, and then later became quite stable kinetically. If the dispersed phase is soluble (or miscible) enough in the solvent, then the phenomenon may be accounted for by molecular diffusion (1) or Ostwald ripening. However, there are many examples in the literature (2–5) where the changes appear to occur primarily through particle–particle aggregation or droplet–droplet coalescence.

The authors have recently observed that urea-

and then inoculated on aluminum foil, they failed to be sterilized with ethylene oxide. Likewise, *Bacillus subtilis* var. *niger* spores suspended in peptone and dried on aluminum foil with a contamination level of only 10 spores/carrier were very difficult to sterilize with ethylene oxide. This would be similar to the protective effect found by previous investigators (6), *i.e.*, occlusion of the spores in crystals.

It is also possible to produce artificial conditions which would seem to make the organisms extremely susceptible to ethylene oxide. Spores suspended in 2% glycerin and then dried on polystyrene were less resistant to ethylene oxide than spores suspended in distilled water (7). *Bacillus subtilis* var. *niger* spores were suspended in 10% glycerin, inoculated on chromatography paper strips, and dried at room temperature. After drying at room conditions, the glycerin will contain a certain amount of water depending on the room relative humidity, for it will gain or lose moisture depending on its surroundings. At 130°F., 1,200 mg./L. ethylene oxide, these strips showed the same resistance (3 min. for inactivation) at 40% RH as at 10% RH even though the strips at 40% RH would contain a greater amount of moisture after equilibration. A similar situation would indicate to the unwary that no optimum RH was required. However, clean spores inoculated from distilled water required 1 hr. at 10% RH and 3 min. at 40% RH for inactivation.

denatured ovalbumin aggregates precipitated in buffered saline near the isoelectric point are often made up of rather uniform particles of around 1 μ diameter (2). Sherman (3) found that emulsions pass through an initial phase of rapid coalescence followed by a second period of slow coalescence, and then the emulsions became relatively stable. All of his emulsions showed a relatively narrow size distribution in the later stages. Wiley (4) and Gillespie (5) have also studied the problem of limited coalescence when droplets in oil-in-water emulsions are stabilized by finely divided particles.

Although the effects of particle size on the stability of colloids have been recognized, quantitation has been limited to the case involving the potential energy barriers for particles of equal sizes (6) or for particles of different sizes in which the mean size is used (3). While the equations for the repulsive potential energy between two unequal spheres have already been derived, an expression for the attractive potential energy between two unequal spheres with retardation factors has not been considered. The present authors are not aware of quantitative computations involving preferential collision of differing particle sizes in the presence of a repulsive force. It is the purpose of this paper to examine the theory as it relates to preferential and limited aggregation (or coalescence). As will be seen, some of the theoretical conclusions consistently describe many of the findings of investigators in the field.

THEORY

Rate of Preferential Aggregation or Coalescence—Let us assume that there are equal concentrations of spherical particles of three sizes, that is, spheres S_1, S_2, and S_3 of radii a_1, a_2, and a_3, respectively, where $a_1 < a_2 < a_3$. The dispersion is in an electrolyte solution and the particles are allowed to aggregate (coalesce) at 25°. The following question is asked: what are the probabilities of S_1 colliding with S_1, S_2, or S_3, of S_2 with S_2 or S_3, and of S_3 with S_3? By means of theory let us determine the initial rates of aggregation or coalescence for the various size pairs.

It will be assumed following the Derjaguin-Verwey-Overbeek concepts, the interparticle interaction results from electrical repulsion and the London-van der Waals attraction. According to the theories of Smoluchowski and Fuchs (7), the rate of collision between spherical particles of sizes i and j is given by:

$$G_{ij} = \frac{4\pi D_{ij} R_{ij} N_i N_j}{W_{ij}} \qquad \text{(Eq. 1)}$$

where G is the initial rate, D is the Stokes-Einstein diffusion coefficient, R is the distance between centers of the spheres, N is the concentration of particles, and W is the stability factor, which will be later discussed in detail. We may also write:

$$D_{ij}R_{ij} = \frac{kT}{6\pi\mu}\left(\frac{1}{a_i} + \frac{1}{a_j}\right)(a_i + a_j) \qquad \text{(Eq. 2)}$$

where k is the Boltzman constant, T is the absolute temperature, and μ is the viscosity of the suspending medium. Then the initial rate is:

$$G_{ij} = \frac{2kT}{3\mu W_{ij}}\left(\frac{1}{a_i} + \frac{1}{a_j}\right)(a_i + a_j)N_iN_j \qquad \text{(Eq. 3)}$$

The factor W_{ij} accounts for the energy barrier to aggregation and is given by:

$$W_{ij} = 2\int_2^\infty \exp.\left(\frac{V_{T(i,j)}}{kT}\right)\frac{ds}{s^2} \qquad \text{(Eq. 4)}$$

where $s = R/\bar{a}$ and $\bar{a} = (a_i + a_j)/2$. The W_{ij} usually ranges from $1 \lesssim W < \infty$ and takes into account the double-layer potential, the concentration of electrolytes, London-van der Waal dispersion forces, and the particle sizes of the two spheres.

Potential Energy of Interaction—In Eq. 4 the $V_{T(i,j)}$ is the total potential energy of interaction between two particles and is given by the sum of the repulsive energy, $V_{R(i,j)}$, and the attraction energy, $V_{A(i,j)}$; thus:

$$V_{T(i,j)} = V_{R(i,j)} + V_{A(i,j)} \qquad \text{(Eq. 5)}$$

The repulsive energy between interacting spheres of sizes i and j can be calculated by the approximate expression derived by Hogg, Healy, and Fuerstenau (8):

$$V_{R(i,j)} = \frac{\epsilon a_i a_j \psi_0^2}{(a_i + a_j)} \ln\left[1 + \exp.(-KH)\right] \qquad \text{(Eq. 6)}$$

where ϵ is the dielectric constant of the medium, ψ_0 is the surface potential, K is the reciprocal of the Debye-Hückel thickness of the double layer, and H is the shortest distance between the surfaces of the spheres. The equation is valid for Ka_i and $Ka_j \gg 1$.

The attraction energy of particles is more difficult to determine because the force between particles is considerably reduced by the retardation between atoms. Since the retardation effect is a function of distance, a single expression for the attraction energy is not available. When $a_i, a_j \gg H$ and $H \lesssim 150°\ A$, the attraction interaction energy can be calculated by the expression:

$$V_{A(i,j)} = -\frac{Aa_ia_j}{6(a_i + a_j)H}\left(\frac{\lambda}{\lambda + 11.116H}\right) \qquad \text{(Eq. 7)}$$

where A is the Hamaker constant, and λ is the characteristic wavelength of the atoms.

For $H \gtrsim 150°\ A$,

$$V_{A(i,j)} = \frac{Aa_ia_j}{(a_i + a_j)}\left[\frac{-2.45\lambda}{60\pi H^2} + \frac{2.17\lambda^2}{360\pi^2H^3} - \frac{0.59\lambda^3}{1680\pi^3H^4}\right] \qquad \text{(Eq. 8)}$$

One should refer to the *Appendix* for the discussion of the retardation factor and the derivation of Eqs. 7 and 8.

CALCULATIONS

Computations employing Eqs. 3–8 were carried out for a wide range of conditions with the aid of the IBM 7090 digital computer. ψ_0 values from 0 to

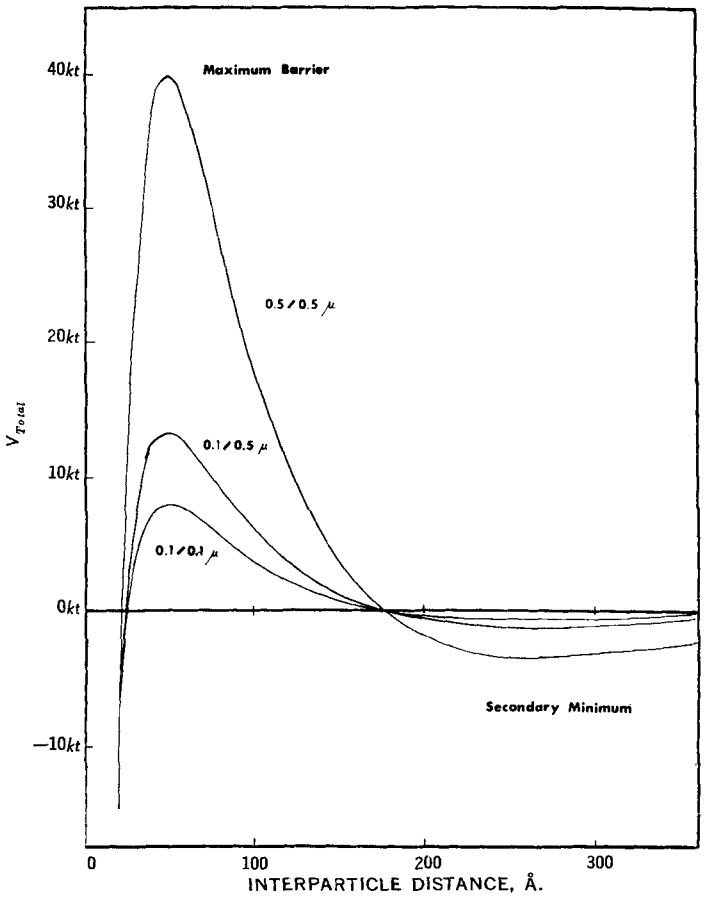

Fig. 1—Influence of particle sizes on the total potential energy of interaction. A = 5×10^{-13} *erg,* ψ_0 = *25 mv., and* K = 2×10^6 *cm.*$^{-1}$.

100 mv. and various radius combinations were taken at different K. Because the Hamaker constant is estimated (9, 10) to be somewhere in the neighborhood of 1 to 5 $\times$ 10^{-13} erg for most organic substances in water, calculations were made using the two values, 1 $\times$ 10^{-13} and 5 $\times$ 10^{-13}. The characteristic wavelength, λ, was taken to be 10^{-5} cm. Some plots of V_T *versus* H are shown in Figs. 1–3.

Table I presents some of the significant results. Calculated values of $V_{T\max.}$, the maximum in the V_T *versus* H curves, are shown. The rate constant, G', is defined as:

$$G' = \frac{G_{ij}}{N_i N_j} \qquad \text{(Eq. 9)}$$

DISCUSSION

Where K is large, *i.e.*, $K \gtrsim 0.4$ to 2 $\times$ 10^7, or when $\psi_0 \simeq 0$, it is seen (Table I) that, for essentially all particle sizes in the range of 0.1 to 5.0 μ radius, the rates of aggregation approach the Smoluchowski rates. Thus, in 1% NaCl solutions, maximum rates may be expected. Figure 4 shows the maximum limiting rate constants under these conditions for which W_{ij} equals unity.[1] The well-known preferential aggregation relationship due to Muller (11) can be seen here. However, under such "rapid" aggregation conditions, the rate constant for a 0.1 μ–1.0 μ pair is only about three times greater than that for particles of the same size.

Let us now direct our attention to the region of kinetic stability where the rates may be regarded as neither very rapid nor very slow. In this intermediate stability region we note a dramatic change in importance of particle size. This can be seen in Table I and in Fig. 5. In Fig. 5 it can be seen how electrolyte concentration may markedly increase the preference for the aggregation (or coalescence) of small particles with each other or with large particles. Thus, when $K \simeq 2$ to 4 $\times$ 10^6 for $\psi_0 \simeq 25$ mv., it can be seen (Table I or Fig. 5) that the rate of aggregation (or coalescence) of 0.1-μ particles with itself or larger particles may be 10 to 30 orders of magnitude greater than that for two 0.5-μ particles. Comparing Fig. 5 with Fig. 6, we note that the rates for various particle sizes are highly sensitive to the Hamaker constant taken as 1 $\times$ 10^{-13} and 5 $\times$ 10^{-13} erg.

The above conclusions depend upon the assumption that other contributions to particle–particle repulsion are absent. Therefore, in the case of emulsion coalescence, strongly adsorbed barrier-forming interfacial films are assumed to be absent. In practice one would expect that when surface coverage of ionic emulsifiers is low, say about 5 to 10% of maximum coverage, the repulsion between two oil droplets in an aqueous medium would be

[1] Actually the limiting W_{ij} values may be somewhat less than unity when all repulsive barriers are removed because V_T will be negative (see Eq. 4).

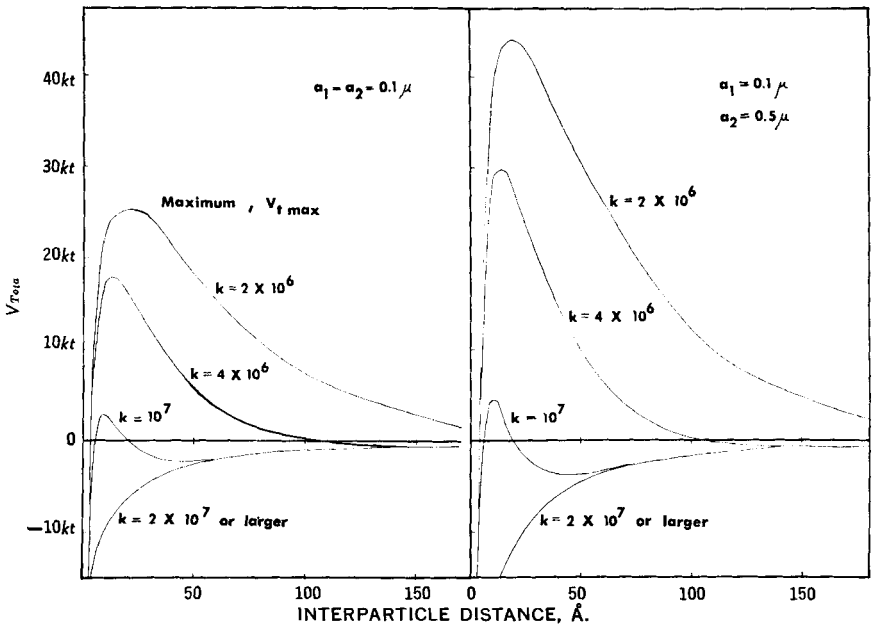

Fig. 2—Influence of electrolyte concentration on the total potential energy of interaction for two particle sizes. A = 1×10^{-13} *erg and* ψ_0 = 25 *mv.*

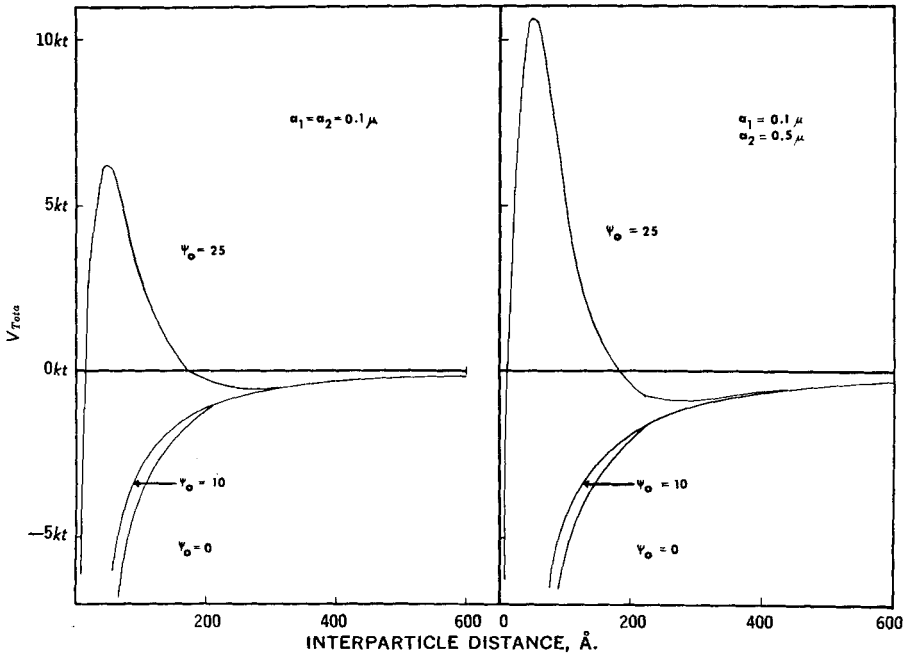

Fig. 3—Influence of surface potential on the total potential energy of interaction for two particle sizes. A = 5×10^{-13} *erg,* ψ_0 = 25 *mv., and* K = 2×10^6 *cm.*$^{-1}$.

primarily electrical. These findings are consistent with the observations (3) that there is frequently an initial period of rapid coalescence with freshly prepared emulsions. Usually this is explained on the basis of the lack of sufficient stabilizer to provide a complete monolayer for the droplets. However, this explanation alone does not account for the relatively narrow size distributions that often result. The absence of small particles indicates that they preferentially disappear rapidly.

It is proposed that in a freshly prepared emulsion the shortage of surfactant prevents the formation of complete interfacial adsorbed films. Consequently, the rupture or displacement of the adsorbed molecules may not be rate determining in coalescence. Then if ψ_0 is low ($\lesssim$25 mv.) or if K is large, the rapid and selective disappearance of small droplets through coalescence would occur. The surviving larger droplets coalesce at a much slower rate as W_{ij} is extremely sensitive to particle size. Thus, a relatively narrow distribution would result if Brownian motion alone is inducing the coalescence.

[a] Note that when $V_{Tmax./kT} < 0$, little repulsive barrier exists, hence aggregation is dependent on London-van der Waal attraction.

Fig. 4—Probability of rapid aggregation between particles of different sizes when the stability factor W_{ij} *equals unity.*

Gillespie (5) has discussed limited coalescence of oil-in-water emulsions stabilized by finely divided solids. He proposed a theory based on the rate of accretion of the solid stabilizer by the oil droplets. Furthermore, he found that there was an optimum concentration range for an ionic surfactant additive that produced the most uniform stable drops. This concentration range of the ionic surfactant appeared to produce a moderate or small electrical repulsive barrier. These findings are consistent with the theoretical results.

While the findings are only tentative, the precipitation of denatured proteins (2) near the isoelectric point appears to involve the formation of relatively uniform primary particles of around 1 μ diameter. Such narrow distributions are consistent with the above theory that selective aggregation of small particles with large ones take place. The extreme situation where only single denatured protein molecules deposit upon the larger particles would lead to the formation of relatively compact spherical particles of relatively narrow size ranges.

The authors believe that the results presented provide a much better understanding of the role of particle size in the mechanisms of aggregation and coalescence. It provides a possible scientific basis for tailor-making dispersion formulations of controlled size and size distributions.

APPENDIX

Attractive Energy between Unequal Spheres and the Effect of Retardation—Hamaker (12) was the first to describe the potential energy of attraction between unequal spheres, $V_{A(S_1/S_2)}$, of similar constitution. For $a_1, a_2 \gg H$, the limiting expression is:

$$V_{A(S_1/S_2)} = -\frac{A a_1 a_2}{6(a_1 + a_2)H} \qquad \text{(Eq. 1}a\text{)}$$

where Hamaker's constant $A = \pi^2 q^2 \beta$, and q is the number of atoms per cm.^{3}, β is the London constant, a_1, a_2, and H are defined as before.

Schenkel and Kitchener (10) made a thorough analysis of the retardation effect. Using the equations for $f(p)$ as a check that are presented in several references (10, 13), they derived empirical expressions that gave the best fit and that would give an analytic solution for interaction energies with modifications for the retardation effect. Accordingly,

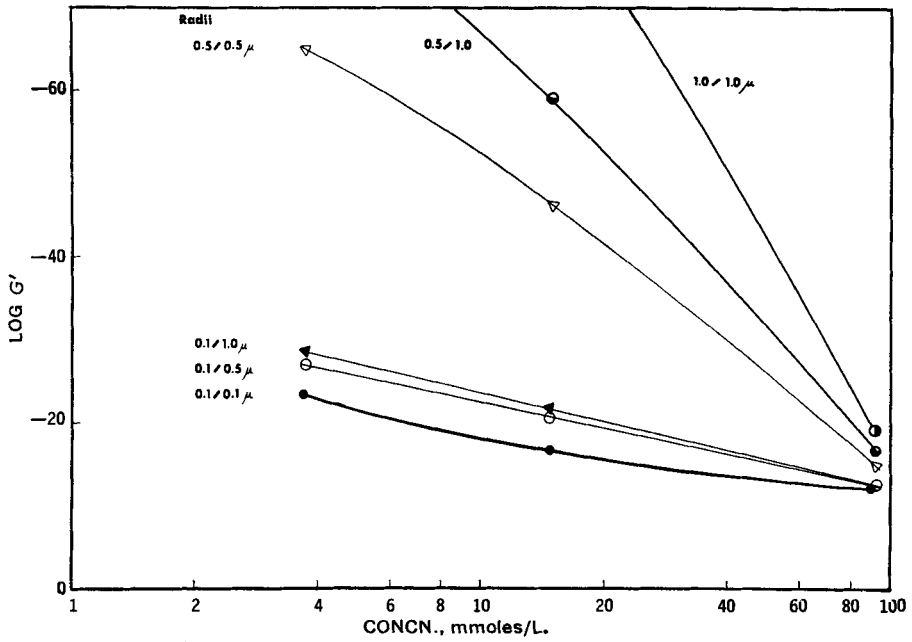

Fig. 5—Rate constant (G′) *as a function of concentration of 1-1 electrolyte for various particle sizes.* A = 1×10^{-13} *erg and* $\psi_0 = 25$ *mv.*

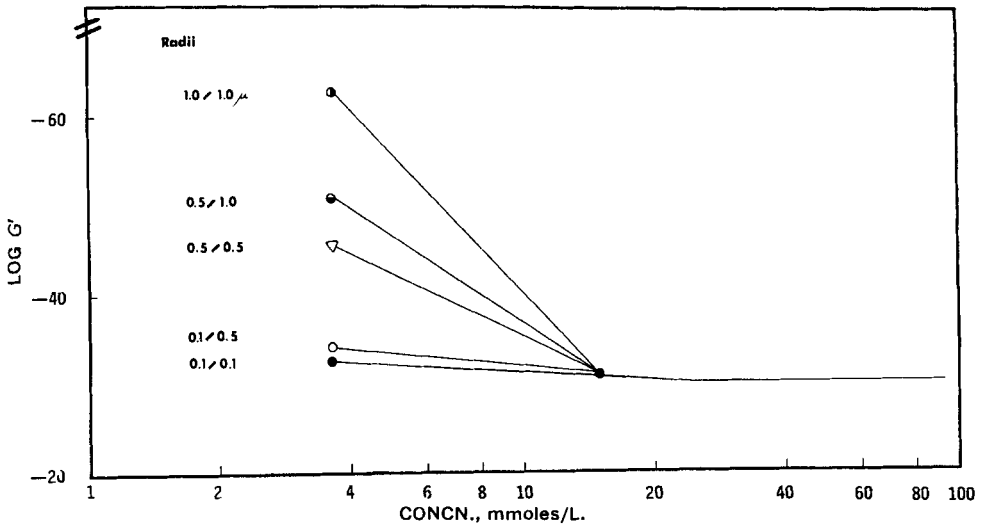

Fig. 6—Rate constant (G′) *as a function of concentration of 1-1 electrolyte for various particle sizes.* A = 5×10^{-13} *erg and* $\psi_0 = 25$ *mv.*

for the range of $0.5 < p < \infty$,

$$f(p) \sim \frac{2.45}{p} - \frac{2.17}{p^2} + \frac{0.59}{p^3} \quad \text{(Eq. 2}a\text{)}$$

For comparatively large distances, Casimir and Polder (14) showed that the London energy between atoms decays very rapidly due to retardation effects. Consequently, the London interaction energy of a pair of atoms of r distance apart,

$$V_{A(\text{London})} = -\frac{\beta}{r^6} \quad \text{(Eq. 3}a\text{)}$$

must be corrected so that

$$V'_{A(\text{at./at.})} = V_{A(\text{London})} f(p) \quad \text{(Eq. 4}a\text{)}$$

where $p = 2\pi r/\lambda$, and λ is the characteristic wavelength of the atoms and β is the London constant. Equation 4a may be rewritten:

$$V'_{A(\text{at./at.})} = -\frac{2.45\lambda\beta}{2\pi r^7} + \frac{2.17\lambda^2\beta}{(2\pi)^2 r^8} - \frac{0.59\lambda^3\beta}{(2\pi)^3 r^9} \quad \text{(Eq. 5}a\text{)}$$

In deriving the expressions for the retarded interaction energies for equal spheres, Schenkel and Kitchener used Derjaguin's method (15, 16) for calculating the interaction of spheres. It was pointed out that the algebra was simpler than for Hamaker's method (12) and that the results obtained were the same by both methods, provided it is only the limiting expressions that are required. In a similar manner, the method is applied to the interaction between unequal spheres.

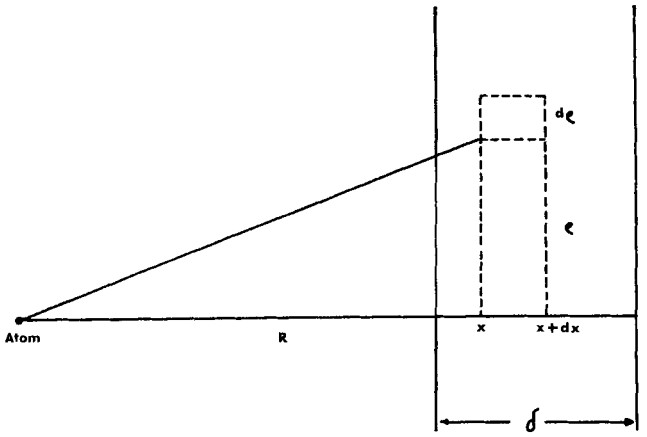

Fig. 7—Geometry of the London-van der Waal interaction between an atom and an infinitely large plate of thickness δ. The plate is built up of infinitesimal rings of diameter ρ, cross-section dρdx at a distance (R + x) from the atom (17).

Applying Eq. 4*a* to the geometry in Fig. 7, the interaction energy between an atom and all of the atoms in an infinitely large flat plate, $V'_{A(\text{at./}p)}$, may be described by the superposition of their retarded attractive energies, *i.e.*,

$$V'_{A(\text{at./}p)} = V''_A + V'''_A + V''''_A \quad \text{(Eq. 6}a\text{)}$$

where

$$V''_A = -\int_0^\delta\int_0^\infty \frac{2\pi q\phi\rho d\rho dx}{[(R+x)^2+\rho^2]^{7/2}} \quad \text{(Eq. 7}a\text{)}$$

$$V'''_A = \int_0^\delta\int_0^\infty \frac{2\pi q\theta\rho d\rho dx}{[(R+x)^2+\rho^2]^4} \quad \text{(Eq. 8}a\text{)}$$

$$V''''_A = -\int_0^\delta\int_0^\infty \frac{2\pi qZ\rho d\rho dx}{[(R+x)^2+\rho^2]^{9/2}} \quad \text{(Eq. 9}a\text{)}$$

and $\phi = 2.45\lambda\beta/2\pi$; $\theta = 2.17\lambda^2\beta/(2\pi)^2$; and $Z = 0.59\lambda^3\beta/(2\pi)^3$. Also, the Hamaker constant $A = \pi^2q^2\beta$. It follows that the interaction between two flat plates, $V'_{A(p/p)}$, is

$$V'_{A(p/p)} = \int_R^\infty qV'_{A(\text{at./}p)}dR \quad \text{(Eq. 10}a\text{)}$$

If the surface of two spheres is thought to be built up of parallel pairs of infinitesimally small rings with radius h (8), the interaction of unequal spheres, $V'_{A(S_1/S_2)}$, is expressed by:

$$V'_{A(S_1/S_2)} = 2\pi\left(\frac{a_1a_2}{a_1+a_2}\right)\int_H^\infty V'_{A(p/p)}dH \quad \text{(Eq. 11}a\text{)}$$

The edge effects are neglected. Finally, the limiting expression for the interaction energy for unequal spheres is:

$$V'_{A(S_1/S_2)} = \frac{Aa_1a_2}{a_1+a_2}\left[-\frac{2.45\lambda}{60\pi H^2}+\frac{2.17\lambda^2}{360\pi^2H^3}-\frac{0.59\lambda^3}{1680\pi^3H^4}\right] \quad \text{(Eq. 12}a\text{)}$$

(for $H \ll a_1, a_2$; $0.5 < p_0 < \infty$).

Since $p_0 = 2\pi H/\lambda$ and λ is usually taken as 10^{-5} cm., Eq. 12*a* should not be used for approximately $H < 150°$ *A*. It is noteworthy that the equation reduces to the identical expression[2] obtained by Schenkel and Kitchener for interaction of equal spheres, *i.e.*, $a_1 = a_2$.

For the range below $p_0 = 0.5$, the retardation effect is still significant until the interparticle distance is comparatively very small, in which case Eq. 1*a* will apply. Based on extrapolation of the attractive potential energy curve, an empirical expression that represents the region $0 < p_0 < 2$, approximately $H < 300°$ *A*, is given by Eq. 7.

[2] See equation (x) in the appendix of *Reference 10.*

Synthesis of Tropine-Labeled Atropine III

Synthesis of *N*-Methyl-^{14}C-Tropine and *N*-Methyl-^{14}C-Atropine

By GILBERT C. SCHMIDT, THOMAS E. ELING, and JOHN M. McOWEN

Using a previously described modification of the Robinson condensation, *N*-methyl-^{14}C-tropine, specific gravity 1 mc./mmole, was synthesized from methylamine-^{14}C-HCl in 65 percent of theoretical yield. Subsequent esterification with unlabeled tropic acid gave *N*-methyl-^{14}C-atropine, specific activity 1 mc./mmole, in 45 percent of theoretical yield, based on methylamine. Synthesis of these compounds validates previous studies and firmly establishes a general pathway for labeling the carbon skeleton of tropine with radioactive carbon.

THE HIGH toxicity of atropine dictates that minute doses be administered to test animals and, thereby, limits studies of atropine metabolism. Exclusive use of separations and purifications to trace and locate metabolites is precluded. Selective, isotopic labeling of the alkaloid is essential. Studies of intermediary animal metabolism, plant biogenesis, the mechanisms of pharmacological actions, and pathways that permit certain microorganisms to utilize atropine as a sole carbon and nitrogen source (1–3) depend on the availability of suitably labeled compounds.

An interest in these problems and the associated need for unavailable compounds stimulated a study of methods for selectively labeling tropine and the tropine moiety of atropine. A general, microsynthetic pathway was established (4) and a prototype method for the synthesis of labeled tropine from labeled arabinose was developed (5). The present communication describes the synthesis of *N*-methyl-^{14}C-tropine and *N*-methyl-^{14}C-atropine from labeled methylamine HCl, confirms for the first time Werner's synthesis of these compounds, and establishes that the previously proposed pathways are suitable for use with radioactive carbon.

EXPERIMENTAL

Microsynthetic methods for tropine and atropine are described in detail in the first two papers of this series (4, 5) and were modified only slightly for the synthesis of *N*-methyl-^{14}C-tropine and *N*-methyl-^{14}C-atropine.

Preparation of O-Acetyltropic Acid—Acetyltropic acid was prepared from 395 mg. tropic acid and 0.36 ml. acetyl chloride in the manner previously described (4).[1] The product was dried over $CaCl_2$ in a vacuum desiccator and was converted to *O*-acetyltropic acid chloride at the time of esterification with tropine.[2]

Preparation of Raney Nickel and Check of Activity—Type W-7 Raney Nickel[3] was prepared from 10 Gm. of alloy by the method of Augustine (6).[4] Although the catalyst is active for at least 2 weeks,[5] catalysts used in radiosyntheses were checked for activity on the evening prior to reduction of labeled tropanone.[6]

Using the apparatus and experimental conditions employed in radiosyntheses, 100 mg. unlabeled tropanone was reduced overnight. During early stages of the reduction, hydrogen uptake was checked, and on the following morning a 10-μl. sample of the reaction mixture was spotted on filter paper, air dried, and checked for completness of reduction by spraying with 2,4-dinitrophenylhydrazine solution (7). Tropine was also isolated as the picrate and the melting point of the picrate determined.[7] If reduction was complete, the catalyst was used for the reduction of labeled tropanone.

***N*-Methyl-^{14}C-tropine HCl from *N*-Methyl-^{14}C-Tropanone**—Labeled tropanone, synthesized from the stated quantities of reactants and weighing approximately 100 mg. when dried for 12 hr., was reduced over W-7 Raney nickel by the general method of Van de Kamp (8).[8]

Tropanone was dissolved in 2 ml. absolute ethanol and, while stirring slowly,[9] the system was flushed three times with ultra-pure hydrogen.[10] The gas buret was filled with hydrogen, the system closed, and reduction continued with constant stirring, at room temperature, until the rate of gas uptake

Received July 5, 1967, from The Children's Hospital, Division of Pharmacology, Departments of Pediatrics and Biological Chemistry, University of Alabama Medical Center, Birmingham, AL 35233

Accepted for publication October 19, 1967.

Abstracted, in part, from a thesis submitted by Thomas E. Eling to the Graduate School, University of Alabama, Department of Biological Chemistry, in partial fulfillment of Doctor of Philosophy degree requirements.

This investigation was supported by grant GM-13844 from the National Institutes of Health and by grant AFOSR 87-65,66 from the U. S. Dept. of the Air Force.

Presented in part, to the Pharmacology and Biochemistry Section, APhA Academy of Pharmaceutical Sciences, Dallas meeting, April 1966.

[1] M.p. 87–88°, yield 468 mg.

[2] The product must be thoroughly dry. Storage for 4 days under previously described conditions usually is adequate and storage for 3 months causes no decrease in atropine yields.

[3] Type W-2 catalyst was used in earlier work. Reduction is more rapid and less difficulties are encountered with the W-7 catalyst.

[4] When prepared as described and stored under 250 ml. ethanol, the suspension contains 28 mg. catalyst per ml.

[5] Stored in the refrigerator in bottles filled with absolute ethanol.

[6] A check of catalyst activity under experimental conditions circumvents many difficulties and prevents losses of radioactive intermediates. Traces of impurities of hydrogen quickly poison the catalyst. The gas must be purchased in highly purified form, or it must be purified before use.

[7] Yields should be practically quantitative. M.p. picrate 295°.

[8] Van de Kamp did not indicate the grade of Raney nickel used. Although W-2 catalyst was used in earlier work, the W-7 grade was more satisfactory.

[9] A glass-coated magnetic stirring bar was used.

[10] Ultra-pure hydrogen, E. H. Sargent and Co. Use of ultra-pure hydrogen is virtually mandatory. Although commercial hydrogen of ordinary purity may be purified by passing through concentrated H_2SO_4, results are still erratic.

asymptotically approached zero. A 2-μl. aliquot of the reaction mixture was spotted on filter paper, air dried, and tested with 2,4-dinitrophenylhydrazine solution. If a negative test was not obtained,[11] the reaction mixture was filtered through a fine-porosity filter and the catalyst washed with approximately 10 ml. absolute ethanol. Filtrate and washings were concentrated to approximately 2 ml.[12] and the reduction repeated with fresh catalyst. Finally, the catalyst was removed by filtration and all solvent was removed by use of the flash evaporator. The product was stored in a desiccator, without vacuum, over NaOH pellets,[13] until converted to the hydrochloride.

After suitable storage, *N*-methyl-^{14}C-tropine[14] was converted to the hydrochloride, in the exact manner described previously (4). The hydrochloride[15] was stored in the 10-ml. reaction vessel, in a vacuum desiccator, over NaOH pellets, until used for esterification.

Synthesis of *N*-Methyl-^{14}C-Atropine from O-Acetyltropic Acid and *N*-Methyl-^{14}C-Tropine HCl—To the *O*-acetyltropic acid chloride obtained from 150-mg. *O*-acetyltropic acid (4)[16] was added the thoroughly dried *N*-methyl-^{14}C-tropine HCl produced from the quantities of reactants used in the Robinson condensation.[17] The reactants were esterified to form *O*-acetyl-*N*-methyl-^{14}C-atropine, the acetylated compound was hydrolyzed to the alkaloidal free base, and *N*-methyl-^{14}C-atropine finally isolated, exactly as described for the unlabeled alkaloid (4). The product was dried immediately in a vacuum desiccator over $CaCl_2$. The dry product was dissolved in 75 ml. anhydrous petroleum ether, the solution was concentrated to approximately 10 ml., and labeled atropine precipitated by cooling in the deep freezer. Petroleum ether was decanted from the crystals,[18] the product recrystallized from petroleum ether, then dried in a desiccator over $CaCl_2$.[19]

Synthesis of *N*-Methyl-^{14}C-Tropanone—Labeled tropanone was prepared from methylamine-^{14}C-HCl, succindialdehyde, and acetone dicarboxylic acid, according to previously described procedures (4, 5). The earlier papers should be consulted for essential experimental details.

Acetone dicarboxylic acid was prepared from 1-Gm. citric acid, collected after the final cooling to −8°, and immediately used in the Robinson condensation. During collection of acetone dicarboxylic acid, succindialdehyde was prepared. To 5 μl. of concentrated HCl and 5 ml. water, contained in a 10-ml. beaker, was added 0.34 ml. of 2,5-diethoxytetrahydrofuran. The mixture was hydrolyzed by stirring, at room temperature for 10 min. The resulting dialdehyde[20] was used immediately in the Robinson condensation.[21]

To the solution of succindialdehyde was added 40% of the moist acetone dicarboxylic acid from 1 Gm. of citric acid. Saturated, aqueous Na_2HPO_4 was added to adjust the pH to 4.5–5.0, using a glass electrode. The buffered mixture was transferred to a previously assembled, 250-ml., conical, side-arm flask and the system purged with nitrogen for 10 min. To the buffered mixture was added 5 ml. water, containing 33.8 mg. of methylamine-^{14}C-HCl[22] and 33.8 mg. unlabeled methylamine HCl. The volume was adjusted to 50 ml. and the system quickly evacuated to remove most of the gas phase.[23] The system was closed and the mixture allowed to stand at room temperature for 12 hr. The slight evacuation was repeated and, after standing at room temperature for an additional 12 hr., the solution was saturated with Na_2CO_3.

Tropanone was extracted with 100-ml. portions of petroleum ether, exactly as previously described (4), except that extraction was continued until significant amounts of radioactivity no longer were removed. The petroleum ether extracts were dried over Na_2SO_4, transferred to a 250-ml. sublimation flask, and the solvent removed, *in vacuo*, on the flash evaporator, at 40°. Tropanone, which remained in the flask as a brown oil, was dried *in situ*, in a desiccator, over $CaCl_2$ and NaOH, overnight. The crude product was purified by repeated sublimation at 40° and 1×10^{-4} mm. Hg. After each sublimation, the product was washed from the cold finger with small amounts of absolute ethanol. Sublimation was repeated until the washings no longer contained significant amounts of radioactivity. The combined, alcoholic solutions of *N*-methyl-^{14}C-tropanone were evaporated to dryness in the flash evaporator, in a previously tared 25-ml. flask. The product[24] crystallized quickly on cooling, was dried in a desiccator for 12 hr., then reduced to tropine.

RESULTS AND DISCUSSION

The synthesis of tropine, labeled with ^{14}C in the carbon skeleton, and of atropine labeled in the tropine moiety, has remained an unsolved problem. For synthesis of the heterocycle, the Robinson condensation (9, 10) is inherently versatile and has been proven adaptable for microsynthesis (4, 11). In a similar way, the Wolffenstein and Mamlock esterification has been adapted for microsynthesis (4, 11, and 12) and has been proven adequate for the

[11] Disappearance of the 2,4-dinitrophenylhydrazine color was a more reliable index of complete reduction than was hydrogen uptake. In no instance was a negative color accompanied by unexpectedly low tropine yields. At times, theoretical or greater than theoretical hydrogen uptake was accompanied by a positive 2,4-dinitrophenylhydraline test. Repetition of the reduction gave a negative color and the expected tropine yields.

[12] Losses may occur by volatilization. Evaporation of the solvent must be done carefully.

[13] The product must be dry before it is converted to the hydrochloride, yet drying must not be unduly prolonged because losses occur by volatilization. Crystallization usually occurs within 12 hr. and storage for an additional 24 hr. usually is adequate for drying. A maximum storage of 2 days, without vacuum, is recommended.

[14] Yield 93.8 mg., specific activity 1 mc./mmole, m.p. 63–65°.

[15] Yield 119 mg., specific activity 1 mc./mmole, m.p. 280° with decomposition.

[16] Requirements for freshly prepared acyl halide, removal of all traces of thionyl chloride, and exclusion of moisture must be re-emphasized.

[17] Labeled tropine HCl from the stated amounts of methylamine HCl, acetone dicarboxylic acid and succindialdehyde weighed 115 mg., specific activity 1 mc./mmole, m.p. 280°, when corrected for tropanone contamination.

[18] At this point, the product usually contains small amounts of tropine. In no instance did tropine represent more than 8% of total counts, equivalent to 4% of product weight.

[19] Yield 130 mg. (45% based on methylamine HCl), specific activity 1 mc./mmole, m.p. 114–116°, after recrystallization from petroleum ether.

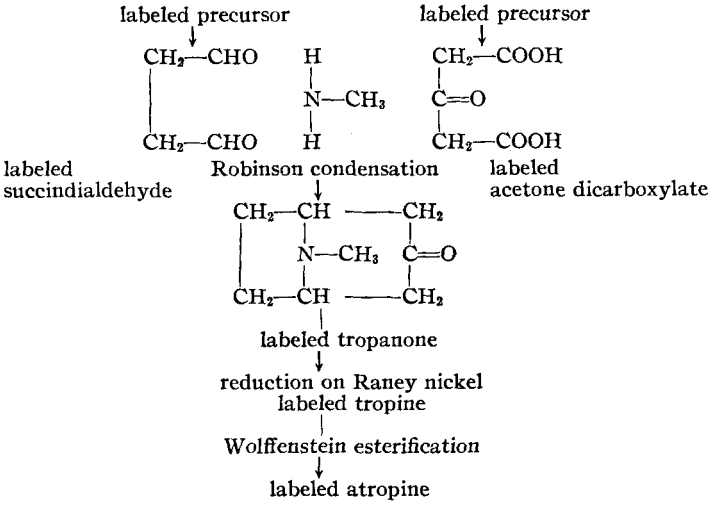
[20] This quantity of diethoxytetrahydrofuran produces 2 mmole (173 mg.) of succindialdehyde.

[21] Ideally, collection of acetone dicarboxylic acid and hydrolysis of diethoxytetrahydrofuran should be completed at the same time.

[22] Mallinckrodt Nuclear (formerly Nuclear Research Chemicals), Orlando, Florida. Specific activity 2 mc./mmole.

[23] Flask evacuated to the point at which the liquid in it bubbles slightly but does not boil vigorously.

[24] Yield 94.3 mg., needles, m.p. 41–43°, specific activity 1 mc./mmole.



Scheme I

esterification of tropine and tropic acid. It is clear, from the reaction sequence (Scheme I), that labeled precursors of succindialdehyde or acetone dicarboxylic acid become logical instruments for labeling the carbon skeleton of tropine.

Several studies with unlabeled compounds support the feasibility of this scheme, but the use of labeled intermediates has been limited and published findings remain unconfirmed. For convenience of discussion, the esterification and condensation steps may be considered as separate entities.

After a single esterification, Werner (11) obtained 70% of theoretical yields for the esterification of *N*-methyl-^{14}C-tropine with unlabeled tropic acid. This is in agreement with yields obtained in the microesterification of unlabeled intermediates (4), but other observations indicate a potential lack of reproducibility. Fodor (13) also esterified *N*-methyl-^{14}C-tropine with unlabeled tropic acid. In this instance, yields were "slightly less than 60%" and the author did not comment on the extent of contamination. Werner obtained similar yields for the esterification of unlabeled tropine with labeled tropic acid, and reported that two esterifications were necessary. These discrepancies indicated a potential lack of reproducibility, possibly associated with the use of ^{14}C-labeled intermediates. To clarify this point and to establish for future studies reproducibility of the esterification, the authors synthesized *N*-methyl-^{14}C-atropine from *N*-methyl-^{14}C-tropine and unlabeled tropic acid. The results indicate that the use of labeled tropine has little or no effect on the esterification. It is clear, from the data in Table I, that synthesis of the labeled heterocycle is the major obstacle encountered in the synthesis of tropine-labeled atropine.

Excluding biosynthetic methods, syntheses of ^{14}C-labeled tropine and correspondingly labeled atropine have been confined to labeling the methyl group attached to the endo nitrogen bridge. Two general approaches have been through the Robinson condensation, employed by the authors and by Werner, and through methylation of nortropine or norhyoscyamine, employed by Fodor (13). Comparative yields are shown in Table I. Fodor's approach does not permit labeling of other positions n the tropine moiety and yields are prohibitively low. The authors' findings with unlabeled intermediates, and Werner's findings with methylamine-^{14}C implied that use of the Robinson condensation would be a far more efficient approach. The data shown in Table I confirm, for the first time, Werner's synthesis of *N*-methyl-^{14}C-tropine and *N*-methyl-^{14}C-atropine. The near identity of results obtained with labeled and unlabeled intermediates indicates no isotope effect on either the condensation or the esterification. These observations firmly establish the Robinson condensation as an instrument for labeling tropine and thereby open the way for introducing radioactive carbon into other ring positions.

Identity of the products was established by melting points, and by paper[25] and thin-layer[26] chromatography in a variety of solvent systems. Paper and thin-layer chromatograms of *N*-methyl-^{14}C-tropine demonstrated traces of an impurity, which represented less than 3% of the total radioactivity and chromatographed as tropanone in all solvent systems used. This impurity disappeared in subsequent steps and no attempt was made to further purify the tropine[27] or more positively identify the impurity. On precipitation from petroleum ether, *N*-methyl-^{14}C-atropine contained an impurity that chromatographed as tropine[28] in all solvent systems used. The impurity represented 7.6% of total radioactivity, equivalent to 3.8% of product weight, and disappeared after a single recrystallization from petroleum ether. Representative paper and thin-layer chromatograms of the final, recrystallized product are shown in Fig. 1.

[25] Paper chromatograms by the ascending technique, Whatman No. 1 paper, using butanol–acetic acid–water (344:56:130). Spots were located by cutting inch-wide strips into 1-cm. segments and counting individually in a Packard Tri-carb liquid scintillation counter. Counting done in toluene, using POP and dimethyl POPOP.

[26] Thin-layer chromatograms on Eastman Silica Gel G sheets, using chloroform, diethylamine, acetone, 25% aqueous ammonia (50:10:35:5). Strips were cut and counted as described for paper chromatograms. For both paper and thin-layer chromatograms, samples were adjusted with HCl to pH 4.5 before application to the chromatograms.

[27] If tropine were the desired end product, tropanone could be removed by repeating the reduction or by fractional sublimation of the impure tropine.

[28] Preliminary studies with labeled tropine have shown that it is not metabolized by mice. Thus the product can be used after a single crystallization from petroleum ether, the trace of tropine serving as an internal standard for locating tropine on chromatograms.

TABLE I—COMPARISON OF OBSERVED AND REPORTED YIELDS[a] FOR THE SYNTHESIS OF *N*-METHYL-^{14}C-TROPINE AND *N*-METHYL-^{14}C-ATROPINE

CONCLUSIONS

Using a previously described, micro adaptation of the Robinson condensation, *N*-methyl-^{14}C-tropine was synthesized from methylamine-^{14}C-HCl in 65% of theoretical yield. The product contained less than 3% of an impurity that chromatographed as unreduced tropanone. The impurity was lost in subsequent steps and no attempt was made to further purify the product or more positively identify the impurity.

Labeled tropine was converted to *N*-methyl-^{14}C-atropine in 45% of theoretical yield, based on methylamine ^{14}C-HCl. When crystallized from petroleum ether, the product contained approximately 4% tropine, representing approximately 8% of the total radioactivity. The impurity was removed by a single recrystallization from petroleum ether.

Werner's synthesis of *N*-methyl-^{14}C-tropine and *N*-methyl-^{14}C-atropine is confirmed for the first time. A comparison of present findings, Werner's data, and previous observations with unlabeled Robinson intermediates indicates that no unusual difficulties are encountered in the use of labeled compounds. Accordingly, a general pathway for labeling the carbon skeleton of tropine is firmly established. Labeled succindialdehyde or labeled acetone dicarboxylic acid become logical precursors of labeled tropine. As indicated previously (5), the use of commercially available pentoses-^{14}C would permit labeling of the ring carbons that arise from succindialdehyde. No other method for labeling the carbon skeleton of tropine has been published.

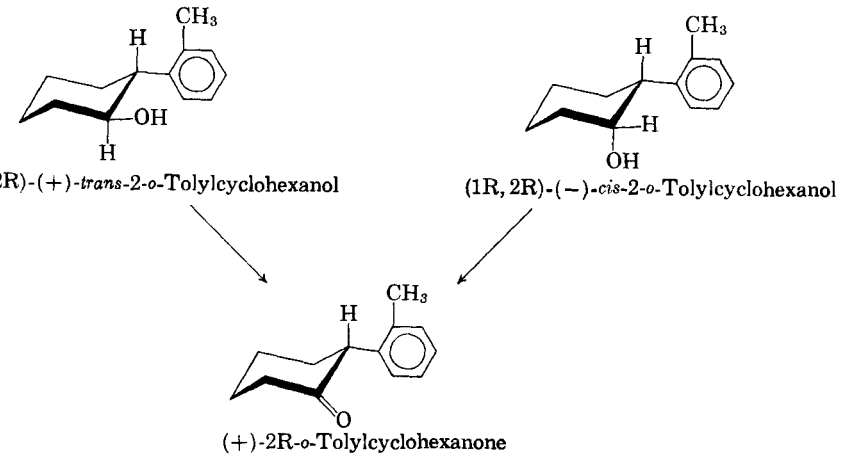
Absolute Configuration of *trans*- and *cis*-2-*o*-Tolylcyclohexanols

By DONALD R. GALPIN* and ALAIN C. HUITRIC

Optically active *trans*- and *cis*-2-*o*-tolylcyclohexanols were obtained by basic hydrolysis of their (−)-menthoxyacetate esters previously prepared and separated. Oxidation of (1S, 2R)-(+)-*trans*- (I) and (1R,2R)-(−)-*cis*-2-*o*-tolylcyclohexanol (II) yielded the same ketone, 2R-(+)-*o*-tolylcyclohexanone (III). The absolute configuration of III was established from ORD and CD measurements. This also established the absolute configuration of I and II. I and II have the same absolute configuration about C-2, but the signs of their Cotton effect in the aromatic region are opposite.

THE ABSOLUTE CONFIGURATION of an optically active ketone is available from optical rotatory dispersion (ORD) and/or circular dichroism (CD) studies to determine the sign of the Cotton effect associated with the carbonyl chromophore (1). If the conformation or significant conformations are known or can be predicted, then an application of the octant rule (2) or some of its extensions (3) will provide the absolute configuration. This rule is limited almost exclusively to ketones,[1] but since optically active secondary alcohols can be oxidized to their corresponding carbonyl compounds with retention of optical activity (4), their absolute configuration can be obtained by this method.



Recently the benzene ring has received attention as a chromophore for ORD and CD studies (5–7). The relatively scant information available concerning the anomalous dispersion of the long wavelength transition of this chromophore has precluded the formulation of a definite rule for the correlation of absolute configuration with the sign of the Cotton effect. As with the carbonyl group the Cotton effect associated with the benzene ring is conformationally dependent (5–7) and since most of the studies involving this chromophore have been conducted on compounds with aliphatic side chains of which there are several rotameric forms, the observed ORD and CD data result from a composite of the various conformers present. Brewster and Buta (5) attempted to circumvent this problem by examining rigid 1-substituted indans and based upon their observations suggested that an octant rule might also be applicable to the benzene ring. Because *trans*- and *cis*-2-*o*-tolylcyclohexanol have been shown by NMR to exist very predominantly in the chair conformation with the tolyl group in equatorial orientation (8a), these compounds appeared to provide excellent systems for the investigation of the Cotton effect in the 260 mμ region of the aromatic ring and the influence of a β axial and equatorial hydroxyl group on the optical activity of this transition.

* Present address: College of Pharmacy, Washington State University, Pullman, WA 99163
[1] An octant rule for azides has recently been formulated; see Djerassi, C., Moscowitz, A., Ponsold, K., and Steiner, G., *J. Am. Chem. Soc.*, **89**, 347(1967).

We wish to report on the absolute configuration of (+)-*trans*- (I) and (−)-*cis*-2-*o*-tolylcyclohexanol (II) obtained from ORD and CD measurements on (+)-2-*o*-tolylcyclohexanone (III), the oxidation product of these alcohols, and the anomalous dispersion of the aromatic ring in these compounds.

RESULTS AND DISCUSSION

The resolution of racemic I and racemic II was accomplished through their (−)-menthoxyacetate esters (9). Racemic I and II have been reported previously and some of their pharmacological properties have also been reported (8b, c). The diastereomeric esters of I were separated by fractional recrystallization and column chromatography over neutral alumina and those of II exclusively by column chromatography over this same adsorbent.[2] The progress of both separations was followed by NMR (9). The individual esters were hydrolyzed in an aqueous ethanol solution of 10% sodium hydroxide to obtain the enantiomers.

The chromic acid oxidation (4) of I and II in a two-phase system of ether and water yielded III in both instances. Although I was optically pure and II was approximately 85% one enantiomer (about 70% optical purity), the ketone III isolated from I and II had comparable rotations. The oxidation method is reported to result in little enolization of optical centers adjacent to the carbonyl group (4) but a small degree of racemization through enolization cannot be ruled out. In the oxidation of racemic *trans*-2-*o*-tolylcyclohexanol by this method on a larger scale we obtained about 10% of the keto acid ring opening product (10). This indicates that the rate of oxidation of the enolized form is faster than the rate of racemization, since racemization, if it occurred, was very slight during the oxidation of the optically active alcohols. The progress of oxidation of the optically active alcohols was followed by gas chromatography. Gas chromatography analysis of the purified ketone III obtained from I and II showed only one volatile component. Compounds I, II, and III have different emergence times on the column employed.

The ORD data for the compounds of this study are recorded under *Experimental*. All curves were determined in methanol on two separate samples. On one of each of these samples the determination was repeated on the solution which had been stored for 24–48 hr. The curves were reproducible to within 2% over the region of interest and no change was noted in the curves of the samples which had been stored.

Figure 1 shows the ORD and CD[3] curves for III.

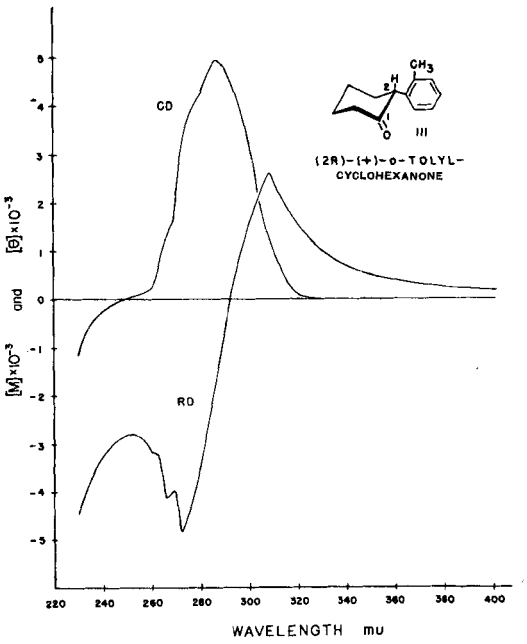

Fig. 1—Rotatory dispersion and circular dichroism curves for 2R-(+)-o-tolylcyclohexanone in menthanol; [M] is molecular rotation and [θ] is molecular ellipticity.

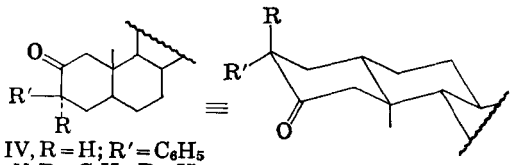
The Cotton effect associated with the carbonyl group is positive as well as the overlapping bands of the aromatic nucleus which appear as shoulders on the CD curve at 274 and 266 mμ. The sign of the Cotton effect of the carbonyl absorption is in agreement with the absolute configuration depicted based upon the octant rule (2) and its extensions (3).



IV, R = H; R′ = C_6H_5
V, R = C_6H_5; R = H

This assignment is supported by the work of Cookson and Hudec (11) who have shown that for the isomeric 3-phenylcholestan-2-ones, the 3-β-isomer IV (phenyl group equatorial) has a molecular amplitude[4] of somewhat less than +53, in which the presence of the aromatic ring gives a negative contribution to the amplitude of the Cotton effect when compared to the unsubstituted cholestan-2-one which has a molecular amplitude of +122 (12). Conversely, in the 3-α-isomer V, which has a molecular amplitude of +303,[5] the axial aromatic ring gives a large positive contribution to the Cotton effect as a result of homoconjugation of the benzene and carbonyl π electrons (3, 11).

The NMR spectrum of III (13) is consistent with the conformation shown in which the tolyl group is equatorially oriented and rules out any large populations of twist or axial conformers. Since the Cotton

[2] Pure (+)-*trans*-2-*o*-tolylcyclohexyl (−)-menthoxyacetate has $[\alpha]_D^{27}$ −32.5° (c 10, chloroform); pure (−)-*trans*-2-*o*-tolylcyclohexyl (−)-menthoxyacetate has $[\alpha]_D^{28}$ −67.9° (c 10, chloroform). The most pure sample of (−)-*cis*-2-*o*-tolylcyclohexyl (−)-menthoxyacetate isolated has $[\alpha]_D^{28}$ −143.5° (c 10, chloroform) and was judged to be at least 95% pure on the basis of its NMR spectrum; the sample of this ester from which II was obtained had $[\alpha]_D^{25}$ −123° (c, 0.1026 methanol) and was considered approximately 85% pure on the basis of its optical rotation and NMR spectrum (9).

[3] The CD curves were also obtained in methanol. The authors are deeply indebted to Dr. William F. Trager who made all the CD determinations reported in this paper while he was at the Chelsea College of Science and Technology, London, England.

[4] The trough was not quite reached in this determination. Moscowitz *et al.* (3) report a value of +45 in dioxane.

[5] Moscowitz *et al.* (3) show a value of +375.

effect of III is positive, it must have the configuration corresponding to the mirror image of the equatorially substituted 3-β-phenylsteroid IV (3). For an independent assignment of the absolute configuration of III based on chemical evidence see Huitric and Newell (14).

The influence of the *o*-tolyl methyl group on the carbonyl Cotton effect in compound II is unknown and difficult to predict. Examination of Dreiding molecular models indicates that rotation of the equatorially oriented tolyl group causes the position of the methyl group to alternate between back and front upper- and lower-left octants, but the weighted time-average positions are uncertain. There is also some question regarding the applicability of the octant rule to front-octant perturbations (15). It would appear that the predominant effect of the *ortho* methyl group is through its influence on the preferred conformation of the molecule. For example, it will decrease contribution from a chair conformation with the aromatic group in axial orientation and will also affect the rotation of the phenyl ring. It is interesting to note that in the other chair conformation of III (aromatic group axial) the phenyl ring is located in the lower-right back octant. Any contribution from this conformation would therefore also contribute to the positive Cotton effect and would also cause an enhancement of the molecular amplitude (3, 11).

The ORD and CD curves for I and II appear in Figs. 2 and 3, respectively. In both instances there is a weak multiple Cotton effect associated with aromatic absorption in the 260 mμ region. The strength of the Cotton effect is best obtained from a comparison of the CD curves. If the background curve in the ORD is steeply rising, it may obscure the Cotton effect (6, 16). Although both compounds have the same absolute configuration about the carbon atom bearing the tolyl group, the signs of their Cotton effects, measured in methanol, are opposite. The CD curve of I was determined on its enantiomer $[\alpha]_D^{26}$ −70.6° (c 10, chloroform)[6] and the mirror image is reproduced.[7] The CD curve of II, which was determined to 225 mμ, exhibits another negative transition beginning to appear at 227 mμ; the CD curve for I was measured only to 230 mμ.

In the 1-substituted indan series Brewster and Buta (5) concluded that a large Cotton effect in the 250–270 mμ region appears to be associated with the presence of a group capable of direct perturbation of the π electron cloud of the ring by hydrogen bonding or by electrostatic effects. In our systems intramolecular hydrogen bonding with the π electron cloud should be solvent dependent. The ORD curve of I measured in isooctane[8] showed a smoothing off in the region of 260–270 mμ. Our system lacks the conformational rigidity of the indans and our data on the aromatic chromophore are not yet sufficient to draw conclusions. Solvent effects will be studied more thoroughly from CD measurements and the authors are in the process of studying the *p*-tolyl isomers and the 2,6-dimethylphenyl analogs.

[6] The extremely weak pen displacements in the CD determinations of these alcohols did not permit the elucidation of fine structure. Consequently, the shape of these curves is only approximate and the sign and magnitude of the absorption are the more significant information.

[7] The ORD curve was determined on both enantiomers and the curve of (−)-I was the exact mirror image of that of (+)-I and agreed in absolute values of rotation to within 2% over the entire spectrum.

[8] The ORD curve in isooctane was determined by Todd D. Cochran.

EXPERIMENTAL

(1S,2R)-(+)-trans-2-o-Tolylcyclohexanol (I)—A mixture of 4.0 Gm. of (+)-*trans*-2-*o*-tolylcyclohexyl (−)-menthoxyacetate (9) and 100 ml. of a 10% solution of sodium hydroxide in 70% ethanol in water was refluxed for 2.5 hr., cooled, and diluted with 100 ml. of water. The mixture was extracted four times with 50-ml. portions of ether and the combined ether extracts were washed twice with 25-ml. portions of 5% sodium hydroxide, once with 5% hydrochloric acid, then with water until the washings were neutral, and dried over anhydrous calcium sulfate. Filtration, solvent removal, and distillation yielded 1.70 Gm. of I, b.p. 81–82° at 0.20 mm.; $[\alpha]_D^{26}$ +70.6° (c 10 chloroform). Analysis of this alcohol by VPC on a Carbowax 20 M column at 190° showed a single volatile component present. The IR spectrum on sodium chloride plates was essentially the same as racemic I, exhibiting minor variations in the fingerprint region; RD in methanol (c 0.1096) showed $[M]_{600}$ +132°, $[M]_{589}$ +141°, $[M]_{500}$ +222°, $[M]_{400}$ +399°, $[M]_{300}$ +1084°, $[M]_{273}$ +2056° (peak), $[M]_{270}$ +1671° (trough), $[M]_{266}$ +1900° (peak), $[M]_{263}$ +1730° (trough), $[M]_{230}$ +4999°.

The levorotatory enantiomer was obtained by the same method, $[\alpha]_D^{26}$ −71.1° (c 10, chloroform); the ORD curve was the exact mirror image of that of (+)-I.

Acidification of the combined basic solutions and workup yielded after distillation 1.82 Gm. of (−)-menthoxyacetic acid, b.p. 108–110° at 0.4 mm.; $[\alpha]_D^{26}$ −94.7° (c 10, chloroform). Reported: b.p. 134–137° at 2 mm. (17); $[\alpha]_D^{25}$ −91.5° (c 2, 95% ethanol) (18).

(1R,2R)-(−)-cis-2-o-Tolylcyclohexanol (II)—A 2.1-Gm. sample of the *cis* esters ($[\alpha]_D^{25}$ −123° [c 0.1026, methanol]), approximately 85% (−)-*cis*-2-*o*-tolylcyclohexyl (−)-menthoxyacetate (9), was hydrolyzed as described for the isolation of I. Following workup the product was distilled to give 0.85 Gm. of II, b.p. 76–78° at 0.18 mm.; $[\alpha]_D^{25}$ −102° (c 0.1280, methanol). Analysis of this alcohol by VPC on a Carbowax 20 M column at 190° showed it to be free of volatile contaminants. The IR spectrum on sodium chloride plates was identical to racemic II. The reported b.p. of racemic II is 76–78° at 0.15–0.17 mm. (8). On the basis of the specific rotation and NMR spectrum (9) of the starting ester the compound is estimated to be about 85% one enantiomer (about 70% optical purity). RD in methanol (c 0.1280) showed $[M]_{600}$ −188°, $[M]_{589}$ −195°, $[M]_{500}$ −300°, $[M]_{400}$ −530°, $[M]_{300}$ −1231°, $[M]_{272}$ −1896° (trough), $[M]_{270}$ −1876° (peak), $[M]_{267-265}$ −1944° (shoulder), $[M]_{250}$ −2556°, $[M]_{230}$ −5932°.

2R-(+)-o-Tolylcyclohexanone (III)—This ketone was obtained by the oxidation of either I or II by the method of Brown and Garg (4). The oxidation of I is given. To a stirred solution of 0.905 Gm. (4.76 mmoles) of I in 10 ml. of ether in a 50-ml. flask, fitted with a reflux condenser, dropping funnel, and a magnetic stirrer, a solution of 0.905 Gm. (3.17 mmoles.) of sodium dichromate dihydrate and 0.72 ml. of 96% sulfuric acid in 10 ml. of water was added over a period of 30 min. The progress of the reaction was followed by VPC on a Carbowax 20 M column at 190°. When the reaction was complete, the ether layer was separated and the aqueous phase extracted several times with small portions of ether. The combined ether solutions were washed twice with 10-ml. portions of 5% sodium bicarbonate followed by two water washings and dried by passage through anhydrous sodium sulfate. The solvent was removed and the residue recrystallized once from *n*-hexane to give a first crop of 0.500 Gm. of colorless crystals, m.p. 72–73.5° (Fisher-Johns); $[\alpha]_D^{25}$ +11.80° (c 1.000, methanol). The IR spectrum (potassium bromide disk) was essentially identical to that of racemic III, exhibiting only minor variations in the fingerprint region. Analysis of this ketone by VPC showed a single peak with the same emergence time as racemic III; RD in methanol (c 0.0996) showed $[M]_{600}$ +20.7°, $[M]_{589}$ +22.2°, $[M]_{500}$ +50.6°, $[M]_{400}$ +183°, $[M]_{350}$ +502°, $[M]_{308}$ +2598° (peak), $[M]_{272}$ −4824° (trough), $[M]_{269}$ −3978° (peak), $[M]_{266}$ −4138° (trough), $[M]_{263}$ −3209°, $[M]_{255}$ −2839°, $[M]_{250}$ −2812°, $[M]_{230}$ −4442°.

The oxidation of II by this method yielded III, m.p. 73.5–74.5° (Fisher-Johns), mixed m.p. with III obtained from I 73–74.5°; $[\alpha]_D^{25}$ +11.00° (c 1.000, methanol). Analysis of this ketone by VPC showed one component present. The m.p. of racemic III is 55.5–56.5° (19).

The ORD curves reported in this paper were obtained on a Cary 60 recording spectropolarimeter using a 250-w. xenon lamp as the light source at 25° in a 1.0-cm. cell and employing a fixed slit width of 0.3 mm. from 600 mμ to 450 mμ and the manufacturer's preprogrammed slit width from 450 mμ to 230 mμ. The specific rotations quoted at the sodium D line (589 mμ) in methanol were also determined on this instrument employing the same fixed slit width and cell length as for the ORD curves.

All specific rotations determined in chloroform were performed on a Rudolph polarimeter using a sodium lamp and a 1-dcm. tube. Rotations were taken at room temperature.

Specific Assay Methods for Droperidol and Fentanyl Citrate in a Pharmaceutical Combination

By CASIMIR A. JANICKI, RONALD J. BRENNER, and BARBARA E. SCHWARTZ

In acid solution, droperidol, 1-{1-[3-(*p*-fluorobenzoyl)propyl]-1,2,3,6-tetrahydro-4-pyridyl}-2-benzimidazolinone, is decomposed to form 4′-fluoro-4-(4-oxopiperidino)butyrophenone and 2-benzimidazolinone. Fentanyl, *N*-(1-phenethyl-4-piperidyl)propionanilide, is decomposed in acid solution to form 4-anilino-1-(2-phenylethyl)piperidine. A procedure to assay droperidol in the presence of its hydrolysis products, fentanyl, and its hydrolysis product is given. Droperidol is analyzed by its UV absorption after being separated from interfering products. A procedure to assay fentanyl in the presence of its hydrolysis products, droperidol, and its hydrolysis products is given. Droperidol and 4-anilino-1-(2-phenylethyl)-piperidine are separated from fentanyl through the formation of a reineckate derivative and fentanyl is subsequently determined by a methyl orange procedure. Data are presented to show the accuracy and precision of the methods.

DROPERIDOL, 1 - {1 - [3 - (*p* - fluorobenzoyl)-propyl]-1,2,3,6 - tetrahydro - 4 - pyridyl} - 2-benzimidazolinone, was first synthesized by Janssen *et al.* and has been shown to be a sedative or tranquilizer (1, 2). Fentanyl citrate [*N*-(1-phenethyl-4-piperidyl) propionanilide dihydrogen citrate] was also synthesized by Janssen *et al.*, and has been shown to be a potent narcotic analgesic (2). It has been reported to be 100 times more potent on a weight basis than morphine as an analgesic (3).

A combination of droperidol and fentanyl citrate in solution has been employed for neuroleptanalgesia or as an adjunct to nitrous oxide for general anesthesia in man (4). It has also been successfully employed in veterinary medicine as an analgesic tranquilizer[1] for use in surgery in dogs (5).

The specific assays for each active ingredient in the presence of the other was essential to study the stability of the various combinations prepared in these laboratories. The usual ratio of droperidol to fentanyl in solution was 50:1. The fentanyl content varied from 20 mcg./ml. to the concentration used in the veterinary product 400 mcg./ml.

Fentanyl, because of its low concentration and its low ratio with respect to droperidol, presented a formidable analytical problem. For the assay of fentanyl to be specific, fentanyl had to be separated not only from its own hydrolysis product, but also from a large amount of droperidol and hydrolysis products of droperidol.

The proposed assay methods for droperidol and fentanyl, alone or in combination, are specific for the intact drug.

EXPERIMENTAL

Hydrolysis Studies—Droperidol (I) was refluxed overnight in 1 *M* hydrochloric acid and was found to undergo complete hydrolysis. Two major products were isolated, 4′-fluoro-4-(4-oxopiperidino)butyrophenone (II) and 2-benzimidazolinone (III) (Scheme I).

A solution of droperidol in monoglyme was refluxed overnight in 2 *M* sodium hydroxide and was recovered unchanged.

Fentanyl (IV), prepared from its citrate salt, was refluxed overnight in 1 *M* hydrochloric acid and was found to undergo complete hydrolysis. One

major product was isolated, 4-anilino-1-(2-phenylethyl)piperidine (V) (Scheme II).

A monoglyme solution of fentanyl was recovered unchanged after refluxing in 2 *M* sodium hydroxide overnight.

Method Development—*Droperidol Assay*—Droperidol exhibits a strong ultraviolet absorption spectrum and an assay method was chosen to utilize this property. The two major hydrolysis products have ultraviolet absorption spectra which would interfere in a direct ultraviolet assay for droperidol. The ultraviolet absorption spectra of droperidol ($\epsilon_{max.}$ 276 mμ = 7100; $\epsilon_{max.}$ 247 mμ = 14,500), II ($\epsilon_{max.}$ 248 mμ = 12,500), and III ($\epsilon_{max.}$ 276 mμ = 6,800) are given in Fig. 1.

Fentanyl ($\epsilon_{max.}$ 258 mμ = 465) and its hydrolysis product (V) ($\epsilon_{max.}$ 257 mμ = 440) have ultraviolet absorption spectra which are of low intensity. The spectra are presented in Fig. 2. Unless they were present in solution at very high concentrations, fentanyl and its hydrolysis product would not be expected to interfere in an ultraviolet assay method for droperidol.

A reaction, which is characteristic of aldehydes and some ketones, is the addition of sodium bisulfite to form water-soluble bisulfite addition products. One of the hydrolysis products of droperidol (II) quantitatively forms such an addition product very readily. The addition of bisulfite would be expected to add first to the piperidino carbonyl group. Sodium bisulfite may also react with droperidol under the proper conditions. When mixtures of droperidol and II were extracted with chloroform from 0.3% aqueous sodium bisulfite solution buffered at pH 6, droperidol was quantitatively found in the chloroform layer, while II was

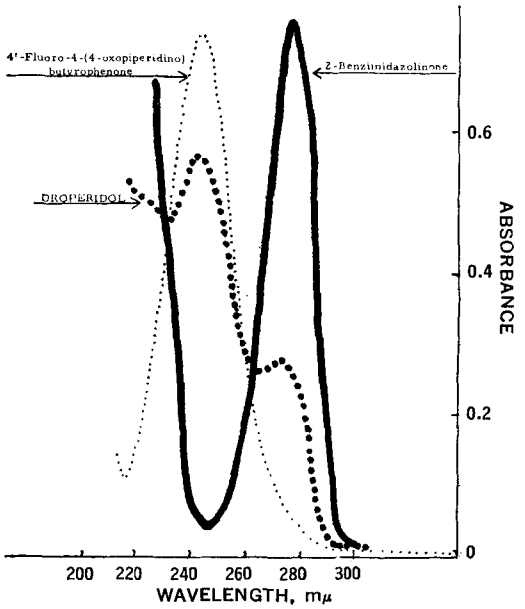

Fig. 1—The UV absorption spectra of droperidol (0.0147 mg./ml.), 4'-fluoro-4-(4-oxopiperidone)butyrophenone (0.0155 mg./ml.), 2-benzimidazolinone (0.0151 mg./ml.) in 0.1 M hydrochloric acid, 1-cm. cells.

quantitatively found in the aqueous layer. The concentration of sodium bisulfite is critical. Increasing the sodium bisulfite concentration from 0.3 to 1.2% resulted in losses of droperidol in the chloroform layer. At a concentration of 0.9% sodium bisulfite, there was a 3% loss of droperidol and a 40% loss at 1.2%. No losses of droperidol were encountered using the conditions described in the proposed assay. Lowering the pH resulted in incomplete extraction of droperidol into the chloroform. The 2-benzimidazolinone is unaffected by sodium bisulfite and is found essentially in the pH 6 layer having a partition coefficient of 0.15 with chloroform.

The droperidol in the chloroform layer was now separated from II and about 96% of III. Droperidol was quantitatively extracted from chloroform into citric acid. The III present in the chloroform was also extracted into the citric acid. Since III has no ultraviolet absorption at 246 mμ, the absorbance at 246 mμ is entirely due to the droperidol (Fig. 1). Mixtures of droperidol and III were assayed for droperidol by the use of the proposed assay. No

interference was found from the hydrolysis product as indicated from the data presented in Table I.

The fate of each component of known mixtures of droperidol and its two hydrolysis products was followed by a thin-layer chromotographic method. Samples spotted on a fluorescent silica plate[2] were developed once, in a tank without a paper wick, *with 5% v/v methanol in chloroform. After air-drying* the plate, droperidol and its two hydrolysis products could be detected under short wavelength UV light. The spots appeared dark against a fluorescent background. However, when mixtures of all three compounds were chromotographed only 2 spots appeared under short wavelength UV light. The droperidol spot overlapped the III spot. When the plate was sprayed with a 0.2% alcoholic solution of dichlorofluorescein, dried at 60° for 15 min., and viewed under long wavelength UV light, only the spot of III could be observed. Under short wavelength UV light, two spots appeared, the II spot and the droperidol–III combined spot. With the dichlorofluorescein spray, as little as 1 mcg. of III could be detected in large amounts (100 mcg.) of droperidol. The thin-layer study confirmed that II remained completely in the aqueous bisulfite solution, while droperidol could not be detected in any significant amounts in the aqueous layer.

The R_f values obtained for droperidol and its hydrolysis products and for fentanyl and its hydrolysis product are given in Table II.

In quantitative TLC work it was necessary to prepare the fluorescent silica plates in the laboratory, using Silica Gel GF_{254}.[3] Impurities in the commercial precoated plates made this necessary.

When the samples were in acidic media it was necessary to obtain the free bases for the TLC study. The aqueous solution was made neutral by the addition of 0.1 *N* sodium hydroxide and evaporated to dryness without the aid of heat. The residue was taken up in methanol or acetone and streaked onto a fluorescent silica plate and developed as previously described. An alternate procedure that can be used is to make the aqueous solution slightly alkaline with 0.1 *N* sodium hydroxide and extract with chloroform. The chloroform solution is then streaked onto the fluorescent silica plate and developed as previously described.

Fentanyl Assay—An ultraviolet assay method for fentanyl was not suitable because of its low $\epsilon_{max.}$ value and its usually low concentrations found in pharmaceutical dosage forms. The ultraviolet absorption spectra for fentanyl and its major hydrolysis product are given in Fig. 2. Fentanyl, because of the basic nitrogen in the piperidine ring, was found to form a chloroform-soluble methyl orange complex. The hydrolysis product of fentanyl also forms a chloroform-soluble methyl orange complex. However, V forms a chloroform-insoluble reineckate in sulfuric acid, while fentanyl under the same conditions is quantitatively extracted in chloroform. The thin-layer method described previously, confirmed that V was not extracted into the chloroform with fentanyl.

Droperidol also forms an insoluble reineckate precipitate in sulfuric acid. Therefore, the use of Reinecke salt quantitatively removes both droperidol and the hydrolysis product of fentanyl. On silica thin-layer plates, no trace of droperidol could be found in the chloroform layer. II also forms an insoluble reineckate under the same conditions while III does not. III does not form a chloroform-soluble methyl orange complex, and therefore does not interfere in the proposed fentanyl assay.

The use of 2% methanol in chloroform was used instead of pure chloroform as a precaution to prevent any possible adsorption of fentanyl by the glassware. The concentration of fentanyl in the chloroform solution in the proposed assay is low, being 0.004 mg./ml.

PROPOSED METHODS

Reagents—Hydrochloric acid, 1 *M;* citric acid, 0.1 *M;* sulfuric acid, 20% v/v methanol in chloroform; sodium bisulfite solution, 1%, prepare fresh daily; methyl orange (Fisher Scientific Co.), aqueous solution; sodium phosphate solution,

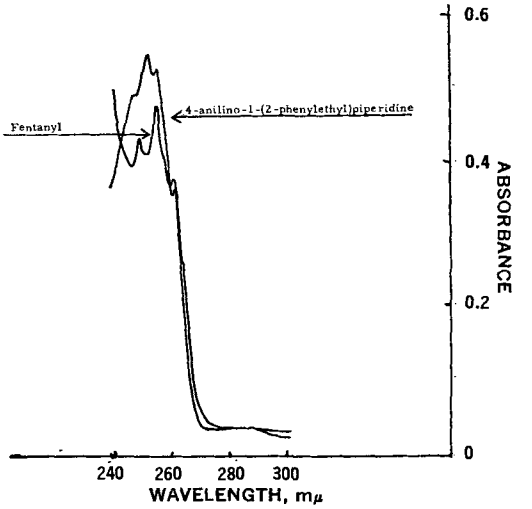

Fig. 2—The UV absorption spectra of fentanyl (0.342 mg./ml.) and 4-anilino-1-(2-phenylethyl)piperidine (0.348 mg./ml.) in 0.1 M hydrochloric acid, 1-cm. cells.

[2] Uniplate, precoated thin-layer chromatography plates from Analtech, Inc., Wilmington, Del.
[3] Brinkmann Instruments, Westbury, N. Y.

0.2 *M;* pH 5 buffer and pH 6 buffer, adjust the 0.2 *M* sodium phosphate solution to pH with 1 *M* sodium hydroxide; lactic acid USP; analytical reagent grades of chloroform, ether, anhydrous methanol.

One percent Reinecke solution, 1 Gm. of Reinecke salt (ammonium tetrathiocyanodiammonochromate, Fisher Scientific Co.) added to 100-ml. water shaker for 15 min., and filtered; prepare this solution immediately before use.

Apparatus—A Beckman DK-2A recording spectrophotometer and a Burrell wrist-action shaker were used. Boston round flint bottles, 30 ml., 60 ml., and 120 ml., fitted with plastic caps having a conical polyethylene liner were obtained from Erno Products Co., Philadelphia, Pa.

Assay for Droperidol—Dilute the sample of droperidol, or the sample of droperidol in combination with fentanyl, with water to obtain a 0.15 mg./ml. solution of droperidol. Pipet 15 ml. of the diluted sample into a 60-ml. bottle containing 10 ml. of the pH 6 buffer, 10 ml. of a 1% sodium bisulfite solution, and exactly 15 ml. of chloroform. Shake for 15 min. on a mechanical shaker, centrifuge, aspirate, and discard the aqueous layer. Pipet 5 ml. of the clear chloroform layer to a 120-ml. bottle containing exactly 50 ml. of 0.1 *M* citric acid. Shake for 30 min. on a mechanical shaker. Centrifuge for a couple of minutes and decant the clear citric acid solution to a clean container. Record the ultraviolet absorption spectrum from 300 to 230 mμ *versus* 0.1 *M* citric acid in 1-cm. cells.

An 0.15 mg./ml. solution of droperidol standard in chloroform is prepared, and taken through the proposed assay. The calculation is then:

$$\frac{\text{absorbance at 246 m}\mu \text{ for the sample}}{\text{absorbance at 246 m}\mu \text{ for the std.}} \times 100 = \%\ \text{droperidol}$$

If the sample contains a preservative such as methyl- or propylparaben, the UV spectrum of droperidol in 0.1 *M* citric acid will be distorted. The following step will remove the preservatives from citric acid solution. The droperidol standard should also be taken through this step.

Extract 20 ml. of the citric acid solution of droperidol with two 70-ml. portions of ether. Discard the ether extracts and record the UV spectrum of the sample as directed.

Assay for Fentanyl—Dilute the fentanyl sample or sample of fentanyl in combination with droperidol with water to obtain a 0.02 mg./ml. solution of fentanyl. Pipet 5 ml. of the diluted solution (rinsing the pipet with the solution once before the sample to be analyzed is taken) into a 60-ml. bottle containing exactly 2 ml. of 20% sulfuric acid. Add exactly 25 ml. of the 2% methanol in chloroform solution and 10 ml. of the Reinecke solution to the sample. Shake the bottle for 15 min. on a mechanical shaker. Do not centrifuge the sample but aspirate and discard the aqueous layer. Filter the chloroform layer through a cotton pledget to remove any traces of the precipitate.

Pipet 15 ml. of the chloroform layer to a 60-ml. bottle containing 10 ml. of pH 5 buffer. Add 1 ml. of the methyl orange reagent and shake the bottle on a mechanical shaker for 15 min. Centrifuge, aspirate, and discard the aqueous layer. Pipet 10 ml. of the chloroform layer to a bottle containing exactly 10 ml. of 1 *M* hydrochloric acid. Shake for 5 min. on a mechanical shaker, centrifuge, and carefully decant the acid layer. Determine the absorbance of the acid layer in 1-cm. cells at the maximum near 505 mμ.

A standard is prepared by dissolving fentanyl citrate in water and diluting it with water to obtain a 0.020 mg./ml. solution expressed as the free base. If the sample contains droperidol, the standard should contain the same amount of droperidol as present in the sample. Droperidol is insoluble in water. It may be solubilized by adding a few drops of lactic acid and heating on a steam bath until dissolved. Upon solution, add hot water and dilute to volume with water after the solution has reached room temperature.

Table III—Precision of the Proposed Assay Method Calculated as the Standard Deviation

Sample	No. of Assays	Droperidol Assay, %	Fentanyl Assay, %
Droperidol	16	1.53	...
Droperidol and fentanyl	118	2.40	3.98
Fentanyl	34	...	2.87

RESULTS AND CONCLUSIONS

The precision of the proposed assays was tested on actual samples that were being tested for their chemical-physical stability. The standard deviations calculated are those which would be normally expected in the laboratory. The standard deviations are presented in Table III.

The proposed assays are stability assays. Each hydrolysis product of droperidol, fentanyl, and the hydrolysis product of fentanyl were taken through the droperidol assay and found not to interfere in the assay. Droperidol, both hydrolysis products of droperidol, and the hydrolysis product of fentanyl were taken through the fentanyl assay and found not to interfere in the assay. The fate of the compounds was followed by a thin-layer chromatographic study of each phase of each extraction procedure.

The assay for droperidol does not appear to have any critical steps. The sodium bisulfite solution should be made fresh daily.

The assay for fentanyl, once started, should be carried to completion without undue delay. Colorimetric reading variation is high when the samples are left in contact with the Reinecke solution for longer than 1 hr. The fentanyl–methyl orange complex in the chloroform decomposes slowly on standing. This does not present a major problem since the chloroform solution is next extracted with 1 *M* hydrochloric acid. The red colored acid solution is stable for days.

If the ratio of droperidol to fentanyl in solution is varied from 50:1 to 25:1; no problems are encountered in either the droperidol or fentanyl assays. However, if the ratio of droperidol to fentanyl is lowered to 15:1, high fentanyl results are encountered. The high results are due to droperidol. From 1 to 3% of the droperidol is not completely precipitated by the Reinecke solution and is extracted into chloroform along with the fentanyl. At this point it is possible to do a TLC separation of fentanyl from droperidol using the TLC method previously described. The fentanyl band is scraped

off and extracted with chloroform and the chloroform solution treated with methyl orange as described. However, it was found that simply by adding sufficient droperidol (in lactic acid solution) to the sample during dilution to raise the ratio of droperidol to fentanyl to 50:1 in the final solution (0.02 mg./ml. fentanyl) complete precipitation of the droperidol was achieved.

The reineckate precipitate of droperidol can be used as a quantitative measure of droperidol. Once 4′-fluoro-4-(4-oxopiperidino)butyrophenone is removed by the addition of sodium bisulfite as directed in the proposed assay for droperidol, the chloroform solution of droperidol can be treated with the Reinecke solution and sulfuric acid. The droperidol-Reinecke precipitate is collected, dissolved in acetone, and the absorbance of the red colored solution read at about 525 mμ. The interference of 4-anilino-1-(2-phenylethyl)piperidine in the Reinecke precipitation of droperidol is small for the droperidol–fentanyl pharmaceutical preparations. The fentanyl would have to be completely hydrolyzed to affect the droperidol reineckate precipitate by 2%.

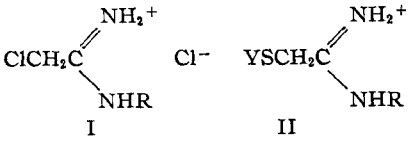
Synthesis of α-Mercaptoacetamidinium Chlorides *via* the Corresponding Phosphorothioates

By TERRY T. CONWAY, ABOO SHOEB, and LUDWIG BAUER

A facile synthesis of α-mercaptoacetamidinium chlorides is described. The procedure consists of treating α-chloroacetamidinium chlorides with trisodium phosphorothioate that formed the corresponding *S*-alkyl phosphorothioates. The latter were not isolated, but were hydrolyzed in the reaction medium by hot dilute acid to furnish the required products.

THE SYNTHESIS of α-mercapto amidines and derivatives as potential antiradiation agents has been under study in this laboratory for some time (1–3). The general approach consisted of treating an α-chloroacetamidinium chloride, I, with a sulfur bearing nucleophile, YS^-, to obtain a substituted acetamidinium cation, II. These



I II

reactions were successful since the substitution reaction of the halo group of the free α-chloroacetamidine was considerably faster than any reaction involving nucleophilic attack at the sp^2 amidine carbon. It was particularly important to exclude the latter type of reaction in an aqueous basic medium since displacement of the halo group by YS^- could easily be accompanied by hydrolysis of the amidine.[1] It was found that a relatively weakly basic, but excellent nucleophile like thiosulfate ion reacted quickly with I to form a series of α-amidinium Bunte salts, III. Due to the relatively easy preparation of

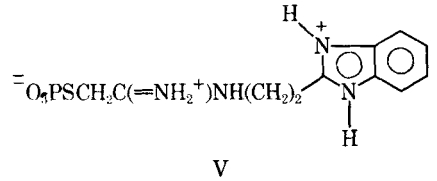
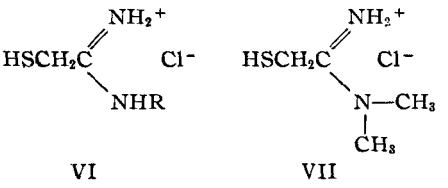
number of these salts, IV, as potential antiradiation agents since a number of analogous *S*-[β-aminoalkyl] phosphorothioates had been shown frequently to afford good protective action against ionizing radiation in mice (4, 5).

The reaction of a number of chloroacetamidinium chlorides with trisodium phosphorothioate in water was followed initially by the change in the NMR spectrum. For example, the proton magnetic resonance spectrum[2] of α-chloroacetamidinium chloride (I, R = H) in water showed a singlet for the CH_2 proton at δ 4.53 which disappeared quickly on the addition of trisodium phosphorothioate. There arose a doublet at δ 3.66 which was assigned to the CH_2—S—P resonance, coupling of the protons over three bonds with phosphorus being observed (J = 13.5 c.p.s.).[3] Addition of methanol to such an aqueous solution furnished the salt (as the trihydrate), IV (R = H). Analogous reactions of I (R = CH_3, $CH_2C_6H_5$, *cyclo*-C_6H_{11}) with Na_3SPO_3 invariably gave aqueous solutions whose NMR spectra showed a doublet (J = 13.5 c.p.s.) in the vicinity of δ 3.70 ± 0.1. Attempts to isolate these phosphorothioates by the addition of alcohols or *N,N*-dimethylformamide to the aqueous solution yielded solids which tenaciously clung to polar solvents. These solids were found to possess varying degrees of stability as was evident by their change in physical appearance and their NMR spectra.[4] One notable exception was the isolation of the relatively stable zwitterion, V. Apparently the basic β-(2-benzimidazole) ethyl group neutralized the second negative charge and V could be kept for months.



V

It was observed, however, that these phosphorothioates, IV, were hydrolyzed readily by hot dilute mineral acids to the corresponding thiols, VI. As a matter of expediency, it was found that the isolation of the intermediate phosphorothioates, IV, was not essential, but these could be hydrolyzed *in situ* and this proved to be a general method for the ready conversion of I to VI. It was possible to synthesize a number of derivatives of VI, where R was representative alkyl and aralkyl groups starting



VI VII

with the corresponding crystalline α-chloroacetamidinium chlorides, I, and without the isolation of IV. These solid α-mercaptoacetamidinium chlorides were stable in air. The only exception in the authors' experience was *N*-methyl-α-mercaptoacetamidinium chloride (VI, R = CH_3), which decomposed quickly. This particular salt began to smell badly of hydrogen sulfide, commenced to liquify within 24 hr. (*in vacuo* at 25°), and its NMR spectrum changed drastically. By contrast, the corresponding *N,N*-dimethyl analog, VII, was quite stable. This salt showed, as expected, two different N—CH_3 signals in the NMR. This restricted rotation about the CN bond is in keeping with that observed in other *N,N*-dimethyl amidinium salts (6).

An extension of this type of synthesis towards *N,N'*-disubstituted α-mercaptoacetamidinium chlorides led into the preparation of imidazole derivatives. For example, 2-(chloromethyl)-imidazoline was readily converted to 2-(mercaptomethyl)imidazoline by this method. An aromatic benzimidazole analog was prepared as shown in Scheme I. This involved originally the preparation of 1-methyl-2-(chloromethyl)-benzimidazole from the reaction of methyl chloroacetimidate (prepared *in situ* from the addition of methanol to chloroacetonitrile) (7) with *N*-methyl-*o*-phenylenediamine hydrochloride.[5] The chloro derivative was then readily converted to the corresponding mercaptan.

Attempts were made to utilize α-amidinium thiosulfates (Bunte salts), III, as suitable precursors to VI. On a preparative scale, the acid hydrolysis of the thiolsulfate group[6] in III was not nearly as satisfactory as that of the

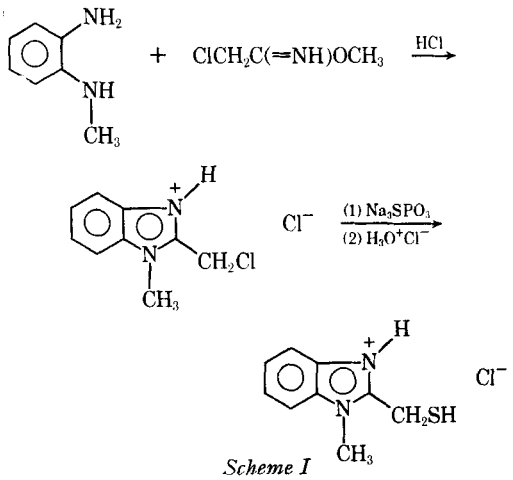
[2] The nuclear magnetic resonance (NMR) spectra were determined at 60 Mc. by means of a Varian A-60 spectrometer and chemical shifts are recorded in parts per million (δ) downfield from such internal standards as tetramethylsilane (TMS) in organic solvents and sodium 3-(trimethylsilyl)-propanesulfonate (TPS) in aqueous or D_2O solutions. Multiplicities are denoted as follows: singlet, s; doublet, d. Assignment of the signals is also based on correct integral information.

[3] Long-range coupling over three bonds, $J_{P\text{-}S\text{-}CH_2}$, has been reported for a number of similar systems: in a number of mercaptophosphazenes, J = 18.1 ± 0.5 c.p.s. [Boden, N., Emsley, J. W., Feeney, J., and Sutcliffe, L. H., *Chem. Ind.*, (London), 1909 (1962)]; in *S*-alkylphosphorothioates, J = 15 c.p.s. [Oswald, A. A., Griesbaum, K., and Hudson, B. E., Jr., *J. Org. Chem.*, **28**, 1262(1963)]; J = 12.7 – 17.5 c.p.s. [Mueller, W. H., Rubin, R. M., and Butler, P. E., *ibid.*, **31**, 3537(1966); Mueller, W. H., and Oswald, A. A., *ibid.*, **32**, 1730(1967)].

[4] Attempts to crystallize these salts with solvent of crystallization or to dry them *in vacuo* at 5° were unsuccessful in most instances and purification resulted in partial decomposition. Most of the *S*-(aminoalkyl)phosphorothioates were isolated with varying proportions of solvent of crystallization (see *References 4* and *5*).

[5] The synthesis of benzimidazoles from *o*-phenylenediamines and imidates was recently reinvestigated [see deSelms, R. C., *J. Org. Chem.*, **27**, 2163(1962)].

[6] For a recent study on the acid-catalyzed hydrolysis of Bunte salts, see Kice, J. L., Anderson, J. M. and Pawlowski, N. E., *J. Am. Chem. Soc.*, **88**, 5245(1966).



Scheme I

phosphorothioate moiety in IV to give VI. The acid hydrolysis of several α-amidinium thiolsulfates, III, was investigated in detail. For example, brief exposure of III (R = benzyl) to hot dilute hydrochloric acid yielded VI (R = benzyl) in poor yield. Prolonged acid treatment (even under nitrogen) produced predominantly the corresponding disulfides, $[-SCH_2C(=NH_2^+)NHCH_2C_6H_5\ Cl^-]_2$, VIII. Presumably, these disulfides are formed by the oxidation of the corresponding mercaptans, although the possibility of displacement of HSO_3^- in III by RSH of VI does exist.[7] This point was not investigated further.

In connection with the general study of nucleophilic displacement reactions of I, *N*-benzyl-α-chloroacetamidinium chloride was treated with sodium sulfite. There was formed the corresponding α-amidinium sulfonate, $^-O_3SCH_2C(=NH_2^+)HNCH_2C_6H_5$, IX. To prove that indeed this substitution reaction involved the formation of a C-S bond, the disulfide, VIII, was oxidized to give IX. The infrared spectrum of IX clearly showed it to be a zwitterion since the characteristic amidinium bands showed up, $-C(=N^+<$ stretching frequency in the vicinity of 1700 and the $>C=NH_2^+$ deformation mode around 1650 cm.$^{-1}$. These bands were also found in III and IV.

EXPERIMENTAL[8]

N-Cyclopentylchloroacetamidinium Chloride—The procedure developed previously (1–3) was used for this and related syntheses. Chloroacetonitrile (7.55 Gm., 0.1 mole) was added slowly to a stirred ice-cold solution of sodium (0.23 Gm., 0.01 Gm.-atom) in methanol (75 ml.). After 1 hr., cyclopentylammonium chloride (13.38 Gm., 0.11 mole) was then added and the mixture stirred for 1 hr. longer. The mixture was filtered and solvent removed at 20–30 mm. and at the lowest temperature. The purple residue was triturated with dry ether and the resultant solid (11.26 Gm., 55%) recrystallized from 2-propanol–ether, m.p. 142.5–143.5° dec.

Anal.—Calcd. for $C_7H_{14}Cl_2N_2$: C, 42.67; H, 7.16; N, 14.22. Found: C, 42.73; H, 7.53; N, 14.00.

N-Cyclohexylchloroacetamidinium Chloride—This salt was prepared in 80% yield in an analogous fashion, using cyclohexylammonium chloride, and recrystallized from 2-propanol, m.p. 181–182.5° dec.

Anal.—Calcd for $C_8H_{16}Cl_2N_2$: C, 45.40; H, 7.62; N, 13.24. Found: C, 45.55; H, 7.83; N, 12.95.

N - [β - (2 - Benzimidazolium)ethyl]chloroacetamidinium Dichloride—When 2-(β-aminoethyl)-benzimidazole dihydrochloride (8) was used as the ammonium salt, the title product commenced to precipitate, was filtered, and an additional quantity obtained when solvents were concentrated. The salt was obtained in 82% yield and was recrystallized from aqueous ethanol, m.p. 244–246°.

Anal.—Calcd. for $C_{11}H_{15}Cl_3N_2$: C, 42.65; H, 4.84; N, 18.09. Found: C, 42.50; H, 4.98; N, 17.98.

1-Methyl-2-(chloromethyl)benzimidazolium Chloride—This salt was obtained in 51% yield when *N*-methyl-*o*-phenylenediamine hydrochloride (Eastman Organic Chemicals) was substituted in the synthesis described above, m.p. 209° (from 2-propanol).

Anal.—Calcd. for $C_9H_{10}Cl_2N_2$: C, 49.77; H, 4.60; N, 12.90. Found: C, 49.49; H, 4.55; N, 12.97.

Sodium S-(Carboxamidiniummethyl)phosphorothioate Trihydrate—α-Chloroacetamidinium chloride (1) (2.58 Gm., 0.02 mole) was added to a solution of trisodium phosphorothioate[9] (3.6 Gm., 0.02 mole) in water (30 ml.) and the resultant solution stirred at 25° for 10 min. A small precipitate was filtered off and the filtrate diluted with methanol (50 ml.), and the mixture chilled for 10 min. The product (3.25 Gm., 66%) was collected, washed copiously with dry ether (two 40-ml. portions), and dried *in vacuo* (over H_2SO_4). On heating in an m.p. tube, it turned yellow and decomposed above 90°.

Anal.—Calcd. for $C_2H_6N_2NaO_3PS\cdot 3H_2O$: C, 9.75; H, 4.91; N, 11.38; S, 13.02. Found: C, 9.75; H, 5.02; N, 11.12; S, 13.11.

Sodium S-[N-(Benzyl)carboxamidiniummethyl]-phosphorothioate Hydrate—*N*-Benzyl-α-chloroacetamidinium chloride (1) (4.38 Gm., 0.02 mole) was added to a stirred aqueous solution of trisodium phosphorothioate (3.6 Gm., 0.02 mole in 35 ml.). After 10 min. at 25°, the mixture was filtered to remove a trace of insoluble material and the filtrate diluted with 2-propanol (50 ml.). The product was filtered, washed with 2-propanol. It was recrystallized by dissolving it in cold water

[7] In their review on Bunte salts, B. Milligan, and J. M. Swan [*Rev. Pure Appl. Chem.*, 12, 72(1962); *J. Chem. Soc.*, 6008 (1963)] state that the reaction of mercaptans with Bunte salts to give disulfides is favored at a high pH. Other relevant literature has been summarized by H. Distler [*Angew. Chem.*, 79, 520(1967)].

[8] All melting and boiling points are uncorrected. Infrared spectra were all determined in Nujol mull (unless otherwise specified) by means of the Perkin-Elmer model 337 spectrophotometer. Microanalyses were performed by Micro-Tech Laboratories, Skokie, Ill. and Dr. Kurt Eder, Geneva, Switzerland. Most of the nitrogen analyses were obtained by Mr. Leo Horner in this department, using a Coleman model D-29.

[9] This salt was prepared from thiophosphoryl chloride (supplied by the Stauffer Chemical Co.) and sodium hydroxide solution at 60°. This modification of S. Akerfeldt's procedure [*Acta Chem. Scand.*, 14, 1980(1960)] was essential and was also reported by J. R. Piper, and T. P. Johnston, [*J. Org. Chem.*, 32, 1261(1967)].

and adding 2-propanol. It was dried at 5° at 20 mm. over concentrated H_2SO_4 until its NMR spectrum showed the absence of signals due to 2-propanol. In H_2O, the salt showed signals due to CH_2S at δ 3.75 (d, J_{CH_2SP} = 13.5 c.p.s.), CH_2N at δ 4.58 (d, J = 6.3 c.p.s.), and C_6H_5 at δ 7.54 (s).

Anal.—Calcd for $C_9H_{12}N_2NaO_3PS \cdot H_2O$: C, 36.01; H, 4.70; N, 9.33. Found: C, 36.46; H, 5.23; N, 8.83.

S - {N - [β - (2 - Benzimidazolium)ethyl]carboxamidiniummethyl}phosphorothioate, V—*N*-[β-(2-Benzimidazolium)ethyl]chloroacetamidinium dichloride (0.3 Gm., 0.001 mole) was added to an aqueous solution of trisodium phosphorothioate (0.18 Gm., 0.001 mole in 10 ml.) and the solution stirred at 25° for 10 min. The product (0.21 Gm., 70%) was collected, washed with hot water, boiling ethanol; m.p. 168–169°. It was dried *in vacuo* at 25° prior to analysis.

Anal.—Calcd. for $C_{11}H_{15}N_4O_3PS \cdot {}^1/_2H_2O$: C, 40.86; H, 4.95; N, 17.33; S, 9.90. Found: C, 41.19; H, 4.97; N, 17.29; S, 9.89.

α-Mercaptoacetamidinium Chloride—All stages of this and cognate experiments were conducted under a blanket of nitrogen. To an aqueous solution of trisodium phosphorothioate (3.66 Gm., 0.02 mole in 25 ml.) was added α-chloroacetamidinium chloride (2.58 Gm., 0.02 mole). The solution was stirred at ambient temperature until the test for phosphorothioate ion was negative [black precipitate with $AgNO_3$ (9), about 3–5 min.]. After 10 min., 6 *N* hydrochloric acid (20 ml.) was added and the solution heated at 90° for 10 min. and then evaporated *in vacuo*. The residue was extracted with 2-propanol (20 ml.) and filtered from inorganic salts. Addition of dry ether (150 ml.) yielded the salt (1.9 Gm., 75%), m.p. 120–122° dec.; infrared absorptions, 2540 (νSH), 1700 (νC=N), 1650 cm.$^{-1}$ (δ C=NH_2^+); NMR signal (D_2O) at δ 3.57 (s) for CH_2S.

Anal.—Calcd. for $C_2H_7ClN_2S$: C, 18.97; H, 5.57; N, 22.13; S, 25.32. Found: C, 18.97; H, 5.55; N, 21.99; S, 25.21.

This procedure was used to convert a number of crystalline α-chloroacetamidinium chlorides to the corresponding thiols.

N,N-Dimethyl-α-mercaptoacetamidinium chloride was prepared in this manner (64%); m.p. 160°; infrared, 2450 (νSH), 1690 (νC=N^+) and 1650 cm.$^{-1}$ (δ C=NH_2^+); NMR, δ (D_2O) 3.65, (s, CH_2S), 3.18, 3.26 (two s, NCH_3).

Anal.—Calcd. for $C_4H_{11}ClN_2S$: C, 31.06; H, 7.12; N, 18.12; S, 20.71. Found: C, 31.15; H, 7.10; N, 18.03; S, 20.64.

N-Cyclopentyl-α-mercaptoacetamidinium chloride was synthesized in this way (72%), m.p. 146–147.5° dec.

Anal.—Calcd. for $C_7H_{15}ClN_2S$: C, 43.17; H, 7.76; N, 14.39; S, 16.47. Found: C, 43.16; H, 7.78; N, 14.59; S, 16.39.

N-Cyclohexyl-α-mercaptoacetamidinium chloride was prepared (44%) as above, m.p. 163–165° dec.

Anal.—Calcd. for $C_8H_{17}ClN_2S$: C, 46.02; H, 8.21; N, 13.42; S, 15.36. Found: C, 45.77; H, 8.15; N, 13.36; S, 15.30.

N-Benzyl-α-mercaptoacetamidinium chloride was made from the corresponding α-chloro compound (1), in 44% yield, m.p. 115–117° dec.; infrared, 2570 (γSH), 1700 (νC=N^+), 1650 cm.$^{-1}$ (δ C=NH_2^+); NMR, δ (D_2O) 3.65 (s, CH_2S), 4.60 (s, CH_2N), 7.46 (s, C_6H_5).

Anal.—Calcd for $C_9H_{13}ClN_2S$: C, 49.87; H, 6.04; N, 12.93; S, 14.80. Found: C, 50.26; H, 5.88; N, 12.91; S, 14.80.

N-(2-Picolyl)-α-mercaptoacetamidinium chloride hydrochloride was produced from the chloro precursor (3) in 63% yield, m.p. 196–197°.

Anal.—Calcd. for $C_8H_{13}Cl_2N_3S$: C, 37.79; H, 5.11; N, 16.53; S, 12.60. Found: C, 37.55; H, 5.15; N, 16.44; S, 12.70.

N - (6 - Methyl - 2 - picolyl) - α - mercaptoacetamidinium chloride hydrochloride was prepared from the corresponding chloro derivative (3) in 48% yield, m.p. 179–181°.

Anal.—Calcd. for $C_9H_{15}Cl_2N_3S$: C, 40.30; H, 5.64; N, 15.64; S, 11.96. Found: C, 40.22; H, 5.53; N, 15.39; S, 11.79.

N - [β - (2 - Pyridyl)ethyl] - α - mercaptoacetamidinium chloride hydrochloride was obtained from the corresponding chloro compound (3) (60%), m.p. 180°.

Anal.—Calcd. for $C_9H_{15}Cl_2N_3S$: C, 40.30; H, 5.60; N, 15.67; S, 11.94. Found: C, 40.15; H, 5.63; N, 15.34; S, 11.91.

2-(Mercaptomethyl)imidazolinium chloride was synthesized in analogous fashion from 2-(chloromethyl)-imidazoline (3) (60%), m.p. 129–130°.

Anal.—Calcd. for $C_4H_9ClN_2S$: C, 31.47; H, 5.90; N, 18.35; S, 20.98. Found: C, 31.60; H, 6.17; N, 18.04; S, 20.40.

1 - Methyl - 2 - (mercaptomethyl) - benzimidazolium chloride hydrate was prepared (in 84% yield) from 1-methyl-2-(chloromethyl)benzimidazolium chloride as described above, m.p. 127°.

Anal.—Calcd. for $C_9H_{11}ClN_2S \cdot H_2O$: C, 46.45; H, 5.59; N, 12.04; S, 13.76; Cl, 15.26. Found: C, 46.53; H, 5.76; N, 12.14; S, 13.80; Cl, 15.30.

N - [β - (2 - Benzimidazolium)ethyl] - α - mercaptoacetamidinium Dichloride—*S*-{*N*-[β-(2-Benzimidazolium)ethyl]carboxamidiniummethyl}phosphorothioate (1.3 Gm., 0.004 mole, prepared above) was heated with 6 *N* HCl (10 ml.) on the steam bath for 10 min. (nitrogen atmosphere). Solvents were removed *in vacuo* to yield a solid (0.8 Gm., 66%), which was recrystallized from a mixture of ethanol–ether to give colorless crystals, m.p. 215–216°.

Anal.—Calcd. for $C_{11}H_{16}Cl_2N_4S$; C, 43.50; H, 5.21; N, 18.23; S, 10.42. Found: C, 43.07; H, 5.13; N, 18.08; S, 10.28.

N-Benzyl-α-mercaptoacetamidinium Chloride from the Hydrolysis of III (R = $CH_2C_6H_5$)—A solution of S-[*N*-(benzyl)-carboxamidinomethane]thiosulfuric acid (1.16 Gm., 0.004 mole) in 6 *N* hydrochloric acid (15 ml.) was heated at 96° for 1.5 hr. (N_2 atmosphere). After removing solvents *in vacuo*, the yellow oily residue crystallized and was recrystallized from ethanol–ether. It weighed 0.2 Gm., (24% yield), m.p. 115–116°, and was identical to the sample made *via* the phosphorothioate.

(N-Benzylcarboxamidinium)methyl Disulfide Dichloride—A solution of S-[*N*-(benzyl)carboxamidinomethane]thiosulfuric acid (1) (2.64 Gm., 0.01 mole) in 6 *N* hydrochloric acid (50 ml.) was heated at 96° for 15 hr. On cooling, the oil which separated solidified and was crystallized from water (1.6 Gm., 75%, m.p. 207–208.5° dec; infrared, 1680 (νC=N^+), 1635 cm.$^{-1}$ (δ C=NH_2^+); NMR in D_2O, δ 3.83 (s, CH_2S) 4.60 (s, CH_2N) 7.48 (s, C_6H_5), in (DMSO-d_6), δ 3.96 (s, CH_2S) 4.72 (d, CH_2N, J_{CH_2-NH} = 5 c.p.s.), 7.49 (s, C_6H_5), 9.95, 9.55, and 10.79 (broad s, NH).

Anal.—Calcd. for $C_{18}H_{24}Cl_2N_4S_2$: C, 50.11; H, 5.61; N, 12.91; S, 14.86. Found: C, 50.43; H, 5.86; N, 12.72; S, 15.21.

(Carboxamidinium)methyl Disulfide Sulfate—A solution of α-(carboxamidino)methanethiolsulfuric acid (1) (10.0 Gm., 0.059 mole) in 6 *N* hydrochloric acid (250 ml.) was heated at 96° for 17 hr. The reaction mixture was evaporated *in vacuo* and the yellow gummy residue recrystallized from 50% aqueous alcohol (4.5 Gm., 55%), m.p. 225–227° dec.; infrared,† 1700 cm.$^{-1}$ (ν C=N$^+$); NMR (D_2O), δ 3.82 (s, CH_2S–S–).

Anal.—Calcd. for $C_4H_{12}N_4O_4S_3$: C, 17.38; H, 4.38; N, 20.27; S, 34.81. Found: C, 17.62; H, 4.50; N, 20.00; S, 35.01.

(N-Benzylcarboxamidino)methanesulfonic Acid—(*a*) To an aqueous solution of *N*-benzyl-α-chloroacetamidinium chloride (1) (5 Gm., 0.019 mole) in 30 ml. was added an aqueous sodium sulfite solution (2.42 Gm. 0.019 mole in 22 ml.) and the mixture heated at the reflux for 0.5 hr. The crystals (1.2 Gm., 37%) which separated were recrystallized from methanol–ether to give the product (0.20 Gm., 47%), m.p. 245–246°; infrared, 1690 (ν C=N$^+$), 1645 cm.$^{-1}$ (δ C=NH_2^+); NMR (D_2O), δ 4.10 (s, CH_2S), 4.60 (*s*, CH_2N), 7.45 (s, C_6H_5).

Anal.—Calcd. for $C_9H_{12}N_2O_3S$: C, 47.35; H, 5.30; N, 12.27; S, 14.05. Found: C, 47.25; H, 5.52; N, 12.27; S, 13.90.

(*b*) A solution of (*N*-benzylcarboxamidinium)-methyl disulfide dichloride (0.40 Gm.), 30% hydrogen peroxide solution (5 ml.), and 6 *N* hydrochloric acid (10 ml.) were heated at 96° (17 hr.). Solvents were removed *in vacuo* and the residue crystallized and found to be identical to that described in *a*.

Selective Determination of Tolbutamide in Pharmaceutical Dosage Forms by Reaction with Ninhydrin

By K. K. KAISTHA and W. N. FRENCH

A colorimetric method is described for the quantitative determination of tolbutamide in pharmaceutical dosage forms. The procedure is based on the interaction of *n*-butylamine, liberated *in situ* from tolbutamide, and ninhydrin to form a blue complex which can be quantitated spectrophotometrically at 585 mμ. No color is produced by *p*-toluenesulfonamide or dibutylurea, two possible decomposition products of tolbutamide. Urea and its acyl derivatives, carbamates, amidines, guanidine, and common tablet excipients do not undergo the reaction. A modified procedure is described for the removal of *n*-butylamine, a major hydrolytic product of tolbutamide, from samples of the drug that have undergone decomposition. Results of the application of the assay procedure to a stability study of tolbutamide tablets are presented.

ALTHOUGH ULTRAVIOLET SPECTROPHOTOMETRIC analysis, as described in the USP XVII (1), is commonly used for tolbutamide preparations, this method is not satisfactory if ultraviolet-absorbing degradation products such as *p*-toluenesulfonamide or impurities such as *p*-toluenesulfonylurea are present in the sample. Similarly, a procedure involving total nitrogen determination, as described in the BP 1963 (2),

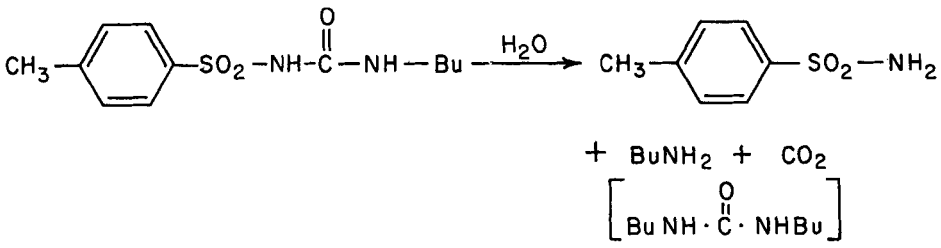

Scheme I

is unsatisfactory if nitrogen-containing contaminants are present. Spingler and Kaiser (3) determined tolbutamide in serum by recording the absorption at 228 mμ, while Spingler (4) reported a colorimetric procedure based on the treatment of an amyl acetate extract of serum with 1-fluoro-2,4-dinitrobenzene followed by measurement of the absorbance at 380 mμ. The latter technique was adopted by Wiseman and co-workers for the estimation of a number of sulfamylureas and their metabolites in plasma and urine (5).

It was observed that a blue color was formed when an ethanolic solution of tolbutamide was heated with ninhydrin. The color was not formed with *p*-toluenesulfonamide or dibutylurea and ninhydrin, but was generated with *n*-butylamine. On the basis of this reaction, a method wherein the *n*-butylamine is generated *in situ* from tolbutamide and subsequently reacts with ninhydrin is presented.

The main hydrolytic decomposition of tolbutamide occurs as shown in Scheme I. Therefore, this method may be applied to decomposed formulations for the selective determination of tolbutamide by prior removal of any *n*-butylamine present.

EXPERIMENTAL

Reagents—Ninhydrin solutions: (*a*) 0.3% ninhydrin (reagent grade) in 80% ethanol. (*b*) 0.3% ninhydrin (reagent grade) in absolute ethanol.

Standard Reference Solution—Tolbutamide USP reference standard (200 mg.) in absolute ethanol (200 ml.).

Assay Procedure for Tolbutamide in the Absence of *n*-Butylamine—Procedure I

Procedure—Twenty tablets were weighed and finely powdered. An accurately weighed aliquot containing about 200 mg. of tolbutamide was quantitatively transferred to a 200-ml volumetric flask with the aid of absolute ethanol. The mixture was made to volume with absolute ethanol, shaken for 10 min., and filtered. A 25-ml. aliquot of the filtrate was heated under reflux in a 100-ml. flask fitted with a water-cooled condenser by immersing the flask up to the level of its contents in a stirred paraffin oil bath maintained at 96–100°. A small boiling chip was added to promote continuous and uniform boiling. After 90 min., the solution was cooled, transferred quantitatively into a 50-ml. volumetric flask, and made to volume with absolute ethanol.

A 2-ml. aliquot of the latter solution was pipeted into a 50-ml. flask and diluted with 3 ml. of the 80% ethanolic ninhydrin solution and 35 ml. of absolute ethanol. The solution was heated under reflux for 4 hr. as described above, cooled, then transferred quantitatively to a 50-ml. volumetric flask, and made to volume with absolute ethanol. The absorbance of the sample solution and that of tolbutamide standard carried simultaneously through the assay procedure were measured at 585 mμ against absolute ethanol.[1]

Calculations are as follows:

$$\text{mg. tolbutamide per tablet} = \frac{A_U}{A_S} \times \frac{W_S \times W_O}{W_U}$$

where:

A_U = absorbance of sample solution
A_S = absorbance of standard reference solution
W_S = weight of standard tolbutamide (mg.)
W_U = weight of sample (mg.)
W_O = average weight per tablet (mg.)

Procedure for Partially Degraded Tolbutamide Formulations—Procedure II

Total Unchanged Tolbutamide (Part A)—An aliquot of sample originally containing the equivalent of 200 mg. of tolbutamide was placed in a 200-ml. volumetric flask and chloroform added to volume. The mixture was shaken for 10 min., filtered, and a 25-ml. aliquot of filtrate transferred to a 60-ml. separator. The chloroform layer was extracted with 20 ml. of 0.1 *N* hydrochloric acid, and the aqueous extract in turn washed with 4 × 10-ml. portions of chloroform. The combined chloroform extracts were taken to dryness by means of a rotary film evaporator and the residue dissolved in 25 ml. of absolute ethanol. The color was developed as described in the assay procedure for tolbutamide (*Procedure I*) beginning at "A 25-ml. aliquot. . .was heated under reflux. . . ."

n-Butylamine (Part B)—The aqueous extract obtained as described under Part A was washed with 5 ml. of benzene (discarded), made alkaline with 5 ml. of 30% NaOH, and extracted successively with 9 ml. and three 5-ml. portions of benzene. The combined benzene extracts were diluted to 25 ml. with benzene in a volumetric flask, mixed, and passed through a pledget of glass wool.

A 5-ml. aliquot of the filtrate was transferred to a 50-ml. flask, 3 ml. of ethanolic ninhydrin solution

[1] This blank gives the same absorbance as a true "reagent blank."

(0.3% in absolute ethanol), and 25 ml. of absolute ethanol were added, and the color developed by heating under reflux for 3.5 hr. The reaction solution was cooled, diluted with absolute ethanol to 50 ml. in a volumetric flask, and its absorbance determined at 585 mμ. A standard solution of *n*-butylamine in benzene (0.1 mg./ml. ≡ 1.37×10^{-3} mmole/ml.) was analyzed concurrently for comparison purposes. The content of *n*-butylamine in the sample was calculated from the respective absorbance values.

Free Tolbutamide (Part C)—A 25-ml. aliquot of the chloroform filtrate obtained as described in Part A was extracted with three 15-ml. portions of water. The combined aqueous extracts were then extracted once with 15 ml. of chloroform, and the combined chloroform solutions evaporated to dryness by means of a rotary film evaporator. The residue was dissolved in 25 ml. of absolute ethanol, and the color developed as described under the assay procedure for tolbutamide (Procedure I) starting at "A 25-ml. aliquot ... was heated under reflux ..." The amount of free tolbutamide was calculated from the absorbance values of standard and sample.

Tolbutamide—n-Butylamine Salt (Part D)—The combined aqueous extracts obtained as described in Part C were acidified with 10 ml. of *N* HCl, and extracted with three 15-ml. portions of chloroform. The combined chloroform extracts were evaporated to dryness by means of a rotary film evaporator, and the residue dissolved in 25 ml. of absolute ethanol. The color was developed as described under the assay procedure for tolbutamide (Procedure I) starting at the words "A 25-ml. aliquot ... was heated under reflux ..." Ten-milliliter aliquots of this refluxed solution which had been diluted to 50 ml. with absolute ethanol were used for the color development instead of 2 ml. The amount of tolbutamide forming a salt with *n*-butylamine was calculated from the absorbance values of standard and sample.

p-Toluenesulfonamide (Part E)—A 25-ml. aliquot of the chloroform filtrate isolated as described in Part A was assayed according to the USP XVII procedure for tolbutamide tablets, and the apparent amount of tolbutamide calculated. The weight of *p*-toluenesulfonamide was calculated by subtracting the weight of tolbutamide per tablet as determined by the colorimetric method (Part A) from the apparent weight of tolbutamide per tablet as determined by the USP assay procedure.

Thin-Layer Chromatography—Silica Gel GF and layer thickness of 250 μ were used throughout. For the separation and detection of *p*-toluenesulfonamide and/or *n*-butylamine in tolbutamide preparations, a solvent system of benzene–acetone–methanol–acetic acid (70:20:5:5) (6) was used. R_f values were 0.60, 0.05, and 0.70, respectively. Examination under short-wave ultraviolet light enabled the detection of the aromatic compounds. Spraying with 0.5% ethanolic ninhydrin solution followed by heating at 80–100° for 10–15 min. caused the formation of orange to pink spots for *n*-butylamine and tolbutamide (limiting sensitivities of 2 and 10 mcg., respectively). *p*-Toluenesulfonamide was visualized with a spray of 3% $KMnO_4$ in H_2SO_4 (limiting sensitivity of 6 mcg.). Alternatively, chlorine treatment followed by benzidine reagent (7) gave blue spots for *p*-toluenesulfonamide (limiting sensitivity of 5 mcg.). Semiquantitative thin-layer chromatographic estimation was accomplished by comparing spot areas of unknown and standard.

RESULTS AND DISCUSSION

The blue color formed during the assay of tolbutamide arises from the interaction of *n*-butylamine and ninhydrin. Although *n*-butylamine is formed readily from tolbutamide in boiling ethanol, the ethanolysis proceeds only partially when no reagent such as ninhydrin is present to remove *n*-butylamine from the equilibrium. Thus, when ethanolic tolbutamide solutions (1 Gm./100 ml.) were refluxed for 1 or 40 hr., the reaction was found to have proceeded to the extent of about 10% only, as indicated by semiquantitative thin-layer chromatography for the amount of released *n*-butylamine. Further evidence that *n*-butylamine was the species interacting with ninhydrin was furnished by isolation of *n*-butylamine as its hydrochloride salt from a refluxed ethanolic solution of tolbutamide, by its absence in the solution after complete color development with ninhydrin (as determined by thin-layer chromatography), and by the fact that similar absorbance curves (Fig. 1) were obtained for the final solution when either tolbutamide or *n*-butylamine was used in the assay procedure. The absorption maximum near 585 mμ was independent of the ninhydrin concentration in the reaction solution while the maximum near 410 mμ was affected by ninhydrin concentration.

Although it was observed that the colorimetric reaction went to completion on heating tolbutamide in absolute ethanol in the presence of ninhydrin (as indicated by the absence of tolbutamide by thin-layer chromatography), the color formed was not sufficiently reproducible for quantitative analysis. Only by refluxing a solution of tolbutamide in ethanol for 90 min. followed by dilution and subsequent reaction of an aliquot with ninhydrin were accuracy and reproducibility achieved.

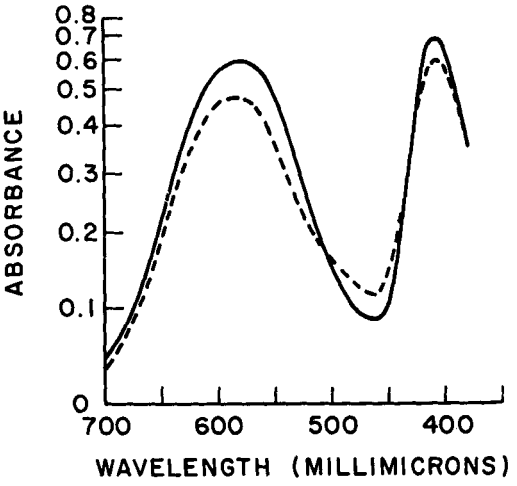

Fig. 1—Absorption spectra of final solutions. Key: ——, tolbutamide and ninhydrin after 4 hr. (concentration equivalent to 7.39×10^{-5} mmoles of tolbutamide per ml.); —, n-butylamine and ninhydrin after 3.5 hr. (concentration equivalent to 5.48×10^{-5} mmoles of n-butylamine per ml.).

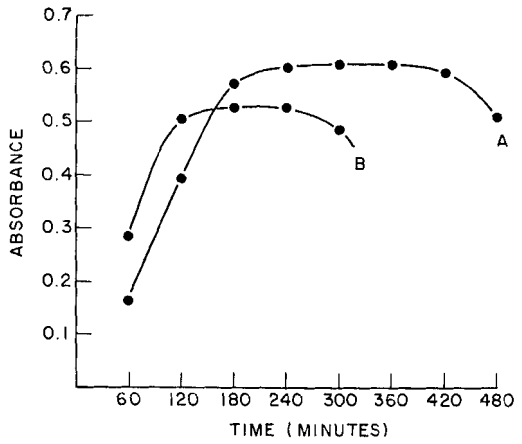

Fig. 2—Effect of time on color formation. Curve A, *tolbutamide concentration equivalent to 7.39 × 10^{-5} mmoles/ml. after dilution to final volume; Curve* B, *n-butylamine concentration equivalent to 6.08 × 10^{-5} mmoles/ml. after dilution to final volume.*

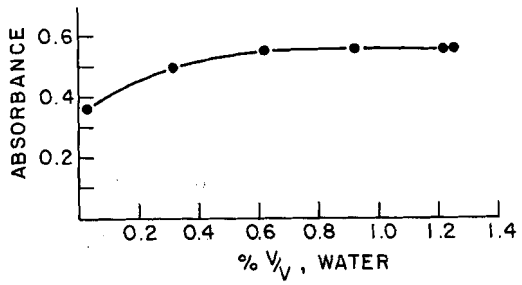

Fig. 3—Effect of water content on color formation after 4 hr. refluxing of the reaction solution (concentration equivalent to 20 mcg. of tolbutamide per ml. after dilution to final volume).

Variables examined to obtain optimum color development and reproducibility were: (*a*) Ninhydrin concentration—Satisfactory color development occurred using a molar ratio of 13.5:1 of ninhydrin to tolbutamide, although molar ratios as high as 22.8:1 did not adversely affect the reaction. On the other hand, a molar ratio of 4.6:1 was insufficient for maximum color development. (*b*) Reaction time—A minimum reflux time of 90 min. for tolbutamide in ethanol prior to color development was found to be an essential requirement to obtain reproducible results. Longer reflux times affected neither color intensity nor rate of color formation. Maximum color development in the ninhydrin reaction occurred within 4–6 hr. for tolbutamide and 3–4 hr. for *n*-butylamine alone (Fig. 2). (*c*) Water content of solvent—Variations in color intensity occurred with the use of "absolute" ethanol. The presence of 0.6 to 1.2% water (v/v) in the final reaction solution resulted in more reproducible results as well as maximum color development (Fig. 3). A higher water content did not adversely affect the amount of color formed, but did cause more nonreproducibility than a water content of 0.6–1.2%. It is essential, however, to use absolute ethanol in the initial reflux stage to achieve reproducible results. (*d*) Temperature of reaction—Reproducible color development occurred only when the reaction solution was maintained under continuous but gentle solvent reflux. This was achieved by immersing the flasks containing the reaction solutions in a stirred paraffin oil bath kept at 96–100°.

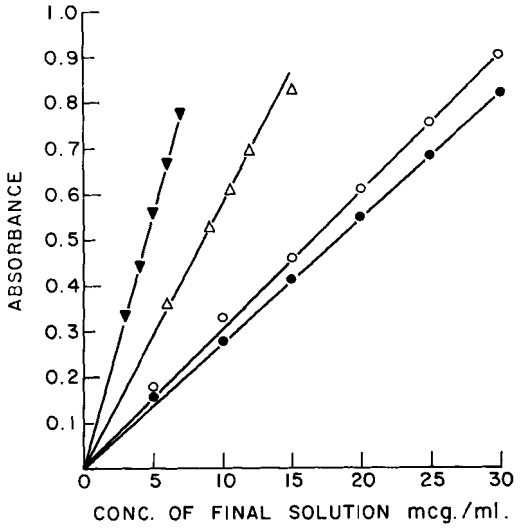

Fig. 4—Relationship between concentration and absorbance. Key: ●, *reaction solution of tolbutamide at 585 mμ;* ○, *at 410 mμ;* △, *reaction solution of* n-*butylamine in absolute ethanol;* ▼, *reaction solution of* n-*butylamine using benzene (5 ml.) with absolute ethanol (28 ml.).*

As shown in Fig. 4, a linear relationship exists between concentration and absorbance for both tolbutamide and *n*-butylamine throughout the region most practical for absorbance measurement. A final reaction solution containing the equivalent of 20 mcg./ml. of tolbutamide or 5.4 mcg./ml. of *n*-butylamine (7.38 × 10^{-5} mmole/ml.) gave an absorbance value of about 0.58. The color intensity of *n*-butylamine in ethanol–benzene was less than that obtained in ethanol alone. In all cases, the color developed was stable for at least 1 hr. with the absorbance decreasing 1–2% after 3 hr.

Results obtained by applying assay Procedure I to six products containing tolbutamide are shown in Table I. Comparison of the experimental data with

dilute hydrochloric acid, and subsequent color development of the remaining tolbutamide. The amount of *n*-butylamine in the aqueous phase then could be determined by extraction (after making alkaline with NaOH) with benzene, followed by ninhydrin color development. The *n*-butylamine generated during the hydrolytic decomposition of tolbutamide in the powdered tablets formed a salt with unchanged tolbutamide, and this salt could be readily extracted into water from a chloroform extract. Analysis of these aqueous solutions gave curves D and E of Fig. 5 while the chloroform-soluble tolbutamide, which had not formed a salt with *n*-butylamine, yielded curve C.

Curve A shows the assay values obtained by the USP XVII procedure. Although *p*-toluenesulfonamide was carried through this assay procedure, a

those obtained by the USP XVII method shows a good correlation between the two, with comparable precision for products A and B.

Although the direct colorimetric procedure (Procedure I) is applicable to dosage forms of tolbutamide containing degradation products such as *p*-toluenesulfonamide or impurities such as *p*-toluenesulfonylurea, it is not applicable to those containing *n*-butylamine. Therefore, for stability studies, or for the analysis of decomposed samples, the procedure was modified to allow for the separation of this interfering amine prior to color development. For decomposed products, the presence of *n*-butylamine may be readily determined by thin-layer chromatography (sensitivity of 2 mcg.) and the appropriate procedure followed.

The specificity of the modified procedure (Procedure II) was demonstrated by its application to tolbutamide tablets which had been subjected to hydrolytic conditions. Weighed aliquots of powdered tablets were stored in individual open vials in a chamber maintained at a temperature of 70° and a relative humidity of about 75% (by means of a saturated sodium chloride solution), and analyzed at various time intervals by assay Procedure II. Results are shown in Fig. 5. As determined by thin-layer chromatography, the decomposition products were *p*-toluenesulfonamide and *n*-butylamine. Dibutylurea, which has been reported as a decomposition product (8), was not detected in the present study.

Since only *n*-butylamine and tolbutamide were found to form colored products with ninhydrin under the reaction conditions, the amount of total unchanged tolbutamide (curve B of Fig. 5) could be readily determined by removal of *n*-butylamine from the chloroform extract of the tablet powder into

small decrease in assay values with length of hydrolytic exposure was observed because this compound's molecular extinction coefficient is lower than that of tolbutamide. Of interest, however, is the fact that both compounds have the same absorptivity value. Therefore, the difference in assay values obtained by the USP procedure and the ninhydrin method is equivalent to the weight of *p*-toluenesulfonamide present in the sample. Since the determination involves a difference between two relatively large numbers, each of which may have significant inherent errors, assay values must be treated with caution if the content of *p*-toluenesulfonamide in a tolbutamide sample is relatively low.

A comparison of the results obtained for tolbutamide by the USP procedure and the ninhydrin method is shown in Table II along with the percent error in results obtained by the USP method. The amount of *p*-toluenesulfonamide, deduced from the difference between these assay values, is also depicted along with the amounts ascertained by thin-layer chromatography as a check on the overall procedure.

Under the conditions described, the ninhydrin method was found to be specific for tolbutamide and did not give a color with many related compounds such as carbamates, urea, barbiturates, amidines, guanidine, and excipients commonly used in tablet formulations.

Determination of Microgram Quantities of Belladonna Alkaloids in Neomycin-Kaolin-Pectin Suspension

By ALFRED BRACEY and GEORGE SELZER

A method combining liquid–liquid extraction and column chromatography has been developed to determine microgram quantities of belladonna alkaloids in kaolin-pectin suspensions. The alkaloids are first separated from the suspension by several ethanol-ether extractions. Interfering substances, such as methylparaben and propylparaben, are eliminated by extracting the alkaloids with chloroform from a basic solution. The alkaloids are further purified by column chromatography. The chloroform extract is passed through an acid siliceous earth column, which retains the alkaloids. The column is made basic with ammonium hydroxide, and the alkaloids are eluted with chloroform. The isolated alkaloids are nitrated, then reduced to the aromatic amine, and finally diazotized and coupled with the Bratton-Marshall reagent for color formation. Recoveries of atropine sulfate added to blank kaolin-pectin suspensions ranged from 92.9 to 99.4 percent.

THE BELLADONNA ALKALOIDS, atropine sulfate, hyoscyamine sulfate, and scopolamine hydrobromide, are often formulated with kaolin and pectin in aqueous suspensions for treatment of intestinal disorders. These preparations may also contain neomycin. The suspensions combine the adsorbent and detoxifying effects of kaolin (which functions in the stomach and small intestines) and pectin (which functions in the large intestines) with the antispasmodic effect of the belladonna alkaloids to help control hypermotility and hypersecretion in the gastrointestinal tract.

Methods for assaying belladonna alkaloids in multicomponent formulations include Koch, Levine, and Zenker's method (1) for belladonna alkaloids in combination with phenobarbital and Woodson's procedure (2) for determining atropine sulfate and hyoscyamine in the presence of methylene blue. However, no procedure has been reported that involves the assay of microgram quantities of belladonna alkaloids in suspension with strong adsorbents such as kaolin.

This paper presents a method of extracting the alkaloids from kaolin–pectin suspensions (3) and determining their total concentration, using the color development procedure of Koch, Levine, and Zenker (1).

Since atropine sulfate and hyoscyamine sulfate are optical isomers, and are not differentiated by this assay procedure, they are considered analytically equivalent. The third alkaloid component of the preparation is scopolamine hydrobromide, which constitutes only 5% of the total alkaloid dose. This compound has been demonstrated to be equivalent to atropine sulfate in the assay procedure except for a small difference in the colorimetric absorptivity, which is made insignificant by its low concentration. Therefore, the belladonna alkaloids are expressed as the equivalent of atropine sulfate.

ASSAY PROCEDURE

Reagents—The following reagents are used: absolute ethanol; ethyl ether; fuming nitric acid (90%); concentrated hydrochloric acid; ammonium

Determination of Microgram Quantities of Belladonna Alkaloids in Neomycin-Kaolin-Pectin Suspension

By ALFRED BRACEY and GEORGE SELZER

A method combining liquid–liquid extraction and column chromatography has been developed to determine microgram quantities of belladonna alkaloids in kaolin-pectin suspensions. The alkaloids are first separated from the suspension by several ethanol-ether extractions. Interfering substances, such as methylparaben and propylparaben, are eliminated by extracting the alkaloids with chloroform from a basic solution. The alkaloids are further purified by column chromatography. The chloroform extract is passed through an acid siliceous earth column, which retains the alkaloids. The column is made basic with ammonium hydroxide, and the alkaloids are eluted with chloroform. The isolated alkaloids are nitrated, then reduced to the aromatic amine, and finally diazotized and coupled with the Bratton-Marshall reagent for color formation. Recoveries of atropine sulfate added to blank kaolin-pectin suspensions ranged from 92.9 to 99.4 percent.

THE BELLADONNA ALKALOIDS, atropine sulfate, hyoscyamine sulfate, and scopolamine hydrobromide, are often formulated with kaolin and pectin in aqueous suspensions for treatment of intestinal disorders. These preparations may also contain neomycin. The suspensions combine the adsorbent and detoxifying effects of kaolin (which functions in the stomach and small intestines) and pectin (which functions in the large intestines) with the antispasmodic effect of the belladonna alkaloids to help control hypermotility and hypersecretion in the gastrointestinal tract.

Methods for assaying belladonna alkaloids in multicomponent formulations include Koch, Levine, and Zenker's method (1) for belladonna alkaloids in combination with phenobarbital and Woodson's procedure (2) for determining atropine sulfate and hyoscyamine in the presence of methylene blue. However, no procedure has been reported that involves the assay of microgram quantities of belladonna alkaloids in suspension with strong adsorbents such as kaolin.

This paper presents a method of extracting the alkaloids from kaolin–pectin suspensions (3) and determining their total concentration, using the color development procedure of Koch, Levine, and Zenker (1).

Since atropine sulfate and hyoscyamine sulfate are optical isomers, and are not differentiated by this assay procedure, they are considered analytically equivalent. The third alkaloid component of the preparation is scopolamine hydrobromide, which constitutes only 5% of the total alkaloid dose. This compound has been demonstrated to be equivalent to atropine sulfate in the assay procedure except for a small difference in the colorimetric absorptivity, which is made insignificant by its low concentration. Therefore, the belladonna alkaloids are expressed as the equivalent of atropine sulfate.

ASSAY PROCEDURE

Reagents—The following reagents are used: absolute ethanol; ethyl ether; fuming nitric acid (90%); concentrated hydrochloric acid; ammonium

Received August 4, 1967, from the Division of Antibiotics and Insulin Certification, Bureau of Science, Food and Drug Administration, U. S. Department of Health, Education, and Welfare, Washington, DC 20204
Accepted for publication October 10, 1967.

hydroxide; chloroform distilled from a mixture of chloroform and 1 *N* sulfuric acid (4:1); 20% sodium hydroxide solution; 0.2 *N* sulfuric acid; 5% sodium nitrite solution; 5% ammonium sulfamate solution; 0.1% *N*-(1-naphthyl)-ethylene diamine dihydrochloride (prepared fresh before use); solid sodium hydrosulfite.

Standard Solution—Atropine sulfate, prepared by stepwise dilution as an aqueous solution containing 0.100 mg./ml. of USP atropine sulfate reference standard.

Apparatus—(*a*) An acid trap column is prepared by placing a small wad of glass wool at the juncture of the barrel and the stem of a chromatographic tube about 150 mm. long and 20 mm. in diameter. The column was packed with 5.0 Gm. of chromatographic siliceous earth[1] thoroughly mixed with 4.0 ml. of 0.2 *N* sulfuric acid, transferred to the column in several portions, and packed firmly with a tamping rod after each addition. (*b*) Filtering tube consisting of a wad of glass wool at the juncture of the barrel and the stem of a tube about 250 mm. long and 40 mm. in diameter. (*c*) Colorimeter or spectrophotometer

Extraction of Alkaloids—Place a 60-ml. aliquot of the suspension containing about 250 mcg. of alkaloids into a 500-ml. glass-stoppered conical flask. Add 100 ml. of ethanol and 4.0 ml of hydrochloric acid. Stopper tightly and place on a mechanical shaker for 30 min. Add 240 ml. of ether and shake vigorously. Add 10 ml. of ammonium hydroxide, swirl gently, and then shake well. Allow the suspended material to settle. Decant the supernatant through the filtering tube, collecting the filtrate in an 800-ml. beaker. Extract the sample a second time by adding 10.0 ml. of water and 50 ml. of ethanol to the flask. Stopper and shake well. Add 120 ml. of ether and shake. Add 2.0 ml. of ammonium hydroxide, swirl gently, and then shake vigorously. Allow the suspended material to settle and pour the supernatant through the filtering tube, combining the filtrates. Add 50 ml. of ethanol and 120 ml. of ether; then shake vigorously. Add 1.0 ml. of ammonium hydroxide, swirl gently, then shake, and allow suspended material to settle. Pour the supernatant into the filtering tube, followed by as much of the residue as possible. Finally, rinse the flask with 25 ml. of ether and pour it into the filtering tube. After the tube drains, acidify the combined filtrate with hydrochloric acid until it is acid to pH paper and evaporate it to about 50 ml. on a warm steam bath under a gentle stream of air.

Transfer the aqueous residue quantitatively to a 125-ml. separator. Adjust the solution to about pH 9 with 20% sodium hydroxide and immediately extract with one 50-ml. portion and three 30-ml. portions of chloroform. Pass each extract through the acid trap column. Add 2.0 ml. of ammonium hydroxide to the column, followed by 125 ml. of chloroform, and collect the alkaloid eluate in a 250-ml. beaker. Evaporate the eluate to about 30 ml. and transfer it quantitatively to a 50-ml. graduated glass-stoppered centrifuge tube. Add about four drops of hydrochloric acid to the tube, stopper, and shake. Evaporate to dryness by placing the tube in a hot water bath under a gentle stream of air.

[1] Celite 545, Johns-Manville Corp., New York, N. Y.

A procedural blank, consisting of 60 ml. of water, and a procedural standard, consisting of 200 mcg. of atropine sulfate in 60 ml. of water, are treated as samples throughout the assay.

Color Development—Add 1.0 ml. of fuming nitric acid to each tube containing the chloroform residue and to a reagent blank tube. Stopper each tube loosely, place on a steam bath with test tube clamps, and heat vigorously for 30 min. Remove the tubes from the steam bath and to each one add 10 ml. of water, 2.0 ml. of ammonium hydroxide, and about 50 mg. of sodium hydrosulfite. Shake each tube gently to dissolve the sodium hydrosulfite and allow to stand at room temperature for 20 min. Add 5.0 ml. of 5% sodium nitrite and 2.0 ml. of hydrochloric acid. Shake each tube gently and place in an ice-water bath for 30 min. Slowly add 10.0 ml. of 5% ammonium sulfamate in 5-ml. portions, and shake the tube gently after each addition to dispel the nitrous oxide fumes. Add 4.0 ml. of freshly prepared 0.1% solution of *N*-(1-naphthyl)-ethylenediamine dihydrochloride. Allow 30 min. for color development before diluting to the 50.0-ml. mark with water. Determine the absorbance at 550 mμ against the reagent blank. Correct the absorbance of the standard and sample for that of the procedural blank.

RESULTS

The recovery of atropine sulfate added to blank preparations containing all the ingredients except the alkaloids ranged from 92.9 to 99.4%, as shown in Table I. The amount of atropine sulfate added was approximately equivalent to the belladonna alkaloid concentration in commercial preparations. As shown in Table II, the assay results for commercially available preparations ranged from 90.3 to 106.5% of label claim. These batches represent formulations ranging in date of production from recent to those

nearing expiration date. In Table III is shown the interference of a blank preparation from each manufacturer in terms of apparent atropine sulfate. By the method presented, this interference was found to be 1.2 and 4.1%.

DISCUSSION

The liquid extraction column chromatography (4) method described here permits the isolation and quantitative determination of belladonna alkaloids in kaolin-pectin suspensions. Conventional extraction methods were ineffective because of the strong adsorptive properties of kaolin and the strong tendency of this type of preparation to form an unmanageable emulsion with organic solvents. Therefore, the first phase of the assay consists of a desorption procedure (3), in which ethanol, water, and ether are used to remove all of the soluble ingredients from the suspension. After evaporation of most of the organic portion of the extract, the aqueous portion is adjusted to pH 9 with 20% sodium hydroxide and the alkaloids are extracted with chloroform, leaving behind most of the methyl and propylparaben preservatives. If tropic acid is present most of it will also be retained by the aqueous phase. Tropic acid is one of the principal degradation products of the belladonna alkaloids and the portion of the molecule responsible for the color reaction. The alkaloids are further purified by column chromatography. The column retains the alkaloids while traces of methylparaben, propylparaben, and tropic acid are washed through. Then the purified alkaloids are eluted and determined colorimetrically by the method of Koch, Levine, and Zenker (1).

An aqueous kaolin suspension containing only kaolin and atropine sulfate at concentrations equivalent to that of commercial preparations was centrifuged to remove the kaolin and a portion of the supernatant assayed according to the color development procedure. Duplicate determinations yielded recoveries of 17.2 and 17.5% (or 82.8 and 82.5% adsorption). The recovery for a similar preparation extracted by the proposed procedure and assayed colorimetrically was 99.7%. One of the problems encountered in developing this method was the relatively high absorbance of the procedural blank. This high blank was found to be caused by impurities in the chloroform. Attempts were made to purify the chloroform by filtering it through columns containing either silica gel or aluminum oxide, without satisfactory improvement. Reagent grade chloroform gave a procedural blank with an absorbance of about 28% of that from a 200 mcg. atropine sulfate standard. The column-purified chloroform gave procedural blanks with absorbances of about 10% of the same standard. However, when the chloroform was purified according to the distillation method of Koch, Levine, and Zenker (1), the procedural blank had an absorbance of about 5% of that from a 200-mcg. atropine sulfate standard.

Determination of Phenylephrine Hydrochloride in Combination with Other Drugs

By CARL PONDER

Phenylephrine is retained on an acetic acid–NaCl–diatomaceous earth column, while other amino compounds and drug excipients are eluted with chloroform acidified with acetic acid. Phenylephrine is eluted with ethyl ether and is determined by ultraviolet spectrophotometry.

THE USP XVII general analytical procedure for organic bases is a liquid–liquid extraction in which the free bases partition into the organic phase and the salts into the aqueous phase. The phenylephrine base deviates from this solubility rule by partitioning predominately into the aqueous phase. This characteristic makes phenylephrine difficult to isolate from colors, flavors, and other extraneous substances.

Phenylephrine possesses both a secondary amino group and a hydroxyphenyl nucleus. Several analytical methods for phenylephrine based on the action of these functional groups have been published. Auerbach (1) coupled the hydroxyphenyl group with diazotized *p*-nitroaniline and determined the resulting colored compound photometrically at 495 mμ. Kelly and Auerbach (2) developed a method for phenylephrine based on reactions with both functional groups. Nitrogen bases were isolated by ion exchange and color was developed with those bases containing a phenolic group. Koshy and Mitchener (3) published a colorimetric method using 4-aminoantipyrine as the color-developing reagent. This method also depends upon the presence of the hydroxyphenyl nucleus. Each of these methods has one or more of the limitations inherent to colorimetric determinations. An obvious objection is that phenylephrine is often formulated with other ingredients that contain a common functional group.

Recently published methods are based on ultraviolet spectroscopy, which is more specific than colorimetric measurements, although the phenylephrine must first be separated from all interfering substances. Clark and Rosenberg (4) eluted nonphenolic amines from a sodium borate–diatomaceous earth column with chloroform. Phenylephrine remained on the column until acetylated. It was then removed with chloroform, saponified with alcoholic potassium hydroxide, and determined spectrophotometrically. Hyatt (5) used essentially the same procedure for the analysis of phenylephrine. Smith (6) used a sodium hydroxide–diatomaceous earth column to separate phenylephrine from other amines. After the free amines were eluted, phenylephrine was removed from the column with ethanol and determined spectrophotometrically at 290 mμ.

The present paper describes chromatographic column procedures which permit phenylephrine to be isolated from a wide range of compounds and determined by ultraviolet spectrophotometry. These procedures are based upon the "salting out" of phenolic compounds from an aqueous medium by sodium chloride and the selective elution of organic salts with different solvents from a chromatographic column. The principle evolved from the author's discovery (7) that a sodium hydroxide–ether liquid–liquid partitioning of phenolic compounds such as diethylstilbestrol can be reversed by saturating the basic solution with sodium chloride. Subsequent work has shown that phenylephrine behaves in a similar manner when the sodium hydroxide is omitted and the volume of the aqueous phase is limited.

The first procedure presented separated phenylephrine from other amino compounds. Ammonium hydroxide is added to the sample aliquot to liberate phenylephrine from the chloride, and the hydroxide is neutralized with an excess of acetic acid. Codeine, dextromethorphan, phenylpropanolamine, and most antihistamines can then be eluted from the column with chloroform or ether, but phenylephrine can be eluted only with ether.

Aspirin, magnesium hydroxide, and phenylephrine hydrochloride combinations require a different separation method. Traces of salicylic acid in aspirin interfere with the extraction of phenylephrine. Experimental recoveries of phenylephrine in the presence of salicylic acid averaged only 50% by the first procedure. This difficulty can be avoided by extracting aspirin and salicylic acid from a hydrochloric acid solution with ether before the ammonium hydroxide–acetic acid neutralization phase of the procedure.

Received August 11, 1967, from the U. S. Department of Health, Education, and Welfare, Food and Drug Administration, Atlanta District Laboratory, Atlanta, GA 30309
Accepted for publication October 20, 1967.

TABLE I—RECOVERIES OF MIXED STANDARDS

Mixture	mg. Added	% Recovery
Phenylephrine hydrochloride	1	97.8
Chlorpheniramine maleate	1	100.0
Dextromethorphan hydrobromide	5	100.0
Phenylephrine hydrochloride	1	98.0

Phenylephrine hydrochloride	1	97.6
Aspirin	125	...
Chlorpheniramine maleate	1	100.0

The mixed antihistamine standards in Table I were assayed according to the methods of Levine (8, 9).

EXPERIMENTAL

Apparatus—A recording spectrophotometer with matched 1-cm. glass-stoppered silica cells was used for ultraviolet assays.

Chromatographic Column—Pack a pledget of fine glass wool in the base of a 25 × 300-mm. column. Overlay this support with a mixture of 1 Gm. of diatomaceous earth[1] and 2 Gm. of 100-mesh sodium chloride.

Tamping Rod—Use a disk of stainless steel, aluminum, or glass, with a diameter slightly less than that of the column, and with a handle 15 in. long.

Reagents—*Sodium Chloride*—Finely powdered to pass 100-mesh sieve.

Standard Phenylephrine Hydrochloride—Accurately weigh a suitable quantity of USP phenylephrine hydrochloride reference standard and dissolve in 0.1 *N* hydrohloric acid. Dilute quantitatively stepwise with 0.1 *N* hydrochloric acid to obtain a solution containing 40 mcg./ml.

Procedure—*Tablets Containing Phenylephrine Hydrochloride, Antihistamines, and Dextromethorphan Hydrobromide*—Weigh and finely powder 20 tablets. Weigh accurately a portion of the powder equivalent to 1 mg. of phenylephrine hydrochloride and transfer to a 250-ml. beaker. Wet the powder with 1 ml. of water. Add one drop of concentrated ammonium hydroxide, mix thoroughly, and then neutralize with three drops of glacial acetic acid. Add 3 Gm. of powdered sodium chloride and mix until the salt-liquid mixture forms a thick paste. Let sit for approximately 10 min. and then knead 3 Gm. of diatomaceous earth into the mixture. When all ingredients are uniformly dispersed, transfer quantitatively to the column containing the mixture of 1 Gm. of diatomaceous earth and 2 Gm. of 100-mesh sodium chloride. Gently tap the column, then tamp with the rod, using firm pressure to compress into a uniform mass. Scrub the beaker with 1 Gm. of dry diatomaceous earth, follow with a pledget of glass wool, and tamp both into the column. Measure 150 ml. of redistilled, water-saturated chloroform containing 3 drops of acetic acid into the beaker. Pass this solvent mixture through the column to elute chloroform-soluble acetate salts. Collect the eluate in a beaker and save for antihistamine and dextromethorphan assay. Elute phenylephrine from the column with 300 ml. of redistilled, water-saturated ether ino a 500-ml. separator. When elution is complete, immediately extract the phenylephrine from the ether with 10-, 10-, and 5-ml. portions of 0.1 *N* hydrochloric acid. Combine the extracts in a 25-ml. volumetric flask. Make to volume with acid and mix. With 0.1 *N* hydrochloric acid saturated with ether in the blank cell, scan the solution from 350 to 225 mμ. Determine the absorbance at 273 mμ. Calculate the quantity in milligrams of phenylephrine hydrochloride in the portion of the tablet taken by the formula $25C(A_U/A_S)$, in which C is the exact concentration of the reference solution in mg./ml.; A_U is the absorbance of the sample solution; and A_S is the absorbance of the reference standard solution.

Syrups Containing Phenylephrine Hydrochloride, Antihistamines, Codeine, Dextromethorphan Hydrobromide, and Phenylpropanolamine Hydrochloride—Measure a quantity of syrup equivalent to 1 mg. of phenylephrine hydrochloride into a 250-ml. beaker. Evaporate to approximately 1 ml. on a steam bath at 80–100° under a gentle air current. Add 1 drop of concentrated ammonium hydroxide, mix thoroughly, and then neutralize with 3 drops of glacial acetic acid. Determine phenylephrine hydrochloride by the method for tablets above, beginning with "Add 3 Gm. of powdered sodium chloride...."

Tablets Containing Phenylephrine Hydrochloride, Aspirin, and Antihistamines, or Phenylephrine Hydrochloride, Aspirin, and Magnesium Hydroxide—Weigh accurately a portion of the finely powdered tablets equivalent to about 2.5 mg. of phenylephrine hydrochloride and transfer to a 60-ml. separator containing 10 ml. of 1.0 *N* hydrochloric acid. Shake vigorously for 5 min. Add 25 ml. of ether. Shake 1 min. and drain the acid phase into a second separator containing 25 ml. of ether. Shake and repeat this procedure with a third and fourth 25-ml. ether extraction in a 60-ml. separator. Filter the acid phase through a small, loose pledget of glass wool into a 25-ml. volumetric flask. Extract each of the four ether extractions successively with 10- and 5-ml. portions of 1 *N* hydrochloric acid and combine the extracts in a 25-ml. volumetric flask. Dilute to volume with acid, mix, and pipet 10 ml. of the acid solution into a 250-ml. beaker. Immediately evaporate to dryness on a steam bath at 60–70° under a gentle air current. When acid odor is no longer perceptible, add 1 ml. of water and 1 drop of concentrated ammonium hydroxide. Mix and add 3 drops of acetic acid. Proceed as directed in the assay for phenylephrine hydro-

chloride and antihistamines beginning with "Add 3 Gm. of powdered sodium chloride..." The formula for the calculation of phenylephrine hydrochloride gives the quantity in the 10-ml. aliquot taken for the assay.

RESULTS AND DISCUSSION

The procedure for amino compounds has been applied to the determination of phenylephrine in tablets and syrup preparations, including those containing antihistamine mixtures, codeine, dextromethorphan hydrobromide, and aromatics. The phenylephrine–aspirin procedure has been applied to commercial and simulated tablet preparations which also contained either antihistamine, magnesium hydroxide, bioflavonoids, or a mixture of these.

Table I shows recoveries of phenylephrine hydrochloride and of the added components in simulated preparations. The added components include examples of each antihistamine structural type and those specific antihistamines most often found in commercial preparations.

The analyses of some commercial products are given in Table II. These analyses are in good agreement with their labeled declarations. The precision of these analyses, the quantitative recoveries obtained with standard simulated samples (Table I), and the purity of the isolated material, based on the ultraviolet spectra, establish the validity of the procedures reported.

Gas Chromatographic Assay for α-Tocopheryl Acetate in Multivitamin Products

By P. B. BOWMAN and W. E. WEST

A gas chromatographic procedure for α-tocopheryl acetate in soft elastic capsules, liquid formulations, and compressed tablets is described. The procedure compares favorably with the NF and USP dipyridyl procedures with respect to speed (10 *versus* 5 per day per analyst), precision (1.2 percent coefficient of variation *versus* 1.5 percent), and specificity. Unlike the dipyridyl procedures, the α-tocopheryl acetate is separated completely from other tocopherols.

THE NEED for a more precise, specific, and rapid assay for α-tocopheryl acetate (vitamin E) led to the development of a gas chromatographic procedure that met these requirements. The procedure is applicable to soft elastic capsules, liquid formulations, and coated compressed tablets.

Considerable work has been done on the gas chromatography of the tocopherols (3–7), but it has been concerned primarily with the separation of the various tocopherols and their determination in natural products. In 1966, at the 80th annual meeting of the Association of Official Analytical Chemists, Pillsbury *et al.* described a gas chromatographic procedure for vitamin E in pharmaceuticals (8, 11). Since the chromatography has been studied in the above references, this paper will be concerned with the procedural aspects of the assay.

EXPERIMENTAL

Instrument—An F & M model 402 gas chromatograph[1] equipped with a flame-ionization detector and U-shaped glass columns, 2 M. long × 3 mm. i.d., was used for this work. The columns were packed with 3% SE-30 on 100/120 mesh Gas Chrom Q.[2] The carrier gas was helium, at a flow rate of approximately 50 ml./min. and hydrogen and air flows were adjusted for maximum flame response. The column oven was operated isothermally at 235°, the flash heater at 275°, and the detector at 300°. The overall sensitivity of the instrument was 64 × 10^{-11} amp. full scale. The recorder was equipped with a model 227 Disc chart integrator[3] that was used for all peak area measurements.

Reagents and Chemicals—Chloroform, USP, anhydrous sodium sulfate, A.R., anhydrous diethyl-ether (no further purification required), 3-(*p*-methoxyphenyl) - 2,4,5 - triphenylcyclopentadieneone,[4] *d*-α-tocopheryl acetate, NF type 6-100,[5] and dry *d*-α-tocopheryl acetate types 667 and 333-S.[6]

The internal standard solution was 3-(*p*-methoxyphenyl)-2,4,5-triphenylcyclopentadieneone, approximately 1 mg./ml. in chloroform. This material was selected on the basis of its retention time (1.6 relative to α-tocopheryl acetate) and thermal stability.

The reference solution was prepared by dilution of a stock solution of the working standard of *d*-α-tocopheryl acetate in chloroform to a final concentration of approximately 1 mg./ml. An aliquot of this solution was evaporated to dryness then the residue dissolved in an equal volume of internal standard solution.

The surfactant solution used in the assay of coated compressed tablets was prepared according to the procedure of Ames and Tinkler (9).

Sample Preparation—Soft elastic capsules were prepared for assay by processing for 5 sec. with 50.0 ml. of internal standard solution at high speed in a blender. (The blender was equipped with a screw-cap jar and Teflon gaskets.) Enough capsules were processed to give a final concentration of α-tocopheryl acetate of approximately 1 mg./ml. The sample for chromatography was filtered by withdrawal through a fluted filter paper.

Liquid formulations were assayed by mixing a volume of the formulation containing 10 mg. of α-tocopheryl acetate with 5 ml. of surfactant solution in a 30-ml. glass-stoppered centrifuge tube, and shaking for 10 min. with 10.0 ml. of internal standard solution. The mixture was centrifuged if necessary, to break any emulsions formed. A portion of the chloroform layer was withdrawn for chromatography.

The assay of coated compressed tablets required the following preparation prior to chromatography: A number of tablets (color coating first removed by water washing) equivalent to approximately 50 mg. of α-tocopheryl acetate was introduced into a 125-ml. glass-stoppered conical flask with five 5-mm. glass beads and 25 ml. of surfactant solution. The mixture was shaken on a mechanical shaker until the tablets were completely disintegrated (1–3 hr.). If desired, the samples can be allowed to soak overnight before shaking. Ten grams (1 teaspoon) of granular anhydrous sodium sulfate and exactly 50.0 ml. of internal standard solution were added to the flask. The flask was stoppered tightly and shaken again for 10 min. on the mechanical shaker. A portion of the liquid was transferred to a 30-ml. glass-stoppered centrifuge tube, centrifuged, and a portion of the chloroform

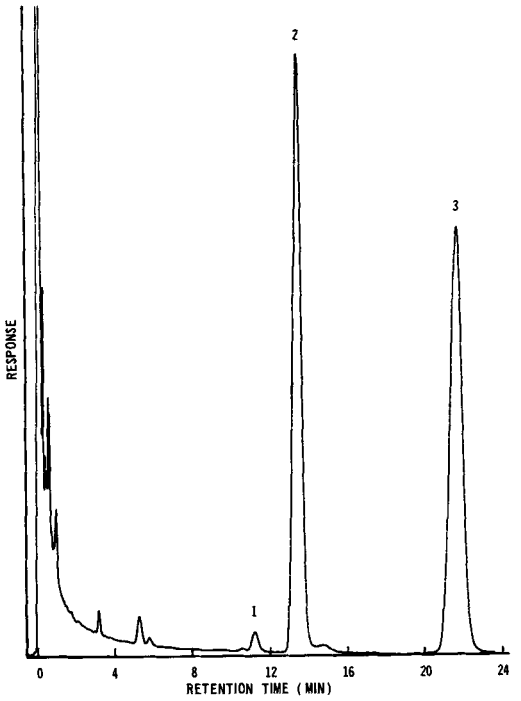

Fig. 1—Chromatogram of α-tocopheryl acetate from a lot of coated compressed tablets. Key: 1, impurity in internal standard; 2, α-tocopheryl acetate; 3, internal standard. The slopes of the integrator trace before and after the α-tocopheryl acetate were determined at 12.5 and 15.5 min., respectively. The peak width was taken at 1.6 min.

layer withdrawn and filtered through a fluted filter paper. The filtrate was then used for chromatography.

The volume of solution injected was adjusted to give nearly full-scale response for the α-tocopheryl acetate peak; this required between 1–2 mcg. of α-tocopheryl acetate. It was found necessary to saturate the column with one or two injections of reference solution at the beginning of each day's run. At least two additional injections of reference solution were made before any samples were run. Reference solution was then injected at intervals, usually after every third sample.

Calculations—The potency of α-tocopheryl acetate in the product was calculated according to the following formula:

$$\text{potency} = \text{Ru} \cdot \frac{\text{Cr}}{\text{Rr}} \cdot \text{X}$$

where

Ru = area of α-tocopheryl acetate peak in sample/area of internal standard peak
Rr = area of α-tocopheryl acetate peak in reference/area of internal standard peak
Cr = concentration of α-tocopheryl acetate in mg./ml in the reference solution
X = dilution factor

RESULTS AND DISCUSSION

Chromatography—An actual chromatogram of a sample of a production lot of coated compressed tablets is shown in Fig. 1. The small peak after the α-tocopheryl acetate peak was not identified. This peak was not considered in the integration; since it was present in the working standard as well as the products. In some cases a base line correction was required, particularly in the soft capsule formulations in which the injected oil bled from the column at an appreciable rate. This correction was done with the drift corrector No. 1290 supplied with the integrator, according to the manufacturer's directions.

Earlier work on the tocopherols (3–7) suggested a number of column packings that were applicable to these compounds and several of these were examined. However, the desired specificity was obtained only with SE-30 on 100/120 mesh Gas Chrom Q. It was found in our laboratories that

[a] Soft elastic capsule. [b] Liquid formulation. [c] Coated compressed tablet.

there was considerable variation in the performance of different lots of this packing, even among the pretested lots; hence some selectivity may be required to find a satisfactory lot of the material. The best indications of a good lot of support were found to be column efficiency (> 700 theoretical plates per foot for α-tocopheryl acetate)[7] and retention time (12–14 min. at the prescribed temperature and flow rate).

Mass spectral and infrared examination of α-tocopheryl acetate eluted from the column indicated that no decomposition occurred during chromatography. The infrared spectrum of the chromatographed material was compared with that of a sample of the same material that had not been chromatographed. No significant differences were visible. The mass spectrum of the chromatographed material showed the molecular ion at *m/e* 472 and major peaks at *m/e* 430, 207, and 165. These peaks are consistent with the structure of the molecule.

Although no concentration limits were established, the chromatographic response was linear over the range from 0.1 to 4 mcg. of α-tocopheryl acetate which bracketed the concentration ranges of the assay procedure.

Recovery—Recovery of α-tocopheryl acetate was determined to be quantitative (> 99%) for each of the three formulations. For soft elastic capsules, recovery was determined by replicate assays of the same fomulation without α-tocopheryl acetate but using chloroform that contained both internal standard and the theoretical quantity of α-tocopheryl acetate. These results are listed in Table I. Although this was not the ideal procedure for a recovery study, it proved to be a practical approach. For the liquid formulation, a similar procedure was followed; the organic phase again contained the internal standard and the α-tocopheryl acetate. The results are shown in Table I. In this case, it was impossible to dissolve the α-tocopheryl acetate in the blank formulation.

Recovery from coated compressed tablets was determined by assaying tablets without α-tocopheryl acetate, but with the label amount of the appropriate dry form weighed into the flask before addition of the surfactant solution. These results are in Table I. Recovery of the α-tocopheryl acetate from the dry material alone was also determined and found to be quantitative.

Precision—Assay precision was determined for each type of formulation by replicate assay of a single lot of the material. In each case, the coefficient of variation (percent standard deviation) was less than 1.2%. According to Lehman (10), the interlab coefficient of variation was 1.52% in a collaborative study of the dipyridyl method (1, 2). The latter procedure suffers from the lack of a recognized standard for α-tocopherol, thus requiring the use of a somewhat arbitrary absorptivity and careful timing of the reaction before measuring the absorbance.

Comparison of the Gas Chromatographic and Dipyridyl Procedures—The results of the gas chromatographic procedure on several lots of each type of formulation are listed in Table II. For comparison, the results obtained by the NF procedure and the label potency are listed.

It should be noted that the gas chromatographic results are consistently higher than those of the NF procedure. The USP procedure gave results similar to those obtained by gas chromatography. The NF method requires a column chromatographic separation to eliminate the interference of vitamin A, whereas this is accomplished by a hydrogenation step in the USP procedure. The low results obtained by the NF procedure can probably be attributed to loss of α-tocopherol during the column chromatography step.

An experienced analyst in our laboratory was able to complete three assays for α-tocopheryl acetate in a working day using the NF XII procedure. Using the USP hydrogenation, five assays could be completed. The gas chromatographic procedure permits the assay of at least 10 samples a day. An analyst operating two chromatographs could double this daily output and still have sufficient time to prepare samples and perform the calculation of results.

[7] Theoretical plates per foot $= \left(\frac{\text{retention time}}{\text{width at half height}}\right)^2 \frac{5.5}{\text{column length}}$

Determination of Terpin Hydrate by Gas-Liquid Chromatography

By ERNEST J. KUBIAK

A gas chromatographic procedure has been developed for the quantitative determination of terpin hydrate. The procedure may be applied to any of the NF dosage forms containing this compound. The terpin hydrate is extracted with chloroform from a saturated sodium chloride solution and chromatographed as intact terpin on a hydrogenated castor oil column. Degradation products of terpin hydrate, other terpenes, and formulation excipients do not interfere. The method is specific, rapid, and accurate. A coefficient of variation of less than 1 percent was determined from replicate analyses.

METHODS FOR THE ANALYSIS of terpin hydrate, which have been proposed and described in the literature, include precipitation with mercury salts (1, 2), esterification with 3,5-dinitrobenzoyl chloride (3), and spectrophotometric determinations (4, 5). These methods lack specificity. They do not distinguish terpin hydrate from its decomposition products, and are not satisfactory for many formulations.

A method for the determination of terpin hydrate is presented in "Official Methods of Analysis"(6). In this procedure terpin hydrate is converted by acid dehydration to a mixture of terpenes which is reacted with molybdo-phosphotungstic acid to produce a blue reduction product which is measured spectrophotometrically. Any mixture of terpenes, treated similarly, will result in comparable color formulations.

The gas chromatographic (GLC) procedure presented in this paper is specific for the intact terpin molecule. Degradation products, other terpenes, and formulation excipients do not interfere with the quantitation of terpin hydrate by the procedure described.

Received September 13, 1967, from the Control Research and Development Department, The Upjohn Co., Kalamazoo, MI 49001
Accepted for publication October 19, 1967.
After this manuscript was submitted, a paper by L. Kurlansik, C. Damon, and E. F. Salim was published on the gas chromatographic determination of terpin hydrate (7).

METHOD

Reagents—(*a*) *Internal Standard Solution*—Prepare a chloroform solution containing 5.5 mg. of 3-tert-butylphenol per ml. of chloroform. (*b*) *Reference Preparation*—Dry terpin hydrate NF ($C_{10}H_{20}O_2 \cdot H_2O$) at 60° in vacuum at 10 mm. mercury for 3 hr. Determine any residual moisture in the terpin hydrate reference material by Karl Fischer, and use on the completely anhydrous basis for preparation of the reference solution. Transfer an accurately weighed portion of the anhydrous terpin ($C_{10}H_{20}O_2$), approximately 158 mg., into a 200-ml. volumetric flask. Add exactly 25.0 ml. of the internal standard solution and dilute to volume with chloroform.

Sample Preparation—Transfer an accurately measured portion of the formulation containing approximately 170 mg. of terpin hydrate NF ($C_{10}H_{20}O_2 \cdot H_2O$) into a 250-ml. separator. Add about 80 ml. of saturated sodium chloride solution and mix. Extract the terpin hydrate with two successive 50-ml. portions of chloroform. Collect the chloroform extracts in a 200-ml. volumetric flask, add exactly 25.0 ml. of the internal standard preparation, and dilute to volume with chloroform.

Chromatography—Chromatograph aliquots of the sample and reference preparation. Under typical circumstances the following instrument conditions were found to be satisfactory.

Chromatograph—F & M 402 with flame ionization detector. Column—Glass 3 mm. i.d. × 1.2 meters, 5% hydrogenated castor oil[1] on 80–100 mesh

Collect the chloroform extracts in a 200-ml. volumetric flask, add exactly 25.0 ml. of the internal standard preparation, and dilute to volume with chloroform.

Chromatography—Chromatograph aliquots of the sample and reference preparation. Under typical circumstances the following instrument conditions were found to be satisfactory.

Chromatograph—F & M 402 with flame ionization detector. Column—Glass 3 mm. i.d. × 1.2 meters, 5% hydrogenated castor oil[1] on 80–100 mesh

[1] Castorwax, the Baker Castor Oil Co., Bayonne, N. J.

Diatoport-S, operated isothermally at 140°. Sample volume—8 μl. Carrier gas—Helium at about 60 ml./min. Attenuation—10 × 64.

Calculations—Calculate the quantity, in mg., of $C_{10}H_{20}O_2 \cdot H_2O$ in each ml. of the formulation taken by the formula:

$$\frac{R_1}{R_2} \times \frac{C}{D} \times F$$

in which,

R_1 = Sample terpin peak area / Internal standard peak area

R_2 = Reference terpin peak area / Internal standard peak area

C = Weight in milligrams of anhydrous terpin ($C_{10}H_{20}O_2$) in the reference preparation

D = The milliliters of the formulation in the sample preparation

F = 1.1045 = the factor for converting anhydrous terpin ($C_{10}H_{20}O_2$) to terpin hydrate NF ($C_{10}H_{20}O_2 \cdot H_2O$)

RESULTS AND DISCUSSION

In the proposed procedure, time-consuming distillation and the conversion of terpin to a mixture of terpenes by acid dehydration are avoided. Terpin hydrate is quantitatively extracted with chloroform from a saturated salt solution; a partition coefficient of $K > 100$ was determined for this system.

Based on replicate determinations, the procedure described gave an average recovery of 100.8% with a coefficient of variation of 0.75% (Table I). Three NF dosage forms manufactured by various pharmaceutical companies, were assayed for terpin hydrate (Table II). Except for one lot which showed evidence of decomposition, the results were in good agreement with the label requirements.

The procedure is specific for anhydrous terpin. The infrared spectra of a GLC fraction showed terpin hydrate chromatographed with a loss of water but without rearrangement or decomposition.

The accuracy of the procedure is dependent on the careful preparation of the reference anhydrous terpin. Terpin hydrate sublimes at 60° in vacuum with the possibility of incomplete dehydration. Therefore, the dried terpin reference material should be corrected for residual moisture, as determined by the Karl Fischer procedure, and used on the anhydrous basis for preparation of the reference solution.

The ratio of the areas of terpin to the internal standard, *3-tert*-butylphenol, *versus* the amount of terpin hydrate in the sample is linear for injected quantities between 0–75 mcg. of terpin hydrate.

Observations Concerning a Gas Chromatography Study of Resorcinol Monoacetate

By LEON KURLANSIK and EDWARD F. SALIM*

Initial investigations to develop a gas chromatographic assay for resorcinol monoacetate indicated that commercial material was not a single substance but a three-component mixture. A resorcinol monoacetate standard has been prepared and studies conducted at elevated temperatures to evaluate the conversion of resorcinol monoacetate to a mixture which includes resorcinol and resorcinol diacetate. Thermodynamic values have been calculated from experimental data. Characterization of the composition of commercial resorcinol monoacetate has been demonstrated by gas chromatography.

THE SYNTHESIS of resorcinol monoacetate (RMA) was first reported in 1899 (1). In 1931 Chattaway (2) prepared the compound by reacting resorcinol and acetic anhydride in sodium hydroxide solution and published physical constants for the material. Israelstam and Simpson (3) produced RMA by a modification of Chattaway's method and by the reaction of

resorcinol diacetate (RDA) and disodium resorcinate. Recently, investigators have synthesized the monoacetate by acetylation of resorcinol with ketene (4, 5).

A survey of the literature indicated an almost total absence of methods of analysis for RMA. Brud and Daniewski (6) have effected a thin-layer chromatographic separation of resorcinol, RMA, and RDA on the product of RMA synthesis and quantitatively determined each component. It was felt that gas chromatography could be employed for determination of RMA but initial chromatograms of commercial RMA were characterized by the presence of three components which persisted throughout variations in chromatographic conditions. An early report (1) which indicated that RMA could be prepared from resorcinol and RDA and the analysis of Brud and Daniewski (6) offered the suggestion that resorcinol monoacetate is not a pure compound but rather an equilibrium mixture consisting of resorcinol and its mono- and diacetates. The following study has been undertaken in support of this theory.

EXPERIMENTAL

Standards—*Resorcinol*—USP grade material was recrystallized twice from 1,1,1-trichloroethane, m.p. 110.5–111.0°.

Resorcinol Monoacetate—Prepared according to the method of Chattaway (2). The RMA so obtained was not chemically pure when examined by GLC and further purification was necessitated. About 30 Gm. of the product was transferred to a separator containing 25 ml. of ethylene glycol. After mixing, 45 ml. of water was added, and the contents shaken and extracted with 25 ml. of chloroform. The chloroform wash was discarded. To the separator was added 50 ml. of water and the solution extracted with two 25-ml. portions of chloroform. Evaporation of the combined chloroform extracts *in vacuo* resulted in a slightly yellow, viscous liquid; density 1.234; n_D^{20} 1.5349 [lit. (4) 1.5328]. The product was observed to yield only one peak chromatographically.

Resorcinol Diacetate—Matheson, Coleman and Bell RDA was purified by alternate washings with cold 5% sodium hydroxide solution and water until the material was chromatographically pure; density 1.185; n_D^{20} 1.5029 [lit. (4) 1.5034].

Equilibrium Studies—About 5 ml. of resorcinol monoacetate standard was placed in a test tube and heated in an oil bath at the specified temperature. At varying time intervals, a 0.1-ml. aliquot was diluted to 25.0 ml. with a mixture of chloroform–methanol (20:1). A 4-μl. portion of this solution was injected into an F & M model 810 dual-column gas chromatograph equipped with a dual-flame ionization detector and a Minneapolis Honeywell recorder. The columns were stainless steel (6 ft. × 1/8 in.) packed with 10% SE-30 on Diatoport S, 60–80 mesh (prepared by F & M Scientific Company). Chromatographic conditions: column temperature, 105°; injection port temperature, 110°; detector temperature, 110°; helium flow, 83 ml./min.; hydrogen, 66 ml./min.; air, 450 ml./min.

RESULTS AND DISCUSSION

The appearance of three distinct peaks by gas chromatographic injection of commercial RMA dissolved in chloroform indicated impure material or degradation of the compound on the column. RMA was subjected to thin-layer chromatography by application on a silica gel strip (Eastman Chromagram, type K301R2) and development of the chromatogram in a solvent system consisting of chloroform–hexane–acetone (50:75:10). Visualization with iodine vapor disclosed the presence of three spots that were identified as the suspected resorcinol, RMA, and RDA by R_f values corresponding to reference compounds chromatogrammed on the same thin-layer strip. This confirmed the composition of commercial RMA to be a mixture but it was not certain that the samples tested were simply below expected quality.

Equilibrium studies were conducted whereby RMA standard was exposed to constant heat at selected temperatures to note the production of GLC peaks corresponding to resorcinol and the diacetate and a simultaneous reduction in the height (in actuality the area) of the original single RMA peak. Experimentation at each temperature was continued to a point at which the reduction of the RMA peak was no longer significant and it was assumed that equilibrium had been attained. Equilibrium concentrations of resorcinol, RMA, and RDA at experimental temperatures are recorded in Table I. Quantitative determination of each constituent observed chromatographically was based on a comparison of peak area to a calibration curve prepared for each standard using the same instrument parameters. Data obtained from these investigations were used to calculate thermodynamic values included in Table II. Substantiation of experimental equilibria has been obtained by a graphical representation of log K *versus* reciprocal

283	56.3	3069	636	4.38

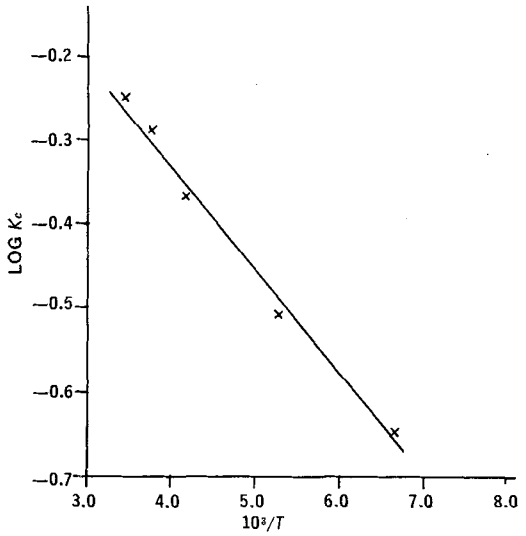

Fig. 1—Effect of temperature on equilibrium constants of RMA.

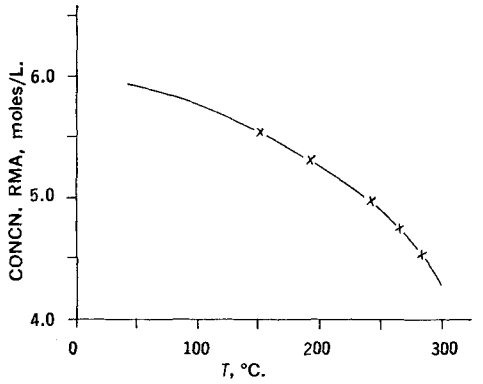

Fig. 2—Influence of temperature on equilibrium concentrations of RMA.

temperature to yield a linear relationship as shown in Fig. 1 and by the converse reaction of resorcinol and RDA to form the monoacetate at selected temperatures. The influence of temperature on equilibrium concentrations of RMA is plotted in Fig. 2.

Commercially available RMA has been characterized as a mixture whose composition can vary depending on the method of manufacture, purification, and age. Nevertheless, analysis can be achieved by gas chromatography to accurately determine the percentage content of each major constituent. An accurately weighed quantity of RMA is diluted to volume with chloroform–methanol (20:1) and a sample injected into the instrument. A typical resultant chromatogram is shown in Fig. 3. The percentage of RMA is calculated by correlation of the peak area to the calibration curve prepared for use in the equilibrium studies. In a similar manner is is possible to obtain the quantities of resorcinol and RDA. Total analyses of three commercial samples have been investigated and the recoveries summarized in Table III.

[a] NF material.

Quantitative analysis of RMA has been attempted by formation of trimethylsilyl (TMS) ethers by the method of Brobst and Lott (7) and other conventional procedures. A GLC chromatogram of the reaction mixture would represent TMS derivatives of resorcinol and RMA and unreacted RDA. Inspection of chromatograms prepared subsequent to etherification indicated the presence of two peaks instead of the expected three. Supporting investigations on standard materials have shown that the TMS ethers of resorcinol and RMA are eluted simultaneously as a single peak and that this approach is not feasible as a specific assay for RMA in the presence of resorcinol.

Granulation of Griseofulvin

By C. F. HARWOOD and N. PILPEL

Griseofulvin, in fine and coarse grades, has been bowl granulated using binder solutions. The granules have been assessed for strength and flow characteristics. A mechanism of granule growth has been suggested, which satisfactorily explains the experimental results.

GRISEOFULVIN tablets are normally prepared from granules containing griseofulvin powder. Granulation facilitates handling, prevents segregation in the formulated mix, and eliminates the problem of dust. Methods of granulation include slugging, wet granulation, spray drying (1, 2), bowl and dish granulation (3, 4). In bowl granulation, the powder is rotated in a tablet coating pan and is lightly sprayed with binder solution which causes it to aggregate into granules. Dish granulation is similar, but involves the use of a low walled dish which is tilted to the horizontal. This is a continuous process for obtaining uniform granules. Both techniques yield a smooth, rounded product, and theories concerning them have been developed by Newitt and Conway-Jones (5), Capes and Dankwerts (6), and by Rumpf (7).

The purpose of this investigation has been to granulate two grades of powdered griseofulvin in order to study the effect of the starting powder on such properties of the granules as their shape, density, and flow characteristics. No excipients were used, but the pharmaceutical grade of polyvinylpyrrolidone,[1] was employed in various concentrations as a binder and a study made of its effects on the strengths of the resulting granules.

EXPERIMENTAL

Materials—Two closely sized pharmaceutical grades of griseofulvin were used, the fine grade (USP microfine grade) having an average particle size of 4 μ, as measured on the Fischer subsieve sizer, and the coarse grade an average particle size of 10 μ. The actual size data, obtained by Coulter counter measurements (8), are given in Table I.

Water and aqueous solutions of polyvinylpyrrolidone (PVP), in 5, 10, 15, and 20% concentrations by weight, were used as the binding fluids.

Granulation Method—Four hundred grams of powder was placed in a 16-in. copper tablet coating pan, mounted on a Manesty Varispeed motor, which was rotated at 30 r.p.m. The binding liquid was sprayed tangentially onto the powder from a Burgess electric spray, type VS 625, in 2-sec. periods every 10 sec. for approximately 15 min. The granules formed without the provision of flights and quickly attained a limiting size. Rotation was continued for a further 15 min., while warm air was blown into the bowl, and the granules were finally dried in shallow trays for 12 hr. at 70°.

Batches were also prepared using a dish granulator of 60-cm. diameter, with 5-cm. walls, tilted at 45° and rotated at 15 r.p.m. In both methods the coarse powder yielded rounded granules but the fine material produced only irregular granules, when viewed under a low power microscope, even when all the operating variables were altered. In further attempts to produce rounded granules from the fine powder, alcohol–water and acetone–water solutions and methylcellulose solution in water were also used as binding fluids; all, however, were unsuccessful.

Measurements on the Granules—*Sieving*—The granules were separated into size fractions by sieving for 10 min. on a vibration sieve. Surface fines were removed by resieving 30-Gm. portions for 1 min. on the Alpine airjet sieve. Microscopic examination confirmed that the granule fractions were uniform in size and free from fines.

PVP Content—The PVP contents of the granules were measured by extracting a known weight with boiling water, filtering, evaporating the filtrate to dryness, and weighing the extracted PVP. Blank tests were conducted using griseofulvin powder and PVP powder alone.

Granule Strength—The breaking strengths of individual granules were measured by raising single granules on a flat plate by means of a lab jack, just into contact with a second flat plate fixed to the underside of a chemical balance pan (Fig. 1). Lead shot was poured steadily onto the balance pan until the granule broke. The weight of the lead shot was then taken as the breaking load. Typical results are recorded in Table II.

Granule Porosity—This is given by the expression:

$$\text{porosity} = \frac{\text{void vol.}}{\text{total vol.}} \times 100$$

where the void volume = $(1/\rho_G - 1/\rho_\rho)$. The granule density, ρ_G, was determined from the weight

and volume of about 200 granules and the powder density, ρ_p, was determined by the British Standards specific gravity bottle method.

Bulk and Tapped Density—Bulk and tapped density values were measured in the Heywood apparatus, using the method described in British Standards 1440.

Granule Flow—The flow of granules in each size fraction was measured from a vertical copper tube of internal diameter 3.8 cm., fitted with a flat base plate with circular orifices of 0.605, 0.707, 0.900, 1.130, 1.330, and 1.650 cm. diameter (9).

RESULTS

The histograms of the granules formed from the fine and from the coarse grades of griseofulvin are shown in Fig. 2. It is seen that the 20% PVP binder solution leads to a slight increase in granule size, compared to water as a binder. As the two liquids have practically the same surface tensions, 64 and 72 dynes/cm., respectively, the effect is probably due to their different viscosities, 40 cps. and 1 cps., respectively. The surface tension force holding two particles together is enhanced if the liquid between the particles has a high viscosity; this is because the liquid has a resistance to deformation, which would result from separation. Thus the "suction" pressure increases with the rate of particle separation and a bond, once formed, resists separation (10).

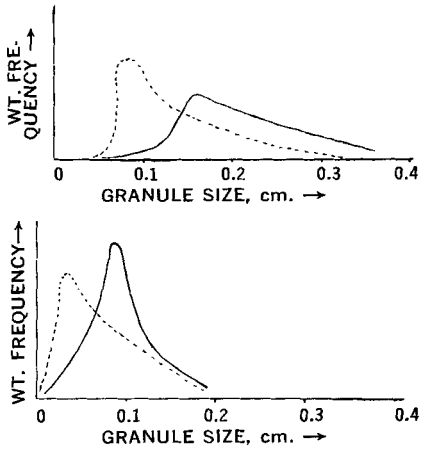

Fig. 2—Histograms. Top, fine grade, yielding irregular granules. Bottom, coarse grade, yielding rounded granules. Key: ——, granulated with 20% PVP solution; - - -, granulated with water.

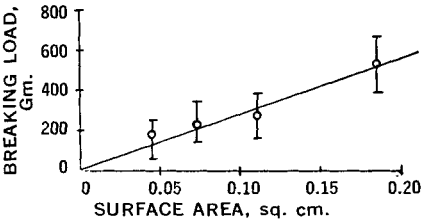

Fig. 3—Increase in granule strength with surface area.

Table III shows that the PVP content of the different size fractions varies through a particular granule batch. During granulation, segregation of sizes occurs so that particular fractions may be favorably presented to the binder spray, and this would account for the variation.

Figure 3 shows that a definite relation exists between granule strength and granule size (*i.e.*, surface area) and that within limits the relation, granule strength = $k \times$ surface area, is applicable. Figure 4 indicates that the granule strength in a particular size group depends on the PVP content. In both cases, considerable scatter of results occurs and this was observed also by Rumpf (7) when measuring the tensile strength of moist granules.

Average porosity values are given in Table IV for the two grades of powder and for the rounded granules containing PVP. These results may be

compared with those quoted by Ono and Taneya (11) for hard, ideal spheres in loosely packed and tightly packed states, Table V. The fine and coarse griseofulvin powders have a high porosity, indicating bridging by the cohesive forces: these forces are overcome by the granulation process and a tighter state of packing is achieved.

Bulk and tapped density figures are plotted in Fig. 5, which shows that, because of their geometry, rounded granules pack together more closely than irregular granules. Typical flow rates for the two types of granules through a particular sized orifice are plotted in Fig. 6. The flow rate of rounded granules is seen to be considerably higher than of irregular ones.

DISCUSSION

Some understanding of the growth of granules during granulation can be gained by considering the centrifugal forces acting on two coalescing granules. The values given in Table VI are calculated for equal sized granules by assuming that one of them is thrown around the other with a speed equal to that of the peripheral speed of the drum.

The centrifugal force at the point of coalescence would have to be balanced by the number of pendular bonds acting between individual particles. The value of the pendular bonds can be calculated from (12):

$$F = \frac{2\pi r T}{1 + \tan \theta}$$

where F is the bond strength in dynes, r is the radius of the particles, T is the surface tension of the binder solution, and θ is related to the quantity of binding liquid forming the bond. The values of the pendular bond strengths, calculated for different particle sizes, are given in Table VII, taking θ as 14°.

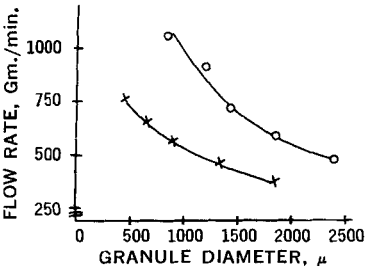

Fig. 6—Granule diameter against flow rate through 1.330-cm. orifice. Key: O, rounded; ×, irregular.

TABLE VI—CENTRIFUGAL FORCE FOR DIFFERENT GRANULE DIAMETERS

Granule Diam., cm.			
0.05	0.1	0.5	1.0
Centrifugal Force, dynes			
7.24	28.9	724	2890

TABLE VII—PENDULAR BOND STRENGTHS AT DIFFERENT PARTICLE SIZES

Particle Size, μ			
4	10	50	200
Bond Strength, dynes			
6.4×10^{-2}	1.6×10^{-1}	8.0×10^{-1}	3.2

The limit of growth by coalescence is probably about 0.5 cm., since, above this size, the centrifugal force becomes very large. However, growth can continue by a secondary process in which small granules are crushed by larger ones (6); the fragments then join the larger granule by coalescence. The limit of growth probably occurs when the crushing effect becomes so frequent that granules are prevented from reforming.

In the case of griseofulvin, in fine and coarse grades, the limit of growth is quickly reached, due to the weak pendular bonds formed at small particle sizes. Thus the granule size at which crushing occurs is never reached.

In the dry state, the strength of a granule is due to the cohesive forces in the griseofulvin and, to a larger extent, to the solid bridges formed from the evaporated binder. PVP in the solid state is an

extremely brittle substance and the large strength variation (Figs. 3 and 4) is consistent with the theory of brittle solids proposed by Griffith (13). Dollimore and Gregg (14) have shown that the ratio of the theoretical strength, R_m, to the practical strength, R, is given by:

$$\frac{R_m}{R} = \left(\frac{\pi c}{a}\right)^{\frac{1}{2}}$$

where a is the range of the attractive forces, and $2c$ is the length of a crack in the brittle solid. Taking $a \approx 3 \times 10^{-8}$ cm., and $c \approx 1 \times 10^{-4}$ cm., then a crack of only 2 μ in the binder would cause a 100-fold reduction of strength. The strength of the granules would also be expected to vary due to irregularities in their shape and the presence of localized powder or binder voids.

CONCLUSION

Griseofulvin can be granulated by the bowl method and the strength of the granules formed has been shown to be dependent on both their size and on their PVP content.

It appears to be more difficult to prepare smooth, rounded granules with good flow and storage characteristics from the fine grade than from the coarse grade, although the former is preferred for therapeutic reasons.

"Crushing-Strength" of Compressed Tablets I

Comparison of Testers

By DAVID B. BROOK and KEITH MARSHALL

By means of a piezo-electric force transducer the actual compressional load exerted at certain scale readings by four types of commercially available "crushing-strength" instruments has been determined. The results indicate that variations in crushing-strength values between instruments are due in part to inaccuracies in instrument scale values, zero errors and varying methods of applying the load. Calibration is therefore necessary for accurate measurements using one instrument or when comparing results from more than one tester.

THE MECHANICAL strength of medicinal tablets is an important property of this form of drug presentation and plays a significant role in development and control procedures. It has been described by various terms including "fracture resistance" (1), "friability" (2), "hardness" (3), "bending strength" (4), and "crushing-strength" (5). Measurement of the latter is probably the most widely used technique and may be precisely defined as "that compressional force which, when applied diametrically to a tablet, just fractures it." In most cases the tablet is placed upon a fixed anvil, and the force is transmitted to it by means of a moving plunger.

Crushing-strength is widely employed in commercial production as a control procedure and has been compared by several authors with other properties of the tablet (5–9). Many individual instruments for crushing-strength determinations have been described (3, 9–12) and comparisons between commercially available testers made (3, 11, 13).

In the present investigation a comparative study, against an absolute standard has been made on four commercially available instruments, "Strong-Cobb," "Monsanto," "Pfizer," and "Erweka" hardness testers.

"Crushing-Strength" of Compressed Tablets I

Comparison of Testers

By DAVID B. BROOK and KEITH MARSHALL

By means of a piezo-electric force transducer the actual compressional load exerted at certain scale readings by four types of commercially available "crushing-strength" instruments has been determined. The results indicate that variations in crushing-strength values between instruments are due in part to inaccuracies in instrument scale values, zero errors and varying methods of applying the load. Calibration is therefore necessary for accurate measurements using one instrument or when comparing results from more than one tester.

THE MECHANICAL strength of medicinal tablets is an important property of this form of drug presentation and plays a significant role in development and control procedures. It has been described by various terms including "fracture resistance" (1), "friability" (2), "hardness" (3), "bending strength" (4), and "crushing-strength" (5). Measurement of the latter is probably the most widely used technique and may be precisely defined as "that compressional force which, when applied diametrically to a tablet, just fractures it." In most cases the tablet is placed upon a fixed anvil, and the force is transmitted to it by means of a moving plunger.

Crushing-strength is widely employed in commercial production as a control procedure and has been compared by several authors with other properties of the tablet (5–9). Many individual instruments for crushing-strength determinations have been described (3, 9–12) and comparisons between commercially available testers made (3, 11, 13).

In the present investigation a comparative study, against an absolute standard has been made on four commercially available instruments, "Strong-Cobb," "Monsanto," "Pfizer," and "Erweka" hardness testers.

Received August 21, 1967, from the Industrial Pharmacy Unit, University of Bradford, Bradford England.
Accepted for publication October 23, 1967.

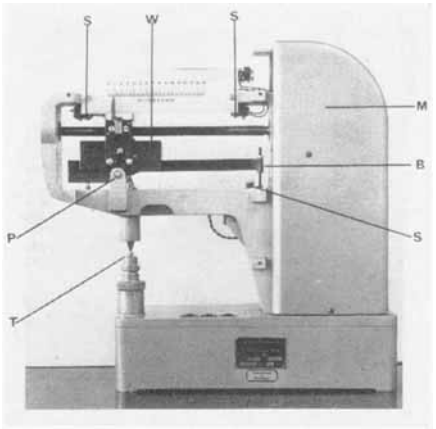

Fig. 1—The Erweka tablet hardness tester, type TBT. (Cover and attached zero light removed.) Key: B, beam; M, motor housing; P, beam pivot; S, microswitch; T, tablet; W, sliding weight.

The first three of these testers are adequately described elsewhere (3, 11, 12). In the "Erweka" tablet hardness tester (type TBT) the compressional force is applied by a loaded beam. The loading is produced by a sliding weight moved along the beam by an electric motor, which is stopped automatically, immediately the tablet fractures (see Fig. 1). The initial zero position is indicated by a red warning light. Hence, errors associated with a nonuniform rate of loading and varying zero adjustment are minimized. A recent report (14) using this instrument suggests that a more realistic test is to apply the force axially to the tablet, a procedure suggested by other authors (1) for the Strong-Cobb hardness tester.

In fact almost all the published work on the crushing-strength of tablets refers at some point, to discrepancies between readings obtained by different techniques. The work described endeavors to correlate results and explain the observed variations in crushing-strength values.

EXPERIMENTAL

Calibration of Force Transducer—In order to ascertain the absolute load transmitted to a tablet by the four instruments at certain scale readings, a small load washer was substituted for the tablet. The transducer employed (Kistler, type 901A) was based on the piezo-electric effects of a quartz crystal. Compressional loads on these cause a re-orientation of electrons within the crystal, giving rise to an electrostatic charge on it. The transducer was coupled to a piezo-charge amplifier (Kistler, type 568) which precisely converted this charge into a voltage output signal which was registered on a digital voltmeter (Weyfringe, type 4NP).

Although conversion data were supplied with the transducer, it was felt desirable to calibrate the instrument accurately over the intended range of loading. This was carried out by two methods: (*a*) by placing known weights at fixed distances from the fulcrum of a simple, freely pivoted beam (illustrated diagrammatically in Fig. 2) which rested on one of the transducer's sensitive surfaces, and (*b*) using an accurate compression/tension testing machine (Instron, floor model TT-C).

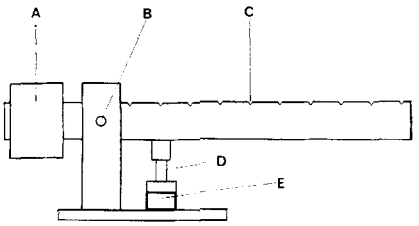

Fig. 2—Diagram of simple beam used to calibrate the load transducer. Key: A, counterbalance weight; B, beam pivot; C, beam graduated in exact 2-cm. divisions; D, plunger fixed to beam and resting on transducer surface; E, load transducer.

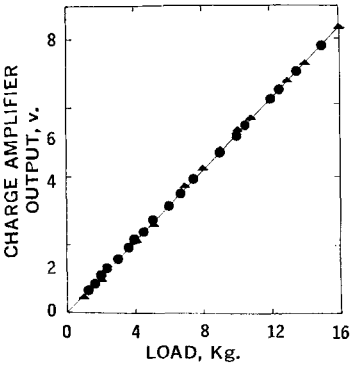

Fig. 3—Calibration curve for load transducer. Key: ●, reading obtained by loaded beam; ▲, reading obtained on Instron testing machine.

The results summarized in Fig. 3 indicated that the relationship between compressional load and voltage output was substantially linear over the range tested; *i.e.*, compressional load (Kg.) was equal to 1.925 × voltage output. This relationship was used in the subsequent experiments.

Calibration of Instrument Scales—The four testers were then taken in turn and with the load transducer in place of a tablet, loads were applied to fixed scale intervals, the resulting voltage being noted. Each series of readings was repeated to give a total of 25 at each level of loading. The arithmetic mean of these was then converted into Kg. using the above relationship. The values obtained are plotted against instrument scale readings in Fig. 4. Calibration values were only obtained up to actual loads of about 15 Kg. since in normal use the testers are unlikely to be operated beyond this point.

The Monsanto hardness tester is probably the most well known and it was therefore decided to compare five instruments of this type to ascertain the individual variation. In addition to the tester in the authors' laboratory, three new testers were donated by the manufacturers and a well used instrument was obtained from an industrial source. The results of calibration tests similar to those described above on these testers are given in Table I and Fig. 5.

15				15.705	14.696
16					15.797

[a] Testers A, B, and C were new. Tester D had been used in the authors' laboratory for 3 years and tester E was a well used instrument obtained from an industrial source.

DISCUSSION

The results shown in Figs. 4 and 5 indicate discrepancies between the load as registered on the instrument scales and the actual load as determined by load transducer. The graphs approximate to straight lines over most of the range studied, and it is therefore convenient to utilize the slopes S (which were determined graphically) of these plots as a means of comparison with the ideal line of slope one. Since all lines should ideally pass through the origin, S is the correction factor necessary to adjust instrument scale readings so that they lie on the theoretical line.

Strong-Cobb—This tester registers the air pressure required to crush the tablet and has a scale graduated in Kg./sq. in. Comparison with other results is therefore only possible if these readings are converted to compressional load in Kg. The manufacturer of the instrument specifies a conversion factor based upon piston dimensions of 0.780. In this investigation the value of S was found to be 0.728 and Table II gaves the values of instrument scale readings corrected by this factor.

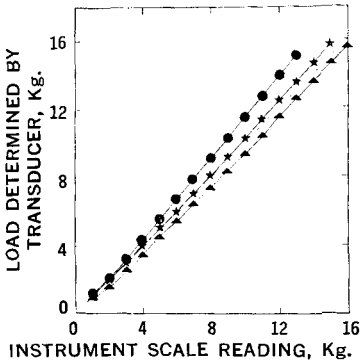

Fig. 5—Relationship between instrument scale reading and actual load being exerted as determined by load transducer for 3 Monsanto testers. Key: ●, Monsanto A (new); ★, Monsanto D (authors); ▲, Monsanto E (well used). Dotted line is theoretical ideal of slope one.

[a] Actual loads determined by load transducer. [b] Scale reading × 0.728.

Monsanto—The results for these testers appear to indicate that the springs applying the load become fatigued with prolonged use, *i.e.*, S values falling, although when new they exert loads which are consistent but in excess of the scale reading.

McCallum, Buchter, and Albrecht compared the Monsanto and Strong-Cobb hardness testers and calculated a conversion factor of 0.625 for Monsanto to Strong-Cobb units (3). The results reported here gave a factor of 0.627 (new Monsanto) and 0.697 (well used).

Pfizer—This tester was found to exert loads in excess of the scale readings (S value 1.260), and since the instrument was comparatively new it is probable that, as with new Monsanto testers, the spring does not match the scale graduations initially. In addition it was noted that at loads below 3.0 Kg. the load was less than the scale reading, probably due to frictional losses.

TABLE III—DIFFERENCES IN TABLET HARDNESS TESTER CONSTRUCTION WHICH MAY CONTRIBUTE TO VARIATION IN CRUSHING-STRENGTH VALUES BETWEEN INSTRUMENTS

Loading Mechanism	Monsanto Coil Spring	Strong-Cobb Hydraulic Pressure	Pfizer Coil Spring	Erweka Loaded Beam
Scale length/Kg.	0.3 cm.	0.79 cm.	0.88 cm.	0.935 cm.
Scale graduated in:	1.0 Kg.	0.728 Kg.[a]	0.2 Kg.	0.25 Kg.

[a] One scale unit is equal to 0.728 Kg.

Erweka—Examination of this tester revealed a zero error because at the moment the zero warning light became activated the instrument was already exerting a load of about 0.5 Kg. Furthermore, as soon as the sliding weight began to move along the beam there was a sudden increase in load to about 1.4 Kg. Subsequent increase in loads of one scale division resulted in an increase in true load of 1.211 Kg.

The initial errors were traced to an incorrect zero adjustment and frictional losses in the pivot. Utilizing the principle of moments it was possible to calculate the theoretical load from the known scale dimensions (0.935 cm./division) and the magnitude of the sliding weight (1.925 Kg.). The distance of the plunger from the fulcrum was accurately measured as 1.425 cm. From these readings a value of 1.262 Kg./scale division was obtained. The difference between this and the observed reading (1.211 Kg./scale division) was thought to be due to frictional effects.

From these experiments a true zero position was attained by adjustment of the zero light trip switch position and a new scale was constructed. These modifications were entirely successful in producing true response to actual loads (see Table II).

Krowczynski (13) compared the Monsanto and Erweka hardness testers and found that the results from the two instruments differed widely. This author calculated a conversion factor of 1.6 for Erweka to Monsanto units. In the present investigation it was impossible to determine such a simple factor because a large constant zero error in the Erweka tester results in a factor which increases as the crushing-strength values decrease. This may well account for the difficulty reported by Krowczynski in determining his conversion factor.

Other Differences in the Testers—Any comparison of these four types of testers must take into account the additional factors due to the inherent differences in design summarized in Table III.

For example the variations in scale length for 1-Kg. units of loading are significant enough to introduce considerable errors in estimation of the load. The different methods of applying the load might also be expected, as is shown here, to give rise to differing values of crushing-strength for different instruments.

Since the initial load applied to grip a tablet is, in three types of instruments, subject to operator variation this must also lead to discrepancies. In the Monsanto and Pfizer hardness testers it was found that with extreme care the initial load required to grip the transducer could be as little as 0.1 Kg., but unless the operator exercized this care, loads of 0.3 to 0.5 Kg. were more likely. In the Strong-Cobb hardness tester it appeared that the setting for zero was less critical. Although the pressure gauge needle was sluggish in leaving the zero mark, the load applied at a scale reading of 1 unit was reasonably constant irrespective of the initial "gripping load." Before adjustment of the Erweka hardness tester the average zero load applied to a tablet, when the zero light was activated, was found to be 0.5 Kg. Any slight overshooting of the zero position resulted in initial loads up to 1.3 Kg. which of course were not accounted for in the subsequent crushing strength indicated on the instrument scale. Even after adjustment any overshooting still applies large initial loads.

Finally, it may be noted that all instruments were less accurate at crushing-strengths below about 2.0 Kg. and it is doubtful if values below this figure have any significance.

CONCLUSIONS

Variations in crushing-strength values obtained from different types of tester have been shown to be due in part to inaccuracies in instrument scale values, zero errors, and varying methods of applying the load. Calibration is therefore necessary where a high degree of accuracy is desired or when comparing results from different types of testers. The physical dimensions and shape of the tablet as well as other physical properties must also contribute to the property of crushing-strength. The results reported here are now being used to study these additional factors.

Dissolution Apparatus with Multiple Testing Stations

By R. A. CASTELLO, G. JELLINEK, J. M. KONIECZNY, K. C. KWAN, and R. O. TOBERMAN

An apparatus in which 20 dissolution tests may be conducted simultaneously is described. A single set of controls maintains the test conditions in all 20 dissolution vessels. Provisions have been made to sample automatically and simultaneously from each vessel at predetermined time intervals. Results obtained for the dissolution of experimental potassium chloride tablets using this apparatus are in good agreement with those obtained when tablets were tested individually.

IT HAS BECOME increasingly evident that the rate and extent of the dissolution of drug compounds from solid dosage forms such as capsules or tablets are important criteria for optimum absorption and therapeutic effect. For example, Levy *et al.* (1) have used the dissolution rate of prednisone to differentiate between therapeutically active and inactive tablet formulations. Moore *et al.* (2) demonstrated the value of dissolution tests in evaluating various formulations of nalidixic acid. Under some circumstances, it has been shown (3) that the dissolution data for a given formulation may be injected directly into a relatively complex pharmacokinetic model for the prediction of biological disposition of a drug.

In the course of the development of a dosage form, the examination of dissolution properties may be helpful in various ways. Dissolution may be used to study the effects of formulation and process changes, to evaluate the reproducibility within a batch as well as between batches, and to verify the physical quality of a product. When the dissolution characteristics correlate with the absorption or clinical effectiveness of the dosage form, it may be desirable to include the dissolution test as a regular quality control requirement for that product. The apparatus to be described was designed with this need in view and particularly to accommodate those situations where a large number of individual dissolution tests may be required for proper statistical assessment of the dosage form.

Specifically, this communication describes a mechanical unit in which 20 individual dissolution tests may be conducted simultaneously. A master panel controls the rate of agitation, the position of the agitators, the duration of the dissolution test period, the frequency of sampling, and also provides for the automatic withdrawal of samples at predetermined times. The dissolution vessels are immersed in a constant temperature water bath and are held in fixed positions relative to the stirring mechanism.

Accepted for publication November 14, 1967.

Presented to the Drug Standards, Analysis and Control Section, APHA Academy of Pharmaceutical Sciences, Las Vegas meeting, April 1967.

APPARATUS

The apparatus (Fig. 1) consists of four parts: (*a*) a stand and raising mechanism; (*b*) an agitator support and d.c. motor drive; (*c*) electric controls; and (*d*) a sampling device.

The agitators are raised and lowered by a vertical screw which is driven by a 1/4-hp. Boston Ratiomotor with a 10 to 1 ratio. Upper and lower limit switches which are mounted on the stand allow for maximum vertical travel of 16 in. The electrical equipment is mounted on a sliding tray in the lower part of the stand. All operating controls are mounted on a control panel on the right-hand side of the stand.

The 20 agitators are driven by a single Bodine 1/4-hp. d.c. gear motor with a ratio of 10 to 1. The extended armature shaft is connected by a flexible coupling to a tachometer. The extension on the agitator support is equipped with a knurled adjusting and lock screw that operates the lower limit switch and controls the agitator heights. Agitators operate only with the agitator support at the lower limit of travel.

All operational functions, such as raising and lowering, fast and slow agitation speeds, timing and signals, are accomplished through Allen-Bradley relays and Eagle "Cycl-Flex" timers. Using elec-

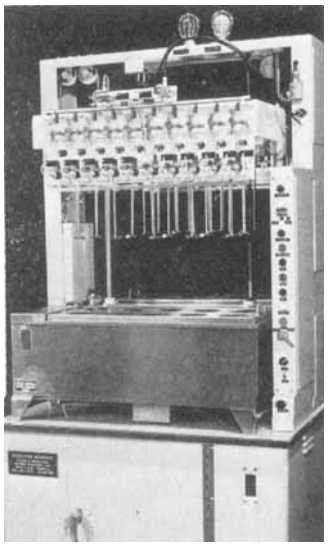

Fig. 1—Dissolution apparatus.

trical interlocks, only one function can be operated at any one time. The speed of the agitators is controlled by a d.c. motor control. Two ranges of speed, slow and fast, provide maximum rates of agitation of 100 and 250 r.p.m., respectively. Speed control is accomplished by balancing the output of the tachometer against a variable voltage obtained from zener diodes by adjusting a potentiometer. The agitator speed can be read directly in r.p.m. on a meter. Speed is maintained to ±2% regardless of line voltage between 105–130 v.

All the necessary push-button switches are mounted on the panel (Fig. 2). Briefly their functions are as follows: (*a*) The main selector switch energizes the whole unit. (*b*) A wing lever selector switch selects the mode of operation—"manual" or "automatic." (*c*) The "sample" push button is used to take samples at any time when the wing lever switch is in the "manual" position. (*d*) The "agitator" push button operates agitators manually while depressed and is active only on "manual" operation. (*e*) The "down" push button is used to lower the carrier while depressed and is active on "manual" operation only. (*f*) The "up" push button raises the carrier while depressed but does not have to be held and is operational only in the "manual" mode. (*g*) "Start cycle" push button starts the automatic cycle if the wing lever switch is in the "automatic" position.

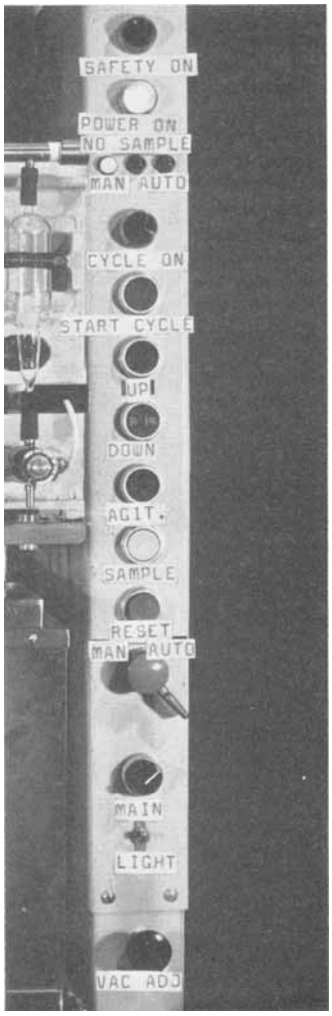

Fig. 2—Operational panel of dissolution apparatus.

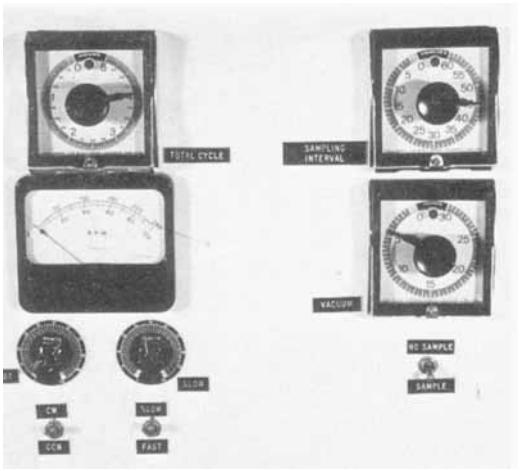

Fig. 3—Preset controls of dissolution apparatus.

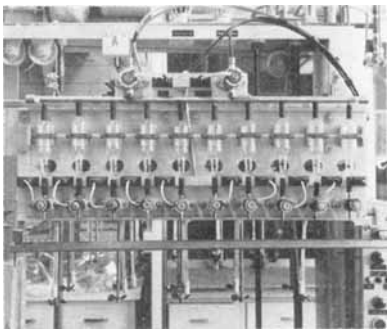

Fig. 4—Sampling device.

Preset controls are all mounted on the front panel of the electrical equipment tray (Fig. 3). A total cycle timer controls the length of agitation during the automatic cycle. A sample interval timer energizes the sampling device to take samples at set intervals and may be bypassed at the operator's discretion. The vacuum timer activates a vacuum pump for a set period of time and controls the level of fill in the sampling bulb. A toggle switch controls the direction of motion of the agitators.

The sampling device (Fig. 4) will take a volumetrically controlled sample from each of the 20 dissolution flasks simultaneously and transfer all samples to corresponding sample cups. This is accomplished in the following manner: when the vacuum timer is energized the vacuum pump starts and two vacuum valves open. A vacuum is thus created in a manifold and in all 20 sample bulbs (Fig. 5). Liquid from the flasks is transferred through the suction tubes adjacent to each agitator into the sample bulbs. By setting the vacuum timer or the vacuum adjust valve, the volume of fill can be regulated. When taking samples it is only necessary to let the liquid rise slightly above the narrow portion of the sample bulb. When the vacuum timer stops, the two

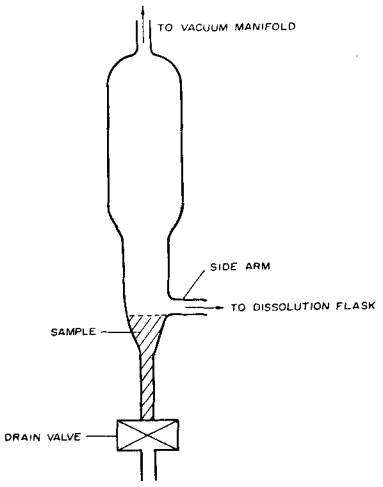

Fig. 5—Schematic drawing of sample bulb.

vacuum valves close and the vacuum pump stops. At the same time, two vent valves open to allow the excess sample fluid to drain back into the flasks leaving only the desired quantity of sample in the bulbs. After a delay of 5 to 10 sec., the 20 drain valves open and the liquid empties from each bulb into 20 sample cups. Suction tubes may be back flushed with air prior to sampling to avoid dead volume in the line; or, alternatively, up to three samples may be flushed through the sampling device prior to actual taking of the analytical specimen to avoid dilution effects. The sample size is fixed by the location of the horizonal extension of the sample bulb.[1]

APPLICATION

Use has been made of the apparatus described to monitor the dissolution behavior of several new dosage forms, but especially an experimental, slow-releasing potassium chloride tablet formulation. Such a tablet was selected for study because it enabled us to use an automated assay procedure where the potassium concentration was measured by flame photometry. For this particular preparation, 20 individual tablets were tested in the apparatus simultaneously. The agitators (2 in., three-blade impellers, A. H. Thomas, 9240-K) were individually adjusted to a height of 3 cm. from the bottom of each of 20 dissolutions flasks (reaction flask, Corning 6947). The flasks were individually centered with respect to the agitator shaft and then fixed in this position. Each flask contained 750 ml. of 0.01 *M* sodium phosphate buffer at pH 7.2 and maintained at 37° in a constant temperature water bath. The rate of agitation was adjusted to 180 r.p.m. in the counterclockwise direction, when viewed from above. Samples were withdrawn automatically at the beginning of the dissolution cycle and at 30-min. intervals during the dissolution test for a total of 4 hr. The sample bulbs were designed to deliver 1.5 ml. of sample into the sample cups for assay. The concentration of potassium in solution in the cups, and consequently in the dissolution flasks at each time was determined by flame photometry. The rates of dissolution measured with this apparatus were compared with those obtained when 20 individual tablets were tested one at a time and consecutively in a single dissolution test apparatus which involved timed sampling by pipet. Dissolution results on samples withdrawn from a single batch of the experimental potassium chloride tablets by both methods illustrate good agreement (Table I) and validate the use of the automated apparatus for large-scale dissolution testing.

SUMMARY

An apparatus capable of performing multiple dissolution tests simultaneously under controlled conditions is described.

This apparatus has the following features: (*a*) 20 individual tests may be performed simultaneously. (*b*) The degree of agitation may be maintained at constant rates up to 250 r.p.m. (*c*) Samples may be withdrawn automatically at any predetermined frequency within a specified length of time. (*d*)

Relative positions of stirrers and dissolution vessels may be adjusted at will. (*e*) Size of samples taken is adjustable.

The dissolution behavior of an experimental potassium chloride tablet was used to illustrate the application of this apparatus in comparison with a more laborious single dissolution flask procedure.

Development and Evaluation of a Sampling Device for the Analysis of Pharmaceutical Aerosols

By SIDNEY P. TUESLEY, JOHN J. SCIARRA, and ANTHONY J. MONTE-BOVI

Various devices and techniques were studied in an attempt to obtain suitable samples of material from aerosol products. Generally accepted sampling procedures cannot be used since the aerosol product contains propellants that are extremely volatile. Several of these methods were investigated and used as the basis for assaying various aerosol products. A sampling device was developed and evaluated. The sampling device was designed in a manner that made available a sample of aerosol product that could then be assayed directly in the chamber. Openings were fitted with specially designed valves that allow for transfer of the contents without loss of volatile propellant or active ingredients. Various samples of aerosol products containing local anesthetics, steroids, and amines, were assayed by this method and found to give acceptable results. In all cases, the amount of active ingredient contained in each product could be accurately determined. The device makes possible a technique applicable to the analysis of most pharmaceutical aerosols. This method, which can be carried out with ease in a relatively short period of time, was shown to produce accurate results when used in the manner described.

THE ANALYSIS of pharmaceutical aerosols presents many unique problems to the analytical chemist. Generally encountered analytical techniques such as extractions and titrations cannot be performed without modification of the intact aerosol product. Since one or more of the components of an aerosol product may be extremely volatile, it is difficult to obtain a representative sample. The vapor pressure of the system may vary from 15 psig to about 40 psig, depending upon the nature and amount of propellant and other solvents that may be present.

All aerosol products consist of a volatile and a nonvolatile portion. The nonvolatile portion, generally referred to as the product concentrate, consists of the active ingredients dissolved, suspended, or emulsified in various solvents and other ingredients. While this concentrate may contain volatile solvents such as ethyl alcohol, acetone, *etc.*, the vapor pressure of these solvents at room temperature is considerably less than the more volatile propellants.

The propellant may consist of a compressed gas such as nitrogen, carbon dioxide, or nitrous oxide or, more commonly, of a liquified gas of the fluorocarbon type. Hydrocarbons such as propane, butane, and isobutane have not been used for pharmaceuticals at the present time. Dichlorodifluoromethane (propellant 12), dichlorotetrafluoroethane (propellant 114), and trichloromonofluoromethane (propellant 11) are generally used for this purpose. The positive pressure within the container indicates the need for a sampling procedure by which active ingredients can be determined from a known amount of aerosol product. The form in which the active ingredients are found will vary accord-

Accepted for publication October 27, 1967.

Abstracted in part from a thesis submitted by Sidney P. Tuesley to the Graduate Division, College of Pharmacy, St. John's University, Jamaica, N. Y., in partial fulfillment for the Master of Science degree requirements, June 1967.

Presented to the Drug Standards, Analysis, and Control Section, APhA Academy of Pharmaceutical Sciences, Las Vegas meeting, April 1967.

ing to the intended use of the product. This can be as a fine mist, wet spray, or foam.

Various attempts have been made to overcome the difficulties caused by the presence of the propellant. Different methods have been employed for the sampling of pharmaceutical aerosols. One commonly used method allows the propellant to escape, leaving behind the concentrate that consists of active ingredients and other nonvolatile agents used in the formulation. The solution may then be assayed and the percent active ingredient(s) in the aerosol formulation determined. This method of sampling, which has been used in a solubility study of different medicinal agents in fluorocarbon propellants by Tinney (1), involved the transfer of a filtered aliquot of a saturated solution of medicinal agent in the fluorocarbon propellant to a tared glass aerosol container. A specially designed transfer valve and actuator was used to effect the transfer. The dip tube, attached to the sample bottle, was removed from the transfer valve so that the propellant could be removed as a vapor. The total weight of the bottle containing the filtered saturated solution was determined. The propellant vapor was then removed from the sampling bottle. Following removal of the propellant, the weight of the container and valve was determined and the solubility of the medicinal agent calculated by the "weight by difference" method. This method is limited to those propellants and solvents that can be removed by vaporization at room temperature.

Young *et al.* (2) developed a method which was applicable to the assay of an aerosol containing epinephrine bitartrate and similar agents. The gross weight of the aerosol package was first determined and then the valve closure was punctured. A hypodermic needle was inserted through the valve closure that then allowed the propellant to escape through the opening of the needle. At this point, the valve could be safely removed. The remaining suspension was then assayed spectrophotometrically. Knowing the weight of the empty container and valve, the amount of active ingredient was determined. In order to determine uniformity of dosage released from a metered valve, Young *et al.* (2) employed a somewhat different method. This method consisted of inverting an aerosol package of epinephrine bitartrate or isoproterenol sulfate over a 250-ml. glass-stoppered graduated cylinder containing 200 ml. of 0.1 *N* acetic acid. A metered dose of medication was released into the cylinder and the cylinder was immediately stoppered and shaken. An aliquot of the acid solution containing the active ingredient was assayed spectrophotometrically.

Another method that was developed for this purpose utilized an "artificial respiratory system" (2). This system was designed to measure the delivery of the active ingredient dispensed through an oral adaptor. This procedure consisted of discharging the aerosol through the oral adaptor into a funnel attached to a glass tube which was immersed into a gas washing bottle containing distilled water. A vacuum was drawn on the system. This procedure essentially simulated conditions closely related to inhalation of the medication by a patient. The solution was then subjected to spectrophotometric assay.

Sampling techniques were developed by Lawless, Sciarra, and Monte-Bovi (3) and by Rifino, Monte-Bovi, and Sciarra (4) for the analysis of various medicinal amines and volatile oils, respectively, in aerosol formulations. Their sampling technique consisted of weighing the intact aerosol package and then bubbling a given volume of the aerosol into a suitable solvent and reweighing the container. The resulting solution, brought to the desired volume, was analyzed using gas-liquid chromatography. From this, the amount of active ingredients present in the aerosol package could be determined. The method whereby an aerosol product was bubbled through a solvent had previously been developed for the analysis of moisture in aerosols by the Fischer titration method (5)

This study was concerned with the development and testing of various devices and techniques which could routinely be applied to the analysis of various pharmaceutical aerosols. The applicability of the method to different types of aerosol packages, the speed with which the sample can be obtained, and the accuracy with which the active ingredients can be removed from the pressurized package were major considerations in the development of the sampling procedures. Various commercially available pharmaceutical aerosols were assayed, using the sampling techniques developed during this study. In this manner the application and suitability of the methods could be determined.

Several materials were investigated in order to determine the suitability of the material for the sampling device. Extruded stainless steel tubing, together with Plexiglas, was fabricated into a chamber. However, difficulty was encountered in securing an efficient seal between the metal and Plexiglas. Several openings had to be drilled, tapped, and fitted with stainless steel bolts. When the device was used, the Plexiglas, under the strain of the bolts, developed cracks. Based

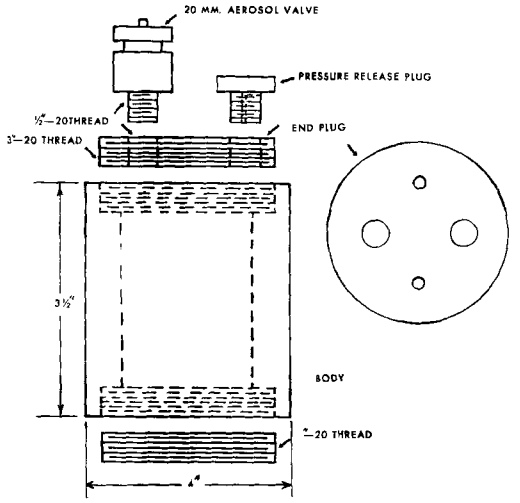

Fig. 1—Sampling chamber for aerosol products.

glass membrane and a 25-ml. buret. This was specially designed so as to allow potentiometric titrations directly within the cylinder.

Assay Procedures—The sampling device was washed with distilled water and dried with acetone prior to and following each assay. An accurately weighed sample of benzocaine NF, about 0.5 Gm., dried over phosphorus pentoxide for 3 hr., was placed into the open sampling device and 30 ml. of glacial acetic acid was added. A Teflon-coated magnetic stirring bar was placed into the container, which served to produce efficient stirring of the solution throughout the titration. The top cover of the device was screwed into place. The combination electrode was placed into one of the openings located in the top of the sampling container so that the tip of the electrode was immersed in the glacial acetic acid solution of benzocaine. A 25-ml. buret was introduced into the second opening. The electrode was connected to a Beckman Zeromatic pH meter, which had been set at the 1400-mv. range and adjusted to 0 mv. at the start of each titration. The benzocaine solution was then titrated with 0.1 *N* perchloric acid in glacial acetic acid. The equivalence point was determined potentiometrically and the milliliter of titrant represented at this point was obtained from a first derivative plot of $dmv./dml.$ *versus* ml. of titrant added. The procedure was repeated several times and these results are shown in Table I.

upon these preliminary results, Teflon was selected as the material of choice for construction of the chamber.

EXPERIMENTAL

Construction of the Sampling Device—This sampling device was constructed from a 3-in. piece of Fluoroflex "T" tubing having an internal diameter of 2.5 in. and external diameter of 3.5 in. The top and bottom of the sampling container were constructed from Fluoroflex "T" sheeting, 0.5 in. in thickness. The inside walls of the tube were threaded 0.5 in. down on each end. Both the top and bottom plates for the container were cut and threaded to match the threads of the sampling tube. The ends were than screwed into the cylinder and tightened, making a pressure-tight seal. Teflon tape was used on the threads to ensure an efficient seal. A piece of Fluoroflex "T" was machined to the same configuration as the neck and mouth of a standard uncoated glass aerosol bottle and fitted with a 20-mm. aerosol valve.[1] This assembly was then fitted into one of the openings on the top cover as shown in Fig. 1. The openings in the top plate were large enough to accommodate a Corning semimicro combination electrode with triple-purpose

[1] The valves used in this study are referred to as the "male-female" valves and were of the type used on various "mother-daughter" aerosol packages. A female-type valve was attached to the sampling device. Other standard aerosol valves can also be used provided a section of tubing or transfer actuator is attached to the valve stem.

Solutions of benzocaine NF were then prepared in a solvent mixture of 55% by weight of ethanol USP and 45% by weight of propylene glycol USP. These solutions were then placed into the sampling cylinder and assayed in a manner similar to the above described method. These results are also shown in Table I.

Having determined the suitability of the sampling device as a titration vessel, a sample aerosol product was prepared. This aerosol contained 6.3088 Gm. benzocaine NF, dissolved in a mixture of 55% by weight of ethanol USP and 45% by weight of propylene glycol USP. A sufficient amount of solvent was added to bring the total weight to 50 Gm. Propellant, consisting of a mixture of propellant 12/114 (40:60) was added to produce a total weight of 100 Gm. This formulation was packaged into a glass aerosol container and fitted with a female-type aerosol valve.

Thirty milliliters of glacial acetic acid was placed into the open sampling device and the top cover sealed into place. The two openings in the top cover were sealed with the two plugs, one containing the aerosol valve and the other the pressure release plug. The entire unit was then weighed and chilled

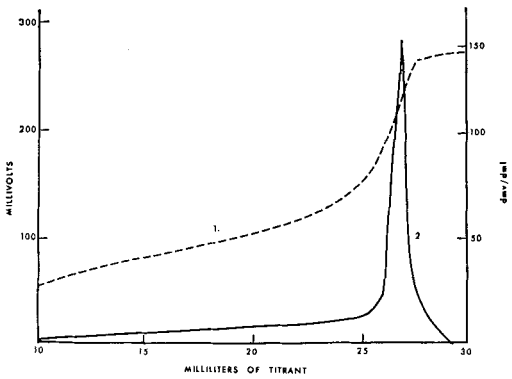

Fig. 2—Titration curve for benzocaine aerosol using 0.1 N perchloric acid as titrant. Key: 1, standard titration curve; 2, first derivative plot.

by placing it into a freezer or dry ice chest for about 10–15 min. A sample of benzocaine aerosol was then injected into the sampling chamber by inverting the sampling device over the upright aerosol container and fitting the valve stem of one valve into the valve opening located on the other container. By pushing the sampling device down, both valves will open allowing the product from the container to flow into the sampling device due to the difference in pressure between the two containers.[2] For the purpose of this study the standard type "male-female" or "mother-daughter" valves were used since these valves allow for transfer of contents from one aerosol container to another without the use of adaptors. Since most commercially available pharmaceutical aerosols do not make use of this valve, an adaptor must be used.

About 5.0 Gm. of aerosol product was allowed to flow into the sampling device. The actual amount acquired is dependent upon the nature of the active ingredient(s) and the type of assay used. This must be determined on an individual basis. The sampling device is than allowed to return to room temperature, dried of any moisture which may have condensed on the surface, and reweighed. The difference between the two weighings indicates the weight of sample.

The propellant was removed from the container by turning the pressure release plug one turn. The aerosol valve and pressure release plug are removed from the top cover and the openings fitted with the electrode and buret as previously described. The remaining solution was then titrated with 0.1 *N* perchloric acid and the equivalence point determined potentiometrically, and the milliliter of perchloric acid was obtained from a first derivative plot as illustrated in Fig. 2. From this result the amount of benzocaine in the formulation was calculated. These results are also indicated in Table I.

Various commercially available pharmaceutical aerosols were assayed using this sampling device and the appropriate assay. The aerosols utilized in this study are indicated in Table II. These products were selected on the basis of being representative of various types of aerosols requiring different analytical procedures for assay.

[2] This procedure is applicable for those aerosols containing a dip tube. Where no dip tube is present, the positions of the sampling device and aerosol container are inverted so that a liquid sample is obtained. Aerosols used in the upright position contain a dip tube attached to the valve housing while those used in the inverted position do not have a dip tube. Certain aerosols containing a dip tube and special valve can be used in either position.

Table II—Representative Pharmaceutical Aerosol Products

Active Ingredient	Concn.	Amount/ Dose, mg.
Epinephrine bitartrate[a]	7.0 mg./ml.	0.3
Ergotamine tartrate[a]	9.0 mg./ml.	0.36
Isoproterenol HCl[b]	2.5 mg./ml.	0.125
Prednisolone[c]	0.332 mg./Gm.	Non-metered
Cyclomethycaine HCl[b]	2.645 mg./Gm.	Non-metered
Pramoxine HCl[c]	10.0 mg./Gm.	Non-metered
Epinephrine HCl[a]	8.3 mg./ml.	0.3
Tetracaine[b]	10.0 mg./Gm.	0.5

[a] Suspended in vehicle of propellent with dispersing agents. [b] Solution in vehicle of propellant, ethanol, and other agents. [c] Solution in vehicle of propellant and other agents.

These products were separated into two groups; those that could be assayed by a potentiometric technique and those that utilize a spectrophotometric method. All of these aerosols contained a valve fitted with a stem. In order to effectively transfer material to the sampling container, a small piece of polyethylene tubing was fitted over the stem and attached to the sampling device. A transfer actuator could also be used.

Potentiometric Method—The aerosol product was sampled by determining the tare weight of the sealed sampling device containing 20 ml. of glacial acetic acid and fitted with the valves previously described. After chilling the device a sample of product was injected into the chamber. The weight of sample was determined by allowing the contents to reach room temperature and then reweighing the container. Where the aerosol product was fitted with a metered valve, the number of doses injected was recorded. In this manner the quantity of active ingredient dispensed each time the valve was depressed could be determined. The propellant was allowed to escape through the pressure release valve. The valves were removed from the top and replaced with the buret and electrode. The active ingredient was then assayed by titrating the nonaqueous solution with 0.01 *N* perchloric acid in glacial acetic acid as previously described.

Aerosol products containing tetracaine, epinephrine bitartrate, epinephrine hydrochloride, pramoxine hydrochloride, and cyclomethycaine hydrochloride were assayed by this method and the results are shown in Tables III and IV.

Spectrophotometric Method—Essentially the same method as described in the previous section was developed for the aerosols assayed spectrophotometrically. In most cases, part of the solvent used in the assay was added to the sampling device which was then weighed. The aerosol sample was injected into the tared and chilled container in a manner similar to that previously described and the weight of sample determined by reweighing the container after the contents attained room temperature. The propellant was allowed to escape and the contents were transferred to a volumetric flask. The sampling container was rinsed with solvent until all of the active ingredient was removed. The rinsings were added to the volumetric flask, necessary reagents added, and the solution was then

brought to the desired volume. Aliquots of the solutions were then assayed using an appropriate spectrophotometer.

Isoproterenol Hydrochloride Aerosol—This aerosol was assayed using a modification of the official method of assay (6). A Beckman DU spectrophotometer was used and the absorbance of the solution at 279 mμ was determined. The absorbance (A_U) was then compared to the absorbance (A_S) of USP isoproterenol hydrochloride reference standard and the amount of isoproterenol hydrochloride in the sample calculated. These results are shown in Table V.

Ergotamine Tartrate Aerosol—Approximately 25 ml. of tartaric acid solution (1 in 100) was added to the sampling chamber that was then sealed, weighed, and chilled. The desired number of doses of ergotamine tartrate aerosol was added, the solution mixed and reweighed after having come to room temperature. This was then treated in a manner similar to the procedure followed for isoproterenol hydrochloride aerosol, and the absorbance (A_U) at 550 mμ was determined, using a Bausch and Lomb Spectronic 20, according to the USP method of assay (7). This result was then compared to the absorbance (A_S) of a standard solution of USP ergonovine maleate reference standard. The amount of ergotamine tartrate in the aerosol sample was calculated using the conversion factor of 1.488 which is the ratio of one-half the molecular weight of ergotamine tartrate to the molecular weight of ergonovine maleate. Table V also indicates these results.

Prednisolone Aerosol—About 30 ml. of ethanol USP was added to the sampling chamber. The chamber was sealed, weighed, and chilled. A sample of prednisolone aerosol was injected and the chamber was allowed to come to room temperature and reweighed. This was then treated in a manner similar to the isoproterenol hydrochloride aerosol and the absorbance (A_U) at 525 mμ was determined using a Bausch and Lomb Spectronic 20 according to the USP method of assay (8). This result was then compared to the absorbance (A_S) of USP prednisolone reference standard, and the amount of prednisolone in the aerosol was calculated. These results are shown in Table VI.

DISCUSSION

The results obtained in this study indicate the applicability of the sampling chamber to the routine

sampling and analysis of several different types of pharmaceutical aerosols. Since the container can be easily closed to make a pressure-tight seal, there is practically no loss of product concentrate or propellant. The transfer from original container to sampling device can be achieved rapidly and accurately.

The sampling device was constructed from Fluoroflex "T" in order to provide a chamber that would be compatible with almost all medicinal materials, solvents, and reagents used in various assay procedures. This material allows for close tolerances and is strong enough to withstand the pressure of the intact aerosol samples when injected into the chamber. The sampling chamber was designed so that it can be easily disassembled for cleaning while the adaptor for the aerosol valve and the pressure relief valve were designed for easy removal so that the sample could be removed or titrated directly in the chamber.

This system was found to be especially applicable to those materials which are assayed by a potentiometric titration, thus eliminating the need to transfer material from the chamber. The value of the chamber and this type of analysis becomes of increasing importance when small amounts of active ingredients are involved. Benzocaine was chosen as the material to test the sampling device since it is found in many aerosol formulations and is suitable for a nonaqueous potentiometric titration. The end points of the titrations for this material were determined potentiometrically since the use of visual indicators were not possible due to the opaque nature of the Fluoroflex "T." However, the chamber can be redesigned to provide a window for titrations utilizing a visual indicator for the end point. The possibility of interference in the titrations due to the presence of dispersing agents, suspending agents, or other adjuncts in the formulation was considered. The benzocaine aerosol consisting of benzocaine in propylene glycol and ethyl alcohol was accurately prepared, with and without the propellant, and titrated. No interference in the titration was observed as indicated by the results.

For the analysis of commercially available aerosol products, the labeled quantity of the medicinal agent present was compared to the quantity found upon analysis of the sample. In all cases, the labeled quantity of drug and the amount of drug found upon analysis varied by no more than 1%; that is, recovery was 99% or better.

Spectrophotometric analysis was performed on various aerosols so that the accuracy of the chamber could be determined for those products requiring a transfer of active ingredients. As can be noted from the results obtained, over 99% of material was recovered. These results indicated the suitability of the sampling chamber for assays requiring transfer of materials from the sampling chamber to another container such as a volumetric flask.

SUMMARY

The sampling chamber proved to provide a simple, fast, and accurate method for the sampling of a variety of aerosol products. No limitations were found in the device with the aerosol products assayed. Those products selected were chosen on the basis of the type of assay which could be used and that they represent different types of aerosols. In addition to allowing for efficient sampling, the chamber was found to be quite suitable as a titration vessel, thus eliminating the need of transferring the material after removal of the propellant to another vessel. All of the aerosol products assayed by this method gave acceptable results. Further study will involve the use of this chamber for solubility determinations of medicinals in fluorocarbon propellants, analysis of water-based aerosols, and for use with aerosol foams.

Apparatus for Solution Kinetics

By J. THURO CARSTENSEN

An apparatus is described which allows for rapid convenient kinetic studies and overcomes several disadvantages associated with other kinetic study arrangements. The thermal degradation of bromothymol blue in alkaline aqueous solution has been used as a trial system to demonstrate advantages and precautions associated with the apparatus.

IT IS A GENERAL PRACTICE in the pharmaceutical industry to conduct accelerated kinetic studies by placing finished containers (ampuls, bottles) in constant temperature ovens and removing samples at appropriate times and assaying them (discarding the unused sample portions). The problem of an initial lag period in which the temperature increases from room temperature to the desired temperature is always problematic as is temperature variation within the oven itself. The fact that solutions in different containers are used at the various sampling times introduces further uncertainty into the kinetic study. When temperatures above 60° are used, short sampling intervals (2–6 hr.) are frequently necessary and under such circumstances the lag-time error becomes large and although compensation methods (equilibrium-time-temperature-equivalent) for this have been described by Eriksen (1), a straightforward method of studying a reaction which is initially at the desired temperature would be desirable. It would furthermore be advantageous to be able to sample from the same bulk at all sampling intervals.

The use of a good thermostatically controlled water (or oil) bath for this purpose can overcome the lag-time problem but is cumbersome and expensive. Agitation is difficult to achieve and sampling usually requires opening the system to the atmosphere, so that oxygen-sensitive reactions may require further precautions.

A simple and more direct means of achieving constant temperature, avoiding lag time, and minimizing air exposure and interactions with oxygen results from the apparatus setup described in the following.

APPARATUS

A schematic layout of the apparatus is shown in Figs. 1 and 2. A 500-ml. round-bottom flask with thermometer joint and equipped with a 24/40 condenser joint (G) is modified by the side arm sampling arrangement ABCD and a sample introduction well (E) with a solid stopcock (F). The stopcocks A, B, C, and D are all solid. The round-bottom flask is attached to a condenser,

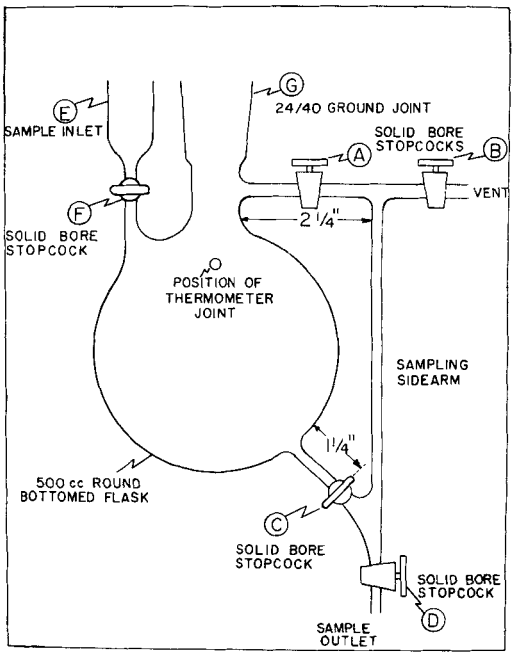

Fig. 1—Reaction flask used in apparatus arrangement showing stopcocks, joints, and sample introduction well.

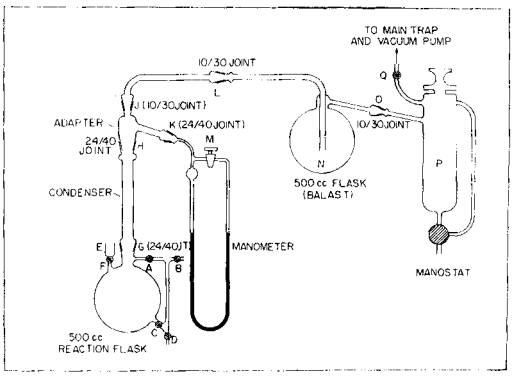

Fig. 2—Apparatus arrangement showing reaction flask, manometer, ballast, and manostat. Cross-hatched circles represent stopcocks.

which in turn is attached at (H) to an adapter with two 24/40 joints and one (top) 10/30 joint. The 24/40 side arm is attached to a direct reading manometer. The top joint (J) is connected *via* a 5-mm. tube equipped with a 10/30 ground joint inlet (L) and outlet (O). This latter is connected to a cartesian manostat[1] which in turn is connected

to a vacuum pump. If desired, a trap may be inserted between manostat and vacuum pump.

The principle and operation of the manostat is described elsewhere (2). By means of the diver the pressure of the system may be adjusted to a desired pressure.

OPERATION

The system is first run empty with the vacuum stopcock (M) open and stopcocks A, B, C, D, and E closed at full vacuum.[2] After the right side arm of the manometer has been evacuated in this fashion, stopcock M is closed and air let into the system by opening E.

The system is now operated by introducing 300 ml. of water (or other liquid)[3] *without boiling stones* or other boiling aids into the reaction flask with stopcocks A, B, C, D, and E closed. If a study at $t°$ is planned, the vacuum pump is started and the manostat operation fixed when a pressure, equivalent to the vapor pressure of water (or other liquid) at $t°$, is reached. A heating mantle[4] with the side opening is then attached to the reaction flask, so that both the bottom and the lower side arm down to stopcock C is covered. The rheostat connected to the heating mantle is adjusted to allow the water (or other liquid) to boil gently and the temperature and pressure checked periodically to ensure that the temperatures and pressure are constant. Since most studies, to which the apparatus applies, are conducted at temperatures between 60 and 100°, the temperature gradient dT/dp is very small (or conversely, dp/dT is large) so small fluctuations in pressure result only in very small fluctuations in temperature.

It usually takes less than 0.5 hr. for the temperature to stabilize. Once the temperature is stable, a concentrated solution of the substance(s) whose degradations are to be followed, are placed in the sample introduction well (E) and sucked into the system by opening and closing stopcock F, and (if desired) washing with a small amount of water. An initial sample is then taken by opening stopcock A, effecting equilibration of the pressure in the sampling side arm with the pressure in the system. Opening stopcock C will then allow the liquid to flow into the side arm. Closing stopcocks A and C and opening B restores atmospheric pressure to the sampling side arm. Opening D allows the sample to be collected. Samples are than collected at predetermined intervals in the same fashion, and assayed by suitable means.

EXAMPLES AND DISCUSSION

A kinetic study of the degradation of bromothymol blue at a concentration of 0.00134% in 0.1 NaOH was conducted by introducing 300 ml. of 0.1 NaOH into the reaction flask, and obtaining constant temperature. The 466 mg. of dibromothymolsulfonphthalein[5] was then dissolved in ethanol and the volume adjusted to 100 ml. with ethanol. The absorptivity (a) at 619 mμ in 0.1 N NaOH is 60.5. One milliliter of the ethanolic solution was then diluted to 10 ml. with 0.1 N NaOH and introduced *via* the sample introduction well, and the first sample taken 2 min. afterwards; the absorbance (A) was then determined at 619 mμ. In this manner, a true initial assay is not achieved. However, to demonstrate that this is not a particular drawback, a study at 90° was performed so that the first sample was not taken until 1 hr. after the start of the degradation study. The ensuing plot of $\ln_e (A)$ *versus* time yields good linearity and extrapolates to an absorbance at zero time, which equals the theoretical figure, calculated from the amounts added and the absorptivity cited above.

The Naperian logarithms of the first-order rate constants obtained in this fashion were plotted against reciprocal absolute temperature, and linearity is quite obvious, as seen from Fig. 3.

The study at 70° was conducted for a total of 45 hr. with the temperature fluctuating between 70 and 70.5°. Twelve samples were removed during this period. The fluctuation in the first 8-hr. period was about 0.3°.

The apparatus, hence, works well, but the following phenomena were observed and serve as good operating practices. The tighter the system is, the better the pressure control. Every time a sample is taken, a small amount of air is introduced. This causes a slight, transient temperature rise. Stopcock C would occasionally freeze up on prolonged runs, preventing the sample from flowing into the sampling side arm. The run need not be discontinued in such a case. By opening stopcock D (stopcocks A and B being closed) and then carefully opening stopcock C, a small amount of air is allowed to enter the reaction flask and the grease will dislodge. The usefulness of the apparatus is probably limited to studies of less than 48-hr. operation, and temperatures should be selected accordingly. It is, however, in these short interval studies, that initial lag time errors are cumbersome to account for, when conventional methods are used, and the method should be viewed as an adjunct to, not a replacement for, common practices.

Figure 4 shows kinetic data obtained in this latter fashion at lower temperatures and longer storage periods. In this case, sample solutions were deaerated by bubbling through nitrogen, and storing the solutions in sealed ampuls (with nitrogen in the head space) in constant temperature ovens (±0.5°). The correlation appears to be good. Finally the results from a study in closed containers in a 37° constant temperature bath is also shown in Fig. 4 and falls in line with the remaining points.

It will be noted that the apparatus described here results in solution kinetics in the absence of dissolved oxygen. This was demonstrated by checking the oxygen content after 0.5 hr. of operation (*i.e.*, when the temperature had stabilized, but prior to sample addition). Oxygen content was determined by an oxygen analyzer[6] and found to be 7.3 p.p.m. before operation and 1.7 p.p.m. after 0.5 hr. of operation.

A loss of solvent may be expected during operation, based on the temperature of the cooling water in the condenser. Using 5-mm. tubing beyond the condenser keeps this loss low. A 48-hr. run at 90° of 350 ml. water gave a total loss (by weight) of

[2] It is advantageous to cool the trap during this operation, but the trap is not needed for subsequent operations.

[3] The type of liquid (water, buffer solution, alkali, organic solvent, *etc.*) is dictated by the kinetic study in question.

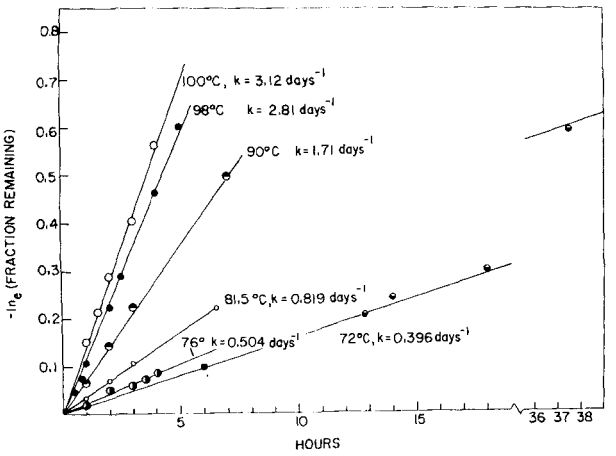

Fig. 3—Results from degradation of bromothymol blue in 0.1 NaOH at various temperatures. The run at 100° was performed at atmospheric pressure, i.e., system disconnected at joint H.

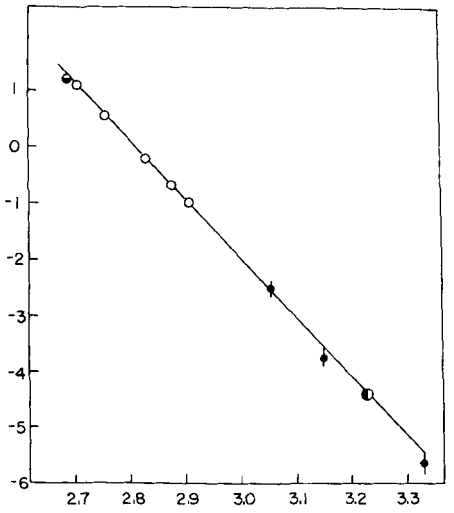

Fig. 4—Arrhenius plot of bromothymol blue degradation in 0.1 NaOH. Ordinate is the natural logarithm of the Naparian rate constant; abscissa is 1,000 × reciprocal temperature (°K⁻¹). Key: ●, runs in stationary ampuls; ◓ ◐, run in constant temperature bath; ○, runs in apparatus described here.

about 1–2 Gm. This aspect hence contributes less than a 1% error on long runs and can be considered negligible on short runs.

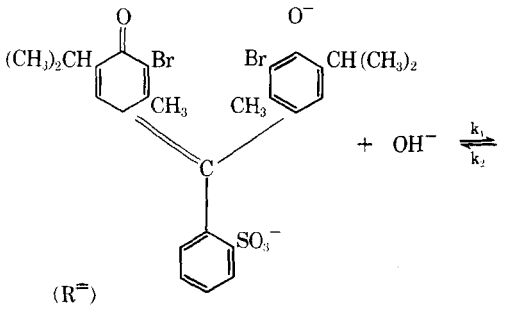
Although the operation of the manostat may be performed with the bleed valve slightly open, it appears best for stable operation, to keep it closed at all times after the required pressure has been reached.

A final point, which is also no shortcoming, is that in starting the manostat in operation at the desired pressure, the pressure attained usually differs slightly from the pressure aimed for. Letting the pressure drop slowly prior to setting the manostat can be accomplished by suitable operation of stopcock Q, and will allow fixing the temperature at the desired point fairly accurately. The point is not critical since one might, at worst, be conducting a study at, say 72°, rather then 70°, and so on, and it is not difficult to obtain six suitably separated temperatures in six separate runs, and this, after all, is the only intent of the kinetic study.

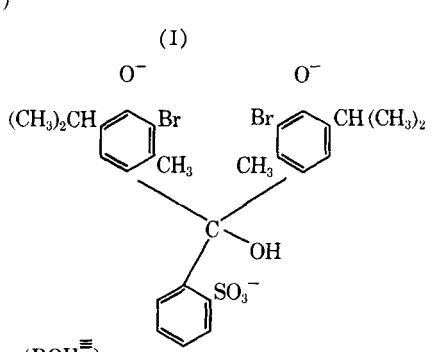
Although the mechanism of breakdown of bromothymol blue in alkaline solutions is not the primary question here, a few notes on the subject are in order. Sager *et al.*(3)[3] have reported on the alkaline degradation of bromothymol blue and find the following rate expression:

$$\frac{d(R^-)}{dt} = 0.028 \cdot 10^{-3}(R^-)(OH^-) - 0.0016 \cdot 10^{-3}(ROH^{\equiv})$$

in units of M^{-1} min.$^{-1}$, at 25.° R^- and $ROH^{\equiv}$ have the structures I and II.



(I)



(II)

At a hydroxyl ion concentration of 0.1 M, therefore, the rate constant should be 2.8×10^{-6} min.$^{-1}$ or 3.98×10^{-3} days^{-1}. The data in Fig. 4 imply a room temperature rate constant of anti-ln$_e$ (−5.45) $= 4.3 \times 10^{-3}$ days^{-1}, *i.e.*, in good agreement with the data of Sager *et al.*

SUMMARY

An apparatus is described which permits kinetic studies in solution. Bromothymol blue degradation

in alkaline solution was checked with this system and gave results in accordance with literature values.

Effect of Size on Other Physical Properties of Granules and Their Corresponding Tablets

By ALAN M. MARKS* and JOHN J. SCIARRA

Investigations were conducted to determine the relationship and effect of granule size upon the physical properties of the granule and the tablets produced from these granules. These properties were evaluated in the areas of spacial capacity, mobility, and physical stability. Additional studies were conducted which involved the manufacture of tablets and the subsequent correlation of the results of the physical testing of these tablets to the corresponding granule size. The physical properties of the granule were found to be interrelated and for the most part, related to the granule size. In the range of the granule sizes studied in this experiment, no direct relationship was found between granule size and granule volume. Both the degree of granule friability and flowability were found to increase as the size of the granule decreased. As the granule size became smaller, the weight variation of the tablets was found to decrease. No defined or observable relationship was found to exist between the granule size and the hardness of the corresponding tablet. The effect of granule size upon tablet disintegration was not distinguishable under the conditions of this study and probably was due to the variability and limitations of the disintegration apparatus used for this determination.

VARIOUS METHODS useful for the measurement of several physical properties of granules have been indicated in the literature. Arambulo and Deardorff (1) conducted a study which showed the relationship between granule size and the resulting tablet weight. They noted that as the granule size was reduced, the average tablet weight increased, presumably due to the decrease in void space. Large granules were found to contain a greater percentage of intergranular void space as compared to smaller granules and the resulting die fill, containing a smaller volume of material, produced tablets of a lighter weight. Arambulo, Fu, and Deardorff (2) noted the effect of granule size upon the weight variation of compressed tablets. As the granule size decreased, the weight variation decreased, passing through a minimum at 400–800 μ and then increased. They also noted that larger granules were found to yield greater weight variation. This effect was presumed to be caused by variation in the proportion of voids, which they attributed in part to the varying amount of breakage of granules and the resultant removal of the powder by the movement of the feed shoe of the single-press tablet machine.

Forlano and Chavkin (3) reported a definite relationship among granule size, disintegration time, and degree of capping. Using a sodium bicarbonate granulation, tablets compressed with granules in the 8–40-mesh range exhibited a rise in disintegration time and a decrease in capping. Tablets compressed using granules of 60 mesh or smaller exhibited a decreased disintegration time and an increase in capping. It was found that the optimum granule size of the granulation they used was found in the range of 16–60 mesh. Augsburger and Shangraw (4) described a method of measuring the fluidity of semifluid powders. They felt that the measurement of tablet weight would not only give comparable fluidity values but would also have practical importance from a production standpoint.

granular pharmaceutical solids which they prepared by five different granulation methods. Each granulation was evaluated for its physical properties. The "particulate hardness" test was of special interest. This test, based on the size of the sample, involved shaking the granules in a closed container for a constant period of time and then measuring the percentage of material retained on a 30-mesh screen. These workers found that the hardness index increased as the density of the granule increased. In order to determine the bulk density, these investigators used a 30-Gm. sample of 20/30-mesh material. The material was placed in a 100-ml. cylindrical graduate and the graduate was dropped from a height of 0.75 in. onto a hard wooden surface. This was repeated 20 times. The results of this study showed that dissimilar shapes have a great effect upon the bulk density of a material. Jones and Pilpel (6) measured the flow of granular magnesium oxide through a circular orifice. The apparatus used for the flow rate determination consisted of a vertical copper tube, with an internal diameter of 3.83 cm., fitted with a base plate. A shutter and sliding aluminum sheet were fitted to the tube. Flow rates (in Gm./min.) were determined in triplicate by collecting and weighing the powder that escaped from the tube in fixed time intervals ranging from 5–60 sec. Shutter manipulation and incipient failure of the powder column were found to affect the flow rate in the initial stages.

This study is concerned with the relationship of granule size to selected properties of the granule and the tablets prepared from these granules. Specifically, bulk volume, friability, flowability, and die fill weight will be determined and evaluated for each of the granule sizes used. A knowledge of the effect of these properties upon the production of the finished tablet will be of value in the development of tablet formulation. The effect of granule size upon the weight variation of tablets produced under production conditions as well as tablet hardness and disintegration will also be of value. The weight variation may exceed limits if the granulation contains an excess of large granules and may laminate if the particles are too fine. A specification relating to the range of granule size could be maintained as a guide and control during the manufacture of the tablet. Several of the above properties can be related to the ability of the granules to withstand the abuse of normal handling during the processing of tablets. The effect of these variables upon tablet properties were investigated and related by correlating the physical properties of the tablet to the corresponding granule size.

EXPERIMENTAL

Three different formulations were introduced into this study. Three batches of each formulation were prepared in order to have sufficient data to subject to statistical analysis.

Preparation of Granules—Formulation I is a placebo granulation, and its formula is shown in Table I. Formulation II is a sulfadiazine granulation and was chosen so that the effect of an insoluble drug constituting a major portion of the tablet weight could be determined. The formula is also shown in Table I. Formulation III is a granulation containing a soluble drug, sodium saccharin, and is present as a minor portion of the total tablet weight. The formula is also shown in Table I.

The formulations used in this study are basically the same except that formulations II and III contain an active ingredient which replaces a portion equal to half its weight each of dicalcium phosphate dihydrate USP and lactose USP. Each granulation was prepared in the same manner. The weighed ingredients were passed through a No. 30 screen and mixed in a Hobart-type mixer. Methylcellulose, 15 cps., was used as the binding agent and added dry with the powders. The powders were granulated by using a mixture of isopropanol and water. The material was spread onto trays and dried at 32° overnight in an oven with an air flow. The dried material was passed through an 8-mesh screen fitted onto an oscillating granulator. This produced granule sizes of not larger than 8 mesh and a great variety of smaller sizes, including powder of 60 mesh and finer.

In order to control the amount of moisture present in each batch, a moisture determination was made using the Cenco moisture balance. It was found that the moisture level for each batch was 1.4 ± 0.1%. By keeping the moisture at approximately the same level in each batch, the effect of moisture

upon the properties evaluated would be the same for each of the granule sizes studied.

The separation of the granule sizes was carried out through use of the Ro Tap testing sieve shaker and USP standard mesh wire screens, 8 in. in diameter. Table II indicates the screens which were used and their position in the Ro Tap sieve shaker. The particles are identified by the number of the smallest screen that they will pass through and by the number of the largest screen they will be retained upon. Depth to the wire cloth and the distance between cloths in adjacent nested series was 2 in. The screens were placed into the apparatus in the order shown in Table II. The screens rotated in a circular motion and a hammer pounded a cork mounted on a cover plate over the screens. The apparatus was operated for a period of 2 min., resulting in the separation of the granulation into the various mesh sizes. Further agitation for periods of 3–4 min. did not appreciably change the results, indicating that complete separation occurred within 2 min. Each group of granules was collected and placed into a plastic bag. The bag was sealed and stored until the granules were ready for testing.

Specific Granulation Bulk Volume—The specific bulk volume of the granulation indicates the volume/unit weight of the solid, the volume of the intraparticle pores, and the void volume or volume of the interparticle spaces. Specific bulk volume is the reciprocal of bulk density.

Fifty grams of each granulation was weighed on a balance. The granulation was then poured slowly through a funnel into a 250-ml. graduated cylinder. The graduate was tapped lightly 10 times on a towel placed on a laboratory work bench and the volume measured. This procedure was repeated three times for each individual group of granules from each of the three different formulations. This involved three granulations of each formulation, and five granule size groupings for a total of 135 readings.

TABLE IV—ANALYSIS OF VARIANCE[a]

Source of Variation	df	SS	MS	F Test
Between treatments	4	41.7	10.4	0.108
Within treatments	10	963.3	96.3	
Total	14	1005		

[a] At the 95% level of significance the tabulated $F(4,10) = 3.48$. The calculated $F = 0.108$. Therefore, the treatment effect (mesh size) is not significant.

The specific granulation bulk volume was calculated by dividing the volume by the weight of the sample. These results are shown in Table III. An analysis of variance to determine the significance of the effect of granule size upon the specific granulation bulk volume is shown in Table IV.

Granule Friability—Granule friability is related to the strength of the granule and its ability to withstand abuse during normal handling. The Roche friabilator (7) was used for this determination. The apparatus was set to rotate 25 times a min. for a 4-min. period. Ten grams of granulation was weighed and placed in the friabilator. At the end of 4 min., all of the material was placed onto a 60-mesh screen and placed into the Ro Tap apparatus. The Ro Tap testing sieve shaker was operated for 15 sec. The material remaining on the screen was weighed and the results are shown in Tables V and VI. Figure 1 indicates the friability of each of the granule sizes studied.

Granule Flowability—Granule flowability is a measure of the rate of flow of granules through an orifice. In order to measure this properly, a special

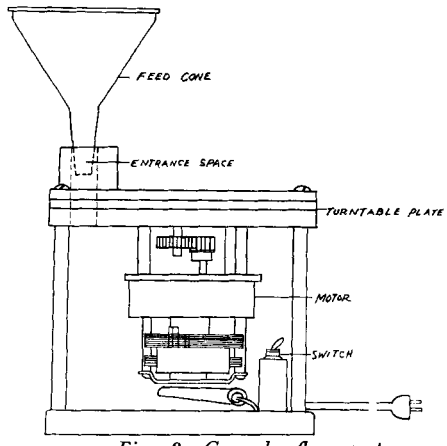

Fig. 2—Granule flow meter.

space which allows for free passage of granules through the opening and prevents the stoppage of granules in the tip of the cone. The disk rotates slowly at a constant rate, and as the opening in the disk aligns with the opening in the frame, the granules are allowed to flow through the opening. The flow of granules stops as soon as the opening in the disk is past the opening in the frame. A tared container was placed beneath the opening and the weight of granules collected during the time period determined. This procedure was repeated three times for each of the granule sizes. These results are shown in Tables VII and VIII.

Granule Size Versus Die Fill Weight—An attempt was made to determine the relationship of the granule size, in several fixed die situations, to the die fill weight. Magnesium stearate USP, in a concentration of 0.25%, was added to each batch of granules as a lubricant. A minimum amount of lubricant was used so as not to significantly influence the results. The bottom punch was lowered to a specified depth and set in place. The following settings were used:

	Diameter of Die, mm.	Depth of Fill, mm.	Tablets/ Min.
A	7	10	60
B	7	15	60
C	7	15	40
D	14	15	60

Approximately 250–300 tablets were produced from each of the granulations using a Stokes single-punch tablet press, model F, and 7-mm. and 14-mm. diameter flat-face punches. Each tablet was weighed on an analytical balance. The percent change in weight from the 8/12-size granule value was calculated. These results are shown in Table IX and

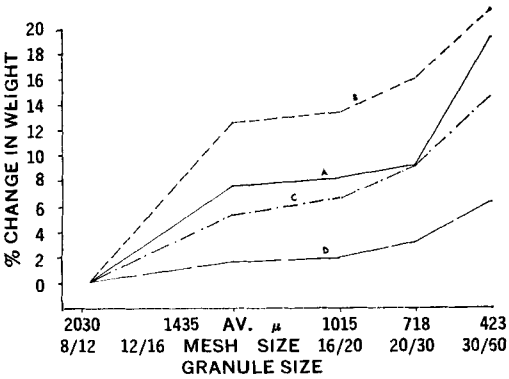

Fig. 4—Granule size versus *die fill (sulfadiazine granulation). Key:* A,——*7 mm. diameter, 10 mm. depth, 60 tabs./min.*; B,—*7 mm. diameter, 15 mm. depth, 60 tabs./min.*; C,—·—*7 mm. diameter, 15 mm. depth, 40 tabs./min.*; D,- -*14 mm. diameter, 15 mm. depth, 60 tabs./min.*

Figs. 3–5. Table X indicates the statistical treatment of these results.

Tablet Weight Variation—For this study it was necessary to adjust the tablet press to produce tablets of a specified weight and thickness. Five mg. of starch and 2 mg. of magnesium stearate were added to the granules to ensure proper lubrication and disintegration. The primary adjustment of the tablet machine was set at a weight of 250 ± 5 mg. and 0.135 ± 0.005-in. thickness. A Stokes single-punch tablet press, model F, and $^{7}/_{16}$-in. flat-face, bevel edge punches were used. The first 10 and the last 10 tablets produced were discarded to prevent weight variation due to initial flow resistance, insufficient weight of granules in the hopper, and excess fines. About 2000 tablets were produced and dusted to remove excess powder. Twenty tablets were weighed individually on an analytical balance. The mean weight, standard deviation, and coefficient of variation were calculated. Results are shown in Table XI and represent the average of 20 tablets for each of three determinations.

Tablet Hardness—Tablets from the tablet weight variation test meeting the specifications of 250 ± 5 mg. and 0.135 ± 0.005 in. were selected from each granule size group. The hardness of the tablet was measured using the Strong Cobb hardness tester fitted with an air pressure attachment. The mean for each group was calculated and the results recorded in Table XII and the analysis of variance in Table XIII.

standard USP XVII disintegration method (8) for uncoated tablets was utilized. This method provides for the disintegration of six tablets in water maintained at 37°. Disks were used during this study. This method did not prove satisfactory due to the error or deviation introduced by the disks. It was reported by Kaplan and Kish (9) that many tablets will either adhere to the rising and falling disks, or adhere to the bottom stainless steel wire cloth. The result may be a flattening out of the tablet core caused by the constant action of the falling disk on the same point of the tablet surface.

The above procedure was modified by the removal of the disks from the disintegration apparatus. The disintegration time of the individual groups varied and overlapped. No definite relationship or trend due to the granule size could be noted. In this case, the error introduced by the disk was eliminated, however, the difference in the specifications of the tablets which were not greatly defined in this case possibly introduced another variable.

TABLE XIII—ANALYSIS OF VARIANCE[a]

Source	*df*	*SS*	*MS*	*F* Test
Between treatments	4	1.74	0.435	0.039
Within treatments	10	110.78	11.080	
Total	14	112.52		

[a] Based on Strong Cobb hardness units. At the 95% level of significance, the tabulated $F(4,10) = 3.48$. Calculated $F = 0.039$. Therefore, the treatment effect (mesh size) is not significant at the 95% level.

In a stricter selection of tablets having the specifications of 245–250 mg. weight and 0.134–0.136 in. thickness, a trend was discernable by one set of results but repudiated by another set, leading to an inconclusive set of data. The trend noted in one case was toward a longer disintegration time as the particles became smaller up to 20/30 mesh and then a shorter disintegration time at 30/60 mesh.

DISCUSSION OF RESULTS

The true effect of granule size upon bulk volume may have been disguised by other contributing factors such as granule shape, rate and direction of flow, positioning of the granules in relationship to each other and to the cylinder, powdering due to the impact and handling of the granules, and experimental error. The erratic results which were obtained may be due to: (*a*) The particle sizes chosen for this study may not have been sufficiently different from one another to show an effect upon the bulk volume. Theoretically, the void space should increase as the granule size is increased, thereby increasing bulk volume; (*b*) the rate and direction of flow of the granules into the cylinder may have been such so as to position the granules in a manner where bulk volume would not change appreciably with the size of the granule.

The degree of friability was found to be inversely proportional to the granule size. A definite reproducible trend in the results is observed. These results were verified by numerous readings and a statistical analysis of variance. The formula treat-

ments or the effect of the mesh size was found to be statistically significant at the 95% level of confidence. As the size of the granule becomes smaller, there is an increase in friability as shown by the greater loss of weight. This weight loss is due to material which has been detached from the granule due to the abuse taken in the apparatus and is comprised of powder 60 mesh and finer. It should be noted that the granules remaining on the screen may be of different mesh size than at the start of the test, but are still in the effective granule size range for tableting. The hardness of the particles is an important factor when considering friability. If the granule is hard, only surface particles will be lost when one particle rubs against another while with soft granules the entire granule will break into smaller particles. It is possible to determine the relative hardness of the granules, subjecting them to the friability test. In most cases, soft granules will lose considerably more weight than hard granules.

Flowability of granules was also found to be affected by the size of the granules studied. As the granule size was decreased, the flow rate of the granules through an orifice was found to be greater. These results were found to be highly significant statistically at the 99% level of confidence. A definite reproducible trend was demonstrated indicating that the size of the granule is related to the flow rate. If the size of the granules is further reduced, other factors such as bridging may interfere with its flow. However, results cannot be projected to all granule sizes. They apply only to the range of granule sizes actually studied in this investigation. Further experimentation is necessary to determine the flow rate of other granule sizes. The flow rate of the granulation and thus the granule size is significant and related to the efficiency of the die fill. This effect would be compounded by irregular shaped dies and greater die fills. The rate at which a tablet press may be operated is partially dependent upon the flow rate of the granulation. In the case of the single-punch tablet press, where there is no overfill of the dies as is found in rotary tablet presses, the flow rate of the granulation becomes more important. Where flow rates cannot be adjusted to produce satisfactory results, then the tablet press must be operated at a slower speed, or in the case of rotary presses, may require the use of force feed units.

A relationship between the granule size and the die fill weight has been noted. As the granule size is reduced the fill weight is increased. This has been observed in all four of the conditions studied. In the case utilizing setting *D*, "14 mm. diameter, 15 mm. depth, 60 tablets/min.," two readings did not follow this trend and may be due to experimental error. These results were tabulated based on a percentage change in weight and have been shown to be statistically significant at a 95% level and higher in all cases except one. The condition found not to be statistically significant when treated in this manner was setting *B*, "7 mm. diameter, 15 mm. depth, 60 tablets/min." Although it was not found to be statistically significant, the change in weight as a result of change in granule size is an important consideration in pharmaceutical production. From the results, the following was noted: (*a*) as the granule size decreases, the weight of granules required to fill the die increases; (*b*) as the depth of fill is increased, the effect of the granule size upon the die fill becomes greater; (*c*) as the speed of the tablet press used in this study is increased, the effect of the granule size becomes less; (*d*) as the diameter of the die is increased (greater fill space), the effect of the granule size is decreased and there is less of a weight difference between the sizes.

In addition to several physical properties of the granule, other factors will also influence the filling of the die in a tablet press. The diameter of the die, the depth of fill, and the speed of the machine are closely related to this property. It has been noted that as the granule size is reduced, the rate of flow of the granules is increased. While no significant difference in bulk volume due to the granule size was found, it has been suggested that the positioning of the granules as they land in the die is an important factor. Thus, the smaller granules flow through the orifice faster and are able to more efficiently fill the die as compared to larger granules. The greater friability of the smaller granules yields an increase in fines and aids in filling of the void spaces.

Experiments previously described in this study have shown that the granule size contributes to the physical properties of the granule. Granule flowability, friability, and die fill weight were shown to be influenced by the granule size. Thus, on the basis of these factors, it would be expected that the granule size would affect the tablet weight variation. In this study, the results showed an interrupted trend in weight variation due to the granule size. Upon close observation, however, a definite and statistically significant trend due to granule size was noted. Eliminating the intermediate groups of 12/16- and 20/30-mesh size from the evaluation, a definite relationship between the granule size and tablet weight variation can be noted. Due to the relative small difference in size between the neighboring groups, it is possible that these results are due to experimental error or that the size difference was not great enough to affect the weight variation. Comparing the 8/12-mesh, 16/20-mesh, and 30/60-mesh groups, the relationship was found statistically to be highly significant. As the granule size becomes smaller the weight variation was reduced. Further studies are indicated to fully substantiate this observation.

No defined or observable relationship between the granule size and the hardness of the corresponding tablet was noted in this study. It was further derived statistically that the treatment effect (mesh size) was not significant at the 95% level of significance. While no trend was noted in the results, there was an observed difference in hardness between the groups. Since granules interlock during the compression stage of tablet manufacture and result in added binding strength, the size of the granule may be related to the degree of interlocking which may take place and hence affect the hardness of the tablet.

It was not possible to obtain significant results in regard to the effect of granule size upon disintegration time. This was probably due to the limitations of the disintegration apparatus as well as the fact that there are other factors which have a greater effect upon the disintegration time.

The evaluation, knowledge, and use of granule

properties is important to the formulation, production, and quality control of tablets. The quality of tablets and the rate of productivity have been found to be influenced by the size of the granule. Automation requires standardization of the granule size for reproducibility. The testing of the granule by means of the granule flow meter and the modified friabilator may prove to be useful methods for evaluating several of the physical properties of granules.

CONCLUSIONS

(*a*) The effect upon the granule volume by the granule size was not clearly defined. (*b*) The degree of granule friability was found to decrease as the size of the granule increased. As the size of the granule becomes smaller, there is a greater loss of weight due to the friability of the granule. (*c*) Granule flowability was found to be inversely proportional to the granule size of the granule sizes tested. As the granule size becomes smaller, the flow of the granules through an orifice was found to be greater. (*d*) As the granule size decreases, the weight of the die fill increases. As the depth of fill is increased, the effect of the granule size upon the die fill is increased. As the speed of the tablet machine is increased, the effect of the granule size upon the die fill is decreased. As the diameter of the die is increased (greater fill space), the effect of the granule size is decreased and there is a smaller weight of fill difference between the sizes. (*e*) As the granule size becomes smaller, the tablet weight variation was found to decrease. This was found to exist especially in the 8/12, 16/20, and 30/60 groups. (*f*) No defined or observable relationship between the granule size and the hardness of the corresponding tablet was noted under the conditions of this test. However, difference in hardness between the groups was observed. (*g*) Due to the variability and limitations of accuracy of the tablet disintegration apparatus, no effect was noted in regard to granule size and disintegration time.

attention. Consequently, the problem associated with electrostatics of solids is still not completely understood, and this has, for the most part, not permitted the characterization of the static electrification behavior of a given material quantitatively.

Static electrification may be defined to encompass all processes which produce segregation of positive and negative electrical charges by mechanical actions operating through contact, impact, or friction between two surfaces, or by rupture or separation of solid and liquid surfaces. It is evident from this description that common pharmaceutical processing procedures, such as mixing, micronizing, milling, sieving, compressing, spray drying and congealing, pan coating, and packaging can induce static electrification. The forces of attraction and repulsion that exist between charged surfaces can cause difficulties in the efficient operation of processing equipment, as well as fire and explosion hazards, and affect the quality of the pharmaceutical product.

For example, in the preparation of tablets there is an accumulation of electrostatic charges resulting from the blending, granulating, and compression processes. In solids blending, electrostatic charges developed on the surface of the particles is one of the principal factors for the phenomenon of unblending. This unmixing effect can cause drugs to be nonuniformly distributed in the mixture resulting in unit doses of variable drug content.

The contact, impact, and friction encountered by the surfaces of the granules as they are fed from the hopper, revolve around the turret and are compressed contribute to the overall charge development on the finished tablets. With the advent of high speed tablet presses and forced-flow powder feeding devices, frictional electrification has become aggravated. The charge on the tablet surface can cause tablets to adhere to the feed frame and "back-up" resulting in serious damage to the tableting equipment. In compression coating the charge developed on the core tablets could cause serious core dislocation problems by adhering to the transfer mechanism and not falling into the center of the bed of coating granulation in a flat position.

Although it has been generally recognized that static electrification can be a serious problem in the processing and handling of pharmaceutical solids, only a minimal number of reports appear in the literature on this subject (1–7). These reports presented limited information, and the data were given essentially in a qualitative manner.

It became evident that before more useful information could be gathered relative to the electrostatic characteristics of various pharmaceutical solids and packaging materials, a more informative method of measuring and evaluating (*a*) the inherent polarity and magnitude of the charge on the material, (*b*) the tendency of the material to take on a negative and positive potential, and (*c*) the decay rate of the charge from the material, must be developed. It is only by having such a reliable instrument available that it will be possible to acquire the fundamental knowledge regarding the electrostatic behavior of these materials to permit a scientific approach toward alleviating static electrification problems in pharmaceutical systems.

Such an instrument was designed and fabricated and is presently being used in these laboratories. Because of its unique capabilities, it should be of considerable utility to the pharmaceutical research scientist concerned with product and process development and packaging materials research. In this report, full details will be given relative to the design and operating characteristics of the electrostatic tester. In addition, certain preliminary findings will be presented on its use with several pharmaceutical solids.

ELECTROSTATIC TESTING INSTRUMENT

The photograph in Fig. 1 shows the electrostatic tester, X-Y recorder, and humidifying chamber. The humidifying chamber is at the right of the photograph and X-Y recorder on the left. In the center of the photograph is located the electrostatic tester that is composed of three parts: a dual polarity high voltage power supply unit, a modified Faraday cage, and an electrostatic voltage sensing pistol. A simple schematic diagram given by Fig. 2 describes the composite photograph in Fig. 1.

In order to more clearly describe the function of the various components shown in Fig. 1, the more important ones will now be described individually. The high voltage power supply component of the electrostatic tester is capable of inducing a positive or negative voltage up to 10,000 v. on the material

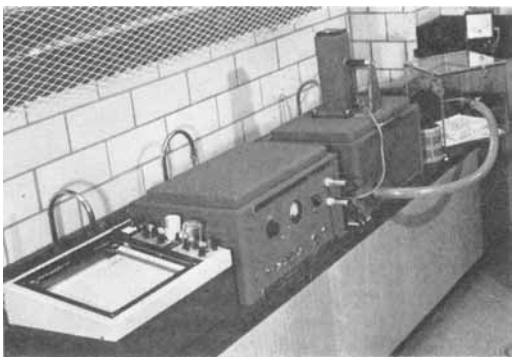

Fig. 1—Composite photograph of electrostatic tester, X-Y recorder, and humidity chambers.

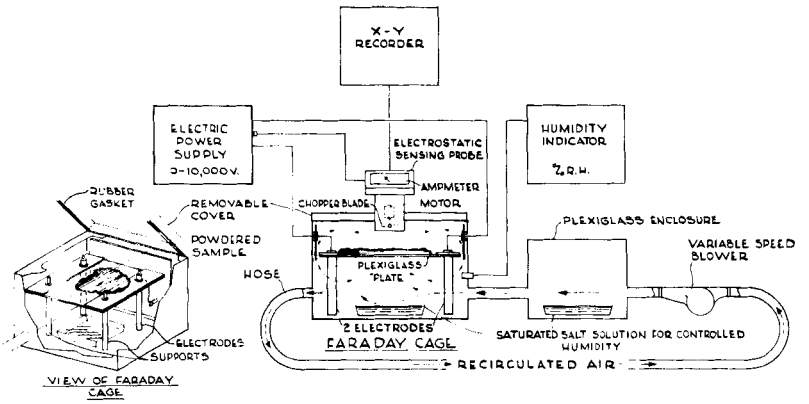

Fig. 2—Schematic diagram depicting the several components of the electrostatic tester and auxiliary equipment.

to be tested in the modified Faraday cage. This power-supply unit also serves to charge the battery system in the electrostatic voltage sensing pistol. The electrical circuitry and components of the power supply are given in Fig. 3, as can be seen from the diagram, it serves a dual function in providing the low voltages to charge the three batteries in the electrostatic voltage sensing pistol, as well as the high voltages for use in inducing a positive or negative potential on the materials in the modified Faraday cage. In one instance, the 110-v. a.c. current supply is converted by 12.6 and 36.0 v. center tap transformers and then full wave rectified to provide $+7.5 \pm 13.5$-v. d. c. for the three batteries. The 2,000 μF capacitors and the chokes smooth out the waveform and remove any ripples from the d.c. supply. The additional resistors and Zener diodes in the circuit provide the stabilized voltages to the batteries. The 110-v. a.c. current supply also feeds the high voltage supply which is a sealed solid state unit having a variac to control the output voltage over a range from 0–10,000 v. The contactor circuitry for the high voltage power supply consists of relay K-2 and conventional start and stop circuitry. The circuitry also contains a safety relay circuit K-1 that is adjusted by a preset resistor to cut out the high voltage power supply in the event the amperage goes beyond 0.0006 amp. The negative or positive on the center tap of the power supply can be grounded in order to achieve a positive or negative, as well as a floating, applied voltage.

The modified Faraday cage, shown at the far left of Fig. 1, where electrostatic voltages are supplied to the sample undergoing evaluation, consists of four Lucite posts which are used to support the sample plate in position. Two of these posts serve as electrodes as is evidenced by the brass collars on them. The plate containing the sample for measurement is made of Plexiglas and is $^1/_{16}$ in. thick, 17 in. long, and 9 in. wide. A 2-in. strip of stainless steel is bonded to each end of the plate and

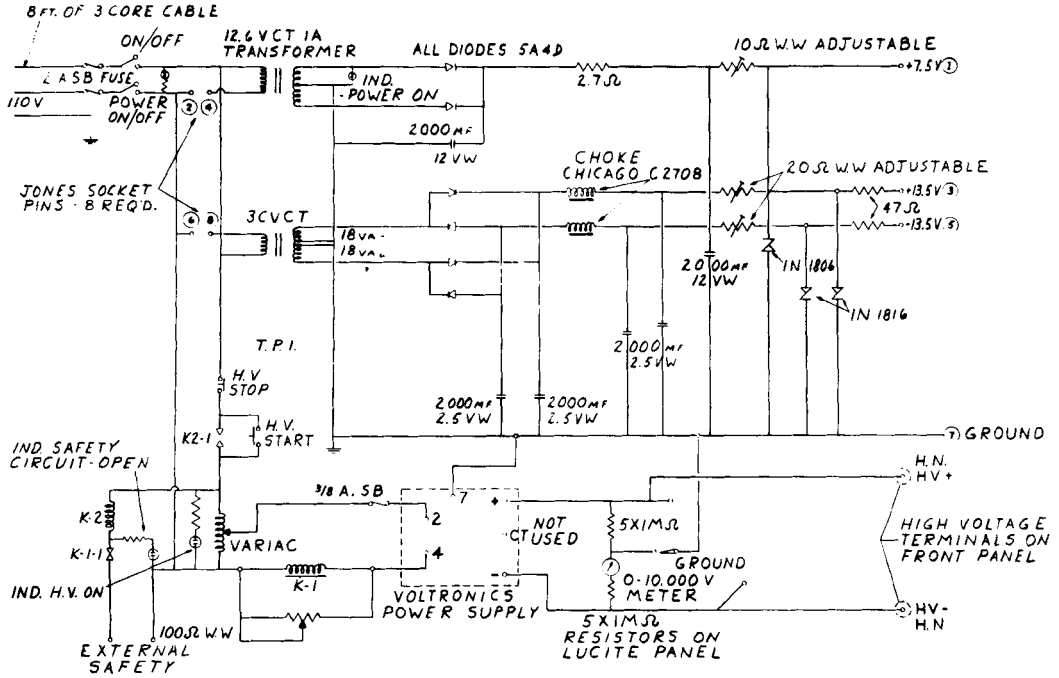

Fig. 3—Composite circuit diagram for power supply to electrodes of modified Faraday cage and batteries of electrostatic sensing probe.

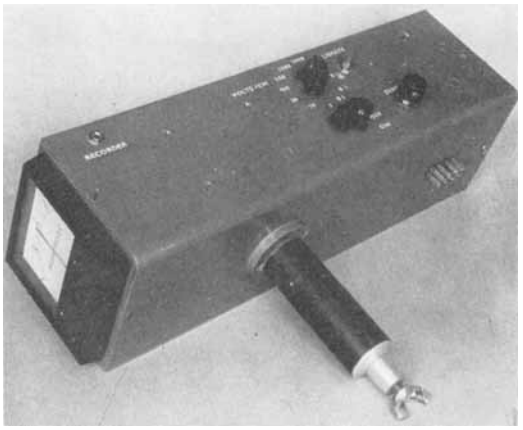

Fig. 4—Electrostatic voltage sensing probe.

the holes in the plate that fit on the Lucite posts go through these steel sections making contact with the electrodes. At the bottom of this cage is located a pan containing a saturated salt solution for humidity control, as well as humidity sensing probe. On two sides of the cabinet housing the Faraday cage, there are openings for connecting the tubing from the humidifying cabinet. The metal cabinet housing the Faraday cage is grounded.

The electrostatic voltage sensing pistol shown in Fig. 4 is detachable from the top of the cabinet housing the Faraday cage for use separately or within the cage. The meter indicator on the sensing pistol is used to standardize the sensor, as well as read out the negative or positive electrostatic voltage on the sample. A jack is located at the side of the sensor near the read out meter which is used for attaching the cable from the X-Y recorder. The recording jack will give an output of 100 mv. for full-scale deflection of the meter and has an output impedance of 100 ohms. For maximum stability, the sensing pistol should be connected to the power supply unit through the Jones plug at the side of the pistol. The pistol will, however, operate on the internal battery system for periods up to 2 hr. Rechargeable nickel-cadmium batteries are used to power the amplifier and chopper motor. The first three positions B_1, B_2, and B_3, shown on the range switch on the side of the pistol are provided for battery checking purposes. A fully charged battery system will read full scale on the positive or negative sides of the meter for battery polarity. The reading ranges for the sensing probe are calibrated in v./cm. Calibration is achieved with the sample plate in place and inducing a positive or negative potential across the plate from the high voltage supply unit. When the pistol is positioned in the holder and cavity at the top of the metal cabinet housing the Faraday cage, its sensing element is 20 cm. from the charged plate. If the plate is then charged to 6,000 v. and with the range switch on the pistol set at 300 v./cm., the pistol is calibrated so that it reads full scale.

A detailed schematic drawing of the electrical circuitry and components of the pistol is shown in Fig. 5. The power supply to the pistol enters through the Jones plug connection to the power supply unit. The probe consists of a 1-cm. metal disk insulated to greater than 10^{14} ohms by a Teflon insulator. The disk is rigidly mounted to assure stability of measurement and the lead to the amplifier is shielded by a grounded conductor so that it does not pick up any stray electrical signals. Between the disk and the source of electrostatic potential is a rotating shutter which is in close proximity to the disk. The disk will see alternately the source of potential and the shutter, and since the shutter is true ground, it will cause the disk to be grounded. Simultaneously with the shutter being opposite the disk, a photocell is exposed to light by another blade of the same shutter. The photocell has an impedance of 10^{10} ohms dark and 10^{6} ohms when exposed to a low level of light. Consequently, the disk is virtually grounded when the shutter is in front of it and has a high impedance when exposed to static charge. The photocell is exposed to low level illumination from the lamp, to give it optimum sensitivity and overcome any failure to return to high resistance during the dark period. A d.c. permanent magnet shielded motor is used to drive the chopper to prevent any electrical noise from developing which could interfere with the charge measurement. The 0.01 μF capacitor on the motor circuitry is used to eliminate any electrical noise from the motor brushes which could interfere with the charge measurement.

The output of the sensing system is a series of half wave pulses whose polarity is opposite that of the electrostatic charge. The potential is amplified

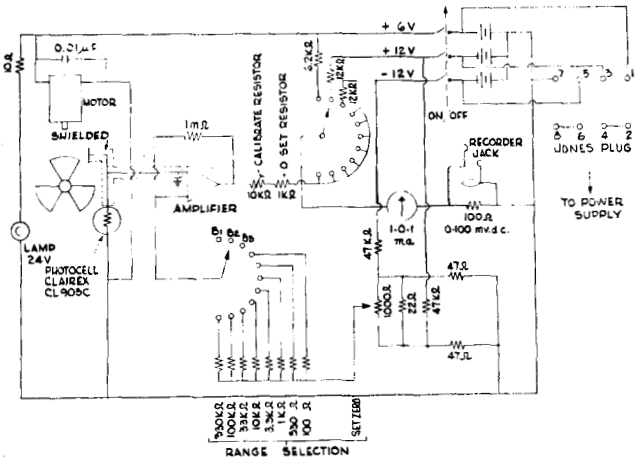

Fig. 5—Schematic drawing of the electrostatic sensing probe circuitry and auxiliary components of the probe.

and integrated by a differential operational amplifier whose gain is controlled by a feedback network consisting of a 1 megohm resistor and a resistor selected by the range selector switch. The output of the amplifier is indicated by a 1–0–1 milliammeter in series with a 10,000-ohm preset variable resistor that is used for calibration. The output could also be taken from the recorder jack as a d.c. signal of 0–100 mv. corresponding to 0–1 ma. on the meter. Consequently, the d.c. restored signal can be read out on the meter or recorded on the X-Y recorder. The ratio of the feedback and series resistors determines the gain of the amplifier and the sensitivity of the instrument. The sensitivity can be varied over the range of 1 v./cm. to 10,000 v./cm. by switching the feedback resistor. Zero adjustment of the sensing pistol is achieved by applying a ±12 mv. offset potential to the feedback system. The zero control consists of a 10-turn helical potentiometer of 1,000 ohm resistance.

The humidifying chamber constructed from Plexiglas employs a saturated salt solution in a tray at the bottom of the chamber for providing the particular humidity condition desired for the test. The chamber also has an in-line blower entering about 1 in. above the pan containing the saturated salt solution, whose speed is regulated by a rheostat. There are two reinforced plastic tubes 2 in. in diameter connected to the Faraday cage from the humidifying chamber for permitting the circulation of the humidified air during electrostatic tests.

EXPERIMENTAL

Material—Sodium chloride USP; stearic acid USP; iodochlorhydroxyquin[1] USP; sulfisomidine[2]; anhydrous ethanol.

Saturated sodium dichromate (Matheson, Coleman & Bell reagent crystal) aqueous solution to give 35% relative humidity.

Saturated sodium sulfate (Baker analyzed grade) aqueous solution to give 75% relative humidity.

Equipment—Electrostatic tester described earlier in the text; Model HR-96 X-Y recorder, Houston Instrument Corp., Houston, Tex. Hygrometer model HID 20-100 with model HS 1-6 sensor, Amlab, Inc., Rahway, N. J. Humidifying chamber for sample conditioning on Plexiglas plate prior to electrostatic measurements. Humidity cabinet for preconditioning sample plates.

Electrostatic Charge Measurement—Before performing any measurements, the unit is allowed to warm up for at least 5 min. with the 110-v. a.c. current to the power supply, sensing probe, blower in the humidity cabinet, and the recorder turned on. The Plexiglas plate which will act as the sample holder is rinsed with double distilled water, dipped into a Teflon-coated tray containing absolute ethanol, wiped gently with tissue paper saturated with absolute ethanol, and then allowed to dry under ambient conditions. The plate is conditioned at a prescribed humidity for 12 hr. before use in the Faraday cage of the electrostatic testing unit.

The electrostatic voltage sensing pistol positioned on the Faraday cage is zero calibrated by placing the palm of one hand at the sensing end of the probe and the dial reading is adjusted to zero with the zero control knob on the probe. With the selector switch of the power supply unit set at either negative or positive ground, a piece of aluminum foil is placed over the Plexiglas plate in the Faraday cage extending from one end covering the electrode and stopping short at least 1.5 in. before the 2-in. stainless steel strip begins on the other end of the Plexiglas. This arrangement will induce a positive or negative potential on the material to be tested. The lid to the Faraday cage housing the electrostatic voltage sensing pistol is closed tightly over the cage. The humidity in the Faraday cage is now allowed to reach its desired value and 10 min. after the humidity has equilibrated to the prescribed value, 6,000 v. of positive or negative potential is applied to the aluminum foil covered Plexiglas plate. With the sensing pistol set at 300 v./cm., the dial reading on the indicator of the pistol is set to +1 ma. with the calibration knob on the sensing pistol. This corresponds to the full-scale deflection of the indicating needle on the dial. The X-Y recorder is adjusted so that the abscissa reads 6,000 v./10 cm. and the ordinate reads 12 cm./min. The applied voltage is then changed to 3,000 v. and the meter reading should be half scale (0.5 ma.) which is indicated on the recorder as 5 cm. above the origin on the abscissa. The applied voltage is then grounded and the meter should read zero (0.00 ma.) which corresponds to the origin on the axis of the abscissa on the X-Y recorder.

After completing the calibration of the electrostatic voltage sensing pistol and adjustment of the axis of the X-Y recorder, the aluminum foil is removed from the Plexiglas plate. The powder sample (150 Gm.) to be measured is spread gently on the plate to cover the same area as did the aluminum foil. The lid on the Faraday cage is secured and the humidity allowed to come up to the desired level. Ten minutes after the humidity has reached its equilibrium level, a preset voltage, which in this study was 6,000 v., is applied and the charge accumulation is recorded on the X-Y recorder. When the charge has reached its equilibrium value, the sample plate is grounded and the decay characteristics of the powder are recorded.

RESULTS AND DISCUSSION

In order to demonstrate the utility of the electrostatic tester to rate pharmaceutical powders as to their static electrification properties, a good conductor (sodium chloride), a poor conductor (stearic acid), and two powdered drugs were chosen.

Since the static electrification characteristics of solids are influenced by temperature (8–9) and humidity (10–12), the studies performed in this investigation were carried out at a temperature between 22–23° and a relative humidity of 34 ±1%. Both a positive and negative electrostatic potential of 6,000 v. were applied to the samples, and their tendencies to accept and dissipate the applied charge were displayed on an X-Y recorder. The rates of charge accumulation and decay were calculated for each of the substances evaluated.

The plots in Figs. 6–8 represent the charge and decay curves for sodium chloride, stearic acid, and sulfisomidine, Since the curve for iodochlorhydroxyquin and sulfisomidine closely resembled that shown for stearic acid in Fig. 7, it was not

presented. It can be seen from Fig. 6 that sodium chloride is a good conductor since the charge accumulation and decay under both positive and negative applied potential takes place readily as demonstrated by an accumulation of approximately 90% of the applied voltage within 5 sec. While in the case of stearic acid which is a poor conductor, the charge accumulation and decay is considerably slower as depicted in Fig. 7 since even after 60 sec. only about 50% of the applied potential has accumulated on the material. This is further evident

TABLE I—EQUILIBRIUM POTENTIAL ON POWDERS AT APPLIED POTENTIAL OF 6,000 V.

Materials	Polarity of Applied Potential +	−
Sodium chloride	85.0%	90.0%
Stearic acid	55.0%	45.0%
Sulfisomidine	60.0%	48.0%
Iodochlorhydroxyquin	50.2%	50.3%

by the data in Table I which summarizes the percent applied potential that has been accumulated on the powder material at equilibrium (t^{∞}).

The data in this table were calculated in accordance with the following equation:

$$\% = \frac{\text{limiting potential at } t^{\infty}}{\text{applied potential}} \times 100$$

The equilibrium time, t^{∞}, is taken as the time at which the voltage on the sample remained essentially at a steady state for 0.5 hr.

It is evident from the data in this table that the percent saturation at equilibrium of the applied potential was approximately twice as great for sodium chloride as for stearic acid regardless of the polarity of the applied charge. This finding is in agreement with the concept that charge flows faster in a good conductor (sodium chloride) as compared to a poor conductor (stearic acid). Equilibrium conditions of about the same magnitude are obtained for the two drugs, sulfisomidine and iodochlorhydroxyquin at both negative and positive applied potentials and are approximately equivalent to stearic acid which is a relatively poor conductor.

For sodium chloride, stearic acid, and iodochlorhydroxyquin, there exists no measurable static charge on the surface of these materials in the steady state. However, as is evident from Fig. 8, sulfisomidine differs from the other three powders in that it shows an initial inherent positive potential of approximately 240 v.

Since it was the main purpose of this initial report to describe the design and operation of the quantitative electrostatic tester, the experimental data obtained with the four powders were treated in accordance with first-order kinetics to obtain charge accumulation and decay rates. It should be understood that although the data were treated in this simple fashion and obtained relative charge accumulation and decay rates, the overall mechanism of electrification is considerably more complex, and detailed treatment of the overall process of electrification of powders will be the substance of a separate report.

The charge accumulation and decay data plotted according to first-order kinetics for positive and negative applied voltage for a poor conductor, stearic acid, are given in Fig. 9 and for the negative applied potential for a good conductor, sodium chloride, are given in Fig. 10. It can be seen that for each material and for both charge accumulation and decay at positive and negative applied voltage, there are two slopes, the first one being steeper than the second one in each case. It is felt that the initial slope is due to the inherent tendencies of the materials to be polarized by the applied electrostatic field and the second slope represents the saturation of the surface of the material with the applied potential, as well as loss of charge from the material due to radiation and conduction to the

TABLE II—ACCUMULATION AND DECAY OF NEGATIVE AND POSITIVE ELECTRIFICATION AT APPLIED POTENTIAL OF 6,000 V.

Materials	Charge	Accumulation Rate, sec.$^{-1}$ k_1	Accumulation Rate, sec.$^{-1}$ k_2	Decay Rate, sec.$^{-1}$ k_1	Decay Rate, sec.$^{-1}$ k_2
Sodium chloride	+	8.04×10^{-1}	1.77×10^{-1}	5.52×10^{-1}	1.62×10^{-1}
	−	5.36×10^{-1}	2.70×10^{-2}	4.90×10^{-1}	3.30×10^{-2}
Stearic acid	+	8.92×10^{-2}	5.90×10^{-3}	1.06×10^{-1}	8.35×10^{-3}
	−	7.90×10^{-2}	6.37×10^{-3}	5.36×10^{-2}	6.96×10^{-3}
Sulfisomidine	+	1.12×10^{-1}	8.01×10^{-3}	8.72×10^{-2}	9.96×10^{-3}
	−	7.59×10^{-2}	3.07×10^{-3}	7.67×10^{-2}	3.58×10^{-3}
Iodochlorhydroxyquin	+	1.12×10^{-1}	4.68×10^{-3}	5.82×10^{-2}	5.41×10^{-3}
	−	5.29×10^{-2}	3.60×10^{-3}	7.60×10^{-2}	9.62×10^{-3}

surrounding air. The rate constants for these plots are summarized in Table II. It is evident from these data that for the four powders the initial rate for either charge accumulation or decay is greater than the second rate. The rate of charge accumulation or decay is generally greater for the positive voltage than for the negative voltage.

These preliminary findings indicate that it is possible to rate the static electrification tendencies of powdered materials by the use of the electrostatic tester and treatment of the data in accordance with first-order kinetic principles. In subsequent publications of this series, the relationship between static and dynamic charge development of solids will be explored.

SUMMARY AND CONCLUSIONS

The design and operational characteristics of an electrostatic tester were presented. This equipment consists of (*a*) a power supply unit capable of inducing up to ±10,000 v. on materials to determine the tendencies of these materials to acquire and leak off electrostatic charges, (*b*) a modified Faraday cage to induce the applied electrostatic potential on the material, and (*c*) an electrostatic voltage sensing pistol capable of reading out the voltage on the sample or displaying the voltage on an X-Y recorder. The utility of this equipment to rate pharmaceutical powdered materials as to their tendencies of acquiring static electrification has been demonstrated.

Cholinergic Receptor I. Cholinomimetic Activities of Some Analogs of *cis*-2-Methyl-4-dimethylaminomethyl-1,3-dioxolane Methiodide

By M. MAY and D. J. TRIGGLE

The cholinomimetic activities of acetylcholine, *cis*-2-methyl-4-dimethylaminomethyl-1,3-dioxolane methiodide, *N*-methyl-6,8-dioxa-3-azabicyclo[3.2.1]octane methiodide, and *N*-methyl-7,9-dioxa-3-azabicyclo[4.2.1]nonane methiodide have been compared and an interpretation of their relative activities in terms of a conformation of receptor-bound cholinomimetic molecules has been put forward. *N*-Methyl-7,9-dioxa-3-azabicyclo[4.2.1]nonane methiodide has been shown to have some acetylcholine releasing activity.

A FUNDAMENTAL assumption in the analysis of structure–activity relationships is that mutual complementarity exists between the drug and receptor. With this assumption, analysis of structure–activity relationships should yield information relevant to an understanding of the binding sites of the receptor. However, with flexible molecules there is no reason to assume that the conformation of lowest free energy in the solution or crystalline state is necessarily that which is involved in binding at the receptor surface. In the absence of evidence concerning the conformation of receptor-bound molecules, analysis of structure–activity relationships in terms of the relative geometry of binding sites becomes equivocal.

A partial solution to this problem may be obtained through the use of conformationally rigid analogs of active molecules where the distances between potentially important binding groups are fixed. A number of workers have used this approach in attempts to define more precisely the structure of the cholinergic receptor (1, 2). Most recently, Smissman, LaPidus, and their co-workers (3) have studied the four isomeric 2-acetoxy-3-trimethylammonium-*trans*-decalins (I*a*,*b*,*c*,*d*), which contain the basic acetylcholine structure, and found them to have negligible muscarinic activity. However, the observed inactivity of these compounds may well be due, not to a failure to reproduce the geometry of receptor-bound acetylcholine, but to the incorporation of additional potential binding groups—specifically the large hydrocarbon skeleton—a feature which has been repeatedly demonstrated to depress cholinomimetic activity and convert agonists to antagonists (4, 5).

This latter point is considered to be of substantial importance. Accordingly, in this approach to the design of semirigid and rigid analogs of acetylcholine the authors have endeavored to meet the requirements of minimum conformational flexibility without the incorporation of additional potential binding groups. In this paper are reported the synthesis

N - Methyl - 7,9 - dioxa - 3 - azabicyclo[4.2.1]-nonane Methiodide (III)—This was prepared by a method similar to that described for II. *cis,trans*-2-Chloroethyl-4-chloromethyl-1,3-dioxolane was prepared from β-chloro-propionaldehyde trimer (55.2 Gm., 0.2 mole, from Shell Development Corp.) and glycerol α-monochlorhydrin (22.2 Gm., 0.2 mole) by refluxing in benzene (300 ml.) in the presence of *p*-toluenesulfonic acid (0.2 Gm.) with continuous removal of water. Fractional distillation gave the product in 85% yield with b.p. 80–85°/0.2 mm., which was shown by GLC to consist of a 3:2 mixture of *cis,trans* isomers.

Anal.—Calcd. for $C_6H_{10}Cl_2O_2$: C, 38.93; H, 5.44; Cl, 38.31. Found: C, 38.81; H, 5.41; Cl, 38.21.

cis,trans - 2 - Chloroethyl - 4 - chloromethyl - 1,3-dioxolane (9.2 Gm., 0.05 mole) and methylamine (7.8 Gm., 0.25 mole) in benzene (100 ml.) were heated at 100° for 16 hr. On cooling the mixture was filtered from methylamine hydrochloride and fractionally distilled to give *N*-methyl-7,9-dioxa-3-azabicyclo[4.2.1]nonane (3.8 Gm., 91% based on presumed *cis*-content of *cis,trans*-2-chloroethyl-4-chloromethyl-1,3-dioxolane) with b.p. 85–87°/25 mm.

Anal.—Calcd. for $C_7H_{13}NO_2$; C, 58.73; H, 9.15; N, 9.78. Found: C, 58.51; H, 9.01; N, 9.71.

The *N* - methyl - 7,9 - dioxa - 3 - azabicyclo[4.2.1]-nonane was quaternized with methyl iodide to give III in 91% yield with m.p. 244–246° [MeOH–EtOH].

Anal.—Calcd. for $C_8H_{16}INO_2$: C, 33.71; H, 5.65; I, 44.51; N, 4.91. Found: C, 33.78; H, 5.64; I, 44.38; N, 4.74.

PHARMACOLOGY

Muscarinic activities of the compounds were determined using the rat jejunum. Male rats (250 Gm.) were decapitated, bled, and a length of jejunum removed and washed through with Tyrode's solution. Short lengths (3 cm.) were then suspended in oxygenated Tyrode solution in 20-ml. muscle baths with the temperature maintained at 37°. The tissues were allowed to relax for 1 hr. and cumulative dose-response curves for the compounds II, III, and IV were obtained. Dose-response curves for acetylcholine were determined simultaneously using jejunum segments from the same animal. Compounds were added in saline to give the expressed final bath concentration and isometric contractions were recorded on a Grass polygraph (model 5.D).

Nicotinic activities were determined using the frog rectus abdominus preparation. The isolated muscle was suspended in oxygenated Ringer's solution at room temperature in 20-ml. muscle baths and sensitized with eserine ($3 \times 10^{-5}M$, final bath concentration) for 20 min. Dose-response curves were determined and isometric contractions recorded with a Grass polygraph.

Acetylcholine release from the rat jejunum was determined essentially according to the method of Schaumann (11). (See also *Reference 12.*) Jejunum from three freshly decapitated rats were washed through with Tyrode's solution and cut into segments of 1.5 cm. length. To one portion (5 Gm.) suspended in oxygenated eserinized ($3 \times 10^{-5}M$) Tyrode's maintained at 35° (20 ml.) was added III to give a final concentration of 10^{-4} Gm./ml. and at 15, 30, and 45 min. additional equal amounts of III were added to give a final bath concentration of 4×10^{-4} Gm./ml. Another portion (5 Gm.) of jejunum served as a control and was treated identically save that Tyrode's was added instead of III. The incubation mixtures were then centrifuged and the supernatant fluid was assayed for acetylcholine-like activity on the rectus abdominus preparation described above.

RESULTS

Muscarinic and Nicotinic Activities—The pharmacological activities are given in Table I. The results confirm the observation of Triggle and Belleau (6) who found *cis*-2-methyl-4-dimethylaminomethyl-1,3-dioxolane methiodide (IV) to be as potent as acetylcholine in the guinea pig ileum preparation: IV is found to be only slightly less potent than

Table I—Muscarinic and Nicotinic Activities

Compd.	Rat Jejunum, ED_{50} Gm./20 ml.	Relative *M* Potency	Frog Rectus, ED_{50} Gm./20 ml.	Relative *M* Potency
Acetylcholine	$2.2 \pm 1.8 \times 10^{-7}$	1.0	$3 \pm 0.5 \times 10^{-6}$	1.0
II	Inactive at 10^{-3}	...	Produced 8% response at 10^{-4}	...
III	$2.7 \pm 4.7 \times 10^{-5}$	0.012[a]	Inactive at 5×10^{-4}	...
IV	$4.0 \pm 3.2 \times 10^{-7}$	0.75	$9 \pm 1.0 \times 10^{-5}$	0.049

[a] Produced only 75% of the maximum response (ACh = 100).

acetylcholine on the rat jejunum preparation and to have only one-twentieth of the nicotinic activity of acetylcholine on the frog rectus preparation. The bicyclic analogs, II and III, of IV were found to have negligible activities at both muscarinic and nicotinic receptors.

Acetylcholine Releasing Activities—Reproducible dose-response curves could not be obtained with III on the rat jejunum preparation. The maximum response elicited decreased with repetition of the dose-response curve until after 4–5 such determinations the response remained steady at 45–55% of the original maximum response. This behavior was in marked contrast to acetylcholine and IV which gave 6–8 highly reproducible dose-response curves over a 60–90 min. period. It was found that III was able to release acetylcholine from rat jejunum. As determined by bioassay on the frog rectus abdominus preparation, III (4×10^{-4} Gm./ml.) liberated 4.2 ± 2.4 mcg./Gm. tissue/hr. compared to a spontaneous release of 1.5 ± 1.08 mcg./Gm. tissue/hr. (P value, 0.05–0.02).

DISCUSSION

The finding that the bicyclic analogs II and III of IV have negligible activities and that, in fact, II is apparently devoid of muscarinic activity is of some interest. This finding clearly suggests that IV, and by analogy acetylcholine, acetyl-β-methylcholine, and muscarine, do not adopt, when bound at the muscarinic receptor, any of the limiting conformations represented by II and III. Whether this is related to the inactivity of II and III remains to be established through the synthesis of further bicyclic analogs of this type (14).

The complete inactivity of II at the muscarinic receptor also relates to the proposed modes of binding of muscarine and muscarone at cholinergic receptors. Waser (9) has suggested that, in order to account for the relative loss and inversion of optical specificity of muscarone relative to muscarine, D-muscarone is bound at the receptors in a conformation in which the trimethylammonium group is symmetrically disposed over the ether and carbonyl oxygen functions; the carbonyl group is assumed to be able to bind equivalently to the receptor site which normally binds the ether oxygen of L-muscarine. According to Waser's argument, II should be extremely active, since in one of its limiting conformations the quaternary ammonium group is centered symmetrically over the two electronically equivalent ether oxygens (the latter feature is not really true in Waser's proposed conformation for D-muscarone). Its complete inactivity reinforces the earlier arguments of Belleau and Puranen (15), based on the relative stereospecificity of L- and D-*cis*-2-methyl-4-dimethylaminomethyl-1,3-dioxolane methiodide, concerning the difficulties with Waser's interpretation of the binding of D-muscarone at the muscarinic receptor and provides further support for their suggestion that the carbonyl group in muscarone binds to an accessory nucleophilic site at the receptor thus introducing a binding characteristic that is not available for muscarine.

The remaining point of interest in connection with these compounds concerns the acetylcholine releasing activity of III. This activity, while relatively feeble, may be related to the steady decrease in maximum response obtained with III on repeated administration and raises again the question that certain cholinomimetic compounds may act, at least in part, by releasing acetylcholine from peripheral storage sites (16–18).

Multiregressional Analysis of the Griffin HLB Numbers for Polyoxyethylene Polyoxypropylene Surfactants

By WERNER LOWENTHAL

Using data from 32 polyoxypropylene polyoxyethylene surfactants and the technique of multiregressional analysis, an equation was determined. This equation describes the relationship between Griffin HLB number, percent polyoxyethylene in the total molecule, and the typical molecular weight of the polyoxypropylene. From the equation, given any two variables, the third variable can be readily determined with good accuracy for this series of polymeric surfactants.

POLYOXYETHYLENE POLYOXYPROPYLENE[1] surfactants are block polymers prepared by adding ethylene oxide to a polyoxypropylene chain. This produces a series of compounds that have the following formula: $HO(CH_2CH_2O)_a(CHCH_3CH_2O)_b(CH_2CH_2O)_cH$, where a and c are the number of ethylene oxide units and b is the number of propylene oxide units. Since the chain lengths can be varied, surfactants having different properties may be prepared. The propylene oxide chain is hydrophobic and the ethylene oxide chains are hydrophilic.

RESULTS AND DISCUSSION

A method called the Pluronic Grid which characterizes the available surfactants in this group has been published (1). This grid is actually a graphical plot of percent polyoxyethylene in the total molecule on one axis, and the typical molecular weight of the polyoxypropylene hydrophobic base on the other axis (1). At the points of intersection of the two variables on this grid, the different surfactants available are noted. The Griffin HLB number (2) for 32 of these surfactants is also available. Using these three sets of data, it is possible to calculate a multiregressional analysis to determine the relationships between the molecular weight of the hydrophobic group, the percent of hydrophilic groups in the total molecule, interactions between these two variables, and the HLB number.

The initial equation for which the constants and coefficients were determined using the RPC 4000 computer[2] was written as:

$$Y = b_0 + b_1X_1 + b_{11}X_1^2 + b_2X_2 + b_{22}X_2^2 + b_{12}X_1X_2 \quad \text{(Eq. 1)}$$

where Y is the HLB number, X_1 is the typical molecular weight of the hydrophobic group, X_2 is the percent polyethylene oxide in the total molecule, b_0 is a constant, and the other b values are coefficients. The constant and coefficients were calculated, and t tests (3) showed that only the coefficients for X_1, X_1^2, and X_2 were statistically significant. Equation 1 then reduced to:

$$Y = 3.01 - 0.00231X_1 + 1.94 \times 10^{-7}X_1^2 + 0.371X_2 \quad \text{(Eq. 2)}$$

A more detailed grid was drawn from HLB values obtained by selecting values of X_1 between 950 and 4000 and values of X_2 between 10 and 80, substituting these numbers into Eq. 2, and solving for the HLB values. The HLB numbers for each corresponding set of X_1 and X_2 values were then plotted on rectangular coordinate paper and lines drawn connecting equal HLB numbers. The topography of this grid showed that, in the range of values used, a flat plain existed inclining from high HLB numbers at high percent hydrophilic groups and low molecular weight hydrophobic group, to low HLB numbers at low percent hydrophilic groups and high molecular weight hydrophobic group.

TABLE I—CALCULATED HLB NUMBERS USING EQ. 2

Surfactant	Given HLB No.	Calcd. HLB No.
L31	4.5	4.7
L35	18.5	19.5
F38	30.5	30.7
L42	8.0	7.9
L43	12	11.6
L44	16	15.4
L61	3	3.3
L62	7	7.0
L63	11	10.7
L64	15	14.4
P65	17	18.1
F68	29	29.2
L72	6.5	6.5
P75	16.5	17.6
F77	24.5	25.1
L81	2	2.5
P84	14	13.6
P85	16	17.3
F87	24	24.8
F88	28	28.5
L92	5.5	5.5
P94	13.5	13.0
F98	27.5	27.8
L101	1	1.3
P103	9	8.7
P104	13	12.4
P105	15	16.1
F108	27	27.2
L121	0.5	0.6
L122	4	4.3
P123	8	8.0
F127	22	22.8

Table I shows the values calculated with Eq. 2 and the published values. The numbers in column one are the commercial names of the polyoxyethylene polyoxypropylene surfactants.

The average difference between the given and calculated HLB numbers is 0.45 units, which is probably within the error in determining HLB numbers.

CONCLUSIONS

The solution of a multiregression equation showed that the Griffin HLB numbers are directly related to the molecular weight of the hydrophobic group and percent of hydrophilic groups in the total molecule,

Cactus Alkaloids IV. Macromerine from *Coryphantha runyonii*

By L. E. BELOW, A. Y. LEUNG, J. L. MCLAUGHLIN*, and A. G. PAUL

Macromerine, a β-phenethylamine alkaloid previously isolated from *Coryphantha macromeris*, has been isolated from *Coryphantha runyonii*

HODGKINS *et al.* (1) have recently isolated a new β-phenethylamine, macromerine, from the cactus, *Coryphantha macromeris* (Engelm.) Lemaire. Physiological tests demonstrated that macromerine has potential hallucinogenic and sympatholytic activities. From physical data, spectra, and elemental analysis they proposed that macromerine is *l*-α-3,4-dimethoxyphenyl-β-dimethylaminoethanol, and they have confirmed this structure by synthesis of the racemic mixture.

Working independently in this laboratory using thin-layer chromatography (TLC) several unknown alkaloids were detected in a related species of cactus, *Coryphantha runyonii* Britton and Rose (2). Since the alkaloids detected produced TLC patterns different from those of previously known cactus alkaloids, isolation attempts were initiated.

EXPERIMENTAL

Using large Soxhlet extractors, alkaloids were extracted with ethanol from 1.8 Kg. of dried and pulverized plant material.[1] Nonphenolic alkaloids were isolated from the ethanolic residue using the procedures and ion-exchange column technique of purification method No. 2 (3). The total nonphenolic alkaloid fraction was chromatographed over 560 Gm. of activated alumina in a 40 × 150 cm. column using chloroform as the developer. Eluant fractions of 15–20 ml. each were collected and analyzed by TLC. Those fractions richest in concentrations of the major alkaloid were combined. The crystalline residue obtained (1.314 Gm.; yield 0.07%) was recrystallized several times from ethyl ether (m.p. 65–65.5°; picrate m.p. 159°; optical rotation: $[\alpha]_D^{26} = -54.2$, c = 0.0120 Gm./ml. in methanol). The isolated alkaloid appeared as a single spot upon TLC analysis in several solvent systems, indicating its homogeneity.

Permanganate oxidation (4) of the alkaloid produced a crystalline derivative which was identified as 3,4-dimethoxybenzoic acid by melting point, mixed melting point, and IR spectral comparison. Elemental analysis[2] of the alkaloid indicated an empirical formula of $C_{12}H_{19}NO_3$.

Calcd. for C, 63.98; H, 8.50; N, 6.22; mol. wt. 225.29. Found: C, 65.02; H, 8.39; N, 6.29.

The UV spectrum (0.016 mg./ml. methanol) showed a $\lambda_{max.}$ at 202 mμ and smaller peaks at 230 mμ and 278 mμ, indicating typical benzene ring absorption. The IR spectrum in KBr revealed a broad band at 3120 $cm.^{-1}$ (hydroxyl). NMR spectra in $CDCl_3$ showed peaks at 6.99 δ and 6.89 δ, indicative of three aromatic hydrogens, and a doublet of doublets centered at 4.67 δ, indicative of a benzylic hydrogen adjacent to two nonequivalent methylene protons (5). An alcohol hydrogen (3.96 δ) showed shifts with varying concentrations and disappeared with D_2O exchange. A doublet centered at 3.90 δ indicated two methoxyl groups, a doublet centered at 2.48 δ indicated a methylene group, and a singlet at 2.35 δ indicated two methyl groups attached to nitrogen.

Analysis by high resolution mass spectrometry[3] showed a weak molecular ion peak at m/e = 225.1362, in agreement with the proposed empirical formula. Prominent peaks appeared at m/e = 208, 207, 192, 180, 167, 166, 165, 164, and 151, postulated structures of which are compatible with the expected fragmentation pattern of macromerine.

The UV, IR, and NMR spectra of the alkaloid and the spectra of natural *l*-macromerine from *C. macromeris* as well as synthetic *d,l*-macromerine are essentially identical. In addition the melting point of *l*-macromerine (m.p. 65–65.5°) was not depressed by admixture (mixed m.p. 65–65.5°) with the alkaloid isolated from *C. runyonii*.[4]

DISCUSSION AND CONCLUSIONS

Following detection of unknown alkaloids in the cactus *C. runyonii*, one of the alkaloids was isolated in crystalline form by employing ion-exchange and adsorption column chromatography. Attempts at characterization of the unknown alkaloid resulted in spectral and chemical data which are in accord with *l*-α-3,4-dimethoxyphenyl-β-dimethylaminoethanol. This compound has recently been isolated by other workers from a related cactus, *C. macromeris*, and has been given the common name *l*-macromerine. Comparison of spectral and chemical data revealed that the unknown alkaloid from *C. runyonii* is identical to *l*-macromerine from *C. macromeris*. Thus, the occurrence of macromerine is not restricted to the latter species.

Deoxyalloxazines (Benzopteridines) II. Methylation of 2,4-Diamino-6,7-dimethylbenzo(*g*)pteridine

By S. L. MUKHERJEE, Z. F. CHMIELEWICZ, and T. J. BARDOS*

Methylation of 2,4-diamino-6,7-dimethylbenzo(*g*)pteridine (I) with excess methyl iodide in boiling cellosolve gave a red methyl-methiodide derivative (II) which, on treatment with hot aqueous sodium carbonate solution was converted to the N_1-methyl derivative (III), as shown by hydrolysis of the product to the corresponding dioxo-compound (IV) and its further degradation to the quinoxaline derivative (V). Reaction of I with methyl iodide in nitromethane solution afforded a quaternary methiodide derivative (VI) which, through a series of reactions with cold, concentrated acid and base reagents, was converted to III. On several occasions, the latter was obtained in what appeared to be a different, unstable tautomeric form. Hydrolysis of the corresponding intermediate methiodide (VI) or, of the hydrochloride salt (VII), with acid or alkali, gave IV; thus the methylation of I in nitromethane, as in cellosolve, appears to have occurred exclusively in the N_1-position of the pyrimidine ring.

THE SYNTHESIS of a series of deoxyalloxazines (benzopteridines) was reported several years ago (1). One of these compounds, 2,4-diamino-6,7-dimethylbenzo(*g*)pteridine (2,4-diamino-2,4-deoxylumichrome, I) was found to be a highly active antimetabolite of both folinic acid and riboflavin in various microbiologic test systems (1, 2), and it also inhibited the growth of several transplanted tumors in mice (3, 4). Unfortunately, the very poor solubility and tissue absorption properties of this interesting compound sharply limited its potential therapeutic usefulness. For this reason, the synthesis of more soluble derivatives was attempted.

Substitution in the N_{10}-position of the central ring appeared to be of particular interest because the resulting flavin-type compounds would display greater structural similarity to riboflavin and may prove to possess higher "anti-riboflavin" activities than I. It was also of interest to investigate the possibility of obtaining quaternary derivatives of I which would bear some structural resemblance to the chemotherapeutically effective acridines and phenanthridines.

Methylations of 4-aminopteridine, 2,4-diaminopteridine, and related compounds, with methyl iodide, were reported by Brown and Jacobsen (5, 6) to give the N_1- and/or N_8-methyl substituted derivatives in the form of their hydroiodides or quaternary methiodides (the N_8-position of the pteridine nucleus corresponds to the N_{10}-position in the benzopteridine system). The N_1-substituted derivative of 2,4-diamino-6,7-diphenylpteridine was obtained by Boon and Bratt (7) by methylation of the parent compound with methyl iodide. In a series of papers, Angier (8) reported his studies on the methylations of 2-amino-4-hydroxypteridines with dimethyl sulfate; substitution in the N_1, N_3, and/or N_8 position was shown to occur under the various conditions employed. Preliminary experiments indicated that I could not be methylated with dimethyl sulfate under the conditions employed by Angier, while the use of methyl iodide appeared to be more promising.

* To whom inquiries should be addressed.

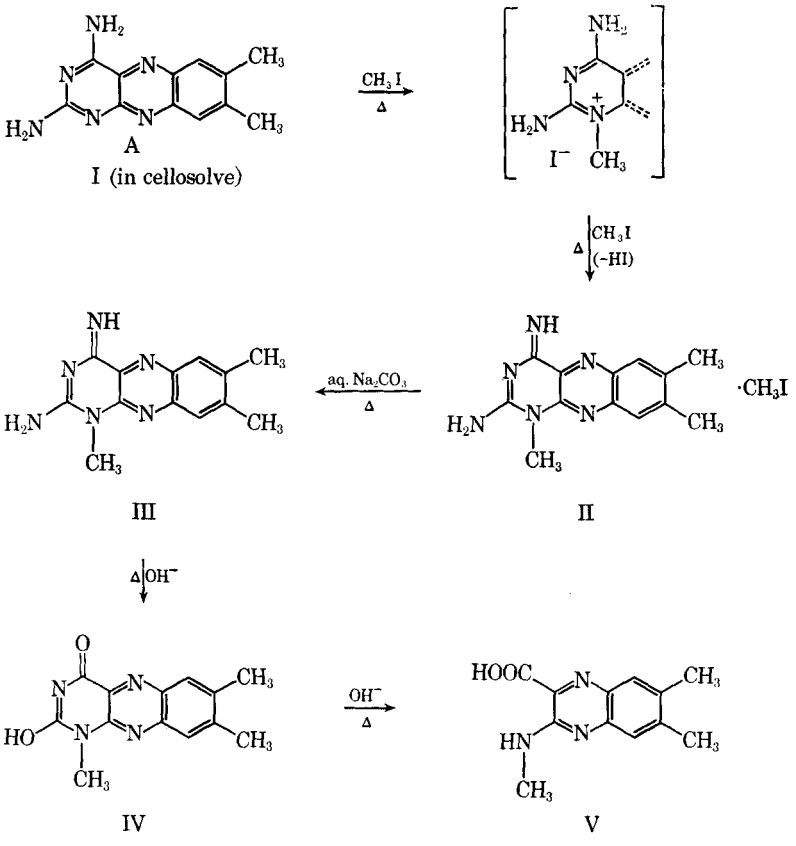
In all of the reactions studied, the very low solubility of I in organic solvents caused considerable difficulties. Boiling ethanol dissolves the compound at less than 0.05 mg./ml. concentration; the resulting yellow, green-fluorescent solution shows absorption maxima at 265, 343, and 420 mμ, almost identical to those reported for the anion of 2-amino-4-hydroxybenzo(*g*)pteridine (9) and the di-anion of lumichrome (1). On the basis of Jones' rule (10), structure A is, therefore, assigned to the tautomeric form of I in ethanol (Scheme I). Somewhat higher solubility, with similar spectrum, was obtained in boiling cellosolve. Treatment of I in cellosolve with excess methyl iodide at reflux temperature resulted in complete dissolution of the starting material; on cooling, an orange-red compound precipitated which, after recrystallization, gave an elemental analysis corresponding to a methyl-methiodide (or, dimethyl-hydroiodide) derivative of I. Subsequent reactions and spectral comparisons suggest that the most probable structure for this compound is the one indicated in formula II.

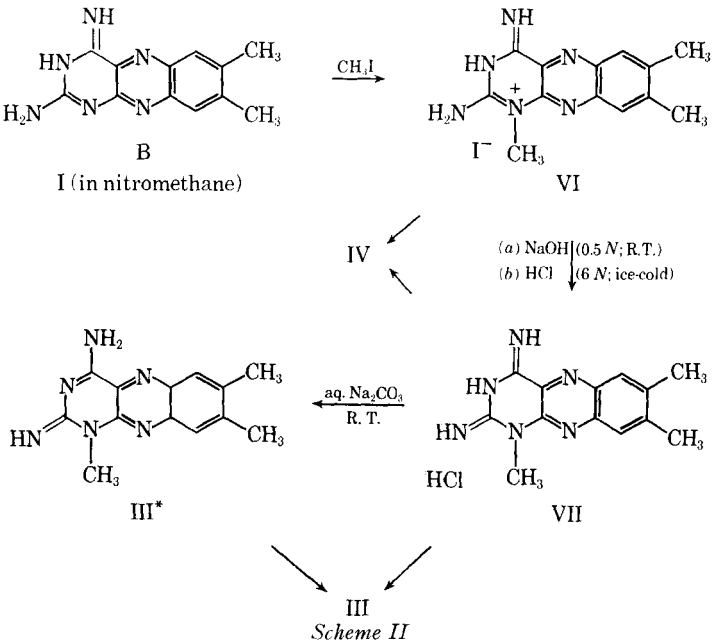
Further treatment of II with an aqueous solution of sodium carbonate at 100° gave the N_1-methyl derivative (III). The position of the methyl group was established by alkaline degradation which yielded 3-methylamino-6,7-dimethylquinoxaline-2-carboxylic acid (V). Milder alkali treatment of III resulted in hydrolysis to the corresponding dioxo-derivative (IV).

Solutions of I in more polar solvents (nitromethane or dimethylsulfoxide) showed no fluorescence, and the second and third absorption bands in the ultraviolet spectra appeared at 360 and 395–400 mμ, respectively (the first absorption band cannot be established because of the absorption of these solvents in the 200–300 mμ region). Structure B (Scheme II) was tentatively assigned to the tautomeric form of I present in these solvents. Reaction of I with excess methyl iodide in boiling nitromethane yielded a water-soluble, red crystalline compound which gave elemental analysis and spectral properties corresponding to a quaternary methyl-iodide (VI) of the starting material. Treatment of this compound with hot sodium carbonate solution, under conditions employed for the conversion of II to III, led to decomposition (evolution of ammonia). However, when the aqueous solution of VI was added at *room temperature* to a solution of 0.5 *N* sodium hydroxide, immediately a red solid precipitated; this could not be purified but could be converted to a crystallizable mono-hydrochloride (VII). The latter was dissolved in water and neutralized with aqueous sodium carbonate to give III.

It should be mentioned that, on several occasions, this series of reactions led to a final product which gave analysis corresponding to a monomethyl derivative of I but appeared to differ from III in appearance, solubility, fluorescence, and ultraviolet spectrum in absolute ethanol. Due to the strong fluorescence and longer-wavelength absorption ($\lambda_{max.}$ 422 mμ) of this compound in absolute ethanol, it was believed, at first, that the methylation in nitromethane occurred at the N_{10}-position; how-



Scheme I



Scheme II

ever, hydrolysis of the corresponding hydrochloride (VII) with either acid or alkali gave a dioxo-compound which was identical with IV (as shown by spectra and thin-layer chromatography). The same dioxo-benzopteridine was obtained by alkaline hydrolysis of VI. It was also found that addition of water to their alcoholic solutions changed the ultraviolet spectra of both III and the "new" monomethyl compound, and the two spectra became identical, both showing in the range above 300 mμ a single absorption maximum (at 360 mμ) and an inflection (at 395 mμ). The spectra of the two compounds in 0.1 *N* HCl were also identical (see under *Experimental*). Moreover, after a sample of the "new" compound was stored in a desiccator for more than a year, all the above-mentioned characteristic differences disappeared, and the sample became indistinguishable from III. It was concluded that the "new" compound represented an unstable tautomeric form of III. Consequently, the methylation of I in nitromethane (as in cellosolve) appears to occur exclusively in the N_1-position of the pyrimidine ring.

These studies indicated that, due to the fused benzene ring, the aromaticity of the pyrazine ring and its resistance to *N*-methylation is greatly enhanced in the benzopteridine system.

EXPERIMENTAL[1]

2 - Amino - 4 imino - 1,6,7 - trimethyl - 1,4 - dihydrobenzo(g)pteridine - methiodide—2,4 - Diamino-6,7-dimethylbenzo(*g*)pteridine (I) (2.0 Gm., 0.0083 mole), was added to a solution of methyl iodide (5.0 ml., 0.1 mole) in 40 ml. of cellosolve, and the reaction mixture was heated at refluxing temperature for 45 min. under vigorous stirring. The resulting clear, deep-red colored solution was concentrated to about one-third of its original volume, then cooled and stored in the refrigerator overnight during which time an orange-red solid precipitated. This was collected by filtration and triturated at room temperature with 125 ml. of methanol; the methanolic extract was filtered from the undissolved solids and concentrated to dryness. The residue of the methanolic filtrate was washed with 60 ml. of acetone. Yield: 1.0 Gm. (30%) of essentially pure product, a portion of which was crystallized from methanolic solution by very slow and careful evaporation of the solvent. Long, orange needles which, however, on repeated crystallization changed into small, red flakes, m.p. > 360°. Similar result was obtained by precipitation of the compound from methanolic solution with slow addition of ether. This process was repeated several times until the UV absorption maxima reached constant values. $\lambda_{max.}^{0.1\ N\ HCl}$ 365 mμ (ε 14,130); 260 mμ (ε 46,770). $\lambda_{max.}^{EtOH}$ 396 mμ (ε 11,090); 360 mμ (ε 12,670); 256 mμ (ε 44,540).

Anal.—Calcd. for $C_{14}H_{17}IN_6$: C, 42.42; H, 4.29; I, 32.07; N, 21.21. Found: C, 42.21; H, 4.15; I, 32.10; N, 21.10.

2 - Amino - 4 - imino - 1,6,7 - trimethyl - 1,4 - dihydrobenzo(g)pteridine (III)—To a boiling, 10% aqueous sodium carbonate solution (25 ml.) was added 170 mg. (0.0043 mole) of the above compound (II), and the mixture was stirred for 15 min. without further heating. A green precipitate was obtained which was allowed to settle at room temperature, filtered, and washed with water followed by acetone. Yield: 100 mg. (92%) of crude III. This was purified by dissolving in boiling methanol and treatment of the hot solution with charcoal (Darco); on cooling, the compound crystallized in the form of yellow micro-needles, no melting point (apparently decomposes above 250°). $\lambda_{max.}^{0.1\ N\ HCl}$ 365 mμ (ε 10,400); 260 mμ (ε 32,760). $\lambda_{max.}^{EtOH}$ 390 mμ (ε

[1] Microanalyses by Galbraith Laboratories, Knoxville, Tenn., and by Dr. S. N. Nagy, Microchemical Laboratory, Massachusetts Institute of Technology, Cambridge, Mass. The melting points were taken on the Kofler block and are uncorrected. The ultraviolet spectra were determined on a Beckman DU spectrophotometer attached to a Gilford model 2000 absorbance indicator. The infrared spectrum was determined on a Perkin-Elmer model 137 Infracord spectrophotometer. The NMR spectrum was determined on a Varian A-60, with tetramethylsilane as external standard.

7,340); 345 mμ (ε 8,100); 258 mμ (ε 32,100).

Anal.—Calcd. for $C_{13}H_{14}N_6$: C, 61.42; H, 5.51; N, 33.07. Found: C, 61.79; H, 5.35; N, 32.87.

2 - Hydroxy - 4 - oxo - 1,6,7 - trimethyl - 1,4 - dihydrobenzo(g)pteridine (IV)—To a boiling solution of 2 - amino - 4 - imino - 1,6,7 - trimethyl - 1,4-dihydrobenzo(*g*)pteridine (III) (100 mg., 0.0004 mole) in 2-methoxyethanol (30 ml.), 1 *N* sodium hydroxide (20 ml.) was added, and the resulting solution was heated for 60 min. on the steam bath (9). The hot, greenish yellow solution was acidified with glacial acetic acid (about 10 ml.) and cooled in the refrigerator overnight. The precipitate obtained was collected by filtration and washed with water until the washings were neutral to litmus paper. The residue (30 mg., 30%) was further purified by dissolving in methanol and treatment with charcoal. Concentration of the solution afforded yellow microcrystals; yield, 20 mg. (20%), m.p. 292–294°. $\lambda_{max.}^{EtOH}$ 392 mμ (ε 8,800); 336 mμ (ε 9,000); 250 mμ (ε 36,500). $\lambda_{max.}^{0.1\ N\ NaOH}$ 400–392 mμ (ε 9,972); 358–332 mμ (ε 8,976); 252 mμ (ε 39,060). Due to sparing solubility of the compound in 0.1 *N* HCl, the cationic spectra of the compound could not be taken.

Anal.—Calcd. for $C_{13}H_{12}N_4O_2$: C, 60.93; H, 4.68; N, 21.87. Found: C, 60.96; H, 4.99; N, 21.75.

3 - Methylamino - 6,7 - dimethylquinoxaline - 2-carboxylic Acid (V)—To a suspension of III (300 mg., 0.0012 mole) in 2-methoxyethanol (30 ml.) was added 50 ml. of 10% aqueous sodium hydroxide. The mixture was refluxed for 52 hr. with stirring. A white amorphous solid appeared which was filtered after cooling. The filtrate was concentrated to one-third of its original volume and then acidified with excess concentrated hydrochloric acid, whereupon a white precipitate was formed. Without separation, the mixture was further concentrated, under reduced pressure to dryness. The residue was then extracted in a Soxhlet apparatus with a chloroform–benzene mixture (3:1 v/v) until no more colored material was eluted by the solvent (about 15 hr.). The yellow solution was evaporated to dryness and the residue was extracted with boiling ether. The hot ether extract was filtered and evaporated to dryness. The residue was dissolved in minimum quantity of methanol, and crystallized at 0°, to yield an orange-colored solid (50 mg., 18%), m.p. 172–175°. Ultraviolet $\lambda_{max.}^{0.1\ N\ HCl}$ 400 (ε 6,650); 340 mμ (ε 8,529); 252 mμ (20,900). $\lambda_{max.}^{EtOH}$ 405mμ (ε 4,650); 315 mμ (ε 4,620); 258 mμ (ε 27,900). Infrared $\nu_{max.}^{KBr}$ (cm.$^{-1}$): 3400(s) (OH, NH); 2920 (m) (CH_3); 2700 (vw); 1720(s) (C=O); 1660, 1620(w) (NH); 1570(s), 1535(sh), 1510(m) (aromatic C=C, C=N); 1460 (m) (C—CH_3); 1400(m) (COOH); 1370(m) (C—CH_3); 1345(s) (C—N); 1290(w) (COOH); 1240(m), 1100(m), 1000(m) (ring-vibrations); 835 (benzene-C—H). NMR (in CF_3COOH): 2.15, 3.10, 7.3, and 7.7 p.p.m. Integrated ratio: 6:3:1:1 (2 benzene-CH_3, 1 N—CH_3, 1 + 1 benzene ring-protons).

Anal.—Calcd. for $C_{12}H_{13}N_3O_2$: C, 62.33; H, 5.63; N, 18.18. Found: C, 62.16; H, 5.89; N, 17.91

2 - Amino - 4 - imino - 1,6,7 - trimethyl - 3,4 - dihydrobenzo(g)pteridinium Iodide (VI)—To nitromethane (75 ml.) was added, under continuous stirring, 2,4-diamino-6,7-dimethyl(*g*)benzopteridine (*a*) (500 mg., 0.00207 mole), and this was followed by dropwise addition of methyl iodide (3.0 ml., 0.059 mole). The mixture was refluxed for 3–4 hr. (during which time its color turned black) and, while still hot, filtered through a diatomaceous earth[2] bed. From the red filtrate the solvent was removed on the flash evaporator, and the residue was taken up in boiling methanol. The hot methanolic solution was treated with charcoal (Darco) and filtered through a diatomaceous earth bed. On concentrating the solution to about 30 ml., red micro-needles separated out; yield, 250 mg. (32%), m.p. 360°. This was further purified by repeated crystallization from the same solvent. $\lambda_{max.}^{0.1\ N\ HCl}$ 460 mμ (ε 2,188); 372 mμ (ε 12,880); 260 mμ (ε 41,690); 220 mμ (ε 35,480). $\lambda_{max.}^{EtOH}$ 460 (ε 4200); 394 mμ (shoulder; ε 11,140); 358 mμ (ε 13,050); 258 mμ (ε 38,200); 219 mμ (ε 45,000).

Anal.—Calcd. for $C_{13}H_{15}IN_6$: C, 40.83; H, 3.92; N, 21.99. Found: C, 40.82; H, 4.09; N, 21.88.

2,4 - Diimino - 6,7 - dimethyl - 1,2,3,4 - tetrahydrobenzo(g)pteridine Hydrochloride (VII)—The quaternary iodide (VI) (450 mg., 0.0012 mole) was dissolved in hot water, and the red solution was added at room temperature to a 0.5 *N* aqueous sodium hydroxide solution (50 ml.) at room temperature. Immediately a red solid precipitated. The reaction mixture was cooled in the refrigerator overnight, then centrifuged, and the clear supernatant was decanted. The residue was washed with one portion of cold water and centrifuged, then added to ice cold 6 *N* HCl (50 ml.); on further cooling in an ice bath, a solid separated out. After filtration, the residue was dissolved in methanol, the solution was charcoaled, and the resulting yellow filtrate was concentrated in the flash evaporator to about 25 ml., whereupon a yellow solid began to separate at room temperature. This was collected by filtration (100 mg., 29%) and further purified by repeating the same process, until an analytically pure sample was obtained.

Anal.—Calcd. for $C_{13}H_{14}N_6 \cdot HCl$: C, 53.70; H, 5.16; N, 28.91. Found: C, 53.42; H, 5.40; N, 28.93.

Conversion of VII to Free Base—Sixty milligrams (0.0002 mole) of VII was dissolved in water (15 ml.), without heating. To the cold aqueous solution, 10% aqueous sodium carbonate solution was added until the solution became neutral to litmus. A red precipitate separated immediately after addition. This was centrifuged, washed thoroughly with water, and then with a minimum quantity of acetone. The crude residue was then dissolved in boiling methanol and treated with charcoal. The yellow filtrate (which showed green fluorescence) was concentrated, until a yellowish-green solid separated. This was further purified by repeated crystallizations from methanol. $\lambda_{max.}^{0.1\ N\ HCl}$ 364 mμ (ε 10,910); 259 mμ (ε 33,400). $\lambda_{max.}^{EtOH}$ 422 mμ (ε 9,612); 355–340 mμ (ε 7,600); 258 mμ (ε 34,370). In some preparations, the 422 mμ absorption of the ethanolic solution was partially or wholly shifted to 390–400 mμ, and the spectrum of the product was similar to the "normal" spectrum of III (see above) in absolute ethanol as well as in 0.1 *N* HCl.

Structure Determination of Compounds Derived from the Reaction in Nitromethane—*Acid Hydrol-*

[2] Celite. Johns-Manville Corp., New York, N. Y.

ysis of VII—The hydrochloride salt (VII) (100 mg., 0.00034 mole) was mixed with 2-methoxyethanol (50 ml.), and concentrated hydrochloric acid (10 ml.) was added. The mixture was refluxed for 36 hr., during which time additional quantities (5 ml.) of concentrated hydrochloric acid were added, after 8 hr. and again after 14 hr. Initially the color of the solution was light brown; on heating for 7–8 hr., some solid separated and the color of the solution turned yellow. On continued heating, the solid dissolved and the solution turned deep brown in color. After evaporation to dryness, the residue was boiled with water for 20 min. and filtered. The residue (35 mg., 40%) was thoroughly washed with acetone and crystallized from ethanol, m.p. 295–296°. $\lambda_{max.}^{EtOH}$ 390 mμ (ε 8,772); 334 mμ (ε 8,772); 250 mμ (ε 36,600).

Anal.—Calcd. for $C_{13}H_{12}N_4O_2$: C, 60.93; H, 4.68; N, 21.87. Found: C, 61.39; H, 5.04; N, 21.97.

Alkaline Hydrolysis of VII—This was conducted in the same manner as described in the preparation of IV from III. $\lambda_{max.}^{EtOH}$ identical with acid hydrolysis product.

Alkaline Hydrolysis of VI—The quaternary methyl iodide (VI) was hydrolyzed, in the same manner, and the product obtained showed the same spectrum as the acid and base hydrolysis products from VII above.

Thin-Layer Chromatography—The above compounds obtained from VII by acid and alkaline hydrolysis, respectively, were compared with IV (obtained by alkaline hydrolysis of III) by simultaneously conducted thin-layer chromatography, using alumina as the adsorbent and dimethylformamide–water (9:1) mixture as the solvent. Each compound gave a single fluorescent spot under ultraviolet light, corresponding to an R_f value of 0.55

Lawsone Derivatives IV. 3-ω-Substituted Alkyllawsones and Related Compounds

By H. MACHATZKE, W. R. VAUGHAN*, C. L. WARREN, and G. R. WHITE

This paper reports the preparation of two 3-alkyllawsones in which there is a nitrogen mustard function in the ω-position. In addition, a potentially general route to the preparation of 3-ω-aminoalkyllawsones is described. The method involves introduction of an ω-amino group *via* an ω-azido group.

THE OBJECTIVES of this continuing research have been discussed in a previous paper (1), and the purpose of the present paper is to report preparation of lawsones (2-hydroxy-1,4-naphthoquinone) with 3-alkyl substituents terminating in an alkylating function. In addition, the development of a potentially general route to preparation of 3-ω-aminoalkyllawsones has been studied, and various ancillary problems have been delineated.

Two related series of lawsone derivatives have been investigated: one in which the 3-position carries a normal pentyl chain terminating in a functional group (general structural formula I, in which lower case letters refer to known starting materials involved in synthesis); and one in which the 3-position carries a normal decyl chain terminating in a functional group (general structural formula II, with notation as for I).

DISCUSSION

Series I—In this series the preparation of methyl 6-(2-methoxy-1,4-naphthoquinon-3-yl)hexanoate (I*A*) and of 6-(2-hydroxy-1,4-naphthoquinon-3-yl)hexanol are trivial, the former involving boron trifluoride-etherate catalyzed trans-methylation of I*a* (1) followed by treatment with dimethyl sulfate of the sodium salt; and the latter involving lithium aluminohydride reduction of I*a* followed by silver oxide oxidation.

However, the preparation of *N,N*-bis(2-chloroethyl)-6-(2-hydroxy-1,4-naphthoquinon-3-yl)hexanamide (I*D*) from *N,N*-bis(2-hydroxyethyl)-6-(2-hydroxy-1,4-naphthoquinon-3-yl)hexanamide (I*C*) proved singularly difficult. In the first place treatment of I*a*, I*b*, and I*c* with varying amounts of diethanolamine afforded in each case a product resembling that expected, but in no instance could an analytically satisfactory sample be obtained owing to the high polarity and hydrophilic character of the material. The general appearance and physical characteristics of the products obtained from I*a*, I*b*, and I*c* were invariably the same, the reported procedures being typical of many runs of each. And while no absolute proof of structure is available, the fact that the infrared spectra of all products correspond in the significant bands, which in turn are favorably comparable to those in the infrared spectra of 6-(2-hydroxy-1,4-naphthoquinon-3-yl)-hexanamide and I*D*, strongly suggests that one obtained I*C* from any of the reported procedures in comparable yield and purity. Unquestionably, the difficulty in converting I*C* to I*D* was a consequence of the difficulty of obtaining analytically pure I*C*. However, in one instance one of the authors (H. M.) was able to effect the conversion by treating a sample of I*C* with thionyl chloride.

Series II—In this series the preparation of the first two members was a relatively simple matter. But is is interesting to note that intended methanesulfonation of the decanol, II*a* (1) surprisingly resulted in simultaneous *methylation* of the 2-hydroxyl group when the reaction was carried out under very mild conditions (methanesulfonyl chloride and excess pyridine in dry benzene at room temperature), giving 10-(2-methoxy-1,4-naphthoquinon-3-yl)decyl methanesulfonate (II*A*). There can be no question of the structure, since the infrared spectrum lacks hydroxyl absorption, the NMR spectrum shows *O*-methyl as well as *S*-methyl, and II*A* is insoluble in alkali, retaining its color rather than turning red, as do free lawsones.

No problems were encountered in the reaction of the decanol (II*a*) with *N,N*-bis(2-chloroethyl)-carbamoyl chloride (2) in pyridine to give *N,N*-bis(2-chloroethyl)-10-(2-hydroxy-1,4-naphthoquinon-3-yl)decyl carbamate (II*B*).

The remaining compounds in this series constitute the culmination of an exhaustive series of attempts to introduce an amine function bonded to carbon at the terminus of a 3-alkyl chain in lawsone. It was originally intended to use the decyl bromide (II*b*) (3) as a substrate for reaction with diethanolamine or bis(2-chloroethyl)amine; and when these two amines failed to give characterizable products, ammonia was also tried, with equally unsatisfactory results. Certainly these failures are attributable in part to complex additions to the lawsone system, such as are described in the preceding paper in this series.

Confronted with this discouraging experience, the authors turned their attention in the final phases of the study to preparation of 10-(2-hydroxy-1,4-naphthoquinon-3-yl)decylamine, which was actually isolated as its acetate salt (II*D*) and was characterized as such and as its acetyl derivative (II*E*). The availability of II*D* should permit future study of methods for *N*-hydroxyethylation and *N*-chloroethylation of ω-(2-hydroxy-1,4-naphthoquinon-3-yl)alkylamines, especially since there is no *a priori* reason why the authors' method of synthesis for II*D* should not be general.

By contrast with wholly unsuccessful attempts to obtain ω-(2-hydroxy-1,4-naphthoquinon-3-yl)alkylamines by various reduction processes applied to amides, notably by means of complex metal hydrides, the route involving reaction of the decyl bromide II*b* with azide ion, followed by hydrogenation was relatively straightforward. The only problem was in preparation of 10-(2-hydroxy-1,4-naphthoquinon-3-yl)decyl azide (II*C*) which had to be carried out in *N,N*-dimethylformamide using lithium azide instead of the more conventional sodium azide-methanol reaction, which led to recovery of unchanged II*b*. Reduction of II*C* to II*D* was achieved by hydrogenation at 3 Atm. over Adams' catalyst, followed by air oxidation, and the product proved to be an extremely stable acetate salt, which could readily be converted to the acetamide (II*E*).

EXPERIMENTAL[1]

Methyl 6-(2-hydroxy-1,4-naphthoquinon-3-yl)-hexanoate—In an attempt to methylate the free hydroxyl group of I*a*, 5.1 Gm. (16.1 mmoles) of this ethyl ester was dissolved in 100 ml. of methanol, and 12 ml. of boron trifluoride-etherate was added. The mixture was held at 70°, with stirring, overnight and then was held at 75–80° for 24 hr. Evaporation to dryness under reduced pressure left a yellow solid, m.p. 79–83°, and recrystallization from petroleum ether (b.p. 60–75°) raised this to 88–90°. Some 85% of this transesterified material was recovered in all.

Methyl 6-(2-methoxy-1,4-naphthoquinon-3-yl)-hexanoate IA—A sodium salt was prepared by adding 297 mg. of sodium (12.9 mmoles) to a solution of the above compound (3.9 Gm., 12.9 mmoles)

[1] Melting points uncorrected. Kofler block method indicated where used. Microanalyses by Spang Microanalytical Laboratory, Ann Arbor, Mich. Infrared spectra of Nujol mulls obtained with Perkin-Elmer model 21 double beam spectrometer. NMR spectra obtained with Varian A-60 spectrometer, 60 Mc., internal TMS reference. We are indebted to Mr. B. E. Wenzel, Mr. Günter Schütze, and Mr. Frank Parker for preparation of most of these spectra.

in 40 ml. of methanol, and the resulting red solution was evaporated to dryness under reduced pressure.

The red sodium salt was heated to 120–130° and treated, with stirring, with 1.64 Gm. (13 mmoles) of dimethyl sulfate. Some yellowing was noted, and more dimethyl sulfate (1.64 Gm., 13 mmoles) was added. After about 1 hr. all red color had disappeared, leaving a brown-yellow reaction mixture. Dilution with water (10 ml.) and addition of 10 ml. of saturated sodium carbonate solution resulted in production of the previous dark red color. Next 60 ml. of 5% hydrochloric acid and 6 ml. of concentrated hydrochloric acid was added and the mixture was extracted with chloroform. After drying (magnesium sulfate), filtration, and evaporation, there was left an oil which crystallized on being triturated with petroleum ether (b.p. 40–60°). Recrystallization from petroleum ether (b.p. 60–75°) afforded 2.339 Gm. (60%) of starting material (infrared spectrum and m.p.).

The mother liquor was concentrated and cooled to −5°, whereupon yellow needles precipitated, m.p. 43°. Recrystallization from the same solvent raised the m.p. to 47° and finally to a constant 57° (805 mg., with an additional 815 mg., m.p. 55° obtained as a second crop: 40% total). The infrared spectrum showed no hydroxyl absorption.

Anal.—Calcd. for $C_{18}H_{20}O_5$: C, 68.34; H, 6.37. Found: C, 68.46; H, 6.52.

6 - (2 - Hydroxy - 1,4 - naphthoquinon - 3 - yl)-hexanol (IB)—To a vigorously stirred suspension of lithium aluminohydride (LAH) (0.57 Gm., 15 mmoles) in 25 ml. of tetrahydrofuran (THF) (distilled from LAH) was added a solution of 3.16 Gm. (10.0 mmoles) of I*a* (1) in 25 ml. of similarly dried THF. Residue of *Ia* was washed into the reaction vessel with an additional 10 ml. of dry THF, and the brownish-red mixture was refluxed for 4 hr. and then cooled to 0°. Next, 6 ml. of ice water was added followed by 26 ml. of 6 *M* hydrochloric acid. Extraction with three 25-ml. portions of ether followed, and the combined ethereal extracts were vigorously stirred with 3.47 Gm. (15 mmoles) of freshly precipitated silver oxide. The mixture was then dried over anhydrous magnesium sulfate and filtered. Removal of the ether under reduced pressure left 2.73 Gm. of a dark brown solid, m.p. 86–87°, which was purified by digestion with three 200-ml. portions of petroleum ether (b.p. 90–100°) on the steam bath. The extracts were combined and evaporated under reduced pressure leaving a solid which was recrystallized from benzene to give 1.24 Gm. (45%) of *IB*, m.p. 103.5–104.0°. The infrared spectrum is appropriate for *IB:*

Anal.—Calcd. for $C_{16}H_{18}O_4$: C, 70.05; H, 6.61; mol. wt., 274. Found: C, 69.99; H, 674; mol. wt., 265.

An additional 0.30 Gm. (11%) of less pure *IB*, m.p. 98°, was slowly deposited from the mother liquor.

N,N - Bis(2 - hydroxyethyl) - 6 - (2 - hydroxy-1,4-naphthoquinon-3-yl)hexanamide (IC)—(*a*) From ethyl 6-(2-hydroxy-1,4-naphthoquino-3-yl)hexanoate (I*a*) (1). A mixture of 0.64 Gm. of I*a* (2 mmoles) and 0.22 Gm. (2 mmoles) of diethanolamine in 10 ml. of ethanol, with which 6 mg. of sodium had been allowed to react, was heated in a sealed tube for 3 hr. at 160°. The product, a dark red tar, was taken up in 30 ml. of chloroform at 65°, concentrated and then chromatographed on Florosil (10 × 2-in. column). After elution of traces of a pale yellow band and a broad pink band (with chloroform), further eluates obtained with chloroform and then methanol possessed infrared spectra comparable in most respects to that of *IC* obtained from I*c* (below). (*b*) From 6-(2-hydroxy-1,4-naphthoquinon-3-yl)hexanoyl chloride (I*b*). A solution of I*b* (1.06 Gm., 0.35 mmoles) and diethanolamine (4.0 Gm., 38 mmoles) in 10 ml. of toluene was stirred with refluxing for 15 hr. Next 45 ml. of concentrated hydrochloric acid was added, and the lower layer was continuously extracted with ether for 24 hr., the original toluene being part of the extraction medium. Evaporation of the filtered red organic extracts left a deep red solid possessing an infrared spectrum comparable in most respects to that of *IC* obtained from I*c* (below). (*c*) From the macrolactide (I*c*). A mixture of 1.0 Gm. of I*c* and 5 ml. of diethanolamine was heated at 100–150° for 2 hr. and then was allowed to stand overnight at room temperature. Next the solution was filtered, acidified with excess hydrochloric acid, and continuously extracted with ether. The ethereal extract was then diluted with 20 ml. of methanol and dried over anhydrous magnesium sulfate. Filtration and removal of the solvent left a red oil whose infrared spectrum possessed the expected characteristic bands for *IC:* (Nujol) 3400–3160; 1740 (shoulder); 1732–1720; 1672; 1650; 1640; 1600; 1470; 1440; 1372; 1280; 1220; 730 cm.$^{-1}$ In no case could *IC* be obtained sufficiently pure for satisfactory analysis.

N,N - Bis - (2 - chloroethyl) - 6 - (2 - hydroxy - 1,4-naphthoquinon-3-yl)hexanamide (ID)—The crude product from the previous experiment was dissolved in 10 ml. of absolute chloroform and treated with 2 ml. of thionyl chloride at ice-bath temperature with subsequent stirring for 2 hr. at room temperature. Next the excess thionyl chloride was removed by evaporation *in vacuo* followed by two additions and vacuum distillations of benzene. The residual red gum was taken up in chloroform and diluted with dry ether, whereupon yellow crystals separated (0.30 Gm.), m.p. 111–112° (Kofler). The infrared spectrum is consistent for *ID*.

Anal.—Calcd. for $C_{20}H_{23}Cl_2NO_4$: C, 58.20; H, 5.63; Cl, 17.20; N, 3.39. Found: C, 58.33; H, 5.80; Cl, 17.06; N, 3.50.

Numerous attempts to repeat this procedure using I*c* from *a*, *b*, and various modifications of *c* were unsuccessful.

10 - (2 - Methoxy - 1,4 - naphthoquinon - 3 - yl)-decyl methanesulfonate (IIA)—A solution of 2.2 Gm. of II*a* [10-(2-hydroxy-1,4-naphthoquinon-3-yl)-decanol (2)] (6.7 mmoles) and 2.3 Gm. (20 mmoles) of methanesulfonyl chloride in 10 ml. of dry benzene containing 5 ml. of dry pyridine was stirred for 8 hr. at room temperature. The solvent was distilled off and the residue taken up in ether and filtered. The ether solution was washed with dilute hydrochloric acid and water and dried over anhydrous magnesium sulfate. Removal of the ether left a yellow oil which was dried *in vacuo* over phosphorus pentoxide. After 4 days, the oil crystallized and then was recrystallized from acetone–water: (2.0 Gm.), m.p. 57–58° Kofler.

Anal.—Calcd. for $C_{22}H_{30}O_6S$: C, 62.53; H, 7.16; S, 7.59. Found: C, 62.12; H, 7.14; S, 7.51.

The infrared spectrum shows no hydroxyl absorption. Treatment with 5% sodium hydroxide at room temperature resulted in no observable color change, although on prolonged standing (over 30 min.) the compound slowly became dark red. The NMR spectrum (in trifluoroacetic acid, 60 Mc.) shows a 4-proton complex multiplet centered at $\sim\tau = 2$, a multiplet integrating for 8 protons at $\tau = 5.85$–6.30 which may be assigned to CH_3O—, CH_3SO_3—, and —CH_2O—. The next band is a broad unresolved multiplet centered at $\tau = 7.20$ (two protons, —CH_2– adjacent to the quinone nucleus), and finally there is a 16-proton multiplet centered at $\tau = 8.60$ (remaining methylenes).

N,N - Bis(2 - chloroethyl) - 10 - (2 - hydroxo - 1,4-naphthoquinon-3-yl)decyl carbamate (IIB)—A solution of 1.7 Gm. (5 mmoles) of II*a* and 0.95 Gm. (5 mmoles) of *N,N*-bis(2-chloroethyl)carbamyl chloride (2) in 5 ml. of pyridine was stirred at room temperature for 8 hr. during which time pyridine hydrochloride precipitated. Water was then added and the mixture was acidified with hydrochloric acid and extracted with ether, the ethereal extracts being washed with water and dried over anhydrous magnesium sulfate. Evaporation of the ether left a yellow oil which was taken up in methanol–water and deposited yellow crystals on being cooled. These were dried over phosphorus pentoxide: 2.2 Gm., m.p. 57–58° Kofler; recrystallized from methanol, m.p. 60–61° Kofler.

Anal.—Calcd. for $C_{25}H_{33}Cl_2NO_5$: C, 60.24; H, 6.67; N, 2.81. Found: C, 60.59; H, 6.79; N, 2.48. The infrared spectrum shows a broad absorption for hydroxyl.

10 - (3 - Hydroxy - 1,4 - naphthoquinon - 3 - yl)-decyl Azide (IIC)—To a stirred solution of II*b* [10-(2-hydroxy-1,4-naphthoquinon-3-yl)decyl bromide (3)] (1.95 Gm., 5.0 mmoles) in 60 ml. of dry anhydrous magnesium sulfate], distilled *N,N*-dimethylformamide (DMF) there was added lithium azide. This was prepared from 6.5 Gm. (0.1 mmole) of sodium azide and 7.05 Gm. (0.055 mmole) of lithium sulfate monohydrate dissolved in 35 ml. of warm water, followed by slow addition of 95% ethanol (175 ml.). Sodium sulfate was filtered off and evaporation of the filtrate under reduced pressure at 80° afforded a yellowish solid which was dried azeotropically with benzene and then used without further purification (4). The reaction mixture, a red solution, was stirred at 95–100° for 16 hr. (5) and then evaporated under reduced pressure to a dark red gum. To this was added 100 ml. of water followed by 10 ml. (excess) concentrated hydrochloric acid (pH = 2 at end of addition). The mixture was then extracted with ether (100 ml. then five 25-ml. portions). Evaporation of the dried (anhydrous magnesium sulfate), filtered ethereal extracts and recrystallization of the yellow residue from petroleum ether (b.p. 60–75°) afforded 1.57 Gm. (94%) of II*C*, m.p. 80.5°.

Anal.—Calcd. for $C_{20}H_{25}N_3O_3$: C, 67.58; H, 7.09; N, 11.82. Found: C, 67.48; H, 7.11; N, 11.96.

10 - (2 - Hydroxy - 1,4 - naphthoquinon - 3 - yl)-decylamine Acetate Salt (IID)—A 2.02-Gm. (5.70 mmoles) sample of II*C* suspended in 200 ml. of absolute ethanol containing 0.25 Gm. of Adams' catalyst was shaken for 19 hr. under 50 p.s.i. of hydrogen. No pressure drop was observed, but a red solid precipitated. This was filtered off and washed with glacial acetic acid until the washings were colorless. The experiment was repeated, and the combined ethanolic acetic acid filtrates were oxidized by bubbling an air stream through the solution for 3 days, by which time the solvent had evaporated leaving an intense red solid, m.p. 190–195°. This was dried over solid sodium hydroxide: 4.093 Gm. (97.5% $B \cdot HO_2CCH_3$).

The product was dissolved in glacial acetic acid, precipitated by addition of water, and collected by centrifugation to give an intensely crimson product, m.p. 196°, with darkening above 185°.

Anal.—Calcd. for $C_{22}H_{31}NO_5$: C, 71.52; H, 8.43; N, 3.79. Found: C, 71.81; H, 8.09; N, 3.87.

***N* - 10 - (2 - Hydroxy - 1,4 - naphthoquinon - 3-yl)decylacetamide (IIE)**—A 426-mg. sample of I*D* was added to 10 ml. of glacial acetic acid to give an orange solution. Next, 1.50 ml. of acetic anhydride was added and the mixture was stirred at room temperature for 2 hr. during which time a yellow precipitate appeared. The mixture was then held at −5° for 2 hr. during which time the color of the precipitate changed. Filtration afforded a pale primrose solid (*A*) (315 mg., m.p. 146°). This was washed with 10 ml. of glacial acetic acid and the filtrate and washings were diluted with water to give 185 mg. of orange solid (*B*) (m.p. 144°).

Both of the products were recrystallized from ethanol-water, the former affording a pale primrose substance softening >140°, m.p. 150° (*A*) and the latter a yellow solid softening >137°, m.p. 146–147° (*B*), and both analyzed correctly for II*E*.

Anal.—Calcd. for $C_{22}H_{29}NO_4$: C, 71.13; H, 7.87; N, 3.77; mol. wt., 371. Found (*A*): C, 70.51, 70.78; H, 7.84, 7.95; N, 4.00; mol. wt., 367, 371. Found (*B*): C, 70.50, 70.76; H, 7.84, 7.94; N, 3.82; mol. wt., 380, 378.

Chromatographic Methods for Analysis of the Metabolites of Acetophenetidin (Phenacetin)

By A. KLUTCH* and M. BORDUN†

A simple, specific means has been developed for routine analysis of *N*-acetyl-*p*-aminophenol and the other possible metabolites of acetophenetidin in the urine of animals given the drug. The analytical procedures fell into two parts: (*a*) the choice of solvent and pH for extraction and (*b*) the most suitable solvent system for thin-layer chromatography and a selective means for visualization of the compound being assayed. Gas chromatographic separations have also been developed for the analysis of the metabolic transformation products of acetophenetidin.

THE METABOLISM of acetophenetidin[1] has been well studied in man and other animals. It has been shown that most of the dose of acetophenetidin can be accounted for as *N*-acetyl-*p*-aminophenol[2] and its conjugates (1–3). Chemical methods have been developed for the analysis of this phenol in the physiological fluids of animals given acetophenetidin (1, 4).

In the course of studies on the metabolism of acetophenetidin in these laboratories, selective chromatographic methods have been developed for the estimation of the various possible transformation products of acetophenetidin present in urine or other biological material. The advantage of these chromatographic methods is their sensitivity and specificity for a compound present in a multicomponent mixture, but they are not as precise as the chemical methods described. The compound to be estimated is first extracted from buffered solution with a suitable solvent and then subjected to analysis by thin-layer chromatography. More recently, gas chromatographic separations have been developed for more accurate quantitation of the metabolites of acetophenetidin.

MATERIALS AND METHODS

Chemicals—Phenetidin as the free base or the hydrochloride salt was obtained from the Aldrich Chemical Co., Inc., Milwaukee, Wis. *p*-Aminophenol as the free base or the hydrochloride salt was obtained from K and K Laboratories, Inc., Plainview, N. Y. *N*-Acetyl-*p*-aminophenol was supplied by Eastman's Distillation Products Industries, Inc., Rochester, N. Y. 2-Hydroxyacetophenetidin was synthesized in these laboratories by Harfenist (5). Acetophenetidin (Burroughs Wellcome & Company, Tuckahoe, N. Y.) and *N*-hydroxyacetophenetidin were used.[3] All the solvents used were of reagent grade.

Animal Experiments—Acetophenetidin was administered orally in gelatin capsules to 2 adult dogs (8.2 Kg. and 10.2 Kg.) at a level of 100 mg./Kg. for 1 day. A human subject *A* received 420 mg. of acetophenetidin for 1 day. Human subject *B* received 1.8 Gm./day of acetophenetidin for 4 days. Human subject *C* received 1.8 Gm./day of *N*-acetyl-*p*-aminophenol for 4 days. Collections of urine were made for 24-hr. periods during the administration of drugs to dogs and human subject *A*. Urine was collected for the first day (the acute sample) and the fourth day (the chronic sample) of drug administration to human subjects *B* and *C*. Urine collected for the 24-hr. period prior to drug administration was used as control urine.

TABLE I—CHROMATOGRAPHIC EXAMINATION OF URINE

Compd.	Average $Rf \times 100$, System[a] 1	2	3	4	Detection[b]
Acetophenetidin	94	30	80	82	a
Phenetidin	94	70	96	95	a, b, e
N-Acetyl-*p*-aminophenol	88	0	14	34	a, b, c, d

Determinations—The samples to be used for the analysis of acetophenetidin and phenetidin excreted by dogs were prepared by extracting 4 ml. of urine buffered with 1 ml. of glycine buffer at pH 9 (6) and 0.1 ml. of 1 *N* NaOH, with 30 ml. of carbon tetrachloride. A 25-ml. portion of the organic solvent was removed, evaporated, and dissolved in a few drops of methanol. For the measurement of acetophenetidin and phenetidin excreted by human subjects, 8 ml. of urine was treated with 2 ml. of the glycine buffer, 0.25 ml. of 1 *N* NaOH, and extracted with 60 ml. of carbon tetrachloride. A 50-ml. portion of solvent was taken for analysis. The extracts were examined chromatographically with system 2 described in Table I. Phenetidin and acetophenetidin were visualized with ultraviolet light.

A 0.5-ml. portion of urine to be analyzed for *N*-acetyl-*p*-aminophenol was buffered with 0.5 ml. of 0.2 *N* acetate buffer at pH 5 (6) and treated with 0.5 ml. of diluted glusulase[4] (Endo Laboratories, Inc., Garden City, N. Y.) for 4 hr. at 37.5°. The solution was extracted with 15 ml. of ethyl acetate and portions varying from 1 ml. to 5 ml. were taken for analysis. The sample size depended on the concentration of the phenol in urine. The best quanti-

[1] Phenacetin USP XVII.

[2] Acetaminophen NF XII.

[3] The authors are indebted to Dr. H. C. White, Edgar C. Britton Research Laboratories, Dow Chemical Co., for a supply of *N*-hydroxyacetophenetidin.

[4] To each ml. of glusulase, 1.5 ml. of the acetate buffer was added.

tative results were obtained when the sample applied to a thin-layer plate contained from 10 mcg. to 40 mcg. of phenol (urine highly concentrated with the compound was diluted prior to hydrolysis). After evaporation of the solvent, the residue was dissolved in a few drops of methanol. The *N*-acetyl-*p*-aminophenol was analyzed chromatographically with system 4 described in Table I. The Pauly Reagent (7) was used to visualize the compound.

The analysis for 2-hydroxyacetophenetidin excreted by dogs required hydrolysis of 1 ml. of urine with 1 ml. of the diluted glusulase and 1 ml. of the acetate buffer at pH 5. After hydrolysis, the urine was extracted with 30 ml. of a carbon tetrachloride–methylene chloride (3:1) mixture, and 25 ml. of the solvent mixture was removed. After evaporation of the solvent, the resulting residue was dissolved in a few drops of methanol and examined chromatographically. For the human studies, twice the amounts described above were taken for analysis. The quantification of the hydroxylated acetophenetidin was carried out with system 3 (Table I) and diazotized *o*-dianisidine (8).

To determine the *N*-hydroxyacetophenetidin excreted by human subjects, 4 or 5 ml. of urine was mixed with an equal volume of the acetate buffer and hydrolyzed with 2 ml. of glusulase (nondiluted reagent). The *N*-hydroxy compound was extracted from the hydrolyzed urine with 60 ml. of carbon tetrachloride and a 50-ml. portion of the solvent was taken for analysis. For the hydrolysis of 1 ml. of dog urine, 1 ml. of the acetate buffer and 0.5 ml. of glusulase were added to the urine and 15 ml. of solvent was used to extract the *N*-hydroxyacetophenetidin after hydrolysis. Chromatographic measurements were made on the residue (dissolved in methanol) obtained after evaporation of 10 ml. of solvent, using system 1 (Table I). *N*-Hydroxyacetophenetidin was visualized with ultraviolet light.

Urines obtained prior to drug administration were used as control samples and were treated similarly in all of the above analyses. The reference standards used in the analysis consisted of the appropriate compound added to control urine. Several concentrations, approximating the value of the experimental sample, were made by dissolving the compound in the acetate buffer at pH 5 or glycine buffer at pH 9 and mixing this solution with the urine before hydrolysis or extraction. Standards dissolved in the buffer could be stored at 5° for a reasonable amount of time, but care was taken never to freeze the solutions because of the extremely low solubilities in aqueous solution at the freezing point of most of the above compounds.

Thin-Layer Chromatography—Thin-layer plates were prepared from aluminum oxide GF[5] using techniques previously described (8).

Gas Chromatography—Synthetic mixtures of the above compounds were analyzed on a Barber-Coleman model 10 gas chromatograph equipped with a Sr-90 detector. The inlet pressure was 30 psig for the 6-ft. columns and 25 psig. for the 4-foot columns; the carrier gas was argon. The outlet pressure was atmospheric. The column packings[6] were a mixture of SE-30 (1%)–Carbowax 20M (1%) coated on Anakrom AS, 80–90 mesh, packed in a U-shaped, glass column, 6-ft. in length and 5 mm. i.d., or an SE-30 (0.5%)–Carbowax 20 M (0.5%) mixture on the same support in a column 4-ft. in length and 3.5 mm. i.d.

The instrument was operated isothermally at 180° for the 6-ft. column and at 190° for the 4-ft. column. The detector temperature was always 225° and the temperature of the flash heater was 240°. The samples dissolved in ethyl acetate varied from 0.1 to 0.5 mcg. The retention times are given in Table III.

RESULTS AND DISCUSSION

The analysis for these metabolites in physiological fluids can be accomplished easily using the techniques described. Urines being analyzed for a hydroxylated derivative of acetophenetidin were first subjected to enzymatic hydrolysis to liberate conjugates. All the analyses required the adjustment of the urine to a particular pH value, and a specific organic solvent or solvent mixture was used for extraction. After evaporation of the organic solvent, the residues obtained were chromatographed in one of the solvent systems described in Table I.

The chromatographic systems described appear to be effective in separating several of the reference compounds. However, because of the great differences in the concentrations of the metabolites in the urine and the presence of contaminating substances, a specific system was developed to assay only one particular metabolite. After spraying the developed thin-layer plates, the determinations were made by visual comparison with standards. For precise quantitation, the concentrations of the standards run with each experiment were close to that of the experimental value. These methods have been applied successfully to the analysis of the metabolites of acetophenetidin in the urines of animals treated with the drug or *N*-acetyl-*p*-aminophenol, and the results are given in Table II; the range of the results given in parentheses indicate that this method is not as precise as the methods reported previously, but it is within the usual biochemical variation.

The sensitivities of the methods are given at the bottom of the table. They were not calculated as dose percentages because of the variation in dosages given and urine volumes. The results for the estimation of unchanged acetophenetidin in the urines of animals treated with the drug are in agreement with the values (0.15–3%) reported by Brodie and Axelrod. The method for the estimation of *N*-hydroxyacetophenetidin is the least satisfactory of those described in the experimental section. The amounts usually present were only slightly higher than could be detected with ultraviolet light. The spray reagents tried had high background color.[7] Phenetidin could not be detected in the urines of experimental animals even though a concentration as low as 1 mcg./ml. could be detected in reference samples. Unconjugated *p*-aminophenol is not stable in urine and so could not be estimated by a method which would involve hydrolysis of any conjugates present. The results of the chromatographic estimations confirm *N*-acetyl-*p*-aminophenol as the major metabolite of acetophenetidin and the

presence of 2-hydroxyacetophenetidin as a minor metabolite (5).

The results are in rough agreement with the earlier studies which employ more time-consuming and less specific methods. There is also present in the urine of animals given acetophenetidin or *N*-acetyl-*p*-aminophenol small amounts of an unknown metabolite with an R_f of 0.35 in solvent system 3[8] which has been reported previously (5).

The analysis of *N*-acetyl-*p*-aminophenol in the urine of animals treated with the tertiary-butyl analog has been reported (11). In this work these separations have been modified and expanded to include acetophenetidin and the other possible metabolites. The separation of acetophenetidin and the related compounds is shown in Table III.

The separation of acetophenetidin from its *N*-hydroxylated derivatives by gas chromatography has not been achieved. Further investigations are continuing in order to find a gas chromatographic means of separating these compounds so that this method can be applied for the analysis of the metabolites of acetophenetidin in the urine of animals given the drug.

[8] It was determined by comparison of the infrared spectrum of this metabolite with the spectrum of 3-hydroxy-acetophenetidin that this compound is not the 3-hydroxylated metabolite.

Effect of Mescaline on Nicotinamide Adenine Dinucleotide Synthesis in the Central Nervous System

By GLENN D. APPELT*, NORMAN O. WALKER, and ROBERT G. BROWN

Nicotinamide adenine dinucleotide (NAD) synthesis in mouse brain was demonstrated following the intracerebral injection of nicotinamide (500 mg./Kg.). Animals which received mescaline hemisulfate (100 mg./Kg.) 90 min. prior to nicotinamide were found to have higher levels of brain NAD at the 2 and 3 hr. time intervals.

NICOTINAMIDE ADENINE DINUCLEOTIDE (NAD) levels have been increased in various organs of experimental animals by pretreatment with nicotinamide (1–3). Reserpine was found to prolong these levels in rat liver (4), and a similar effect has been demonstrated utilizing mouse brain (5). The participation of NAD in many dehydrogenase systems is well known (5), and alterations in the synthesis or degradation of this coenzyme could conceivably affect metabolic activity in the organism. Since certain psychotherapeutic drugs such as reserpine and chlorpromazine alter NAD metabolism (4), it appeared of interest to examine the effect of a hallucinogenic drug, such as mescaline, on this parameter.

EXPERIMENTAL

Young adult albino mice of both sexes were used as test animals in this study. Two brains were pooled and used for each NAD assay. The preparation of brain extracts was performed according to the method of Ciotti and Kaplan (7). The animals were stunned by a blow to the base of the skull, decapitated, and the whole brains quickly removed, weighed, and transferred to a Ten Broek tissue grinder. Homogenization was then accomplished with 5 vol. of cold 5% trichloroacetic acid. The total homogenate was centrifuged at 2,000 r.p.m. for 5 min., the supernatant liquid shaken with ether, and aliquot portions of the aqueous layer employed in the NAD assays. NAD determinations were made spectrophotometrically at 340 mμ with a Beckman DB spectrophotometer employing an ethanol–alcohol dehydrogenase system (7).

Animals were divided into two groups. Those of the first group received nicotinamide (500 mg./Kg.) intracerebrally in an adaptation of the method of Haley (8). NAD synthesis was demonstrated in the brain tissue by determination of the coenzyme level at various time intervals following the injection of nicotinamide. Animals of the second group received mescaline hemisulfate (100 mg./Kg.) intraperitoneally 90 min. prior to the intracerebral injection of nicotinamide. Determinations of brain NAD content in these animals were conducted at the same time intervals employed in the study of the control group which received only nicotinamide. The values reported represent the mean of at least five NAD determinations. The standard error of the mean was calculated for each set of NAD values and is designated by the vertical line through each point.

In addition, NAD assays were made 30 and 60 min. following the injection of mescaline hemisulfate prior to the intracerebral injection of nicotinamide. NAD measurements were made after intracerebral injections with normal saline in an effort to detect possible nonspecific elevation due to the experimental technique.

RESULTS AND DISCUSSION

Figure 1 illustrates the synthesis of NAD in mouse brain after the administration of nicotinamide. The value at zero time indicates the mean level of NAD before the intracerebral injection of nicotinamide. The brain NAD was not significantly increased until the fourth hour after the nicotinamide reinforcement. The NAD levels remained elevated at the 5 and 6 hr. intervals and then returned to a value comparable to the zero time determination.

Figure 2 shows the brain NAD elevation in experimental animals that received mescaline hemisulfate intraperitoneally 90 min. prior to the intracerebral injection of nicotinamide. These data indicate a greater increase in brain NAD at the 2 and 3 hr. time intervals than was observed in the animals which received only nicotinamide at zero time.

Table I is a summary of the mean values for brain NAD obtained at the various time intervals. Any significant differences in the mean NAD values of the animals receiving only nicotinamide and those which were injected with mescaline before the nicotinamide administration are denoted.

There was no significant change from control values in the brain NAD levels of animals which had received mescaline hemisulfate 30 and 60 min. prior to the determination. The intracerebral adminstration of normal saline did not alter the brain NAD levels.

Bonasera *et al.* (5) have shown that reserpine given

enzymatic activities dependent upon its presence. Clark and co-workers have demonstrated that mescaline inhibits the oxidation of pyruvate by brain homogenates; however, no effect was noted on the activity of succinic dehydrogenase (8). Schueler has reported that mescaline does not alter the oxidation of succinate by rat brain minces (9). A considerable amount of evidence indicates that electron transport in the oxidation of pyruvate involves nicotinamide adenine dinucleotide (5). With succinate as a substrate, however, nicotinamide adenine dinucleotide is not required because the electrons enter the transport system at the flavin nucleotide step. It is conceivable that an alteration in NAD metabolism could be a facet in the mechanism whereby mescaline inhibits pyruvate oxidation by brain preparations. This is an important consideration since the major energy source for the brain is glucose. Although the data indicate that mescaline has some effect on NAD synthesis in the central nervous system, it is not possible at this time to correlate any aberration in NAD metabolism with mescaline activity.

TABLE I—NAD LEVELS, mcg./Gm., IN MOUSE BRAIN

Time, hr.	0	2	3	4	5	6	8

intraperitoneally will delay the peak value of the increase in brain NAD following the administration of nicotinamide intrathecally. In addition, these investigators noted that these values remained elevated for at least 24 hr. after the nicotinamide administration. Earlier, Burton and associates (4) had demonstrated a prolongation of elevated level of liver NAD after nicotinamide administration if animals were pretreated with either chlorpromazine or reserpine.

The NAD values reported in this communication compare favorably with the data available for synthesis of NAD in mouse brain after intrathecal injection of nicotinamide. It is interesting to note that in contrast to the alteration in NAD metabolism effected by reserpine, the apparent changes induced by mescaline indicated an earlier elevation in brain NAD. As in the case of reserpine, the values for the experimental animals receiving mescaline never reached a peak level significantly different from control values of animals receiving only nicotinamide.

Participation of NAD in many dehydrogenase systems is well known and any alteration in the metabolism of this coenzyme could possibly affect

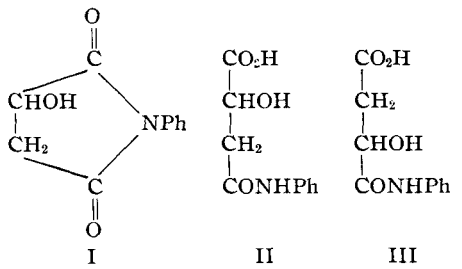
Characterization of Racemic α-Hydroxy- and β-Hydroxysuccinanilic Acids

By ROLF B. PAULSSEN, IAN H. PITMAN, and TAKERU HIGUCHI*

Alkaline hydrolysis of racemic malic acid phenylimide (malanil) yielded two products corresponding to the two possible directions of cleavage. These were shown to be racemic α-hydroxy- and β-hydroxysuccinanilic acid present in the ratio 5:1, the proportion being essentially as expected on the basis of the relative electrophilicities of the respective carbonyl centers.

ALKALINE HYDROLYSIS of DL-malic acid phenylimide (malanil) (I) yielded two isomeric monoanilides of malic acid which had different melting points, ultraviolet spectra, and pKa values. Characterization of these anilides was undertaken so that they could be used as model compounds in an investigation (1) of the anilides formed when aniline was added to a mixture of acetic anhydride in malic acid buffers.

The structures of the anilides were assigned from their pKa values on the basis that the stronger acid would be the one with the hydroxy substituent α to the carboxylic acid function. Thus, the isomer with m.p. 139.5–140.5°; $\lambda_{max.}$ 243 mμ, log ε = 4.06 (in chloroform); pKa = 3.69; was assigned the structure of the α-hydroxy isomer (II), and the isomer with m.p. 149.5–150.5°; $\lambda_{max.}$ = 243 mμ, log ε = 4.12 (in chloroform); pKa = 4.35; was assigned the structure of the β-isomer (III).



I II III

Other examples of the acid-strengthening effect of an α-hydroxy substituent relative to a β-hydroxy substituent include the greater acidity of lactic acid (pKa = 3.86) (2) and ethylmethylglycolic acid (pKa = 3.99) (2) compared to hydracrylic acid (pKa = 4.51) (3) and 2-hydroxy-1-methyl-butyric acid (pKa = 4.65) (2), respectively.

The relative yield of the isomeric hydroxysuccinanilic acids obtained in the alkaline hydrolysis of malanil (I) was [β-hydroxysuccinanilic acid]/[α-hydroxysuccinanilic acid] = 0.2. This is expected as the carbonyl group α to the hydroxy group in malanil is likely to be more electrophilic than the carbonyl group β to the hydroxy group, and thus be more susceptible to attack by hydroxide ions.

Salivary Levels of Antibiotics from Use of Neomycin-Gramicidin Chewing Troches

By F. WERTALIK and R. BONORDEN*

Previous studies demonstrated that a neomycin-gramicidin chewing troche is effective in reducing the oral bacterial flora. The present study shows that this test preparation is highly efficient in terms of the biologic availability of the preparation's antibiotic components.

POST-TONSILLECTOMY hemorrhage due to secondary bacterial infection remains a serious complication. Systemic penicillin prophylaxis does not seem to be effective in improving the appearance of the surgical wound or in hastening healing (1). Several reported studies with a topical antibacterial chewing troche[1] indicate that this preparation has been used successfully in an attempt to control late post-tonsillectomy hemorrhage by preventing secondary local infection (1–6). However, in none of the latter studies was proof of actual reduction in the bacterial count of the oral cavity specifically sought.

More recently, an investigation (7) was undertaken in normal subjects to determine the effectiveness of this antibiotic chewing troche in reducing the oral bacterial flora. The results showed that the use of the chewing troche reduced by 50% the average bacterial count of the oral cavity. The medicated gum had a prolonged effect as evidenced by significant reduction in the oral bacterial counts three hours after chewing.

The present study was conducted in order to determine if chewing gum troches containing neomycin and gramicidin are in actuality an efficient dosage form for releasing into the saliva, over a relatively sustained period of time, significant levels of the antibiotics.

EXPERIMENTAL

Materials and Method—To determine the biologic availability of the neomycin and gramicidin components of the preparation, saliva samples were collected from five subjects over 3 consecutive 5-min. periods, during which each subject chewed one of the antibiotic gum troches. The gum cud was then removed from the mouth, and an unstimulated saliva sample was collected for a fourth 5-min. period. Antibiotic assays were then performed on each of the four saliva samples and on the gum cud. Neomycin and gramicidin assays were conducted according to the methods described by the Food and Drug Administration (8).

Procedure Used for Collecting Saliva—Five graduated 100-ml. beakers, marked S1, S2, S3, cud, and S4, were set before each subject. At the start of the test, each subject placed an antibiotic gum troche in his mouth, which he then chewed for 15 min. The subjects were asked not to swallow any saliva during the course of the test. Saliva was collected during the first 5-min. period in beaker S1. At the end of the 5-min. period, beaker S1 was removed and the second 5-min. salivary sample was collected in beaker S2. This procedure was repeated for the third 5-min. period. Then the chewing gum cud was removed and placed in the appropriately marked beaker. The subject finally collected his unstimulated saliva for an additional 5 min. in beaker S4. (All subjects later repeated the procedure when fresh salivary samples were required for repeat tests.)

Preparation of Saliva and Gum for Neomycin Assay—Preliminary tests using collected saliva indicated that saliva sample No. 1 contained about 3,000 mcg. of neomycin, saliva sample No. 2 about 200 mcg. of neomycin, saliva samples No. 3 and No. 4 less than 10 mcg., and the cud less than 1 mcg. The cud was prepared for assay by first chilling, then breaking into small pieces, then steaming for 5 hr. in 25 ml. of buffer. The suspension was then blended for 2 min. in a blender, filtered, and the filtrate used in the assay.

Preparation of Saliva and Chewing Gum Cud for Gramicidin Assay—Preliminary tests indicated that saliva sample No. 1 contained abut 150 mcg. of gramicidin, saliva sample No. 2 about 4 mcg., and saliva samples No. 3 and No. 4 and the cud approximately 0.8 mcg. The cud was prepared for assay by first freezing under dry ice. The frozen cud was then ground up and suspended in 20 ml. of alcohol. The suspension was steamed for 2 hr., blended for 2 min. in a blender, and filtered. The filtrate was then assayed.

RESULTS

The results of the neomycin assays of the salivary samples and the gum cuds are given in Table I. The mean volumes of saliva collected are also recorded in this table. An average total of 2.6 mg. of neomycin was recovered for the five subjects from the saliva and cud samples. This amounted to 74% of the claimed neomycin content (3.5 mg.). It is assumed that the unrecovered fraction of the neomycin was adsorbed on the mucosal surface of the oral cavity or was lost by swallowing.

As is apparent from the data in Table I, the greatest amount of neomycin was liberated from the chewing gum vehicle during the first 5 min. of chewing.

The results of the gramicidin assays are given in Table II. Volumes of saliva collected are also shown in the same table.

An average total of 171 mcg. of gramicidin was

[a] Approximate values.

recovered from the saliva and cud samples. This amounted to 68% of the claimed gramicidin content of the chewing troche (0.25 mg.). It is assumed, as with the neomycin, that the unrecovered fraction of the gramicidin was adsorbed on the tissues of the oral cavity or was lost by swallowing. As shown by the data summarized in Table II, the greatest amount of gramicidin was liberated from the troche during the first 5 min. of chewing.

SUMMARY AND CONCLUSION

The data indicate that the chewing gum vehicle of the test preparation is highly efficient in terms of the biologic availability of the preparation's antibiotic components. The average amounts of neomycin and gramicidin retained in the gum vehicle after 15 min. of chewing were negligible.

Most of each antibiotic component was liberated during the first 5 min. of chewing. The average amount of neomycin liberated after 15 min. of chewing approximated 74% of the labeled neomycin content of the troche. The average amount of gramicidin assayed from the saliva during the same period was approximately 68% of the labeled gramicidin content of the troche.

The unrecovered fractions of the neomycin and gramicidin were undoubtedly swallowed or adsorbed on the oropharyngeal mucosa. Further, the assay data indicate that, particularly during the first 10 min. of chewing, salivary levels of neomycin and gramicidin were maintained, which far surpassed the inhibitory levels required to suppress the growth of the oral flora.

New Compounds: Synthesis of Some Phosphorus–Nitrogen Compounds for Pharmacological Study II

By A. ABOU-MOUSTAFA and M. KHALIFA

The synthesis of some *N*-substituted derivatives of phosphoric triamide and phosphorodiamidic acid *via* the condensation of phosphorus oxychloride with a number of sulfa drugs is described. Three moles of sulfanilamide, sulfacetamide, sulfapyridine, sulfathiazole, and sulfamerazine condensed with 1 mole of the oxychloride while with sulfisomidine and sulfadiazine 2 moles condensed with the acid chloride. In all the condensation reactions the molecular ratio of the reactants was 2 of the amino compound to 1 of the oxychloride.

IN A PREVIOUS PUBLICATION (1) it was reported that the condensation of phosphorus trichloride with a number of sulfa drugs afforded the *N*-substituted derivatives of phosphorus triamide and phosphorodiamidous acid. In the present investigation the work has been extended to include the phosphoric acid analogs of the previously reported compounds in order that the pharmacological activity of the two series of compounds may be compared. The fact that the phosphoric acid analogs were synthesized by condensing phosphorus oxychloride with the same sulfa compounds offered the opportunity to compare the reactivity of phosphorus trichloride and phosphorus oxychloride in these condensation reactions. With phosphorus trichloride the condensation was complete after 24 hr. except in the case of sulfanilamide where 12 hr. were sufficient. On the other hand, with phosphorus oxychloride a complete reaction was attained after 4 hr. with sulfanilamide and sulfacetamide and after 5 hr. with sulfadiazine, while with the rest of the amino compounds the reaction time never exceeded 12 hr. Moreover, the yields in the condensation reactions in which phosphorus trichloride was used ranged between 20–50%; those in which phosphorus oxychloride was used were much higher, *e.g.*, up to 94% yield was given with sulfapyridine and from 70 to 80% with the rest. In the condensation reactions 8 amino compounds were condensed with each acid chloride. With phosphorus oxychloride six out of the eight condensed in a manner that three molecules of the amino compound condensed with one molecule of the oxychloride. In the case of phosphorus trichloride four out of the eight condensed in this manner. Furthermore, while sulfamerazine failed to condense with phosphorus trichloride, it condensed readily with phosphorus oxychloride affording a 78% yield of the condensation product.

It can be seen from the foregoing that in these condensation reactions phosphorus oxychloride is more reactive than the trichloride.

That the phosphorus atom in the synthesized compounds is linked to the N^4 of the sulfa drug was shown qualitatively by the failure of all the condensation products to diazotize and by their solubility in dilute alkali and their insolubility in dilute mineral acids.

form (20 ml.) to the sulfa compound (0.02 mole) dissolved in the same solvent (150 ml.). For complete reaction the mixture was refluxed 12 hr. in all except with sulfanilamide, sulfacetamide, and sulfadiazine in which case refluxing for 4 and 5 hr. was sufficient. Then the solvent was distilled *in vacuo*, and the residue suspended in dilute hydrochloric acid, filtered, and washed with water until the washings gave a negative chloride test with silver nitrate T.S. The product after being dried was crystallized from the appropriate solvent. (See Tables I and II.)

N,N',N''-tri-β-Naphthylphosphoric Triamide—This compound was prepared by condensing β-naphthylamine with phosphorus oxychloride according to the above general procedure. The product which was obtained in 75% yield melted at 237–238° after being crystallized from aqueous ethanol.

Anal.—Calcd. for $C_{30}H_{24}N_3OP$: N, 8.88 Found: N, 9.07.

N,N',N'' - tri[N - (2 - Pyrimidinyl) - p - sulfamoylphenyl] Phosphorus Triamide—This compound was prepared by condensing sulfadiazine with phosphorus trichloride adopting the general method reported in the previous paper. The product which was obtained in 20% yield melted at 196–200° (255° dec.) (liquid crystal) (2) after being crystallized from absolute ethanol.

Anal.—Calcd. for $C_{30}H_{27}N_{12}O_6PS_3$: P, 3.98. Found: P, 3.56.

N,N'-di(α-Naphthyl) Phosphorodiamidous Acid and N,N'-di(β-Naphthyl) Phosphorodiamidous Acid—These were prepared by condensing the naphthylamine with phosphorus trichloride adopting the general method reported in the previous paper. The yield in both cases was 30% and the product crystallized from aqueous ethanol. The former compound melted at 228–230°.

Anal.—Calcd. for $C_{20}H_{17}N_2OP$: C, 72.26; H, 5.15; N, 8.40. Found: C, 71.41; H, 5.07; N, 8.61.

The latter compound melted at 240–243°.

Anal.—Calcd. for $C_{20}H_{17}N_2OP$: N, 8.40. Found: N, 8.61.

Anticholinergic Agents Based on Ariens' Dual Receptor Site Theory

Sir:

Many drugs classed as competitive antagonists seem to bear a close structural resemblance to the corresponding agonist and are presumed to have an affinity for the same receptor. However, it is frequently observed that in many classes of drugs changes in structure of agonists and competitive antagonists do not result in a parallel change in activity. If affinity is the property altered by the structural modification, then classical receptor theory offers no explanation for this. Ariens has suggested that the receptor site for agonists and antagonists in such a case may not be identical (1-3). Thus, competitive antagonists are pictured as occupying a space that overlaps only a portion of the agonist site and gain affinity through attraction to a subsite not utilized by the agonist. This latter portion of the antagonist receptor is referred to as "additional receptor parts."

In the case of the cholinergic receptor at postganglionic parasympathetic synapses, an agonist should combine with a certain region of the receptor as shown in Fig. 1A for acetylcholine (Ia) or carbachol (Ib). Classical antagonists such as choline benzilate (IIa) or lachesine (2-dimethylaminoethyl benzilate ethobromide, IIb) are then assumed to combine with a portion of the agonist site and some additional receptor parts (which together make up the antagonist receptor) as shown in Fig. 1B.

The authors became interested in the possibility of preparing compounds such as 2-[(2-acetoxyethyl)methylamino]ethyl benzilate methobromide (IIIa) and 2-[(2-carbamyloxyethyl)-methylamino]ethyl benzilate methochloride (IIIb), which could combine with both the agonist and antagonist receptors as illustrated in Fig. 1C. These two compounds contain a cationic head attached to two chains—one resembling the potent agonists acetylcholine or carbachol and the other resembling the potent antagonist lachesine. If all portions of the molecule can bind to the appropriate portions of the receptor simultaneously, then these compounds should have a greater affinity and, therefore, be more active antagonists than compounds not containing an agonist moiety. The compounds IIIa and IIIb were prepared by alkylation of dimethylaminoethyl benzilate with bromoethyl acetate or chloroethyl carbamate. Compound IIIa has been prepared previously (4).

The drugs were evaluated by means of the pA_2 described originally by Schild (5). Segments of isolated ileum from guinea pig were suspended

III a	$CH_3-\overset{\overset{O}{\|\|}}{C}-O-$	7.96 ± 0.06 (10)	7.85 ± 0.05 (10)
III b	$H_2N-\overset{\overset{O}{\|\|}}{C}-O-$	7.19 ± 0.07 (8)	6.90 ± 0.10 (7)

[a] S.E. = standard error. [b] Number in parentheses indicates the number of segments of guinea pig ileum used for each determination.

in Tyrode's solution at 25° and aerated with 95% oxygen and 5% carbon dioxide. Tension development was measured by means of FT 0.03 force displacement transducers and recording made on a Grass model 5D polygraph.

Both acetylcholine and carbachol were used as agonists. Four or five dose-response curves were determined on each isolated tissue preparation, and a fresh segment was used for each agonist–antagonist combination. Increasing concentrations of antagonist produced a parallel shift to the right of the dose–response curves of the agonist and did not depress the maximum response. The compounds themselves did not initiate a response in any concentration. Thus, they do behave as true competitive antagonists. The compounds are highly specific for the cholinergic receptors as evidenced by the fact that they do not alter the response of the isolated ileum to potassium.

The compounds IIIa and IIIb were compared with the potent antagonist lachesine which differs only in that it lacks an acetoxy or carbamyloxy group. The pA_2 values were obtained by linear regression analysis according to the method of Steel and Torrie (6). The results are summarized in Table I. There was no significant difference between the pA_2 values obtained with acetylcholine and carbachol. However, differences between antagonists were significant. Lachesine, the model compound for this series, was significantly more effective than either of the derivatives. The addition of an acetoxy group on the ethyl moiety decreased the pA_2 nearly one log unit, and substitution of the carbamyloxy group in the same position further reduced the activity of the derivative.

Clearly the additional acetoxy or carbamyloxy groups attached to lachesine do not lead to the expected increase in affinity for the receptor. A report has appeared recently from Ariens' laboratory involving antihistamine agents based on the same type of agonist–antagonist double molecule (7). These also failed to show any augmented antagonist action.

The present results do not allow any conclusions concerning the general validity of Ariens' dual receptor site theory since several alternative explanations might be advanced for the lack of higher pA_2 values: (*a*) The lower affinity might be only apparent due to a lowered ability of the compounds to reach the site of action. (*b*) The various receptor parts may not be arranged in a linear fashion as depicted in Fig. 1. In such case, the nonbonded interactions within the molecule may hinder the drug from assuming a conformation in which all parts could combine with their respective subsites simultaneously. (*c*) Ariens' dual receptor site theory may not be applicable to the ester-type antagonist used in the present case. Other compounds employing additional cholinergic agonist–antagonist moiety combinations are being studied. Antiadrenergic agents based on a similar approach are also being investigated.

Matrix Algebra for the Biological Sciences. By S. R. SEARLE. John Wiley & Sons, Inc., 605 Third Ave., New York, NY 10016, 1966. xii + 296 pp. 15 × 23 cm. Price $9.95.

With high school algebra as the only prerequisite, this book shows how to learn matrix algebra, emphasizing its use in biology and statistics. The author points out that his style is informal and that although proofs of the theory are given, they can be omitted if desired in using the text. The mathematical development is illustrated with numerous examples. Matrix algebra up to and including latent roots and vectors and its use in regression analysis are covered. Exercises are included in each chapter.

Naming Organic Compounds. A Programmed Introduction to Organic Chemistry. By JAMES E. BANKS. W. B. Saunders Co., W. Washington Sq., Philadelphia, PA 19105, 1967. viii + 276 pp. 18 × 26 cm. Price $4.50. Paperbound.

An interesting approach to the study of organic nomenclature is this programmed instruction manual. It begins with the simplest of hydrocarbons and gradually takes the student through the various functional groups to the more complex organic molecules. The nomenclature information presented is similar to that in any basic organic chemistry text. However, it may be more fun to learn because of the programmed app oach—one reads a section, answers the questions, and proceeds to the next section—or if one answers incorrectly, goes back and reads the section again. The author has designed the book as self-instructional. Little descriptive chemistry is included and no knowledge of organic chemistry is assumed.

Naming Organic Compounds. A Programmed Introduction to Organic Chemistry. By JAMES E. BANKS. W. B. Saunders Co., W. Washington Sq., Philadelphia, PA 19105, 1967. viii + 276 pp. 18 × 26 cm. Price $4.50. Paperbound.

An interesting approach to the study of organic nomenclature is this programmed instruction manual. It begins with the simplest of hydrocarbons and gradually takes the student through the various functional groups to the more complex organic molecules. The nomenclature information presented is similar to that in any basic organic chemistry text. However, it may be more fun to learn because of the programmed app oach—one reads a section, answers the questions, and proceeds to the next section—or if one answers incorrectly, goes back and reads the section again. The author has designed the book as self-instructional. Little descriptive chemistry is included and no knowledge of organic chemistry is assumed.

Matrix Algebra for the Biological Sciences. By S. R. SEARLE. John Wiley & Sons, Inc., 605 Third Ave., New York, NY 10016, 1966. xii + 296 pp. 15 × 23 cm. Price $9.95.

With high school algebra as the only prerequisite, this book shows how to learn matrix algebra, emphasizing its use in biology and statistics. The author points out that his style is informal and that although proofs of the theory are given, they can be omitted if desired in using the text. The mathematical development is illustrated with numerous examples. Matrix algebra up to and including latent roots and vectors and its use in regression analysis are covered. Exercises are included in each chapter.

Index Nominum 1966. Swiss Pharmaceutical Society, Zurich, Switzerland 1966. 838 pp. 19 × 25 cm. Price Sw. Fcs. 100.—(about $25.00).

This is the fifth, completely revised edition of the Index, and contains more than 11,000 entries. The Index presents—on an international basis—a completely cross-indexed alphabetical listing of drug entities, their synonyms, trade names (from various countries), and manufacturers. Also given under the main entry for a compound are the chemical and structural formulas and a brief mention of therapeutic use. Nonproprietary names are given and identified as to whether they are the International, British Approved, USAN, *etc.* The compendial status of the drugs in several countries is also given. Supplements keep the index current. Its international basis and comprehensiveness make it a most useful reference.

Biologically Active Pyrazoles

By RONALD E. ORTH

"No great change occurs in the general nature of the action of a substance if a pyrazole ring be substituted in place of a pyrrole ring" (1).

THREE DECADES and the wisdom of this conclusion have vanished since 1937; however, an awareness of changing "truths" is no more amply illustrated than with the bio-active pyrazoles. Although the impact of pyrazole chemistry on biological systems is uneven, the recognized value of a few pyrazoles for even fewer purposes has characterized the past. A rapid leveling of interest, however, is reflected in recent literature, and a review of pyrazole implications on biological systems quickly identifies nearly all activity as a "happening" of the past decade. Kost and Grandberg listed 799 references (2) in an excellent review of pyrazole chemistry and an earlier compilation may also be of interest (3). Pyrazole NMR and UV spectra were reported by Elguero *et al.* (4, 5), and the nonaromatic pyrazolones and pyrazolidones were reviewed (6). Tautomeric pyrazolones, alone, were of sufficient interest that a review was written (7), and certainly, much excitement was generated by the clinical efficacy of phenylbutazone and its analogs (8). Among the well-known compounds are antipyrine and pyramidon, the analgetic-antipyretic pyrazolones. Knorr (9, 10) first synthesized a pyrazole derived compound in 1883, which led to the discovery of antipyrine (11).

Received from the College of Pharmacy, University of Kentucky, Lexington, KY 40506
Present address: College of Pharmacy, University of Houston, Houston, TX 77004

Although the thoroughly investigated 5-pyrazolones and their 3-oxo-isomers react as ketones, the 4-isomers are tautomeric and behave like phenols.

Pyrazole (1) consists of a doubly unsaturated 5-membered ring containing two adjacent N-atoms. Three possible ring-tautomers exist (Ia, Ib, Ic), which have not been separated. The ease of pyrazole-tautomerism may be explained if all the N-H bonds in the associated structures are assumed to be equivalent (12). The polar structure (Id), which contributes much to the resonance hybrid of pyrazole, explains the high degree of electrophilic substitution in the 4-position (13). The presence of the N-H moiety allows pyrazole to ionize as a anion, substitute on this N-atom, and possibly tautomerize. The lone pair of electrons on the secondary N-atom, which is utilized to form an aromatic sextet, is not available for affecting water solubility. The doubly bound N-atom does increase pyrazole solubility over pyrrole because the lone pair of electrons on the N-atom is disengaged and available. Annelation to give indazole decreases water solubility. Pyrazoles with free N-H groups are amphoteric, though more basic than acidic and form associated linear dimers and trimers. Good stability generally characterizes the pyrazoles (14).

The great variety of bio-responses promoted by pyrazoles is illustrated by the insecticidal, anal-

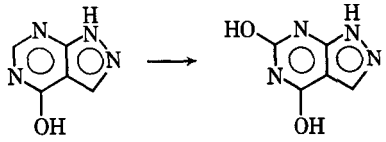
gesic, sedative, anticonvulsant, antipyretic, and anti-inflammatory activity elicited by only the 1- and 2-dimethylthiocarbamoylpyrazoles (15). The analogous 1-carbamoylpyrazoles effect analgesia, diuresis, antipyresis, sedation, and a bitter taste (16). However, these are selectively toxic medicinal agents, and toxicity is always a concern when these compounds are administered. Hydroxy- and amino-pyrazoles (17) and F.D. & C. yellow No. 5 (an azopyrazole) (18) have been studied and fatty liver was detected following the administration of allopurinol, 4-hydroxypyrazolo[3,4-*d*]pyrimidine (IIa), to four species of warm-blooded animals (19).

BIO-ANTAGONISTIC PYRAZOLES

Pyrazole, pyrazolo[3,4-*d*]pyrimidine (II), and their substitution products include many biologically active agents, which possess enzyme-inhibiting properties of interest. For instance, many xanthine oxidase inhibitors are carcino-



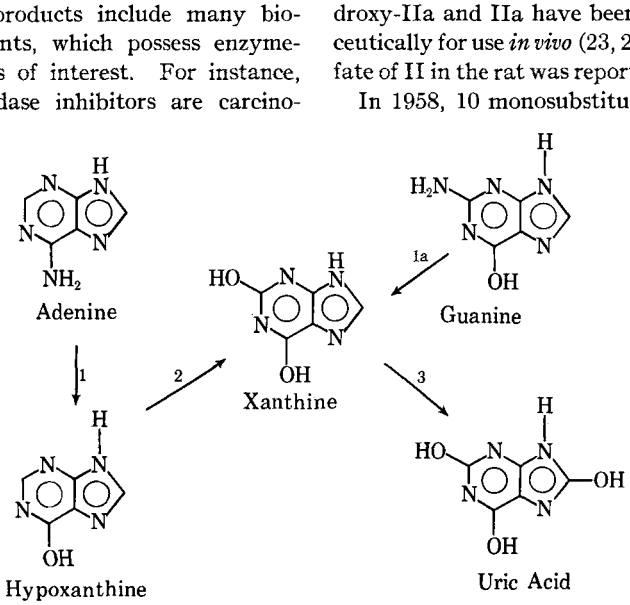
4-Hydroxypyrazolo-[3,4-*d*]pyrimidine (IIa) 4,6-dihydroxypyrazolo-[3,4-*d*]pyrimidine

Scheme II

static or tumor inhibiting, while the effectiveness of pesticides has been correlated with their anticholinesterase activity. Inhibitors of carbonic anhydrase, monoamine oxidase, liver alcohol dehydrogenase, and catalase have been investigated. Some degree of pyrazole activity results from competition with endogenous substances to antagonize an enzyme system. The xanthine oxidase antagonistic pyrazoles, particularly those with antitumor activity, are of great interest. Many of these compounds have been derived from II.

Hypoxanthine and its intestinal metabolites are readily absorbed from the small intestine where xanthine oxidase combines with hypoxanthine, xanthine, and Cu to produce a necessary transport-complex (20). Purine (III) and II-derivatives compete for this common transport process. Although 4-hydroxypyrazolo[3,4-*d*]-pyrimidine (IIa) and 7-hydroxy-IIa strongly inhibited the active transport of uracil across the intestinal wall (Schemes I and II) (21), IIa, uric acid, and adenine form similar transport-complexes with xanthine oxidase. In the chick embryo and chicken, IIa inhibited uric acid formation, but diversion of N to a different end product allowed normal development (22). 6-Hydroxy-IIa and IIa have been developed pharmaceutically for use *in vivo* (23, 24), and the metabolic fate of II in the rat was reported (25).

In 1958, 10 monosubstituted derivatives of II



Scheme I

were prepared and suggested as antimetabolites (26). 6-Hydroxy-IIa and IIa were converted by purinenucleoside phosphorylase to the 1-ribosyl-metabolites and isolated from the urine of treated patients; however, 4-hydroxypyrazolo[3,4-*d*]pyrimidine (IIa) was a better substrate than 6-hydroxy-IIa (27). The sea urchin and other systems have been utilized to investigate the effect of 4-aminopyrazolo[3,4-*d*]pyrimidine (IIb) on purine metabolism (28, 29). Avian glutamine ribosylpyrophosphate 5-phosphate amidotransferase, the first enzyme of purine biosynthesis, was inhibited by IIa-ribonucleotide. A "pseudo-feedback" inhibition of the ribonucleotide may be an important aspect of the *in vivo* biological activity of II derivatives (30).

ANTITUMOR AND CARCINOSTATIC PYRAZOLES

Pyrazole was reported as possessing antitumor activity (31, 32) and 25 courses were given to patients with solid tumors. Bone marrow depression was minimal, while severe thrombocytopenia and hepatotoxic reactions were noted once. Nausea and anorexia were reported, but no objective responses were observed. Pyrazole depressed: adenocarcinoma CA-755 (90–100%); Ehrlich ascites carcinoma (50–60%); and spontaneous mammary tumors in C_3H mice. Crocker sarcoma S-180, leukemia L-1210, and human tumors in conditioned rats, however, did not respond. The i.p. single dose LD_{50} for pyrazole was: 400–600 mg./Kg. for mice and 900 mg./Kg. for rats. Experimentally induced tumors were treated with 4-aminopyrazole (33), and several 1-substituted pyrazoles exhibited significant activity against CA-755 with less effect on S-180. The 1-carboxamide elicited a moderate but consistent action *versus* human tumor HS-1 (34).

The investigation of antitumor activity of II and its substitution products was the most extensive of any for bio-active pyrazoles. The hydrochloride of II showed the greatest activity among 16 pyrimidines tested in 1960.

A xanthine oxidase-inhibiting preliminary screening technique for carcinostatic substances was developed (35) and a large number of II substances were screened *versus* CA-755 and leukemia L-5178 (both were susceptible to inhibition by purine antagonists). Consistent and significant activity was reported using IIb, *N*-alkyl-IIb, *N*-dialkyl-IIb, and their 1-alkyl-derivatives (36). Skipper *et al.* (37), effected antitumor activity with IIb and 1-methyl-IIb. The toxicity of IIb in humans was slight, however, hepatotoxicity and hemorrhage was reported in animals (38). 1-Methyl-IIb and IIb acted on nucleic acid metabolism in ascites carcinoma, but sarcoma S-180 was not sensitive to either material (39, 40).

A Houston team utilized *Neurospora* for screening potential carcinostatic substances and found that 1- and 3-substituted IIb compounds inhibited the growth of this tissue (41). Human HeLa and mouse B-3 adenocarcinoma cells were found to be resistant to IIb (42), but HeLa cell damage was reportedly caused by 13 newer IIb-substances (43). Two of these were more active against *N. crassa* than IIb (44). Active IIb derivatives lower the DNA levels in tumor and liver tissue (45), and 1-methyl-IIb also lowered muscle DNA levels. Interestingly, 12 IIb derivatives gave relief of IIb-inhibition. Since the position of the side chain determines inhibition or relief potential (46), 1-methyl-IIb and IIb were found highly active in recent tumor transplants, while only slightly effective in spontaneous tumors (47). The efficacy of IIb against cultivated human tumor cells, in earlier studies, was greater than for any amino- or 1-substituted-II products (48). Purine synthesis was disrupted in Ehrlich ascites cells by IIb (49), but attempts to establish mutant strains of *N. crassa* with this substance were unsuccessful (50).

Robins (51) reviewed the structure-activity relationship (S-AR) of purines and related compounds (11,300 compounds tested over a 10-year period) against animal tumors (163 references). Similarities of the allowable positions for substitution in II and in purine were most striking. 4-Aminopyrazolo[3,4-*d*]pyrimidine, which is active against CA-755 and numerous other tumors, was the parent compound in that study. Substitution of certain alkyl groups in the 1 position (corresponding to position 9 in purine) provided active compounds, and the presence of a tetrahydropyranyl- or tetrahydrofuryl-group at position 1 also allowed retention of antitumor activity. The 4-alkyl-II derivatives inhibited L-5178 and prolonged L-5178 and L-1210 life span in infected mice. Substitution of alkyl groups on the amino function at position 4 (6 in purine) created less toxic products with superior therapeutic indexes, while substitution at both the 1 and 4 position, simultaneously, usually diminished antitumor activity to a slight degree. 1-Methyl-*N*-*n*-butyl-IIb and *N*-benzyl-IIb were active against Dunnings ascites leukemia, but 1-phenyl-IIb derivatives were inactive. 6-Amino-IIb was active, but the 6-amino moiety (2 in purine) apparently made little difference. The spatial arrangements of II and purine derivatives appear interchangeable, however,

4-mercapto-II and 6-amino-4-mercapto-II, the corresponding analogs of 6-mercaptopurine (IIIa), and 2-amino-IIIa, were without activity *versus* CA-755. An L-1210 azaguanine-resistant strain was found cross-resistant with IIIa, but not with IIb. These results lead to a conclusion that similar steric requirements, alone, were not sufficient to provide antitumor activity. Since IIb cross-resistance did not occur in either case, different mechanisms of action must be involved. Simultaneous administration of IIb with IIIa resulted in potentiation *versus* ascites carcinoma, S-180, and 6C3HED lymphosarcoma. Similar effects were observed with IIb and azaserine or thioguanine (52). This observed potentiation was further evidence favoring separate mechanisms for IIb and IIIa.

The antitumor activity of IIb was probably exerted at the acid-soluble nucleotide level, although it was incorporated readily into nucleic acids of normal and neoplastic tissue. The *de novo* pathway to nucleotide-purines was inhibited, probably by the previously mentioned "pseudofeedback" mechanism. Recent clinical success with *N-n*-propyl-IIb against myeloblastic leukemia has renewed interest in the II tumor inhibitors, and further support for this interest was given by correlation of the pKa values of 4-substituted-II compounds with their antineoplastic activity. Position 5 (1 in purine) may be critical for the adenine-like IIb substances, because a close steric fit was required even at position 3 (7 in purine). 3-Methyl-IIb and the purine analog were devoid of antitumor properties.

Nakajima *et al.* (53), reported correlating the first ionization potential of free doublets of the N-atoms of II and purine and their derivatives with antitumor activity. Electronic structure, chemical reactivity, and the basicity of these agents were related to tumor inhibition (54). Bio-activity was associated with the position of the most basic N-atom and the basic strengths (55). 6-Amino-II was found to be carcinostatic but hepatotoxic, while 5-amino-7-hydroxy-II and a number of trifluoromethyl-derivatives of IIb and *N*-alkyl-IIb were inactive (56–60). Scott and Foye (61) and Sutcliff (62) reported on IIb, which in tumor-bearing mice, decreased formate-^{14}C uptake into polynucleotide purines (DNA, *etc.*) with ^{14}C-accumulation in serine.

The uptake of adenine into the nucleic acids was inhibited by IIb, and nucleic acid synthesis in IIb-sensitive CA-755 and in the less sensitive S-180 ascites was halted for a short period. The S-180 tissue, however, recovers more readily (63), while adenine, given to S-180 ascites-bearing mice prior to IIb, caused a decrease in tumor inhibition (64). 4-Aminopyrazolo[3,4-*d*]pyrimidine was toxic to H. Ep. No. 2 cells, but the "feedback" growth inhibition occurred at much higher concentration and was the mechanism of carcinostasis (65).

Allopurinol (IIa), a powerful xanthine oxidase inhibitor, was found to depress the disappearance rate of ^{32}P-labeled $CrPO_4$ in an attempt to characterize the phagocytic properties of the reticuloendothelial system. Methotrexate, chlorambucil, and thiotepa possessed this facility, while azaserine and busulfan[1] were ineffective (66). A decreased IIIa to thiouric acid oxidation occurred when IIa was given simultaneously to human patients. A severalfold potentiation resulted *versus* CA-755 and in the mouse immune response to sheep erythrocytes. In man, 0.2 to 1.0 Gm. of IIa given daily possessed a higher therapeutic index than other antineoplastic agents (67, 68). When given with IIa or 6-hydroxy-IIa, 6-mercaptopurine was potentiated threefold, while xanthine oxidase oxidation-inhibition of hypoxanthine and xanthine in the liver and kidney gave rise to increased uric acid levels (69). This IIa action was used to test the ability of xanthine to serve as a precursor for nucleic acid purines while being protected from destructive catabolism. The ability of CA-755 (IIIa-resistant)-bearing mice to use xanthine as a precursor was reduced by one-half using IIa (70), and it also inhibited liver and kidney, but not spleen xanthine oxidase in rats (71). Xanthine dehydrogenase-inhibition by IIa was also noted (72).

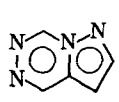
Pyrazolo[3,2-*c*]-*as*-triazines (IV) were more effective S-180-inhibitors in mice and methylcholanthrene-induced tumorstatic agents in rats than IIIa, but the best of the lot were ethyl-4-amino-IV and 6-iodoacetyl-3-methyl-4-methylene-IV (73,74).

1-Methyl-IIb, given to pregnant rats, produced a high number of malformed and dead fetuses (75). The teratogenic nature of IIa, administered with IIIa at subteratogenic levels, was reported (76).

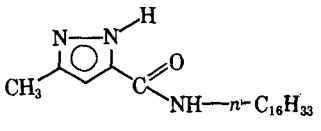
ANTIVIRAL PYRAZOLES

3-Methylpyrazole-5-carboxylic *n*-hexadecylamide (V) demonstrated virucidal activity *versus* the Japanese encephalitis virus (77). Other studies supported that 1-methyl-*N-n*-propyl-IIb, the *N*-isopropyl- isomer, *N*-isopropyl-IIb and IIb suppressed virus plaque formation with *Herpes simplex*, *Vaccinia*, and West Nile (78). Toxicity,

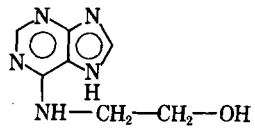
[1] Trademarked as Myleran by Burroughs Wellcome & Co., Tuckahoe, N. Y.



IV



V



VI

but not antiviral activity, decreased when N^6-(2-hydroxyethyl)adenine (VI) was given with IIa (79). In an antiviral formulation (80), one part of the various N^6-(hydroxyalkyl)adenines was combined with 2.5–20 parts of IIa.

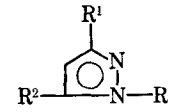
GOUT AND THE PYRAZOLO[3,4-d]-PYRIMIDINES

One of these compounds, allopurinol, is being used in the treatment of patients with gouty conditions. The oxidation of urine xanthine and hypoxanthine was antagonized by the action of IIa on xanthine oxidase (81), which resulted in lower serum and urine uric acid levels (82). Formation of fresh deposits was arrested and mobilization of old deposits occurred, but it was suggested that the best use of IIa was with agents such as colchicine (83, 84). Compound IIa was well tolerated in human patients and was found to be useful in subjects with hyperuricemia who were refractory to uricosuric therapy. Although gouty patients with a low tolerance to other drugs, which lower blood plasma urates, may be helped, no improvement was noted in those with tophaceous gout (85, 86). Further reduction of serum and urine urates and increased urinary hypoxanthines (87) resulted from a sulfinpyrazone and IIa combination. Oxypurinol, 6-hydroxy-IIa, was utilized also in the treatment of gout (88, 90). Toxicity (91), nephropathology (92), human tissue reactions (81), and other pyrazole-gout reports were of interest (93–96).

PYRAZOLES INHIBITING OTHER ENZYME SYSTEMS

One S-A-R report of anti-monoamine oxidase (MAO) 1,3,5-trisubstituted pyrazoles listed several interesting examples (Table I). For instance, transposing of methyl- and the substituted-hydrazide moiety from positions 3 and 5 to 5 and 3, respectively, reduced activity in one series. Activity was found to decrease as R varied, so that when R was aralkyl, separation of the aryl from the hydrazido moiety decreased activity. Benzyl or 2-phenethyl groups produced equal anti-MAO effects, and pyrazole-3,5-dicarboxylic acid hydrazide were ineffective antagonists (97, 98).

TABLE I—MONOAMINE OXIDASE INHIBITORS



Factors Enhancing Inhibition:
- R is benzyl or phenethyl
- R^1 is methyl
- R^2 is benzyl-, β-phenethyl-, or 1-phenethyl-carboxylic acid hydrazide.

Factors That Lower Inhibition or Increase Toxicity:
- R = H
- R^1 = R^2 = CONHNHR
- R^1 and R^2 interchanged
- R^2 alkyl portion > 2 carbon

4-Aminopyrazole *in vitro* and *in vivo* catalase-inhibition was reported, giving the ID *in vitro* as 3.8×10^{-3} *M* (99, 100).

Fundamental biochemical interpretations were derived from the work of Theorell *et al.* (101–103) on liver alcohol dehydrogenase (LADH), and a model of a ternary intermediate in the enzyme reaction LADH-diphosphopyridine nucleotide (DPN)-pyrazole was reported. Pyrazole, the most potent inhibitor of LADH known (1963), adds to the enzyme-coenzyme binary system producing a new complex with a characteristic 290 mμ maximum. The LADH-DPN-pyrazole complex stoichiometry was reported as 1:2:2, respectively. Liberation of one H^+ per complex formed suggested that, following H^+ release, a charged pyrazole carbanion interacted covalently with C-4 of the pyridinium ring of DPN. Binary and ternary complexation increased the stability of LADH toward certain types of inactivation, probably due to conformational changes in the protein molecule. The LADH-NAD-pyrazole and LADH-NAD-4-iodopyrazole complexes have been crystallized to examine "Koshlands Induced Fit Theory." The ternary ligand pyrazoles were found to occupy the active alcoholic binding site and form a bridge between Zn atoms in the LADH and the coenzymic nicotinamide moieties. X-ray crystallography uncovered orthorhombic symmetry for free enzymes and clinic patterns for the ternary complexes. Optical rotatory density data were utilized to calculate Moffitt-Yang plots, and allowance for Cotton effects, introduced by the binding of NAD to the protein, were utilized. The change of Moffitt parameters, b_0, from −100° for the enzyme to −185° in the ternary complex was interpreted as a change of protein conformation due to complex formation.

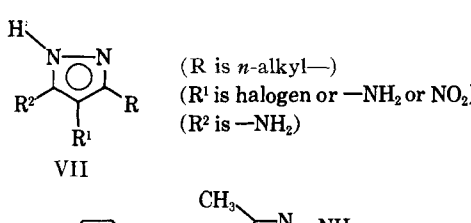
ANTIMICROBIAL PYRAZOLES

The earliest reported anti-infective pyrazole, 5-amino-4-benzeneazo-1-phenyl-3-methyl-

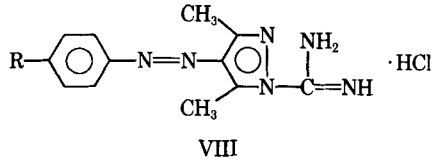
pyrazole, was for use as a urinary antiseptic, but when it was administered orally, albuminuria resulted. A minimum lethal dose (50%) in rabbits was found to be 200 mg./Kg. (104). Grandberg *et al.* (105) tested 96 pyrazoles as effective bactericidal agents, and other investigators reported (106) that 3-nonylpyrazole and its derivatives exhibited bacteriostatic-fungistatic activity. The 3-alkylpyrazoles (VII) reportedly have an extremely specific antibacterial spectrum; *Staphylococcus aureus* and *B. subtilis* were inhibited, but the only sensitive Gram-negative organisms, were *N. gonorrhoeae* and *V. cholerae*. Longer or shorter 3-alkyl chains varied the potency in this series. The *n*-octyl compound possessed the highest surfactant properties (107), while 4-nitro- and 4-halo-3-nonylpyrazoles demonstrated good antimicrobial activity, and the 4-amino-homolog exhibited a marked decrease in efficacy *versus* Gram-positive organisms. Shifting the amino group to the 5 position heightened bacteriostasis, but ring oxidation to the pyrazolone resulted in a loss of activity (108).

1 - Dichloroacetyl - 3 - (*p* - nitrophenyl) - 5 - methylpyrazole inhibited *S. typhosa in vitro* at 500 mcg./ml., but was inactive against several other common organisms (109). 1-Cyclopentyl-*N*-furyl-IIb inhibited the preferential stimulation of the synthesis of DNA, but potentiated kinetin riboside in *D. pneumoniae*. The results indicated a relationship between DNA breakdown products to population changes and DNA synthesis, which illustrated the usefulness of employing a virulent population change system for the study of compounds interfering with DNA synthesis by DNA breakdown products (110).

The adenine isostere 4-aminopyrazolo[3,4-*d*]pyrimidine was effective *versus C. utilis*, *E. coli*, and *B. cereus* (111), inhibiting the growth of *E. coli* and *B. cereus* by about 30%. Adenine or hypoxanthine addition partially relieved the drug-induced inhibition, but a combination of IIb and guanine resulted in potentiated inhibition of cell growth. The formation of 4-amino-5-imidazolecarboxamide, a purine precursor, by an *E. coli* mutant, B-96, was lessened by IIb, resulting in depressed *de novo* purine synthesis. Stimulation of the C-8 guanine, by IIb, to adenosine and ribonucleic acid adenine was observed in *E. coli*, while a depression of the conversion occurred in *B. cereus*. The radio labeling of several purine-containing cell constituents was effected (112). 6-Amino-IIa exhibited good activity *versus B. cereus*, but only slight activity against *E. coli*. Treated *B. cereus* cells elongated, and the RNA content in the cell was reduced, due to the antagonism of an early reaction in purine biosynthesis (113). Three 4-arylazo-1-amidines of 3,5-dimethylpyrazole (DMP) (VIII) were found effective *versus S. aureus* and *S. albus* at $1 \times 10^{-4}M$. They were the 4′-tolyl-, and 4′-chlorophenyl-, and 4-(4′-acetylphenylazo)-3,5-dimethylpyrazolyl-1-amidine aminoguanidine salts, the latter of which possessed good trichomonostatic ($1 \times 10^{-5}M$) and tuberculostatic ($4 \times 10^{-4}M$) activity. Several of these azopyrazoles are also active ascaridostatic agents (114).



VII



VIII

5-Amino-7-methyl-II possessed antitubercular activity and was well absorbed orally in laboratory animals; however, the tuberculostasis produced was less than that shown by streptomycin in the guinea pig and mouse (115, 116). A parallelism was noted between the tuberculostasis and xanthine oxidase inhibition produced by this compound. 4 - (4′ - Acetylphenylazo) - 3,5 - dimethylpyrazolyl - 1 - thiocarbonic acid amide - thiosemicarbazone elicited potent tuberculostatic activity at $1 \times 10^{-4}M$, but unfortunately, the LD_{100} (100 mg./Kg.) in rats was high (114). Certain 4-nitrosopyrazoles were active *in vitro*, but not in the mouse, and some azoxypyrazoles were found to be inactive tuberculostats (118).

Sulfapyrazine, sulfahydantoin, and sulfathiazoline were acclaimed as more promising against *Pneumococcus* than sulfapyrazoles in 1941 (119), however that very year, Jensen introduced 3-sulfanilamidopyrazole as eliciting activity similar to that of sulfathiazole (120). For over 20 years, articles characterizing the chemistry, solubility, microbiology, and toxicity of sulfonamidopyrazoles have been published (121–125).

5-(*p*-Aminobenzenesulfonamido)-1-phenylpyrazole (IX) (sulfaphenazole, orisul), was found to lower an induced rabbit fever, but it is less effective and less toxic than pyramidone for this purpose. Each compound in a series of N^1-aryl-3-pyrazolylsulfanilamides inhibited *S. aureus* at 10 mcg./ml. The *m*-methoxy-homolog was the most active *versus E. coli in vitro* (10 mcg./ml.), and it also exhibits a displacement action of various penicillins bound to blood serum proteins. The decrease in bound penicillin G was 49.5%; peni-

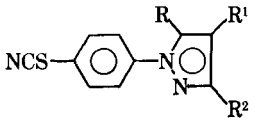
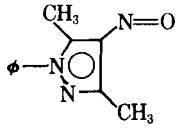
XIII



XIV



XV

cillin V, 39.8%; and ancillin, 35.9%. The relative activity of various sulfonamides as penicillin-displacing agents corresponded closely to the known affinity of each for serum proteins. Over 250 chemicals were tested with ^{14}C-labeled penicillins, and the findings showed that replacement of a 3-methoxyl- group by a 3-methyl- substituent increased the duration of activity (X). Active N^1-aryl-3-pyrazolyl-N^4-acetylsulfanilamides (XI) have been prepared, and a number of chloro-derivatives of 1-phenyl-4-sulfanilamidopyrazole (XII) have been found useful. Padeiskaya *et al.* have contributed to sulfonamide chemotherapeutics (126–135).

Seven of eight fungi tested, including *C. militaris*, converted IIb to the riboside, thus, the fungi may utilize IIb as a nutrient (136). More important is the antifungal activity, which was elicited by a number of pyrazole compounds. Two thiocyanato-, eight 4-(*N,N*-disubstituted-thiocarbamoylthio)-, and five 4-alkoxythiocarbonylthiopyrazoles were effective against *Piricularia oryzae*, *Phytophora infestans*, *Colletotrichum lagenarium*, and *Candida albicans*. The thiocyanato derivatives displayed the greatest fungal inhibition, and of these, 1-(*m*-nitrophenyl)-4-thiocyanato-3,5-dimethylpyrazole possessed the greatest fungal inhibitory activity of all compounds tested (XIII) (137). This same Japanese group found high-level activity in 1-(4-thiocyanatophenyl)pyrazoles (XIV) (138). Maximum fungitoxic activity was attained by substitution of an aryl-group in the 1 position of 3,5-dimethyl-4-nitrosopyrazole (XV). Several of these compounds prevent spore germination at a concentration of 0.1 p.p.m. and provide 95% protection against *Alternaria solani* on tomato foliage at 10–60 p.p.m. (139). Zsolnai has found the nitrosopyrazoles effective *versus* fungi which afflict humans (140, 141); pyrazole was one of 165 *N*-compounds studied for fungitoxicity. 4-Nitrosopyrazole toxicity increased with an increase in the bulk of the hydrocarbon side groups, but the mechanism of action was found to be the same, regardless of the group in this series. Increased fungitoxicity was observed as the oil:water partition coefficient increased for these substances, and generally, lipophilic groups, such as aryl- or alkyl-, increased the toxicity. Amino-, nitro-, nitroso, hydroxyl-, and mercapto-group substitution produced a similar response (142, 143). Six mono-, di-, and tri-substituted 4-nitrosopyrazoles (XVI) are active against *P. oryzae* and *Ophiobolus miyabeanus* (144), and nitrosopyrazoles with 1-substituted cyclic groups are active, particularly against pathogenic fungi. It was found that 1-cyclohexyl-3,5-dimethyl-4-nitrosopyrazole exhibited no dermal irritation and possessed low phytotoxicity (145).

3,5-Dimethyl-4-(4′-chlorophenylazo)pyrazole (XVII), one of 750 chemicals tested, was the most active *versus* 3 selected fungi (146), while a

4-phenylazo-3,5-dimethylpyrazolyl-1-amidine (XVIII) salt was effective *versus T. gypseum*, *E. Kaufman-Wolff*, and *A. quinkeanum* at $2 \times 10^{-4}M$. The 4′-chloro- and 3′-chloro-derivatives (XIX) were effective at $1 \times 10^{-4}M$ against the same fungi. Many of the azopyrazoles were also bacteriostatic, trichomonostatic, and ascaridostatic, but according to Zsolnai, R—N=N—CH— must be present as an intact moiety, in arylazoanti-infective chemotherapeutic agents (114). 3-Nonylpyrazole possessed high antifungal-antibacterial properties (106), and recently, 3-methyl-5-(5-nitro-2-furyl)pyrazole (XX) was introduced for this activity (147). A similar nitrofurylpyrazole was reported in the Netherlands, with claims for effectiveness against a wide spectrum of bacteria and a few fungi (148).

PESTICIDAL PYRAZOLES

Well tolerated 4-aminopyrazoles (XXI) yielded interesting pharmacodynamic spectra; for instance, 1,3,5-trimethyl-4-dimethylaminopyrazole methiodide exhibited a choliomimetic action. Substituting 1-phenyl in place of 1-methyl reversed the action and effected a classical cholinolytic response. Although molecular weight difference was suggested as the underlying factor, the activity of the former substance was attributed to anticholinesterase properties (149). A number of pyrazolyl-carbamates and phosphates, possessing good anticholinesterase activity, were too toxic for use in medicine, but were excellent pesticides. Practical uses of the dimethylcarbamates and dialkylphosphates of 5-hydroxypyrazoles have been studied since 1951 (150–156). 1-Isopropyl-3-methyl-5-pyrazolyl dimethylcarbamate (XXII),[2] and 1-phenyl-3-methyl-5-pyrazolyldimethylcarbamate (XXIII),[3] the 1-phenyl-homolog, were introduced as insecticides in 1952 (157).

Compound XXII exerted a strong systemic action against aphids (158) and was highly toxic to the honey bee (159), however its selectivity is such that it did not affect the insects natural predators (160). Most organophosphate and carbamate pesticides cause inhibition, followed by recovery, of brain cholinesterase activity in *Musca domestica* (housefly) within 21 hr. Compound XXII was the only pesticide tested that did not allow recovery (161). However, it was a less active systemic insecticide in foliage sprays against the citrus whitefly or gardenia than other pesticides (162). Gaines found XXII more toxic to rats by the dermal route than orally (163). The effects of XXII and XXIII on the

stability, toxicity, and reaction mechanisms of human postpartum serum esterase have been reported (164). Aliphatic-esterase activity is inhibited in the housefly by XXII, but resistance to this pyrazole, it was observed, was not related to inhibition of the esterase; mosquito enzymatic activity was not inhibited (165). Many analogs have been reported to have good activity (166, 167). Radio-labeled XXII translocation and persistence in *Theobroma cacao* foliage, and residues in the cacao bean have been studied (168).

2-Dimethylcarbamoyl-3-methyl-5-pyrazolyl dimethylcarbamate (XXIV),[4] was shown to be toxic to laboratory animals in single oral doses (169, 170), but it was reported that XXIV-^{14}C was detoxified in the cockroach through *N*-methyl hydroxylation. Two out of five of the *N*-hydroxymethyl metabolites have been identified (171). The housefly shows maximum cross-resistance levels between XXII and XXIV (172).

Common commercial aromatic and heterocyclic carbamate pesticides exhibited a tenfold potentiation with piperonyl butoxide, sesoxane, sulfoxide, propyl isome, or sesame oil extracts on the housefly (173). Octachlorodipropyl ether

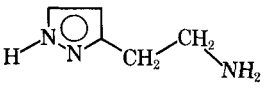
XXV XXVI



XXVII

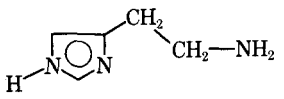
also produced massive potentiation with carbamates on the fly (174), but antagonism, with resultant antidotal protection, was given by atropine and parpanit against all the carbamates tested (175).

Pyrazoxon, containing *0,0*-diethyl-*0*-(3-methylpyrazolyl)-(5)-phosphate (XXV), has become a commercially important foliage spray (176). Phosphoric and thiophosphoric acid derivatives of hydroxy-pyrazolo[1,5-*a*]pyrimidine (XXVI), which were not toxic to warm-blooded animals, acted on insects, red spiders, ticks, nematodes, and fungi (177), and they also exhibited anthelmintic qualities (178). In the Mexican fruitfly, ovaries were affected by IIb sulfate, which reduced oviposition and fertility, acting as a sexual sterilant (179, 180). The screening of various commercial agents against a number of pests has been reported (181).

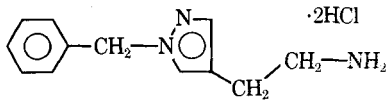
PYRAZOLE HISTAMINE AGONISTS AND ANTAGONISTS

In 1944, Dewar presented histamine-antihistamine models (182), and later, Lee and Jones observed the histamine-like effects produced by several 2-aminoethyl-*N*-heterocyclic compounds. One of these substances 3-(2-aminoethyl)pyrazole, is now known as betazole (XXVII) (183). This isomeric histamine (XXVIII) analog reputedly stimulated gastric acid secretion without producing other histaminic effects (184). Doses of 50 mg. of betazole i.m. elicited a gastric secretory response similar to that for histamine, and like histamine, it was used to study gastric secretions (185). Many clinical studies on betazole HCl have been reported (186–205). Histamine and betazole acted on the same receptors in the guinea pig ileum (206, 207), and additional theoretical histamine-antihistamine models have been reported recently (208, 209).

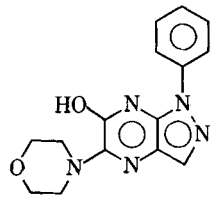
One interesting S-A-R probe indicated that the 1-benzyl-4-(2-aminoethyl)pyrazole·2HCl salt (XXIX) inhibited histamine-stimulated gastric acid secretion. Nevertheless, 4- and 3- (or 5) (2-aminoethyl)pyrazole and bis-2-(3-pyrazolyl)eth-



XXVIII



XXIX

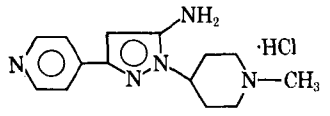


XXX

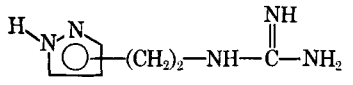
ylamine· 3HCl stimulated acid secretion, even after histamine (210). In one report on the inhibition of histamine, relative to the action of histamine analogs which inhibit histamine methyl transferase, no correlation could be found between antihistaminic activity and enzyme inhibition (211). Alkylamine ethers of 1-phenyl- and 1-benzyl-3-methyl-5-hydroxypyrazole have been prepared as potential antihistaminic substances (212). The 3,5-diphenyl-1-(2-aminoethyl)pyrazole, a diphenyl-substituted analog of betazole, had a procaine-like anesthetic activity and relieved cutaneous pain (213). The allergological significance and toxicity of certain pyrazoles have been reported (214).

DIURETIC, CARDIOVASCULAR, *HYPOCHOLESTEROLEMIC*, AND HYPOGLYCEMIC PYRAZOLES

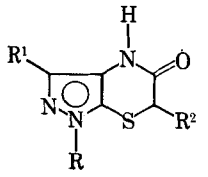
3,5-Dimethylpyrazole (DMP), a true carbonic anhydrase inhibitor with low animal toxicity, given in doses of less than one-half the LD_{50}, only slightly affected blood pressure and respiration (215, 216). Strong K^+ and Cl^- with moderate Na^+ and water excretion patterns were reported (217). It was noted, in a series of DMP relatives, that 3,5-dimethyl-4-bromo- and 1,3,5-trimethyl-4-nitropyrazole caused muscle relaxation and antiedemacious activity (218), while several 3-substituted pyrazolyl-1,2-benzisothiazole-1,1-dioxides showed good hypotensive-diuretic activity. N-Phenethyl-IIb and 1-phenyl-5-morpholino-6-hydroxy-1*H*-pyrazolo-[3,4-*b*]pyrazine (XXX) also produced diuresis. 1-Isopropyl-6-methyl-IIa and 1-isopropyl-6-ethyl-IIa were potent coronary dilators, and 4-mercapto-derivatives of pyrazole and II also elicited strong responses. Ciba-24, 650-Ba suppressed anginose pain, while Ciba-31, 531-Ba, 2-(N-methyl-4-piperidyl)-3-amino-5-(4-



XXXI



XXXII



XXXIII

pyridyl)pyrazole·HCl (XXXI) was a good renal vasodilator. The latter was useful for evaluating renal vascular reactivity to a vasodilating stimulation in various nephropathies. It produced hypotension in conscious dogs and seemed to reduce heart-rate performance in anesthetized unconscious dogs. Pyrazolylguanidines (XXXII) and related substances caused hypotension, sedation, and psychomotor stimulation, and a group of 5-oxo-pyrazothiazines (XXXIII) acted as hypotensive agents (219–224).

Giachetti *et al.* (225, 226), found that IIb decreased α- and β-globulins, and increased γ-globulins in hepatectomized rats, with a three- to fourfold liver-lipid increase occurring in 24 hr. in mice. Neutral lipids increased 10–16-fold, and the cholesterol level rose by 40%. No significant plasma-phospholipid, free fatty acid, or glucose changes were evident but plasma-triglyceride levels were reduced 40% in 1 hr. 4-Aminopyrazolo[3,4-*d*]pyrimidine (IIb) caused 85% inhibition of orotic-^{14}C acid incorporation into RNA. Hyperlipemia, normally elicited by Triton WR-1339, was inhibited by IIb, which suggested that IIb inhibited the secretion of triglycerides from the liver (227).

Bizzi related the action of DMP to fat and glucose fat, and it was reported that nicotinic acid, salicylic acid, or DMP blocked the mobilization of free fatty acids from adipose tissue. The assertion was made that a new method for preventing or controlling the development of liver triglyceride accumulation is possible. Results indicate that drugs which prevent the release of free fatty acids from adipose tissue could prevent and, in some cases, lower the liver triglyceride accumulation. This was true even if the cause of such an increase of triglyceride was not an increased lipid mobilization. DMP and its metabolite, 3-carboxy-5-methylpyrazole, were effective in lowering the plasma-triglyceride level, with the metabolite proving to be more effective than DMP (228–230). The primary action was on fat metabolism, and the effect on glucose oxidation and blood-sugar depression may be secondary (231). A current review of the effect of drugs on the mobilization of free fatty acid is available (232).

Emphasis on hypoglycemic agents was accelerated by the realization that DMP and its metabolite possessed blood-sugar lowering qualities in addition to hypocholesterolemic properties. DMP increased the glucose oxidation by intact rats and lowered plasma free acids of eviscerate rats, but not their blood-sugar levels. DMP markedly depressed plasma-free fatty acids 15 min. to 3 hr. after administration, and it was assumed that part of the hypoglycemic action may have been due to stimulation of glucose oxidation by the intestines and liver. DMP-^{14}C was utilized in these metabolic fate determinations (233, 234). Vetulani mentioned that an interference with some central mechanism was involved, and species differentiation and diuresis were cited (235). DMP is a "unique tool" when it is used in the study of the carbohydrate-lipid metabolic relationship to aid in understanding normal and abnormal metabolism (associated with diabetes).

Dulin *et al.* (236) have reported on hypoglycemic compositions of 3-carboxy-5-methylpyrazole and closely related 3-substituted analogs. In 1964, they noted that a number of pyrazoles with methyl-groups in both the 3 and 5 positions possessed up to 100 times the hypoglycemic activity of tolbutamide in glucose-primed, intact fasted rats (Table II) (237). DMP was 54 times as active as tolbutamide, suggesting that conversion to the acid metabolite, which has 200 times the activity of tolbutamide, accounted for all of the activity (238, 239). This metabolite had a pronounced effect on plasma free fatty acids and it differs from insulin, sulfonylureas, and biguanide in mechanism of action. Pyrazole-1-carboxami-

dines (240) and pyrazole-1-ethanol derivatives were reported (XXXIV) (241). The ethanolic substances which are nontoxic acid-addition salts, also affected antiviral and anti-inflammatory responses. 1-Phenylsulfonyl-DMP controlled blood-sugar levels in rats (XXXV) (242) and an excellent hypoglycemic response resulted when approximately 250 mg. of certain sulfanilamidopyrazoles was administered with 500 mg. of tolbutamide (243).

CENTRALLY ACTING PYRAZOLES

In 1954, a tetra-substituted pyrazole in combination with procaine and a 3,5-dioxopyrazolidine was reported to provoke a strong analgesic-antipyretic response (244). 2-(2-Dimethylaminoethyl)-, 2-alkyl-4,5-DMP homologs, pyrazole, 5-isopropyl-,5-phenyl-, and 4-methyl-5-phenylpyrazoles (XXXVI) caused an analgesic-spasmolytic consequence which paralleled an increase in molecular weight (245). Analgesic 3-hydroxypyrazolecarboxylic acids have been reported (246).

Pyrazole and 3-*n*-alkylpyrazoles (XXXVII) acted as species-selective anticonvulsants in lab animals; optimal convulsion-inhibition occurred with a 4-C side chain in this series (247). Human epileptic seizures were controlled with 4-chloropyrazole or 1 of 3-mono- or 3,4-disubstituted pyrazole·HCl salts (XXXVIII) (248), while a series of 1,4-disubstituted pyrazolecarbinols showed anticonvulsant-muscle relaxant activity (XXXIX) (249).

Phemerazole,3-methyl-5-phenylpyrazole (XL), was one of a group of pyrazoles which evoked sharply pronounced sedative, soporific, anticonvulsant, and hypothermic responses. A tenfold species differential was shown in lab animals upon administration of this compound, which inhibited nikethamide, strychnine, and picrotoxin activity in mice and activated camphor. However, when it was given with arecoline and with nicotine, it moderated tremors and convulsions, but increased animal mortality. Phemerazole potentiated the action of diethylstilbestrol on mammary glands (250–254). The anticonvulsant and toxic properties of its 1-allyl- and 1-methyl-4-nitro- analogs (XLI) have been cited. Phemerazole activity has been compared to that of meprobamate on the suppression of a response to an electric stimulus and to nikethamide overdoses (255). It produced no analgesia in rats but did potentiate morphine; however, this combination was more toxic than either substance singly (256). Phemerazole, several of its homologs, and tetrahydroindazole depressed polysynaptic, but not monosynaptic, reflexes. In mice and rats these "mephenesin-type" central relaxants depressed the "turn-over reflex" (257). The distantly related 3-amino-5-(trifluorophenyl)indazole was also a muscle-relaxant analgesic (258). When given in high doses, the majority of aminopyra-

zoles depress the CNS; some are capable of potentiating the effect of thiopental, while others eliminate aggression in mice without visibly depressing their behavior. Aminopyrazoles displayed a weak antagonism to the spastic action of pentylenetetrazol[5] and some were classified as tranquilizers, with high activity being attributed to 1-phenyl-3-*p*-amino-phenyl-5-aminopyrazole (XLII). 3-Phenyl-5-aminopyrazole (259) and the 1-isopropyl and 1-(2-hydroxyethyl)-homologs (XLIII) produced distinct muscle relaxation (260). The S-A-R of 13 *N*-substituted 3-amino-4-phenylpyrazoles has been reported, and the parent compound has proved to be the most effective in the series (Table III) (261, 262).

Patients with chronic bronchitis and respiratory failure, who were treated with 2-(*N*-methyl-4-piperidyl)-3-amino-5-(4-pyridyl)pyrazole · HCl (XXXI), showed improvement of some parameters of respiratory mechanics and some indexes of external ventilation. The compound produced bronchospasmolytic effects, but no improvement of internal ventilation was observed (263). Some 4-mono- (XLIV) and 1,4-disubstituted pyrazoles (XLV), which lowered muscle tone, motor activity, and body temperature, antagonized nikethamide and strychnine spasms. The 4-ethyl- and 4-isopropyl- compounds provoked the greatest responses. It was found that the less toxic disubstituted substances were also less active (264). 4-Piperazinoalkylpyrazoles incited a wide range of central responses: central depression, narcosis potentiation, sedation, tranquilization, hypnosis, and narcosis (265). Metoquizine (XLVI) and toquizine (XLVII) were found to be interesting "antiulcer" indolo[3,4-*fg*]quinolinylpyrazoles (266), and 3-nitroso-6-amino-1*H*-pyrazolo[1,5-*a*]pyrimidines (XLVIII) promoted central activity (267).

The clonic convulsions and mortality induced by pentylenetetrazol were promoted by 5-benzyl- and 5-isopropyl-3-methylpyrazole carboxylic acid hydrazides (XLIX), known MAO-inhibitors (268). A 1-methylpyrazole-4,5-diamide (II): prolonged chloral hydrate-induced sleep, antagonized caffeine, intensified the spasmodic effects of corazole, nicotine, and strychnine, stimulated gastric secretion by a central mechanism, was less toxic than the imidazole isomer, and exerted a sedative effect on the cerebral cortex. Several 4,5-

diamides (LI) antagonized caffeine and potentiated amphetamine. The effect of pyrazole dicarboxylic acid on EEG tracings has been reported (269–272). 2-Phenyl-3-acetylaminopyrazolo[1,5-*a*]benzimidazole-6-sulfonic acid (LII) stimulated the nervous system without a growth of spontaneous motricity (273).

Takamizawa *et al.*, who prepared and investigated the pharmacodynamics of a large number of pyrazolo[1,5-*a*]pyrimidines (XXVI), found that 4-substituted homologs possessed antipyretic-antiphlogistic activity. The 7-amino-substances were analgesic, anti-inflammatory, antipyretic, and antiphlogistic, and the 7-carbonyl-amido- and 3-methyl-6-carbethoxy-7-oxo-XXVI products tranquilized, depressed inflammation, and lowered body temperature. The 7-imino-4,7-dihydro-XXVI substances were sedative and antiphlogistic-antipyretic. 2,5-Dimethyl-XXVI was analgetic and antipyretic, and 3-cyanoethyl-2-oxo-5-phenyl-XXVI exhibited anti-inflammatory activity. Also prepared were the 2,3-dialkyl- and 7-formamido-XXVI (274–286). One series of XXVI compounds reduced inflammation (287).

ANTI-INFLAMMATORY AGENTS

Pyrazole demonstrated a reasonable correlation between its antierythemic and antirheumatic activity and this inflammation-inhibiting effect was used in the UV erythema pharmacological assay for anti-inflammatory drugs (288). Activity was apparent in several novel 1-carbamoyl-3-amino-4-nitrilopyrazoles (289). 2*H*- and 1*H*-pyrazolo[3,4-*c*]pyridines (LIII, LIV) reduced inflammation (290) and the indazole (LV) isostere of 5-hydroxytryptamine produced similar responses from isolated smooth muscle preparations (291–293). Several pyrrazoloindazoles (LVI) were analgesic and reduced inflammation (294). Citrates, maleates, and sulfates of 3-dialkylaminoalkyoxyindazoles displayed enhanced activity (295).

The first therapeutically important indazole was benzydamine, 1-benzyl-3-[3-(dimethylamino)propoxy]1*H*-indazole (LVII). Benzydamine and its salts possessed excellent inflammation-reducing properties, but the hydrochloride salt was the most active of the compounds examined (296). Absorption and elimination studies indicated large quantities of unchanged drug in the blood; 1 mg./Kg., in man, created significant and prolonged blood levels. The drug passed into the

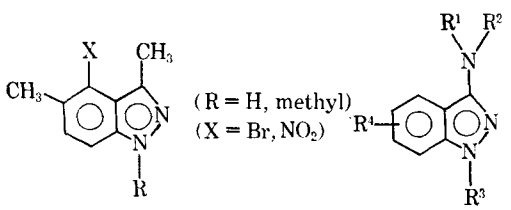
[a] These hydrochloride salts produce sedation, muscle relaxation, and motor incoordination at 20–40 mg./Kg. At 80–100 mg./Kg. depression followed by clonic convulsions at near lethal doses occurs. [b] Using the hot plate and phenylquinone tests it is found that the more toxic *n*-2 side chains are least active. ED_{50}'s of 20–40 mg./Kg. are usual. [c] ED_{50}'s 40 mg./Kg. *vs.* strychnine or electroshock induced convulsions. [d] The guinea pig ileum used. A papaverine-like effect produced (0.3 mcg./ml.). [e] ED_{50} 15 mg./Kg. *vs.* plantar edema and induced granuloma. [f] Active at 0.5 mg./ml. *vs.* corneal reflex and tail pinch. [g] Toxicity varies between 120–150 mg./Kg. (LD_{50}) for the series. Compounds with NH_2 and NO_2 in their nucleus are most toxic.

intestinal lumen, in rats, but was not excreted in the feces, suggesting enteric circle. Fifty percent was excreted in the urine of man (297). Liver response, enzyme induction, and resultant increase in liver weight have been cited (298). Benzydamine was compared to codeine and aspirin, using various pain-threshold techniques in mice (299); the local effect and a lack of interference with the adrenals was observed (300). Axerio introduced a new synthesis for benzydamine (301), which was stated to be the most powerful analgetic-anti-inflammatory drug in use (299). Silvestrini has reviewed benzydamine (302).

Low toxicity, reduced inflammation, analgesia, and a decrease of spasms were attributed to 34 homologs of benzydamine (Table IV) (303). Other interesting work on synthetic nonsteroidal inflammation-reducing agents was reported (304), and of these, the 4-bromo- and 4-nitropyrazoles (LVIII) were impressive anti-inflammatory substances (305). The general pharmacology of a few 3-disubstituted-amino-1*H*-indazoles (LIX) was given in another report (306).



LVIII LIX

BIOLOGICALLY ACTIVE PYRAZOLOSTEROIDS

Pharmacodynamic interest in steroidal pyrazolo-compounds dates to the 1959 work of Clinton *et al.* (307, 308) with psychopharmacological agents. Hypotensive and hypophyseal-blocking action was observed for a series of estra-1,3,5-(10)-triene[17,16-*c*]pyrazoles (LX) (309) and 20-oxo-4-pregn[3,2-*c*]pyrazole guanylhydrazone · HCl (LXI) (310). Hormonal steroids with pyrazole fused to positions C-2 and C-3 were first reported in the androgen family (311), but some A-aza-steroids (LXII) were found to be inactive androgenic, anabolic, estrogenic, or antiestrogenic substances (312). Rosseels has reviewed LXII (313). Progestation was effected with pyrazolo-[3,2-*c*]-19-nor-4,9-androstadienes (LXIII) (314), and 4-androsteno[3,2-*c*]pyrazoles (LXIV) caused progestational, estrogenic, and lower blood-cholesterol responses (315). Steroidal [17,16-*c*]-pyrazoles reduced cholesterol levels equally as well as estradiol, but their estrogenic potency was only 1/10,000 that of estradiol (316).

17β-Hydroxy-17α-methylandrostano[3,2-*c*]-pyrazole, stanozolol (LXV), and the 4-eno-analog, when given to human patients, influenced N-retention and electrolyte balance. Chronically ill geriatric mental patients gained weight with stanozolol and 1 to 20 mg. daily for 24–161 days resulted in no hepatotoxicity. Appetites and mental outlook improved without the occurrence of androgenic or other adverse effects. A posi-

LXV

tive N-balance resulted through an unknown mechanism, and calcium metabolism was influenced also. Stanozolol, given orally, was 30 times as potent as methyltestosterone, but had only one-fourth the androgenic activity. This pyrazolosteroid increased hemoglobin and serum-albumin levels with the former being even more dramatically affected than body weight. Serum cholesterol and phospholipid concentration were lowered by stanozolol. Anabolic effects persisted for several weeks following termination of stanozolol therapy. The most serious problems, which were lowering the α-lipoprotein level and the $\alpha:\beta$-lipoprotein ratio, closely paralleled those met with nonpyrazolo anabolic steroids (317–320).

16α,17α-Dihydroxy-2-oxo-4-pregnene[3,2-*c*]pyrazoles (LXVI) were found to be anti-inflammatory compounds. 2′-(*p*-Fluorophenyl)pregn-4-eno[3,2-*c*]pyrazole (LXVII) was the most potent agent in the series (1964) (Table V) and other phenyl-substituted electron-withdrawing groups were found to decrease the activity of the parent phenyl-homolog. One relative was 500 times more active than cortisol for antagonizing granuloma formation and causing adrenal atrophy. Neither this substance, 9α-fluoro-16α-methylcortisol nor LXVII caused Na retention in

the rat. While studying the activity of pregn-4-eno and 5α-pregnano-[3,2-*c*]pyrazoles, investigators first made the novel observation that a carbonyl function at C-3 was not required for anti-inflammatory activity. The [3,2-*c*]pyrazole function, unlike the 2-α-methyl-, did not enhance mineralocorticoid activity. These results were intriguing, since the highly potent 2′-phenylpyrazole homolog chemically resembled the biologically inactive isoxazole isostere in its double bond structure; whereas, the nearly inactive 1′-phenylpyrazole homolog, like the natural corticoids, had an exocyclic double bond at C-3 (321–326). Two 17β-hydroxyandrost-5-eno-[3,2-*c*]-pyrazoles (LXVII) were the most effective of 42 androstane derivatives examined as inhibitors of β-hydroxysteroid dehydrogenase. The degree of inhibition was dependent upon the nature of the substituents at positions 2, 3, 4, and 17 of the steroid. Spatial presentation of these groups to the enzyme by the arrangements of double bonds or by their absence also affected inhibition. Estradiol-17β was noncompetitive, while these pyrazolosteroids acted by a competitive mechanism. The 50% inhibitory concentration for estradiol-17β of 5×10^{-5} moles/L. as opposed to 5×10^{-7} moles/L. for LXVIII gave evidence that the pyrazole was more tightly bound to the enzyme (327). Interesting new pyrazolyl- and pyrazolosteroids have been synthesized (328–330).

NATURAL PRODUCTS

Until 1963 pyrazoles of natural origin were unknown but with a little help from Takeshita *et al.* (331), β-(1-pyrazolyl-L-alanine (LXIX) was identified and confirmed. A new enzyme, pyrazolealaninase, which is specific for the L-isomer, has been purified from cells of *Pseudomonas cruciviae* (watermelon juice) grown on the new amino acid. Attempts to activate S-protein at high peptide-protein ratios by replacing the histidine moiety with LXIX or its 3-pyrazolyl homolog have failed. It appears that the ionization behavior of histidine was responsible for the ability of S-peptide to activate S-proteins (332).

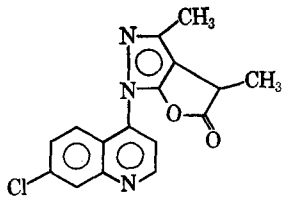
Valcazi *et al.* (333) treated chlortetracycline·HCl with hydrazine in methanol at 20°. The addition product, a conjugated pyrazolotetracycline (LXX), exerted the same action on several organisms as the parent antibiotic. The molecular structure has been established for another natural antimicrobial pyrazolo-compound, formycin, 7-amino-3-(β-D-ribofuranosyl)pyrazolo-[3,4-*d*]pyrimidine (LXXI), and the deaminated product, formycin B (LXXII), also has been identified. 7-Amino- and 7-hydroxypyrazolo-[4,3-*d*] pyrimidine were obtained from LXXI and LXXII, respectively. The semisynthetic hydrazinoformycin (LXXIII) has shown antimicrobial effects (334–337). Withasomnine (LXXIV), isolated from *Withania somnifera* roots, which are used medicinally in India, was structurally proven (338), and 1*H*-pyrazolo[3,4-*b*]quinoxaline "flavones" (LXXV) have been reported (339).

MISCELLANEOUS ACTIVITY

Pyrazole exerted a protective effect on hemin against *in vitro* degradation by ionizing irradiation. A carbamyl-DMP,[6] gave a 50% survival rate at doses of 200 mg./Kg. in mice over a 30-day period (340–342).

DMP stimulated plant growth (343), while 1-aryloxyacylpyrazoles were growth regulators

[6] Dupont-990.



LXXVI

and herbicides (344). 1-Guanyl-DMP·HNO_3, which reacts specifically with the ϵ-amino- groups of lysine (345-347), was utilized for the guanidation of bovine serum albumin, β-lactoglobin, and ovalbumin.

Alkylpyrazoles have been suggested for use in perfumery (348). Pyrazolo[4′,3′:5,6]2-pyrone (LXXVI), a novel annelate, incited no appreciable pharmacodynamic response (349).

CONCLUSIONS

The versatility of action of even the simplest pyrazoles was noteworthy, and pyrazole, itself, was mentioned on several occasions. A dimethylated pyrazole, DMP, and its carboxylic acid metabolite exerted profound effects on diuresis, fat, and glucose metabolism. The simple histamine isomer, betazole, manifested greater specificity on gastric secretions than histamine, while 3-methyl-5-phenylpyrazole, phemerazole, was an excellent central spasmolytic anticonvulsant. The simple pyrazoles, XXII, XXIII, XXIV, and pyrazoxon reportedly are all commercially successful pesticides, and the 1*H*-indazole, benzydamine, has proved to be an excellent nonsteroidal anti-inflammatory agent. Xanthine oxidase inhibitors like allopurinol, used in gout, and its carcinostatic 4-amino analog have been highly effective substances. The androstano-[3,2-*c*]pyrazole, stanozolol, fairly exploded on the scene and has become one of our finest anabolic agents. These drugs were all unknown 10 years ago.

The pyrazoles are exciting entities from which many new biologically active materials have been derived. Unlike the thiophenes (350), there is no slackening of interest in these pi-excessive N-heteroaromatic compounds. Quite to the contrary, the breath-taking pace of discovery of new pyrazolo-ring systems, new substitutions in established nuclei, and the biological responses to these heterocycles and to their modification products has given a momentum to pyrazole researches that has been known to few heterocycles. The widely varied biological activity spectrum is, indeed, unique. Pyrazole has manifested itself, in most instances, as a distinct and accountable portion of any number of diverse chemical structures which effect numerous biological responses. The crest of activity has yet to peak in the vast wave of research in this fertile area of study.

Use of the Coulter Counter and a Digital Computer for the Evaluation of Stability Ratios in Flocculating Monodisperse Systems

By B. A. MATTHEWS and C. T. RHODES

The combined use of the Coulter counter and a digital computer has been shown to be a powerful tool in evaluating stability ratios of flocculating monodisperse polystyrene lattices. The method involves comparing the experimental and theoretical depletion rates of the singlet species and corrections have been applied for the presence of higher species at the start of the flocculation experiment. The influence of particle size, particle concentration, electrolyte concentration, and surfactant upon suspension stability has been examined.

INCREASING ATTENTION has been focused in recent years upon the interfacial properties of powdered drugs. This interest may be attributed, at least in part, to the growing importance of suspensions as a dosage form. Although a considerable number of useful research and review articles on flocculation in pharmaceutical systems, has been published (1–12), there is still need for further investigation. A number of areas in this field are still in need of further illumination; there is, for example, some controversy as to the exact nature of the role of zeta potential in the flocculation of supracolloidal systems (2–9, 13).

The process of flocculation in a disperse system involves the increase in apparent particle size due to the formation of doublets, triplets, and higher species. Thus, *a priori*, one can consider any experimental technique of use in particle-size measurement, for the study of flocculation kinetics. A number of classical physicochemical methods such as light scattering (14), sedimentation (15, 16), and microscopy (11) can be used for work on flocculation kinetics. However, many of these techniques are of limited utility since they measure the total size of floccules and do not distinguish between the singlet, doublet, triplet, *etc.*, species. The Coulter counter (17, 18) measures particle volume and if the original system is monodisperse, the presence of doublets, triplets, and even quadrupulets can be detected. The Coulter counter technique is capable of measuring several thousand particles per second and once the operator has gained experience in the use of the equipment, data can be accumulated in a remarkably short space of time. However, even with the use of electromechanical or electronic calculators, the conversion of raw counts to singlet and multiplet concentrations is both tedious and time consuming. When such data have to be substituted into the somewhat complex flocculation equations (see later), the calculation process is further extended and the possibility of error greatly increased. In the present paper the combination of a Coulter counter and a digital computer is shown to provide a powerful tool for the study of the interfacial properties of monodisperse supracolloidal suspensions.

Most of the physicochemical studies of flocculation kinetics have been limited to systems containing particles well within the colloidal range, the upper limit of which is about 0.5 μ (19), whereas powdered drugs are almost invariably of supracolloidal dimensions (20, 21). Equations governing colloidal flocculation might well be expected to require modification on application to supracolloidal systems, since sedimentation may occur even in the singlet species. In the present paper a method is presented for studying the flocculation of particles in the size range 0.5–5.0 μ.

THEORY

The kinetics of flocculation in colloidal systems is dependent upon two factors, the Brownian motion

Received August 14, 1967, from The Physical Pharmacy Department, School of Pharmacy, Portsmouth, Hampshire, England.

Accepted for publication November 8, 1967.

The authors thank Miss F. Tringham for technical assistance and Mr. B. R. Martin and Mr. A. N. Richmond of the Department of Mathematics, Portsmouth College of Technology, Portsmouth, Hampshire, England, for helpful discussions on the computer program.

of the particles and the extent of their mutual interaction when in close proximity. The simplest case may be defined as when there is no mutual repulsion between the particles, such that any particle entering the sphere of interaction of another coalesces irreversibly with it. This situation was considered by Von Smoluchowski (22, 23) in his theory of rapid coagulation.

Smoluchowski assumed that at the start of flocculation, N_0 spherical particles of equal size are present per unit volume of liquid and that flocculation is started by a sudden removal of the mutual repulsion of the particles. The number of particulate encounters is determined by considering the process as a diffusion problem.

He showed that the number of aggregates of k single particles at any time, t, N_k, is given by the expression

$$N_k = \frac{N_0(t/T_{1/2})^{k-1}}{(1 + t/T_{1/2})^{k+1}} \qquad \text{(Eq. 1)}$$

$T_{1/2}$ is the coagulation time, defined as the time required to reduce the total number of particles by one-half. The coagulation time may be calculated from the equation

$$T_{1/2} = \frac{1}{4\pi D_i R N_0} \qquad \text{(Eq. 2)}$$

where D_i is the diffusion constant of the particles and R is the distance between the centers of two particles when flocculation occurs. This is, in the simplest case, $2r$, where r is the radius of the primary particles. The derivation of these equations has been given by Overbeek (24).

Equation 1 becomes for the singlet

$$N_1 = \frac{N_0}{(1 + t/T_{1/2})^2} \qquad \text{(Eq. 3)}$$

and for the doublet

$$N_2 = \frac{N_0\, t/T_{1/2}}{(1 + t/T_{1/2})^3} \qquad \text{(Eq. 4)}$$

The total number of particles in the system becomes equal to

$$\sum_{k=1}^{\infty} N_k = \frac{N_0}{1 + t/T_{1/2}} \qquad \text{(Eq. 5)}$$

Figure 1 shows a graph of the number of each species up to triplet as a function of time (taken from *Reference 24*, p. 282).

This theory has been tested experimentally by Turkevich (25) using a gold sol of spheres having a diameter of 400 Å., and good agreement was found with K values up to 6 in the early stages of flocculation.

The Eq. 5 gives no information on the stability of colloids, and although these systems are thermodynamically unstable they can remain, with little apparent change, over long periods of time.

Smoluchowski extended his theory to cover slow flocculation by assuming that only a fraction, α, of the collisions leads to permanent coalescence. The course of coagulation is still governed by Eq. 1, but Eq. 2 now becomes

$$T_{1/2} = \frac{1}{4\pi D_i R N_0 \alpha} \qquad \text{(Eq. 6)}$$

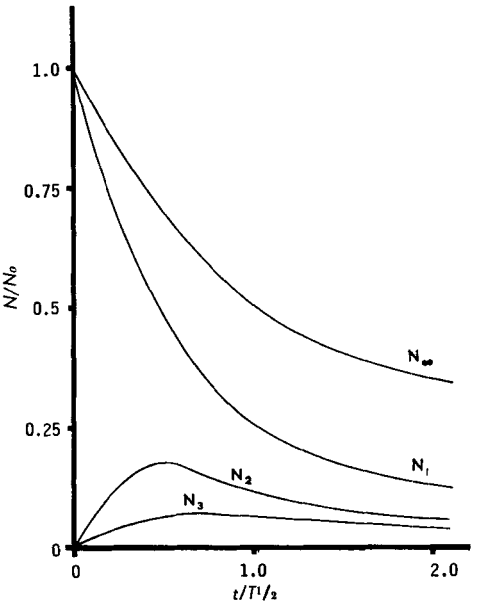

Fig. 1—Theoretical curves for the proportion of various species as a function of time in rapid flocculation (taken from Reference 24).

Smoluchowski assumed that α, which can be called the "collision efficiency," remains constant over the whole period of coagulation but Van Arkel and Kruyt (26, 27) and Tuorila (28) showed that this is not the case and that the rate of coagulation decreases with time. This has been explained by Reerink and Overbeek (29) by the fact that the repulsion between aggregates is larger than that between individual particles.

No theory was available to link the quantity α with such parameters as the zeta potential and electrolyte concentration, and Fuchs (30) modified Smoluchowski's theory to enable collision efficiency to be predicted from a consideration of the energy barrier between the particles.

The total energy of interaction between two particles, V_t, is the sum of the attractive contribution V_a and the repulsive contribution V_r. This potential V_t retards the process for rapid coagulation by a factor W such that

$$W = 2r \int_{2r}^{\infty} \left[\exp.\left(\frac{V_t}{kT}\right)\right] \frac{dS}{S^2} \qquad \text{(Eq. 7)}$$

where r is the particle radius, S is the distance between the particle centers $= 2r$ at coagulation, k is the Boltzmann constant, and T is the absolute temperature.

W denotes the ratio of rapid to slow coagulation, and when V_t is zero for all separations of the particles, $W = 1$ and rapid coagulation occurs according to the Smoluchowski equation. For slow coagulation, Eq. 5 becomes

$$N_k \frac{N_0}{1 + t/T_{1/2}\,(\text{slow})} = \frac{N_0}{1 + t/T_{1/2}\,(\text{fast})\; W} \qquad \text{(Eq. 8)}$$

and the coagulation time becomes

$$T_{1/2} = \left(\frac{1}{4\pi D_1 R N_0}\right) W \qquad \text{(Eq. 9)}$$

From a comparison of Eqs. 6 and 9

$$W = \frac{1}{\alpha} \qquad \text{(Eq. 10)}$$

with α always <1 and W in theory, always >1. W can be <1 (24), and this is explained by the presence of London attraction forces which accelerate coagulation. Equation 7 describes the retardation in flocculation in the initial stages when not many secondary particles have formed, and Overbeek (*Reference 24*, p. 285) has stated that it is not possible to extend the theory to cover collisions between multiple particles. The dependence of W on such factors as particle size, electrolyte concentration, and valency, has been reviewed by Verwey and Overbeek (31), Ottewill and Watanabe (32–36), Somasundaran, Healy, and Fuerstenau (37), and the theory was extended to a dispersion containing two types of particle by Hogg, Healy, and Fuerstenau (38).

Determination of Stability Ratios in Monodisperse Systems—From Eqs. 6 and 9 the collision efficiency α, or stability ratio W, could be determined by simply measuring the change in total concentration of particles with time and recording the $T_{1/2}$. This would, however, not take into account any changes in collision efficiency during the coagulation process and, if coagulation were slow, would require a lengthy experiment. Equations 1, 3, and 4 can be used to determine α or W at any period of time during the reaction provided a method is available to distinguish between the various species in the system. A recent series of papers (39–41) by Higuchi *et al.*, has demonstrated the suitability of the Coulter counter to determine the relative proportions of singlets, doublets, triplets, and sometimes quadrupulets in flocculating monodisperse polystyrene lattices. Study of Fig. 1 shows that the species that undergoes the greatest change in concentration during flocculation is the singlet, and therefore measurement of the concentration of this species is likely to give greatest precision, especially where flocculation is slow, *i.e.*, where α is small and W large, or in systems of low concentration. We have used the Coulter counter to follow the rate of depletion of the singlet species in flocculating monodisperse systems and have used a digital computer to compare this rate with that predicted by the Smoluchowski theory, to evaluate the stability ratio.

Method of Calculation—From Eq. 3 the relative proportion of singlets to the total original concentration at any time t, is equal to

$$\frac{N_1}{N_0} = \frac{1}{(1 + t/T_{1/2})^2} \qquad \text{(Eq. 11)}$$

by rearranging

$$t = \left(\sqrt{\frac{N_0}{N_1}} - 1\right) T_{1/2} \qquad \text{(Eq. 12)}$$

and a graph of t against $\sqrt{(N_0/N_1 - 1)}\, T_{1/2}$ should be a straight line with a slope of 1 if rapid coagulation occurs. When coagulation is slow, the graph has a slope of α or of $1/W$.

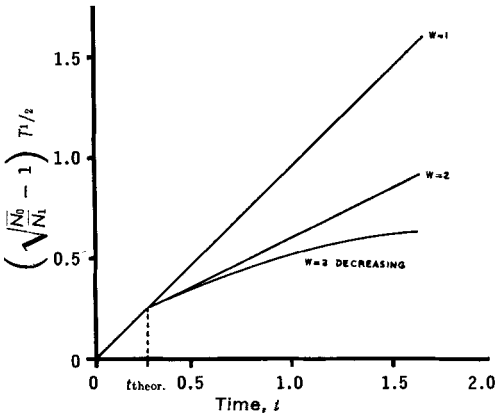

Fig. 2—Theoretical plot of $\left(\sqrt{\frac{N_0}{N_1}} - 1\right) T_{1/2}$ *as a function of time at different stability ratios.*

Since, however, it was not possible to start with 100% singlets, the systems at $t_{exp.} = 0$ always appeared to have already been flocculating for a small time $t_{theor.}$ This value was obtained by substituting the value of N_1/N_0 obtained at $t_{exp.} = 0$, into Eq. 11 and it was added to all subsequent values of $t_{exp.}$ in the flocculation process. This method was considered to be valid since at the beginning of the experiment the relative proportion of singlets, doublets, and tripletsw as always in accord with that which would be predicted from Fig. 1.

Figure 2 shows a graph of t against $(\sqrt{N_0/N_1} - 1)$-$T_{1/2}$ for three systems where $W = 1$, $W = 2$ and where $W = 2$ initially, but falls during the course of the experiment. The graph depicts results obtained from theoretical calculations and illustrates the application of the correction factor $t_{theor.}$ to obtain the true effective zero time.

The coagulation time $T_{1/2}$ was calculated from Eq. 2 (see *Reference 24*, p. 282), which for water at 298°K. becomes equal to

$$T_{1/2} = \frac{2 \times 10^{11}}{N_0 \times 3.6 \times 10^3} \text{ hr.} \qquad \text{(Eq. 13)}$$

In this paper the above approximate equation has been used. However, in studying the flocculation of true colloidal systems when absolute rather than apparent W values can be determined the numerator, under the above conditions, should be stated more precisely as 1.63×10^{11}.

EXPERIMENTAL

A Coulter counter model "B"[1] was employed with 30-μ and 50-μ orifices. The model B is a dual threshold machine, and by setting the upper and lower threshold controls at suitable values, about that which corresponds to the volume of the species to be measured, counts can be obtained directly. Electrolyte, consisting of 1% sodium chloride, filtered through 0.45 μ Millipore[2] filters, was used with the 50-μ orifice and 2% sodium chloride filtered through 0.45 μ and 0.100 μ Millipore filters for the

[1] Manufactured by Coulter Electronics Ltd., Dunstable, Bedfordshire, England.
[2] Marketed by Millipore (U.K.) Ltd., Wembley, Middlesex, England.

30-μ orifice. Background counts, which were always low, were taken on the electrolyte and measurements of the particles were made at concentrations which enabled coincidence to be ignored.

The flocculation was carried out in 150-ml. stoppered flasks which were immersed in a water bath maintained at 25 ± 0.1°.

Materials—Samples of Dow[3] polystyrene lattices of diameter 0.714 μ and 1.305 μ were used, as obtained from the manufacturer.

The standard deviations quoted by the manufacturer for these lattices were 0.0053 μ for the 0.714-μ sample and 0.0158 μ for the 1.305-μ sample. Standard deviations determined from cumulative number/percentage size distribution curves obtained using the Coulter counter were somewhat higher than these values, 0.02 μ and 0.025 μ, respectively. However, the samples are sufficiently monodisperse to enable the vast majority of singlets to be differentiated from higher species, and for the Smoluchowski equation to be employed. Wachtel and La Mer (42) have also noted larger standard deviations of monodisperse polystyrene lattices, measured on the Coulter counter, than those stated by the manufacturers.

Suspensions were diluted in filtered distilled water which had been freshly distilled from an all-glass still and the working level was between 1.0×10^7 and 1.0×10^8 particles/ml. Aluminum chloride hexahydrate, $AlCl_3 \cdot 6H_2O$, was selected as the flocculating electrolyte since it was hoped to extend the work to pharmaceutical suspensions and aluminum was considered the most suitable trivalent metal from the viewpoint of toxicity.

General Method—All glassware used in the flocculation experiments was cleaned with chromic acid and rinsed six times with distilled water and twice with filtered distilled water. All apparatus used for measurement on the Coulter counter was rinsed with filtered electrolyte. Suspensions of the latex particles were prepared at 90% of the required concentration and 90.0 ml. was placed in the reaction flasks and allowed to reach the experiment temperature. Volumes of 2.0 ml. of the suspension were withdrawn and diluted in filtered electrolyte to a suitable working level. A count of singlets, doublets, triplets, and all species above was taken and the results used to determine the original total number of latex particles in the system.

Although ultrasonics and a high speed dispersion mixer were tried, it was not found possible to produce a system of pure singlets to start the reaction. This is in line with the experience of Higuchi *et al.* (39) who took as their starting point 90% singlets, 8% doublets, 1% triplets, and 1% larger aggregates. The method of dilution was standardized as far as possible although variation in the technique was not found to affect the count significantly.

The experiment was initiated by adding 10.0 ml. of the flocculating electrolyte at a concentration of 10 times that required in the reaction mixture and at suitable intervals samples were withdrawn and assayed for the singlet species and the total count. The concentration of singlet species, in the system initially, was calculated from the counts taken at the beginning and the dilution factor.

Experiments were designed to demonstrate the effects of particle size, concentration of particles, concentration of electrolyte, and the presence of surfactant on the stability ratio W.

Computer Program—An Elliot 803 digital computer was programmed in Algol 60 to compute values of W by means of the method outlined above. A print-out of the program is shown in the *Appendix*. Values of the Smoluchowski collision efficiency α were computed also but all results are expressed in terms of W. Mean values of W are given except in a few instances where a pronounced reduction in flocculation rate occurred at the end of the experiment. In these cases initial values of W are used.

RESULTS AND DISCUSSION

Effect of Concentration of Particles on W—The effect of different concentrations of particles on the stability ratio W, at high electrolyte concentrations, was measured using 0.714-μ polystyrene latex at concentrations of 10^7 to 10^8 particles per ml. The concentration of aluminum chloride was 5×10^{-3} M, which is considerably above the critical electrolyte concentration.

The results shown in Fig. 3 indicate a reduction in W with increasing concentration up to a level of about 5×10^7 particles per ml., above which no further decrease occurs. However, in the experiments at the two highest concentrations, it was found that the initial values of N_1/N_0 were very low (0.41 and 0.36, respectively) compared with values of about 0.84 for all of the other systems. This indicates that some spontaneous flocculation, or lack of deflocculation on dilution from the concentrate, occurs at these higher concentrations. While it is known (39) that these polymers contain small amounts of an anionic surfactant which affects stability, the energy barrier is evidently not sufficient to prevent flocculation at this particular concentration. Although values of W on these two systems were, therefore, determined on colloids which were already considerably flocculated, they are in good agreement with the systems at between 4 and 7×10^7 particles per ml. and which were only very slightly flocculated at the start of the experiment. Earlier workers (24, p. 322) with true colloids have reported both increases and decreases in stability with increasing concentration of colloidal

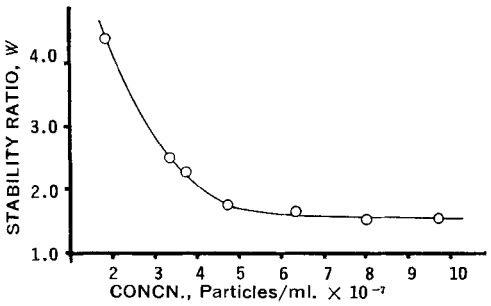

Fig. 3—Influence of particulate concentration on stability ratio.

[3] Kindly supplied by Mr. B. J. Lippie, Dow Chemical Company, Midland, Mich.

[4] This sample when calibrated by means of the 0.714-μ latex and a 1.099-μ latex was found to have a diameter of only 1.20μ but this did not affect the experiments since Coulter threshold settings were calculated from the results of calibration by taking readings at $^3/_2$ and $^1/_2$ of the mean pulse height as recorded on the oscilloscope, as recommended in the instruction manual (43).

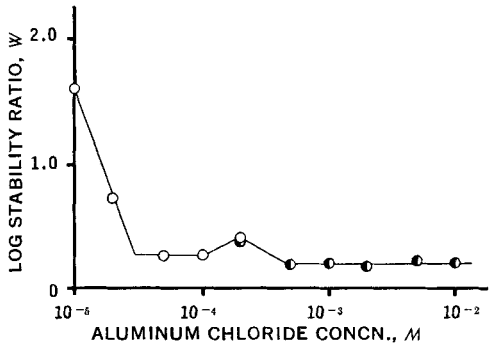

Fig. 4—Stability ratio W *as a function of aluminum chloride concentration for 0.714-μ polystyrene latex. —○— and —◐— are separate experiments.*

particles, but Klompé (24, p. 323) who corrected for exchange of flocculating ions against double-layer ions, reported that for a trivalent electrolyte, higher concentrations of sol required lower concentrations of electrolyte to produce flocculation. Further experiments are required with the lower concentrations of particles to determine whether different concentrations of electrolyte can produce reductions in the value of W. With aluminum salts there is also the possibility of peptization (44) although results on this system suggest that the concentration used in this experiment is higher than the peptizing concentration.

Effect of Electrolyte Concentration on W—After consideration of the results of the above experiment, a concentration of 5×10^7 particles per ml. was selected, and the stability ratio was determined at concentrations of aluminum chloride from 10^{-5} to 10^{-2} M. The results are shown in Fig. 4 (combined results of two experiments).

An initial rapid reduction in W occurs with very low concentrations of electrolyte. If this portion of the graph is extrapolated to log $W = 0$, the critical flocculation concentration is 3.5×10^{-5} M. This is in good agreement with the range 9×10^{-6} to 9×10^{-5} given by Overbeek (24, p. 309) for the flocculation of negatively charged sols by aluminum salts. A small region of partial peptization occurs at 2×10^{-4} M and above this value W reverts to just below its original minimum.

Effect of Particle Size on W—It is of interest that the flocculation rate never reaches the Smoluchowski maximum for rapid coagulation where $W = 1$ and log $W = 0$, in contrast to the experience of earlier workers with conventional colloids (24, p. 32) and of Ottewill and Shaw (45) with monodisperse polystyrene latex particles of diameter 0.06–0.4 μ. The particles used in the above experiments are less than twice the diameter of the largest used by Ottewill and Shaw. The minimum value of W is 1.5 which means that the maximum flocculation rate is 67% of the Smoluchowski rate. This is in good agreement with the results of Higuchi *et al.* (39) who found that the singlet/singlet flocculation rate constant of 1.83-μ polystyrene latex particles approached the Smoluchowski rate to within about a factor of two. Higuchi *et al.* (39) and Swift and Friedlander (46) have suggested that this deviation from theory is due to hydrodynamic interactions when the particles are within one diameter of each other.

The maximum concentration of electrolyte used was 10^{-2} M and providing that peptization does not occur, the energy barrier at such high concentrations will be very low, or nonexistent. Values of W at these concentrations will not be an expression of the energy barrier but of the retardation of coagulation due to these hydrodynamic interactions.

At any concentration of electrolyte

$$W_{exp.} = W_{true} + C \qquad \text{(Eq. 14)}$$

where

$W_{exp.}$ = measured value of stability ratio.
W_{true} = contribution to stability due to energy barrier.
C = additional contribution due to hydrodynamic interaction.

Below a certain critical size, C becomes insignificant and

$$W_{exp.} = W_{true} \qquad \text{(Eq. 15)}$$

This critical size would seem to be somewhere in the region of 0.5 μ which is significantly the upper limit which some authors would place on the colloidal state.

If this explanation is correct one would expect that the minimum values of $W_{exp.}$ would be greater still for particles larger than 0.7 μ.

To test the above theory a similar experiment was performed using the 1.305-μ diameter latex from Dow (Coulter diameter 1.20 μ).

The results (Fig. 5) show that the general rule of increase in stability with increase in particle size stated by Verwey and Overbeek (31, p. 177) is obeyed, the critical concentration having been increased by a factor of about 10^2. The minimum value of $W_{exp.}$ has increased from 1.5 to 2.0, as predicted above. Further experiments are planned on systems in the diameter range 0.5–2.0 μ to investigate this relationship in greater detail.

Effect of Surfactant on W—In order to determine whether adsorbed surfactant was likely to have any effect on the log W/concentration curve an experiment was performed using the same concentration of particles in the presence of 2.5×10^{-5} M ammonium lauryl ether sulfate.[5] This has been shown

[5] Marketed as "Empicol EAB" by Marchon Products Ltd., Whitehaven, Cumberland, England.

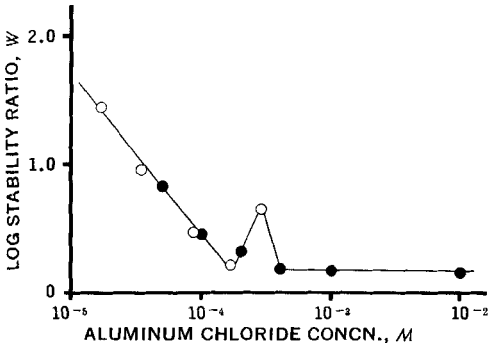

Fig. 6—Stability ratio W, *as a function of aluminum chloride concentration for 0.714-μ polystyrene latex containing 2 × 10^{-5}* M *ammonium lauryl ether sulfate.* —○— *and* —●— *are separate experiments.*

(13) to be compatible with aluminum salts, whereas more commonly used anionic surfactants such as sodium lauryl sulfate and sodium dioctyl sulfosuccinate cause precipitation (6, 13). The results of two experiments are shown in Fig. 6. The graph is similar in form to that obtained in the absence of surfactant, but the latter confers some protective action on the particles at low concentrations of electrolyte. The region of partial peptization occurs at about the same concentration of electrolyte and the ultimate value of $W_{exp.}$ is identical, 1.5. This indicates that the presence of the surfactant has little effect on coagulation at high electrolyte concentrations and is not the cause of the departure from Smoluchowski theory.

SUMMARY

The use of the Coulter counter and a digital computer has been shown to be eminently suitable for evaluating stability ratios in flocculating monodisperse systems, in the particle size range 0.5–2.0 μ. This is above the limits which most workers would set for true colloidal systems and many powdered drugs are likely to have a considerable proportion of particles in this region. Such monodisperse suspensions have been shown to behave in a similar manner to colloidal systems, yet to exhibit important differences particularly in maximum flocculation rates. Further experiments are planned to evaluate more fully the factors which are likely to be of importance in governing the flocculation behavior of pharmaceutical suspensions. Such information is likely to be of great value in rationalizing the behavior of these systems and providing the pharmacist with a sound theoretical basis for formulation

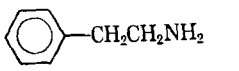
2-(4-Biphenylyl)ethylamines: Potential Cardiovascular and CNS Agents

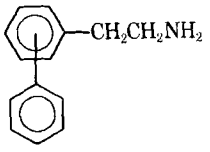
By J. SAM, K. APARAJITHAN, and R. SHAFIK

The syntheses of some 2-(4-biphenylyl)ethylamines are described. The results of preliminary pharmacological tests are reported.

MANY NATURALLY occurring substances which incorporate the phenylethylamine (I) or hydrogenated phenylethylamine moieties in their structures possess interesting biological properties. Ephedrine (1), morphine (2), and bulbocapnine (3) are such examples. The latter two substances also contain the biphenylylethylamine (II) group. Whereas extensive investigations (4–6) have been directed toward the synthesis of phenylethylamines, little effort (7, 8) has been expended in studies of biphenylylethylamines. Consequently, it was of interest to



I



II

determine whether compounds such as II possess central nervous system and cardiovascular properties similar to the phenylethylamines. Moreover it was anticipated that some of the biphenylylethylamines would possess CNS effects similar to morphine and/or bulbocapnine.

The synthetic approaches utilized for the preparation of the biphenylylethylamines are outlined in Scheme I.

The biphenylylethylamines (VIII) were prepared by either the reduction of the corresponding nitriles (VII) or the reduction and hydrolysis of phthalimido-ketones (X). The nitriles were obtained from the corresponding amides (VI).

The biphenylylhydroxyethylamines (XII) were prepared from the chloroacetylbiphenyls (IX). The latter were converted to the phthalimido-ketones (X), reduced with sodium borohydride to the phthalimido-alcohols (XI), and then hydrolyzed to the biphenylylhydroxyethylamines (XII). Alternately, the phthalimido-alcohols were synthesized from the corresponding chloro-alcohols (XIII). The latter also were utilized for the preparation of the *N*-isopropyl derivatives (XIV).

Pharmacological Results[1]—Acute effects after intraperitoneal injection of four compounds (X*b*, IV*a*, V*a*, VI*a*) were observed in albino mice. The LD_{50} values ranged from greater than 1.0 Gm./Kg. for IV*a*, to 261 mg./Kg. for V*a*. No deaths were observed for X*b* or for VI*a* at dosages of 2.1 and 1.0 Gm./Kg., respectively. All of these compounds appeared to produce a mild to moderate sedative effect, but none showed hypnotic or anesthetic levels of CNS depression. Higher (and especially lethal) dose levels of V*a* caused excitation and clonic convulsions. Signs of peripheral vasodilation were noted for compound IV*a* at well below toxic dosages. Signs of pain reflex inhibition led to further examination of IV*a* and V*a* by writhing test in mice. The ED_{50}'s for inhibition of writhing were 300 to 400 mg./Kg. for IV*a* and 112 mg./Kg. for V*a*.

Acute effects after oral administration of VIII*b* were observed in albino mice and rats by several methods. The LD_{50} for VIII*b* was 56 mg./Kg. Toxic doses of VIII*b* caused hyperpnea, muscle weakness, mydriasis, and subconvulsive to clonic convulsive manifestations. At low dosage VIII*b* produced a transient hypotensive effect in anesthetized rats, followed by a slight hypertensive effect. Blood pressure response to standard neurohumoral agents was unaffected by VIII*b*. The latter did not show activity in the hot plate analgesia test, the maximal electroshock anticonvulsant test, or an avoidance-escape behavior test. Compound VIII*b* decreased spontaneous motor activity at all dosage levels, but had only slight ability to increase hexobarbital sleeping time.

EXPERIMENTAL[2]

N-[4-(3′-Chloro-4′-methoxy)biphenylylthioacetyl]morpholine (IVa)—A method similar to that of

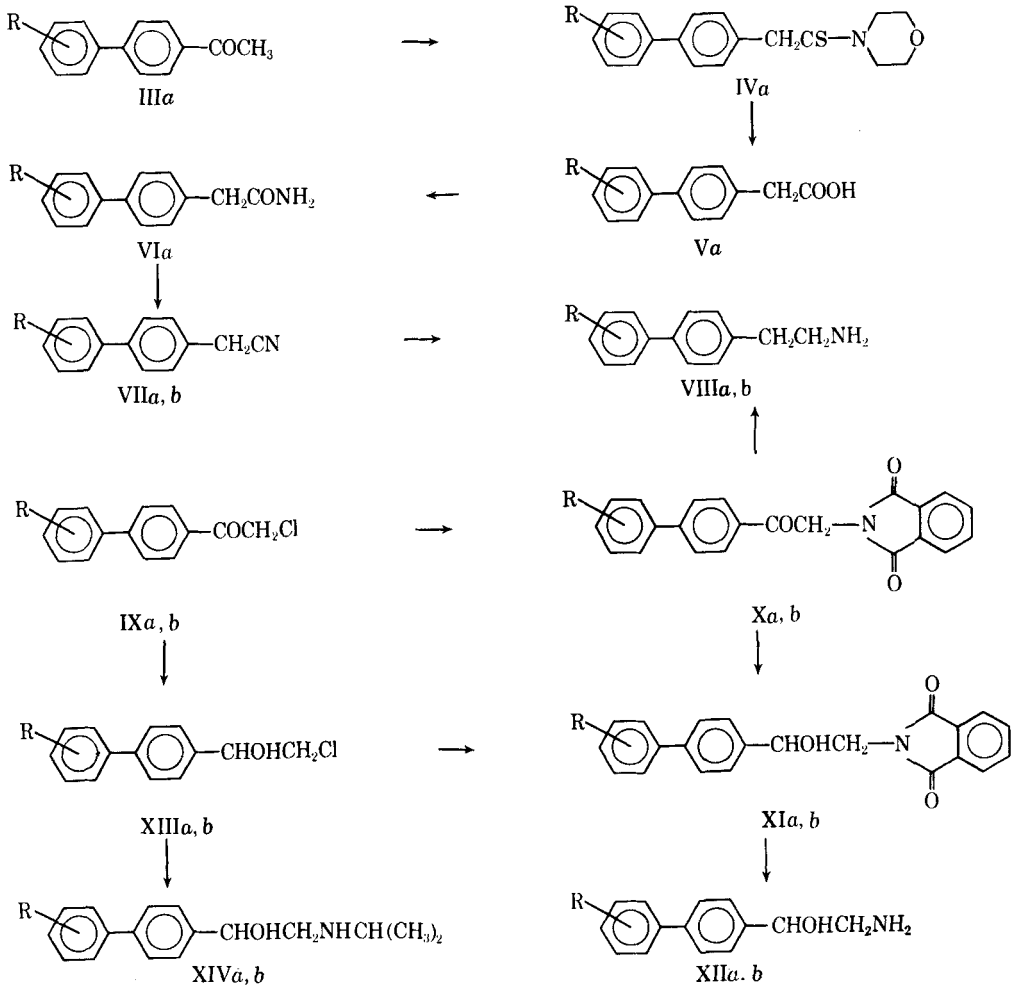
Received August 30, 1967, from the Department of Pharmaceutical Chemistry, The University of Mississippi, University, MS 38677

Accepted for publication October 19, 1967.

This investigation was supported in part by grant MH 05292 from the National Institutes of Health, U. S. Public Health Service, Bethesda, Md., and in part during a tenure of a fellowship (K.A. and R.S.) of the Mississippi Heart Association.

[1] The authors are grateful to Dr. W. Marvin Davis for the pharmacological data of compounds X*b*, IV*a*, V*a*, and VI*a*. Compound No. VIII*b* was evaluated by Hazleton Laboratories, Inc., Falls Church, Va. under contract No. PH 43-63-555 to the Psychopharmacology Service Center.

[2] All melting points were taken on a Fisher-Johns melting point apparatus and are uncorrected. Infrared spectra were determined on a Perkin-Elmer model 137 infracord spectrophotometer using KBr pellets.



Biphenyls (*a* refers to R = 3-chloro-4-methoxy; *b* refers to R = H).

Scheme I

Schwenk and Papa (9) was employed. A mixture of 63.9 Gm. (0.245 mole) of 4-(3-chloro-4-methoxyphenyl)acetophenone (III*a*) (16), 12.5 Gm. (0.4 mole) of sulfur, and 75 ml. of morpholine was heated under reflux for 8 hr. The hot reaction mixture was poured into 300 ml. of methanol and the solid that separated was removed by filtration. The solid was triturated with cold methanol and then recrystallized, $\lambda_{max.}^{KBr}$ 1490, 1260 cm.$^{-1}$.

2-[4-(3′-Chloro-4′-methoxy)biphenylyl]acetic Acid (Va)—A solution consisting of 25.3 Gm. (0.07 mole) of *N*-[4-(3′-chloro-4′-methoxy)biphenylylthioacetyl] morpholine (IV*a*), 16 Gm. of sodium hydroxide, 75 ml. of water, and 110 ml. of ethanol was refluxed for 8 hr. The ethanol was distilled and the residue diluted with water and acidified to pH 2. The solid was removed by filtration, digested with boiling water and recrystallized.

2-[4-(3′-Chloro-4′-methoxy)biphenylyl]acetamide (VIa)—A finely ground mixture of 5.53 Gm. (0.02 mole) of 2-[4-(3′-chloro-4′-methoxy)biphenylyl]acetic acid (V*a*) and 1.52 Gm. (0.02 mole) of thiourea was gradually heated to 200–210° and maintained at this temperature for 1.5 hr. as described by Rehman, Medrano, and Mittal (10). The reaction mixture was cooled, digested with boiling water, and filtered. The brown crystalline solid was triturated with dilute alkali, removed by filtration, and then washed with water. The solid was digested with boiling ethanol, cooled, and removed by filtration; $\lambda_{max.}^{KBr}$ 1640, 1650, 3100, 3280 cm.$^{-1}$.

2-[4-(3′-Chloro-4′-methoxy)biphenylyl]acetonitrile (VIIa)—A mixture of 0.72 Gm. (0.0025 mole) of 2-[4-(3′-chloro-4′-methoxy)biphenylyl] acetamide (VI*a*) and 0.4 Gm. of phosphorus pentoxide was heated at 220–240° in an oil bath for 8 hr. The cooled reaction mixture was extracted with ether. The evaporation of the solvent left 0.15 Gm. (23%) of solid which was recrystallized; $\lambda_{max.}^{KBr}$ 2220 cm.$^{-1}$.

N-(4-Phenylphenacyl)phthalimide (Xa)—The procedure employed was adapted from that described by Sheehan and Bolhofer (11). A solution of 23 Gm. (0.1 mole) of 4-phenylphenacyl chloride in 200 ml. of *N*,*N*-dimethylformamide was treated with 20 Gm. (0.11 mole) of potassium phthalimide. The mixture, after remaining at room temperature for 3 hr., was treated with 500 ml. of water and then extracted with chloroform. The chloroform extract was washed with dilute alkali and water, respectively, and then dried over anhydrous sodium sul-

fate. The solid obtained after distillation of the chloroform solution was washed with ether and recrystallized.

2-(4-Biphenylyl)ethylamine Hydrochloride (VIIIb)—*Method A*—The method described by Nystrom (12) was modified slightly and followed. 4-Biphenylylacetonitrile (13) (7.9 Gm., 0.041 mole) was transferred *via* a Soxhlet extractor into a refluxing mixture of lithium aluminum hydride, anhydrous aluminum chloride, and dry ether (prepared by the rapid addition of a solution of 5.5 Gm. of aluminum chloride in 120 ml. of ether to 2.0 Gm. of lithium aluminum hydride in 80 ml. of ether). The reaction mixture was stirred during and 1 hr. after the transfer of the nitrile into the reaction flask. The reaction mixture, after remaining at room temperature for 16 hr. (during which it was stirred periodically), was treated dropwise with 15 ml. of water and then acidified with 60 ml. of 6 *N* hydrochloric acid. The solid was removed by filtration, washed with ether, and then recrystallized.

Method B—A suspension of 22 Gm. (0.065 mole) of *N*-(4-phenylphenacyl)phthalimide (X*b*) in 350 ml. of methanol was treated with 7.7 ml. of 95% hydrazine and then heated under reflux for 1 hr. The mixture was treated with a methanolic solution of sodium methoxide (prepared from 7.0 Gm. of sodium and 150 ml. of methanol) and then distilled to remove the methanol. Thereafter the mixture was treated with 7.5 ml. of hydrazine and 100 ml. of diethylene glycol. The mixture was refluxed over a free flame for 1 hr. and thereafter the low-boiling material and water were removed by distillation. The reaction mixture was heated to 195–200° and kept at this temperature for 4 hr. The reaction mixture was cooled, diluted with water, and extracted with benzene. The benzene extract was washed with water and dried over anhydrous sodium sulfate. The hydrochloride was prepared in the usual manner and recrystallized. Admixture with the product obtained by Method A showed no depression in the melting point.

4-Phenylstyrene—In the preparation of 2-(4-biphenylyl)ethylamine (Method B) when the heating was continued up to 210–220°, 3.76 Gm. (52%) of a faintly yellow distillate was obtained which solidified. Recrystallization of the solid from methanol gave colorless flakes; m.p. 108–110°, λ_{max}^{KBr} 905, 995, 1625, 2990 cm.$^{-1}$ [lit. (22) m.p. 119°].

Anal.—Calcd. for $C_{14}H_{12}$: C, 93.3; H, 6.7. Found: C, 92.9; H, 6.9.

2-[4-(3′-Chloro-4′-methoxy)biphenylyl]ethylamine (VIIIa)—2-[4-(3′-Chloro-4′-methoxy)biphenylyl]acetonitrile (VII*a*) was reduced with lithium aluminum hydride in the presence of anhydrous aluminum chloride as described for the preparation of 2-(4-biphenylyl)ethylamine (VIII*b*, Method A). The amine was isolated as its sulfate and recrystallized.

α-Chloromethyl-4-biphenylylcarbinol (XIIIb)—A modification of the procedure described by Chaikin and Brown (14) was utilized. To a solution of 4-phenylphenacyl chloride (10 Gm., 0.05 mole) in 125 ml. dioxane were added alternatively and in divided portions 5 Gm. of sodium borohydride and 75 ml. ethanol. The mixture was stirred at room temperature for 18 hr. The solvent was distilled under reduced pressure, the residue was treated with 10% hydrochloric acid, and then exhaustively extracted with chloroform. The extract was washed twice with water and dried over anhydrous sodium sulfate. The solid obtained after removal of chloroform was recrystallized.

N-[2-Hydroxy-2-(4-biphenylyl)ethyl]phthalimide (XIb)—*Method C*—A solution of 1.8 Gm. (0.0077 mole) of α-chloromethyl-4-biphenylylcarbinol (XIII*b*) in 25 ml. of 2-methoxyethanol was treated with 1.5 Gm. of potassium phthalimide and then refluxed for 1 hr. The reaction mixture was cooled and diluted with 150 ml. of water. The solid was removed by filtration, digested with hot methanol, and then recrystallized.

Method D—The procedure described for the preparation of XIII*b* was followed using 7 Gm. (0.02 mole) of *N*-[4-phenylphenacyl]phthalimide, 175 ml. dioxane, 3.5 Gm. of sodium borohydride, and 100 ml. of methanol.

2-Hydroxy-2-(4-biphenylyl)ethylamine Hydrochloride (XIIb)—The procedure employed was adapted from that described by Barber and Wragg (15). A solution of *N*-[2-hydroxy-2-(4-biphenylyl) ethyl]phthalimide (10 Gm., 0.03 mole) in a mixture of 70 ml. chloroform and 70 ml. ethanol was treated with 7 ml. of hydrazine hydrate (50% aqueous solution). The reaction mixture was refluxed for 48 hr. and then left at room temperature for 48 hr. The solvent was distilled under reduced pressure. The residue was stirred for 2 hr. with a mixture of 50 ml. 2 *N* ammonia, 60 ml. of water, and 70 ml. of chloroform. The chloroform layer was separated and extracted with 10% hydrochloric acid. The acid layer was washed twice with chloroform; the solid obtained after distillation of the water under reduced pressure was recrystallized.

α-Isopropylaminomethyl-4-biphenylylcarbinol Hydrochloride (XIVb)—To a solution of α-chloromethyl-4-biphenylylcarbinol (10 Gm., 0.05 mole) in 100 ml. of ethanol was added dropwise a solution containing 1 Gm. of sodium hydroxide, 3 ml. of water, 80 ml. of ethanol, and 15 ml. of isopropylamine. The reaction mixture was stirred at room temperature for 18 hr. The solvent was distilled under reduced pressure and the residue treated with water and exhaustively extracted with ether. The ether extract was washed twice with water and then extracted with 10% hydrochloric acid. The acid layer was concentrated under reduced pressure; the residue was recrystallized.

2-Chloro-4′-(3-chloro-4-methoxy)phenylacetophenone (IXa)—A mixture of 5.5 Gm. (0.025 mole) of 3-chloro-4-methoxybiphenyl (16), 40 ml. of dry carbon disulfide, and 2.4 ml. of chloracetyl chloride was treated with 3.8 Gm. of anhydrous aluminum chloride by a procedure similar to that described by Buu-Hoi, Sy, and Riche (16). The reaction mixture was poured onto crushed ice and the solid that separated was extracted with chloroform. The chloroform extract was washed with an aqueous solution of sodium bicarbonate and thereafter dried over anhydrous magnesium sulfate. The solvent was distilled under reduced pressure and the residual red oil crystallized from ethanol.

N-[4-3′-Chloro-4′-methoxy)phenylphenacyl]-phthalimide (Xa)—The method described by Sheehan and Bolhofer (11) was modified slightly. A solution of 2-chloro-4′-(3-chloro-4-methoxy)phenyl acetophenone (20 Gm., 0.068 mole) in 170 ml. *N,N*-dimethylformamide was treated with 13.6 Gm.

(0.073 mole) of potassium phthalimide. The reaction mixture was stirred at room temperature for 18 hr. and then treated with 500 ml. of water. The solid that separated was removed by filtration, washed several times with water, dried, and then recrystallized.

N-{2-Hydroxy-2-[4-(3'-chloro-4'-methoxy)biphenylyl]ethyl}phthalimide (XIa)—The procedure described for the preparation of XIII*b* was followed using 10 Gm. (0.025 mole) of *N*-[4-(3'-chloro-4'-methoxy)phenylphenacyl]phthalimide, 750 ml. of dioxane, 6 Gm. of sodium borohydride, and 250 ml. of methanol.

2-Hydroxy-2-[4-(3'-chloro-4'-methoxy)biphenylyl]ethylamine Hydrochloride (XIIa)—The procedure for the preparation of XII*b* was followed using 1 Gm. (0.002 mole) of *N*-{2-hydroxy-2-[4-(3'-chloro-4'-methoxy)biphenylyl]ethyl}phthalimide, 10 ml. of chloroform, 10 ml. of ethanol, and 1 ml. of hydrazine hydrate (50% aqueous solution).

α-Chloromethyl-4-(3'-chloro-4'-methoxy)biphenylylcarbinol (XIIIa)—The procedure described for the preparation of XIII*b* was followed using 2.95 Gm. (0.01 mole) of 4-(3'-chloro-4'-methoxy)phenylphenacylchloride, 25 ml. of dioxane, 1 Gm. of sodium borohydride, and 15 ml. of methanol.

α-Isopropylaminomethyl-4-(3'-chloro-4'-methoxy)biphenylylcarbinol Hydrochloride (XIVa)—The procedure described for the preparation of XIVb was followed using 4 Gm. (0.013 mole) of α-chloromethyl-4-(3'-chloro-4'-methoxy)biphenylylcarbinol, and 10 ml. of isopropylamine.

N-[2-(4-Biphenylyl)ethyl]acetamide (XVb)—*Method E*—A suspension of 0.1 mole of 2-(4-biphenylyl)ethylamine (VIII*b*) or its hydrochloride in 15% aqueous ethanol, treated with acetic anhydride and sodium acetate, in the usual manner provided the amide.

Method F—A suspension of 19.3 Gm. (0.1 mole) of 4-biphenylylacetonitrile in 50 ml. of freshly distilled acetic anhydride was hydrogenated at 22 p.s.i. with 0.6 Gm. of platinum oxide catalyst according to a modification of the procedure described by Carothers and Jones (17). After 17 hr. the reaction mixture was treated with water; the crystalline solid was collected by filtration and recrystallized.

2-Phenyl-N-(4-biphenylylethyl)acetamide (XVIIb)—A solution of 1.5 Gm. (0.0076 mole) of 2-(4-biphenylyl)ethylamine (VIII*b*) in 5 ml. of pyridine was treated with 2 ml. of phenylacetyl chloride and set aside at room temperature for 25 hr. The amide was isolated in the usual manner and recrystallized.

N-{2-[4-(3'-Chloro-4'-methoxy)biphenylyl]ethyl}acetamide (XVa)—A solution of 0.68 Gm. (0.0026 mole) of 2-[4-(3'-chloro-4'-methoxy)phenylyl]acetonitrile (VII*a*) in 10 ml. of acetic anhydride was hydrogenated at 15 p.s.i. with 0.1 Gm. of platinum oxide catalyst for 12 hr. according to the procedure described for XV*b*, (Method F); $\lambda_{max.}^{KBr}$ 1285, 1545, 1645, 3250 cm.$^{-1}$.

2-[4-3'-Chloro-4'-methoxy)biphenylyl]-N-(phenethyl)acetamide (XVIa)—2-[4-(3'-Chloro-4'-methoxy)biphenylyl]acetyl chloride was prepared in the usual manner from 7.1 Gm. (0.026 mole) of the acid (V*a*) and 7 ml. of redistilled thionyl chloride. A suspension of the acid chloride in 20 ml. of pyridine was treated with 3.2 Gm. of phenethylamine and then allowed to remain at room temperature for 24 hr. The product was isolated in the usual manner.

Pharmacological Tests—Adult male albino mice were utilized for gross symptomologic characterization concurrently with lethality determination. Observations continued for 3–4 hr. after injection and further checks were made daily thereafter for 3 days. Compounds injected intraperitoneally were in aqueous solution or were in acacia suspensions. The one injected intravenously was dissolved in 10% ethanol and the one given orally was suspended in 0.5% methylcellulose. LD_{50} and ED_{50} values were determined using the method and tables of Horn (18).

Blood pressure studies in male albino rats utilized urethan anesthesia, carotid artery cannulation, and recordings *via* a Sanborn pressure transducer.

Analgesia measures used in mice were the benzoquinone writhing test (19) or the hot plate method (20). The standard maximal electroshock testing procedure (21) was utilized. Locomotor activity was recorded in a commercial photocell activity device.

The analytical data for the biphenyls are given in Table I.

Some Studies of Flocculation Phenomena in Pharmaceutical Suspensions

By B. A. MATTHEWS and C. T. RHODES

The increasing use of suspensions as a form of pharmaceutical preparation has emphasized the need for further evaluation of the factors controlling the physical stability of these systems. A number of attempts have been made recently to prevent impaction of suspensions by controlled flocculation with polyvalent ions. This paper reports the use of a number of experimental techniques, including microelectrophoresis, the Coulter counter, and standardized stability methods, in studies of the effect of a number of variables upon flocculation and sedimentation, in some systems of pharmaceutical interest.

THE PHYSICAL STABILITY of pharmaceutical suspensions has been the subject of a number of recent research and review articles (1–13). Several workers have found that controlled flocculation is a particularly useful technique for formulating pharmaceutical suspensions, which do not impact on storage (5). In this paper the authors report investigations of flocculation, by polyvalent ions, of an important synthetic drug, griseofulvin, and of a monodisperse model system. Because griseofulvin, like many other modern drugs, is hydrophobic in nature, it was found necessary to include wetting agents. Doscher (14) found that nonionic wetting agents caused changes in flocculation without affecting zeta potential. In this study anionic wetting agents, which have been shown not to precipitate with the flocculating ions, have been selected.

Aluminum chloride was selected as the flocculant since a 3:1 electrolyte was required and aluminum is probably the most suitable trivalent metal with regard to toxicity. Other workers in this field (15) have shown that, above pH 4, hydrolysis products of aluminum ions cause peptization of colloidal systems because of charge reversal. At pH 3 and below, however, the Al^{3+} ion causes flocculation. Experiments were, therefore, restricted to this pH region, although it was realized that a somewhat higher pH value would probably be more suitable for a pharmaceutical formulation.

The effect of a number of variables upon flocculation have been investigated by microelectrophoretic measurement of zeta potential, determination of sedimentation volumes, redispersibility, and stability ratios.

EXPERIMENTAL

Materials—The drug, griseofulvin[1] (16), was chosen for this study because, (*a*) it is available commercially in two particle sizes (17) of mean particle diameter about 4 and 15 μ, (*b*) it has a low water solubility, (*c*) it is stable chemically in aqueous suspension, (*d*) the molecule has no ionic groupings which could react with polyvalent ions of opposing charge, (*e*) the powdered drug is difficult to wet and thus is likely to present problems to the formulator, and (*f*) the drug is often given over long periods of time and a suspension is thus a suitable dosage form, especially for pediatric use.

A total of seven anionic surfactants was screened for possible precipitation with the flocculant by preparing 0.1% solutions of surfactants containing 0.1% aluminum chloride. After storage for 1 week at 25°, solutions of the following surfactants, sodium isopropyl naphthalene sulfonate,[2] sodium dioctyl sulfosuccinate,[3] sodium dodecyl sulfate,[4] and sodium alkyl naphthalene sulfonate[5] showed opalescence. However, solutions of sodium diamyl sulfosuccinate,[6] ammonium lauryl ether sulfate,[7] sodium lauryl ether sulfate,[8] and the sodium salt of sulfated lauryl alcohol ethoxylate[9] remained clear. Further tests for precipitation at high electrolyte concentration and evaluation of wettability with respect to griseofulvin showed that ammonium lauryl ether sulfate was a very suitable surfactant for this study.

The aluminum chloride[10] used in this investigation was reagent grade $AlCl_3 \cdot 6H_2O$. All solutions were prepared with glass-distilled water.

Preparation of Suspensions—The drug was dispersed in solutions of the wetting agent by means of a Silverson[11] mixer/emulsifier. Suspensions were refined for 20 min. and then made up to 90% of the

final volume. Ninety-milliliter quantities of the suspensions were distributed into 100-ml. graduated cylinders, 10 ml. of the flocculating electrolyte solution at 10 times the required flocculant concentration was added, the cylinders stoppered and shaken. After storage at 25 ± 0.5° for 3 days, the suspensions were examined.

Measurement of Sedimentation Volume—The sedimentation volumes were recorded in terms of the ultimate settled height, H_u, to the original height, H_o, as suggested by Robinson (18) and Ward and Kammermeyer (19).

$$\text{sedimentation volume} = H_u/H_o \quad \text{(Eq. 1)}$$

Measurement of Redispersibility—To standardize evaluation of redispersibility, a machine was constructed which would turn the cylinders through 360° at a constant speed of 20 r.p.m. Experimentation showed that this speed was the optimum for the supernatant liquid to strike the sediment with the maximum force at each revolution. The number of revolutions necessary to restore the suspension to homogeneity was recorded. This design is similar to that described by Lesschafft and De Kay (20), but their apparatus measured redispersibility by shaking the suspensions in a 90° arc not by complete revolution.

Measurement of Electrophoretic Mobility—Electrophoretic mobilities were measured in a flat electrophoresis cell[12] of rectangular cross-section similar to that originally described by Abrahamson (21, 22). The calibration and use of this type of cell has been discussed by Black and Smith (23, 24) and Haines and Martin (6).

The dimensions of the flat portion were 2.11 × 0.51 cm. and the electrodes were zinc/zinc sulfate. A M 2150F2[13] research microscope, fitted with a ×1.5 binocular body and ×17 eyepieces, was used to view the particles. Objectives used were ×10 or ×20 with a long working distance. The uniformity of the fine adjustment of the microscope was checked by recording the thickness of a glass cover slip coated with lycopodium powder over different regions of the fine adjustment. Measurements were made using the most uniform region. Brinton and Lauffer (25) have discussed the need for temperature control and conclude that electrophoretic velocity at constant current is independent of temperature changes within a range of 10°, so that the cell needs to be thermostated only to remove excess heat in order to prevent convection. The flat area of the cell was therefore immersed in a thermostatic bath which was maintained at 25 ± 0.2°, by means of circulated water. The power source was a Shandon[14] Vokam power supply unit type 2541, which could be maintained at constant current. The field strength was determined by measuring the current in the cell by means of a multirange milliameter and a Pye[15] conductance bridge and conductivity cell to record the conductivity of the suspension. The field strength was calculated by substitution into Ohm's law. The position of the stationary layers of the cell was calculated by Komagata's equation (26).

$$a = {}^1/_2 \pm \sqrt{{}^1/_{12} + 32/\pi^5 k} \quad \text{(Eq. 2)}$$

where a is the fractional depth from the top of the cell and k is the cell width/depth ratio.

This was checked by recording the mobility of human erythrocytes in 0.067 M standard phosphate buffer at pH 7.4 at the lower stationary level. Abrahamson (21, p. 257) has reported a standard mobility of $-1.31\,\mu$/sec./v./cm. which is independent of age, race, sex, or blood group. Results obtained on two separate occasions were -1.29 and $-1.31\,\mu$/sec./v./cm. All measurements were subsequently made at this lower stationary level. For each measurement 20 particles were timed (10 in each direction) over a suitable number of squares in the eyepiece graticule. Times were recorded on a stopwatch, accurate to 0.1 sec.

The cell was cleaned regularly with chromic acid and rinsed with distilled water and acetone between measurements. Great care was taken to avoid air bubbles and the cell was filled and emptied by displacement using vacuum.

Visual Examination of Supernatant—The supernatants of the stored suspensions were examined for evidence of opalescence caused by very small discrete particles, which are slow to settle. This is found in deflocculated suspensions, whereas when flocculation occurs, these very small particles are incorporated in the sedimenting flocs and the supernatant is clear.

RESULTS AND DISCUSSION

Calculation of Zeta Potential—From a consideration of the properties of the electrical double layer at the surface of a particle and the laws of liquid flow, the Helmholtz-Smoluchowski equation can be derived

$$\zeta = \frac{4\pi\eta\mu}{D} \quad \text{(Eq. 3)}$$

where η is the viscosity of the suspending medium, μ is the electrophoretic mobility (velocity per unit field), D is the dielectric constant, and ζ is the zeta potential.

The assumptions made in deriving this equation have been listed by Brinton and Lauffer (25, p. 431). The most important of these are: (*a*) The product of the Debye-Hückel constant, k, and the radius of curvature of the particle a, is large. (*b*) The particle surface is nonconducting.

These assumptions are made so that the electric field can be considered parallel to the surface everywhere within the double layer.

Making the assumption that the field is everywhere in the direction of the applied field, Debye and Hückel derived the following equation for spheres which is valid when ka is small:

$$\zeta = \frac{6\pi\eta\mu}{D} \quad \text{(Eq. 4)}$$

Henry (27) has derived an equation valid for any value of ka which can be expressed in the form

$$\zeta = \frac{6\pi\eta\mu}{D} f(ka) \quad \text{(Eq. 5)}$$

When ka is less than 0.1 the 6π factor holds.
When ka is greater than 100 the 4π factor holds.
When ka is between 0.1 and 100 values of $f(ka)$ can be calculated to correct the general equation.

[14] Shandon Scientific Co. Ltd., London, England.
[15] W. G. Pye and Co., Ltd., Cambridge, England.

Matthews and Rhodes (17) have shown that fine-particle griseofulvin has a mean diameter of 3–4 μ measured on the Coulter counter. Using a particle radius of 1.5-μ values of the factor to be used in the Debye-Hückel equation have been calculated for different concentrations of aluminum chloride. These range from 4π at 10^{-2} *M* and above, to 4.3π at 10^{-5} *M* and these values have been used in calculating zeta potentials. Similar factors were calculated by Nash and Haeger (13) for a 1:1 electrolyte and alternative correction factors for various electrolytes and for different zeta potentials have been given by Overbeek (28).

Flocculation at pH 3.0—The results of flocculation studies at pH 3.0 are shown in Fig. 1 and Table I, the suspension pH had been adjusted to 3.0 by addition of hydrochloric acid.

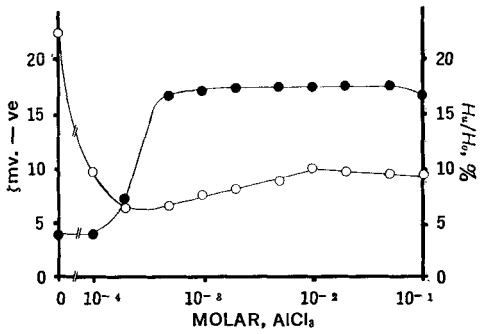

Fig. 1—Flocculation of fine-particle griseofulvin wetted with ammonium lauryl ether sulfate by aluminum ions at pH 3.0. Key: ●, H_u/H_o; ○, *zeta potential.*

From Fig. 1 it may be observed that at this pH value, aluminum ions are very effective in causing flocculation of the suspensions. A concentration of 5×10^{-4} *M* aluminum chloride reduced the zeta potential from −22.7 mv. to −6.2 mv., increased the sedimentation volume from 3.5 to 17.0%, and produced suspensions which redispersed after a very few revolutions in the machine (Table I). Higher concentrations of electrolyte produced little further change in the sedimentation volume, but the measured zeta potential rose slightly.

Flocculation at pH 2.0—The above experiment was repeated in 10^{-2} *N* HCl which gave a constant pH of 2.0 in all systems. The results are given in Table II and Fig. 2.

At this electrolyte concentration, values of *ka* are always greater than 100 and the 4π factor was therefore used in the zeta potential equation. At this pH value, zeta potentials were greater than at 3.0 and higher concentrations of aluminum chloride (10^{-3} *M*) were necessary to achieve maximum flocculation. There was no point of inflection in the zeta potential curve and maximum flocculation occurred at about −15 mv. The above experiment was repeated using the coarse-particle griseofulvin (see also Table II and Fig. 2). In this system there is no sudden increase in sedimentation volume but the concentration of $AlCl_3$ at which the rise begins to occur is the same for both materials (approx. 2×10^{-4} *M*). The progressive rise in sedimentation

volume was accompanied by an increase in ease of redispersibility, but again no sudden change occurred. This change in behavior, as the particle size increased, indicated the potential utility of a comparison of flocculation of a colloidal system with the same surfactant and electrolyte combination.

Comparison with a Model Colloid—The kinetics of flocculation in colloidal systems was considered by Von Smoluchowski (29, 30) in his theory of rapid coagulation. Smoluchowski showed that when every collision between particles results in aggregation, then the coagulation time, $T_{1/2}$, or time taken for the total number of particles to fall by one-half is given by the equation:

$$T_{1/2} = \frac{1}{4\pi DRN_0} \qquad \text{(Eq. 6)}$$

where D is the diffusion constant of the particles, R is the distance between the center of two particles when flocculation occurs, and N_0 is the original number of particles.

When there is an energy barrier between the particles the rate of flocculation is reduced, since only a fraction, α, of the collisions is effective. Fuchs (31) modified Smoluchowski's theory to enable the energy barrier to be related to a reduced rate of flocculation and introduced the stability ratio, W, which is given by

$$W = 2r \int_{2r}^{\infty} \left[\exp. \left(\frac{V_t}{kT}\right)\right] \frac{dS}{S^2} \qquad \text{(Eq. 7)}$$

where r is the particle radius, S is the distance between the particle centers $= 2r$ at coagulation, V_t is the total energy of interaction between the particles, k is Boltzmann's constant, and T is the absolute temperature.

Matthews and Rhodes (32) have developed a method involving a digital computer and the Coulter counter to estimate W in flocculating monodisperse systems. The method involves comparing the experimental rate of depletion of the singlet species with that which would be expected from theory. The method has been used to investigate the flocculation of a polystyrene latex polymer in the same system of anionic wetting agent and cationic flocculant as was used for the griseofulvin.

The system selected was a 0.714-μ polystyrene latex[16] which can be considered to be on the borders of colloidal dimensions. The particles are of such low density that sedimentation can be ignored and the polymer is devoid of any ionic groupings on the particle surface and thus is a suitable model for the drug. The particles were present at a concentration of 5×10^7 per ml. Wetting agent, 3×10^{-6} M ammonium ether lauryl sulfate, was added. The pH was standardized as before by the use of 10^{-2} N HCl and the concentration range of aluminum chloride was from 10^{-4} to 10^{-2} M.

The results of the measurements of stability ratio W and zeta potential against log concentration are given in Fig. 3. The graph of log electrolyte concentration against zeta potential is a straight line, similar to that obtained by Ottewill and Watanabe (33) for a silver iodide colloid coated with an anionic surfactant. The graph of log W against log concentration of electrolyte is also characteristic

of a colloid. A rapid decrease in stability occurs at a concentration of about 10^{-3} M $AlCl_3$ although the value of log W does not quite reach zero as it should for a true colloid according to the Smoluchowski equation. This may be due to the presence of the surfactant or to the particle size being just above the upper limits of the colloidal range.

A comparison of the flocculation of this model colloid with that of fine-particle griseofulvin (*cf.* Figs. 2 and 3) under identical conditions reveals that the minimum concentration of electrolyte required to produce maximum flocculation is the same in each system (2×10^{-3} M). The zeta potential at this point in each system is also identical (−15 mv.).

Measurement of stability ratio as a function of aluminum chloride concentration was also made at pH 3 and the results are also given in Fig. 3. The change from pH 2 to 3 results in a displacement of the vertical portion of the graph toward lower concentrations of electrolyte, in the same way as the vertical portion of the sedimentation height/aluminum chloride concentration graph was changed for fine particle griseofulvin (*cf.* Figs. 1 and 2).

This is strong evidence that flocculation in systems with a mean particle size of 3 to 4 μ is essentially similar to that in colloidal systems where van der Waals forces are operative. Kruyt (34) has referred to the theoretical existence of long range London/van der Waals forces in hydrophobic suspensions in the 2–5 μ range, and has stated that flocculation is possible in the secondary minimum that occurs in the energy of interaction curve at about 1000–2000 Å. distance. The particles can, therefore, approach one another to this distance and yield a loosely flocculated structure.

It has been noted by earlier workers (8) and by the present authors that flocculation in pharmaceutical suspensions with polyvalent ions is very rapid, and Wilson and Ecanow (8), in their discussion of the earlier work of Haines and Martin (5), stated that flocculation in colloidal systems was, by contrast, a slow process depending on random collisions due to Brownian motion.

The Eq. 6 for the coagulation time shows that it

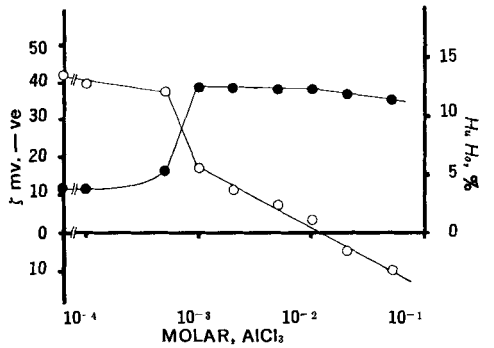

Fig. 4—Flocculation of fine particle griseofulvin wetted with ammonium lauryl ether sulfate by aluminum ions at natural pH. Key: ●, H_u/H_o; ○, zeta potential in 0.1 M sodium acetate.

is dependent on the total number of particles in the system, and an estimate of the number of particles in the 2.5% w/v fine-particle griseofulvin used above was made, by performing a total count with the Coulter counter using the 30-μ orifice. This gave a value for the suspensions of 1.5×10^8 particles per ml. which would have a coagulation time of 20 min. This is quite in accord with the results obtained in the experiments, since sedimentation and heterodispersity are likely to accelerate the process and the Coulter counter is unable to detect the very fine particles of diameter less than 0.5 μ

Measurement of Zeta Potential by Dilution in Electrolyte—Because of the differences in the shape of the zeta potential/electrolyte concentration graphs between systems with different total electrolyte concentrations (*e.g.*, Figs. 1, 2), it was decided to examine the effect of diluting the suspensions in equal parts of a 1:1 electrolyte solution before measurement.

Suspensions of griseofulvin were prepared as before, using the ammonium lauryl ether sulfate wetting agent and different concentrations of aluminum chloride, but at the natural pH. For measurement of zeta potentials the suspensions were diluted with equal parts of 0.1 *M* sodium acetate at pH 5.0. The results are shown in Fig. 4. Good correlation between the zeta potential and sedimentation volume was observed with a rapid reduction in zeta potential and increase in sedimentation volume at 10^{-3} *M* aluminum chloride. Reversal of charge occurred at about 10^{-2} *M*, as has been noted by other workers (15) using aluminum salts with colloids. Slight reduction in the sedimentation volume occurred in these systems with a low positive zeta potential, which may indicate a small degree of deflocculation.

SUMMARY

It has been demonstrated that in suspensions with a mean particle size in the range 3–4 μ, flocculation is essentially similar in character to that in lyophobic colloids, and that such flocculation is accompanied by changes in the zeta potential of the particles.

Suspensions flocculated in this way may be readily redispersed and although the experiments quoted above only lasted 3 days, other experiments still in progress indicate that controlled flocculation in this way can produce suspensions which remain redispersible over long periods of time. Highly flocculated suspensions are somewhat inelegant due to the coarse appearance of the large flocs. However, by controlling the amount of electrolyte, it is possible to produce suspensions with just a sufficient degree of flocculation to prevent impaction. However, these results with the different types of griseofulvin, suggest that some consideration of the particle size is necessary to decide the exact amount of electrolyte necessary. Martin (3) has also remarked that the influence of other ingredients such as flavorings, colorings, and preservatives must be considered.

The work reported in this paper strongly supports the utility of the concept of controlled flocculation in the formulation of pharmaceutical suspensions, although it is felt that further research is required into the variables involved before formulation can be placed on a truly rational, rather than an *ad hoc* basis.

Physics of Tablet Compression XV

Thermodynamic and Kinetic Aspects of Adhesion Under Pressure

By ALBERT S. RANKELL and TAKERU HIGUCHI*

A theoretical analysis has been made of the processes by which interparticle adhesion can occur during the compression of tablet granulations in the absence of added fluid adhesives. A reasonable explanation for the development of adhesion in these systems is based on the occurrence of either partial fusion or partial dissolution at the surfaces of the particles induced by energy added during the compression. The possibility that these phenomena do occur gains partial support from an examination of the thermodynamics and kinetics of surface processes that may take place. The Clapeyron equation cannot be applied directly to these processes, but must be modified to take into account the nonuniformity of the pressures exerted on the particles during compression. Another factor which may affect particle adhesion is the production of highly localized frictional heat and slow diffusion of this heat from the particle surfaces into their interior.

THE PROCESSES by which powder particles are made to adhere by compression in a tablet press are not well understood. Pharmaceutical literature concerning the mechanism of interparticle bonding in compressed tablets is not extensive, and most studies applicable to this area are found in the literature of powder metallurgy and of solid friction (1, 2). This report is concerned with theoretical examination of physical processes that may be responsible for compressive bonding of ingredients of pharmaceutical tablets.

In a summary of existing theories of bonding and sintering in powder metallurgy, Goetzel (3, 4) finds three proposed mechanisms to be worthy of extended discussion: (*a*) interatomic forces (surface adhesion, cold-welding, and surface tension), (*b*) liquid surface cements, and (*c*) mechanical interlocking. The liquid surface cement mechanism, which attributes adhesion to the presence of thin films of liquid at the interface between the particles being compressed, has much to recommend it in the analysis of binding in tablets.

Tablet triturates obviously require the presence of liquid at the interparticular interface during their production. The use of solutions of polymeric materials as binding agents for compressed tablets is common knowledge (5, 6) as is the importance of granulation humidity (7, 8). It is possible, however, to compress some materials into tablets without the addition of a binding agent. For such materials, the liquid cement mechanism would indicate that the cementing film is the product of fusion or solution at the particle surface induced by the energy added during the compression.

The reason why substantial melting has not been observed during the compression of commonly tableted materials can be made clear by consideration of a single case. It has been shown that the energy expended in the compression of a 400-mg. sulfathiazole tablet is in the order of 2 calories (9). Assuming that all of the energy expended appears as heat, the resultant temperature rise of the tablet would be only about 5°. This temperature is nowhere near the normal melting point of the material being tableted.

EFFECT OF STRESS DISTRIBUTION ON MELTING POINT

During the compression process, however, conditions at the surfaces of the particles are radically different from those in the particle interior. The load applied by the upper and lower punches is exerted only on particles directly in contact with the punch surfaces. The stresses on the rest of the particles in the mass are the result of particle-to-particle contact. The irregular surface of the particles causes each individual point of contact to have a very small area; thus, the pressures involved are extremely large.

The relative magnitude of these effects is demonstrated by a measurement of the real area of contact between two flat steel plates under pressure (10). It was found that when the surfaces were pressed together under a load equivalent to 4.6 Atm., the true area of contact was only 1/2000 of the apparent macroscopic area. Thus, the pressure at the points of contact was actually 9200 Atm.

Clapeyron Equation—The high pressure at the points of contact have a definite effect on the melting point of the substance being compressed. A relationship between pressure and melting point derived from thermodynamic considerations is the

Clapeyron equation (11):

$$dT/dP = T(V_L - V_S)/\Delta H \quad \text{(Eq. 1)}$$

where: dT/dP is the change in melting point with pressure, T is the absolute temperature, V_L is the volume per mole of the liquid melt, V_S is the volume per mole of the solid, and ΔH is the molar latent heat of fusion.

The latent heat of fusion is positive, thus, the Clapeyron equation predicts that for a solid which expands on melting ($V_L > V_S$), the melting point is increased by raising the pressure, while for a solid which contracts on melting ($V_L < V_S$), the melting point is lowered by increasing the pressure. Except for a few substances, such as water, most solids expand on melting.

Thus, Eq. 1 would indicate that during tablet compression, the rise in melting point with pressure for most substances would make it highly unlikely that fusion could take place. The Clapeyron equation, however, is derived for an ideal process in which the solid is exposed to uniform hydrostatic pressure, and which is thermodynamically reversible. In the case of tablet compression, on the other hand, the process is essentially nonreversible, and the pressure exerted on each particle is far from uniform.

Thermodynamics of Stressed Solids—Thermodynamic relationships for particles being compacted in a tablet press must take into account the stress distributions induced by the point pressures involved. The Clapeyron equation is derived by equating the Gibbs free energies of the two phases of the equilibrium:

$$\text{liquid } (V_L) \rightleftarrows \text{solid } (V_S) \quad \text{(Eq. 2)}$$

At constant temperature and pressure, the equation is of the form:

$$dF_L = dF_S = V_L dP - S_L dT = V_S dP - S_S dT \quad \text{(Eq. 3)}$$

which reduces to Eq. 1. If the system is not under constant pressure, but is subjected to nonhomogeneous stress, the free energy, dF, is a function of the strain, and must be represented in a suitable form, such as that suggested by Li and co-workers (12):

$$dF = \int (\epsilon_i \sigma_i d\epsilon_i) dV - SdT \quad \text{(Eq. 4)}$$

where: σ_i is one of the six components of the stress, and ϵ_i is the corresponding strain component. In such a case, the derivation of an equation corresponding to the Clapeyron equation would be quite involved.

Stressed Beam Analogy—The effect of stress distribution on particle melting points during compression can be more easily illustrated by the following analogy. Consider a crystal which is supported at each end and which is subjected to a point pressure on its upper surface, as shown in Fig. 1. For ease in mathematical treatment, the

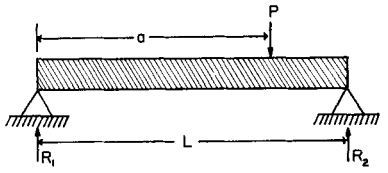

Fig. 1—Point loading on a simply supported beam.

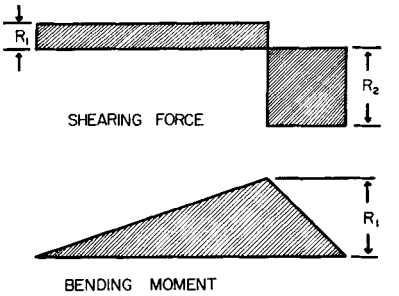

Fig. 2—Shearing force and bending moment diagrams for point loading on a simply supported beam.

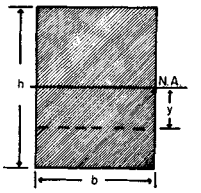

Fig. 3—Cross-sectional view of a beam showing the neutral axis.

crystal can be considered to be a beam with rectangular cross-section. The point pressure p is opposed by the resultant forces R_1 and R_2, producing both shear and bending stresses, as shown in Fig. 2. The shearing force is uniform on either side of the point of application of p, but the bending moment increases to a maximum at the point of application of p.

The bending stress on a cross section of the beam can be shown to be (13):

$$\sigma_n = My/I \quad \text{(Eq. 5)}$$

where: σ_n is the normal stress (force/unit area); M is the bending moment (force × length); y is the distance from the neutral axis of the beam (length); and I is the moment of inertia of the cross-sectional area about the neutral axis (length^3). The moment of inertia for a rectangular cross-section is

$$I = bh^3/12 \quad \text{(Eq. 6)}$$

where: b is the thickness of the beam, and h is the height, as shown in Fig. 3. Thus, the bending stress is

$$\sigma_n = 12(My/bh^3) \quad \text{(Eq. 7)}$$

The range of values for y is

$$-h/2 \leq y \leq +h/2 \quad \text{(Eq. 8)}$$

and the variation of stress over the depth of the beam can be plotted as shown in Fig. 4. It can be seen that there is no stress at the neutral axis, and that the stress is greatest at the surfaces of the beam. The nature of the stress is different on each side of the neutral axis; while the upper surface of the beam is being compressed, the lower surface is under tension, or negative pressure.

Referring once more to the Clapeyron equation (Eq. 1), it may be seen that while the right-hand side of the equation is positive for substances which expand on melting, the left-hand side is negative for those portions of the solid which are under tension. In these areas the melting point will be lowered when point pressure on the opposite side of the crystal is increased. Thus, under the conditions

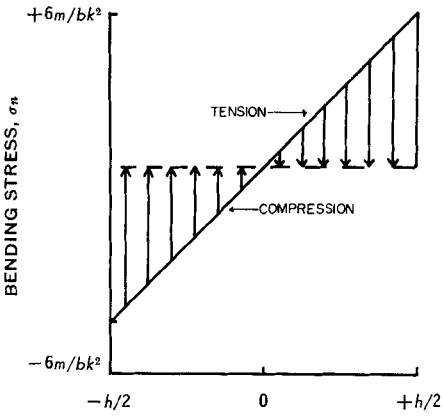

Fig. 4—Stress distribution for point loading on a simply supported beam.

of tablet compression there will be a reduction of melting point on some portion of the surface of each particle, whether the material in question expands or contracts on melting.

Skotnicky Equation—A more recent derivation of the relationship between melting point and pressure is that of Skotnicky (14). The change of equilibrium temperature (melting point) for each phase in the system of Eq. 2 can be shown to be:

$$(\partial T/\partial P)_F = V/S = TV/H \qquad \text{(Eq. 9)}$$

If a pressure P_L acts on the liquid, and a pressure P_S acts on the solid, then the molar latent heat of fusion, ΔH, can be expressed as a function of the change of equilibrium temperature with pressure:

$$\Delta H = H_L - H_S = TV_L(\partial P_L/\partial T)_F - TV_S(\partial P_S/\partial T)_F \qquad \text{(Eq. 10)}$$

For an ideal process, in which the system is exposed to a uniform hydrostatic pressure ($P_L = P_S = P$), Eq. 10 reduces to the usual form of the Clapeyron equation (Eq. 1). However, if a point pressure is exerted on the solid only, and the liquid is subjected to a constant atmospheric pressure P_L, then Eq. 10 reduces to:

$$dT/dP_S = -V_S T/\Delta H \qquad \text{(Eq. 11)}$$

For such a system, the isolated pressure acting locally on the solid always lowers the melting point regardless of the expansion or contraction of the solid on melting.

Skotnicky showed that Eq. 11 agrees qualitatively with the experimentally observed lowering of the melting point of naphthalene under point pressure. This substance, which expands on melting, would be expected to show a rise in melting point with increased pressure by the usual Clapeyron equation.

EFFECT OF STRESS DISTRIBUTION ON SOLUBILITY

The reasoning employed in the analysis of point pressure effects on melting point can also be extended to changes in solubility of solids with pressure. It can be shown that the variation in solubility of a solid with uniform hydrostatic pressure is of the form (15):

$$(\partial \ln x/\partial P)_T = -(V_L - V_S)/RT \qquad \text{(Eq. 12)}$$

where ln x is the natural logarithm of the mole fraction of the solid in saturated solution, and R is the gas law constant. This equation predicts that if the solid expands on melting ($V_L > V_S$), an increase in pressure will diminish its solubility. Conversely, if the solid contracts on melting ($V_L < V_S$), an increase in pressure will increase the solubility.

A consideration of the stress distribution resulting from point pressures under the conditions of tablet compression leads to the conclusion that there will be an increase in the solubility on some portion of the particle surface whether the material in question expands or contracts on melting. The liquid in which solution takes place is usually the film of moisture adsorbed on the particle surface.

The essentially nonadherent nature of most insoluble materials and the ease of compaction of water-soluble substances would seem to indicate that pressure-induced solubilization plays an important role in adhesion of tablet particles. The importance of adsorbed moisture is pointed up by studies on the relationship of tablet compacting properties to granulation moisture content (5, 6). Generally, granulations which are absolutely dry have poor compacting properties (16).

EFFECT OF HEAT TRANSFER KINETICS ON FUSION

A basic requirement for the occurrence of surface fusion, regardless of changes in melting point, is the formation of localized high-temperature areas, or "hot spots," on the particle surface. If the temperature of these hot spots reaches the melting point of the substance being compressed, surface fusion will occur. The temperature reached is a function of the balance between the heat transferred to the surface of the particle and the heat transferred away from the surface by conduction into the interior of the particle.

The heat transferred to the surface of the particle is produced by the conversion of the mechanical energy of compression to thermal energy and is essentially independent of temperature. The rate of heat conduction into the interior of the particle is a function of the specific heat and thermal conductivity of the solid and of the particle geometry. The surface temperature reached cannot be determined exactly because of the time-dependent nature of the heat transfer rates and the complicated geometry of the average particle. However, qualitative estimates can be made by the use of a simplified equation.

The average rate of heat transfer to the particle surface can be estimated by dividing the energy of compression by the total time of compression. The rate of heat transfer into the particle interior can be estimated by neglecting the effects of particle geometry and calculating on the basis of one-dimensional heat transfer into a slab of semi-infinite thickness. A suitable equation for heat transfer under these conditions has been derived by Carslaw and Jaeger (17), and is of the form:

$$\Delta T = (2q/Ak)\,(kt/c\rho\pi)^{0.5} \qquad \text{(Eq. 13)}$$

where: ΔT is the rise in surface temperature, q is the rate of heat transfer to the surface per un t time, A is the surface area, k is the thermal conductivity of the solid, t is the heating time, c is the specific

heat, and ρ is the density of the solid.

The above equation can be applied to the case of the compression of the 400-mg. sulfathiazole tablet mentioned previously. The properties of the granulation particles can be estimated from the published data (7, 18) as: A_t = 1800 cm.²/Gm., k = 0.01 cal. sec.$^{-1}$ cm.$^{-1}$ deg.$^{-1}$, c = 0.75 cal.-Gm.$^{-1}$ deg.$^{-1}$, and ρ = 1.58 Gm.-cm.$^{-3}$. The heating time, t, can be estimated from typical tablet compression times (19) as 0.1 sec., and the heat added is 2 cal. The true area of contact can be represented as the product $f \cdot A_T$, where f is the fraction of area in actual contact, and A_t is the total surface area. Substituting these values into Eq. 13 yields:

$$\Delta T = 0.046/f \qquad \text{(Eq. 14)}$$

Thus, for values of f in the range 10^{-3} to 10^{-4}, the surface temperature of the granules will reach the melting point of commonly tableted organic materials and surface fusion will take place.

The existence of high local surface temperatures produced by the conversion of mechanical energy to thermal energy has been demonstrated by several investigators. Bowden and Ridler (20) measured the temperature of the contact points of dissimilar metals sliding over each other by thermoelectric methods, and found temperatures reaching the melting point of the lower melting metal. In the case of metals with high melting points, transient temperatures of 500–1000° were obtained. Smekal (21) found that when glass was scratched by carborundum, a eutectic melt of $Na_2OSiO_2Al_2O_3$ was produced, indicating that a surface temperature of 700° had been reached.

SUMMARY

The mechanism of interparticle bonding during tablet compression has not been satisfactorily explained as yet, although a number of theories have been advanced. The liquid surface cement theory is compatible with known facts about tableting, although it has not been proven experimentally. The possibility of formation of a liquid film at the particle surface is supported by thermodynamic analysis of the effects of stress distribution on melting point and solubility, and by heat transfer kinetics at the surface.

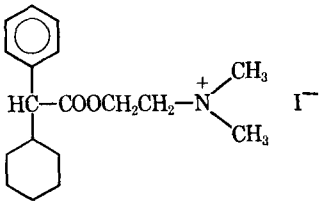
α-Phenyl-α(2,3-cyclohexenyl) Acetic Acid Derivatives as Potential Antispasmodics

By HEINO A. LUTS, J. F. GRATTAN, S. Z. HAIDRI, and W. L. NOBLES*

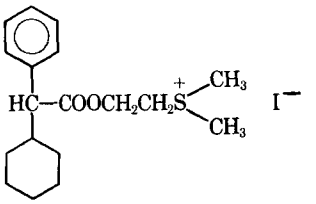
A group of compounds having the (2,3)-cyclohexene moiety has been prepared for pharmacological evaluation. The preparation and biological activities of these compounds are presented.

MANY α-phenyl-α-cyclohexyl acetic acid derivatives have been prepared (1–4) for pharmacological evaluation. They are generally very active antispasmodics, and are often superior to the diphenyl analogs.

Protiva and Exner (5) first reported the active sulfonium compound, thiospasmin, in which the nitrogen of compound I below has been replaced by the sulfur of compound II. This agent demonstrated exceptional antispasmodic activity; it was regarded as being 10 times as active as atropine.



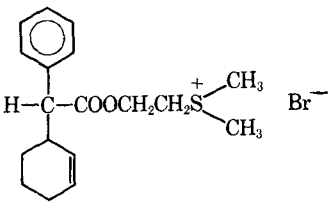
I



II

Thiospasmin has found successful clinical application in Czechoslovakia and in the Union of Soviet Socialist Republics. In radioactive studies Francova and his associates (6) found that orally administered thiospasmin was distributed in the rats in the following order: liver, kidney, lungs, spleen, heart, plasma, muscle, blood cells, skin, and brain. The maximum activity was found after 4 hr. in the gastrointestinal tract.

While proceeding with their studies on the interdependence and effectiveness of substances, Votava and his associates (7) then synthesized α - phenyl - α - cyclohexyloxyacetoxyethyldimethylsulfonium iodide and α-phenyl-α-*n*-propylhydroxyacetoxydimethylsulfonium iodide. Both compounds proved to be superior to thiospasmin in activity and were also less toxic. Since 1953, several structural modifications have been made. In 1956, Neesby and his associates (8) synthesized a series of compounds in which the substituent on the α-carbon atom and the nature of the ionic radical were altered. They found that dimethylsulfonium ethylphenyl α-(2, 3-cyclohexenyl) acetic acid bromide (III) completely voids the xerostomic effect without decreasing the antispasmodic activity.



III

It is noteworthy that in their studies the addition of a hydroxyl group to the α-carbon atom did not increase the activity, which is the generally accepted rule.

To our knowledge, this selectivity does not exhibit itself in any other antispasmodic compound reported to the present. It is speculated that possible hydroxylation takes place in the detoxification process on the 2,3 position of the cyclohexene ring.

In order to explore more extensively the 2,3 cyclohexene analog structures of this type, we have prepared a group of them for pharmacological evaluation (Table I).

MATERIALS AND METHODS

Compound II was made by the standard method of adding *trans*-1,2-dibromocyclohexane to the sodium salt of phenyldiethylmalonate, and the α-phenyl-α-(2,3-cyclohexene) acetic acid (III) was accomplished by hydrolysis and partial decomposition

Received May 22, 1967, from Structure-Activity Research, Inc., College Hill, Oxford, MS 38655, and Smith, Miller and Patch, Inc., New York, NY

Accepted for publication October 18, 1967.

Presented to the Medicinal Chemistry Section, APhA Academy of Pharmaceutical Sciences, Las Vegas meeting, April 1967.

Scheme I

of the diacid formed. Compound IV was obtained by esterifying the acid; the alcohol V, was prepared by reducing the acid with $LiAlH_4$. The alcohol was then converted to the ether as indicated in the accompanying synthetic scheme. Reducing compound II with $LiAlH_4$ gave compound VII as the main product and the corresponding nitrate (VIII) was accomplished by nitration. Compound IX was made by the addition of 2 moles of the corresponding acid chloride. The 2-hydroxycarbamate (X) was obtained by reaction with phosgene and ammonia. The monocarbamate XI was prepared from compound V by reacting with phosgene and ammonia and compound XII by reacting compound III with thionyl chloride. The acid chloride was then converted to amides (XIII) by reaction with the corresponding amines (Scheme 1).

PROCEDURES

Phenylquinone Writhing Test in Mice—The principle of this test is that phenylquinone, when administered subcutaneously to mice, will induce painful writhing movements. Analgesics will significantly reduce these movements.

Four groups of fasted male mice of the Swiss-Webster strain (body weight 15–17 Gm.) were utilized in this experiment. The drug in question was administered orally to three groups of mice at dose levels of 25, 50, and 100 mg./Kg., respectively, in a volume of 0.2 ml. per mouse. The fourth group which was used as the control received 0.01 ml./Gm./body weight of saline. Five animals per group were employed. Phenylquinone at 20 mg./Kg. was injected subcutaneously to all groups of mice 30 min. after the administration of the tested compound.

Tremorine Test—Five groups of fasted male mice (body weight 15–17 Gm.) were utilized in this experiment. The drug was administered at the standard levels of 25, 50, and 100 mg./Kg. For ready comparison, it was tested with a standard antitremorine drug, in this instance trihexyphenidyl HCl[1] (5 mg./Kg.). Untreated controls were utilized at 0.9% saline. All drugs were prepared in distilled water. All drugs were administered orally 30 min. prior to the tremorine which was administered intraperitoneally.

Hexobarbital-Induced Sleep in Mice—Four groups of fasted male mice of the Swiss-Webster strain (body weight 15–17 Gm.) were utilized. The drug was administered orally at 25, 50, and 100 mg./Kg. concentrations. Hexobarbital was administered intraperitoneally at 100 mg./Kg. 30 min. after the initial administration of the tested drug. The animals were then observed for the time intervals of the onset and duration of sleep. The tested comporids were prepared in distilled water; however, hexobarbital was prepared in 5% sodium hydroxide in the final volume of 9 ml. of water, making a total volume of 10 ml.

Antipyretic Activity—Male rats of the Sprague-Dawley strain (body weight 100–125 Gm.) were utilized. They were given a 20% yeast solution at a volume of 2 ml. per rat, subcutaneously, 24 hr. prior to the administration of the tested compound.

After the yeast treatment, the animals were fasted for 24 hr. and a rectal temperature was taken each hour for 2 successive hr. prior to the administration of the drug (each animal served as its own control). After the drug was given, the rectal temperatures were taken each hour for 4 consecutive hr. to determine whether the tested drugs reduced the body temperature.

Ganglionic-Blocking Action—It has been found through previous experiments that the cat gives the greatest response with respect to this test; therefore, a cat was used. A cat of either sex was anesthetized with diallylbarbituric acid[2] with urethan solution (0.7 ml./Kg.), administered intraperitoneally. The surgery included the exposition of the carotid sheath (the carotid artery and the vagus nerve). Also, included was the exposition of the right femoral vein for the purpose of injection and the left femoral artery for the recording of the blood pressure. There was a unilateral severing of the vagus nerve and an exposition of the superior cervical ganglion, for the purpose of controlling the nictitating membrane. Sustained contraction of the nictitating membrane that disappears after intravenous injection of a ganglion-blocking agent is indicative of preganglionic electrical stimulation.

Hypotensive Activity—This test was conducted on five species of animals—rat, guinea pig, rabbit, cat, and dog.

The rat and the guinea pig were anesthetized with urethan, 1.2 Gm./Kg., administered intraperitoneally. The right sublingual vein was exposed, and cannulated for injection of the drug. The left carotid artery was exposed, and cannulated for recording blood pressure. The blood pressure was measured by means of a mercury manometer and recorded directly on a kymograph. In both species, the pressure was allowed to stabilize approximately 30 min. to 1 hr., depending upon the responses of the individual animals. There was a 30-min. interval between each dose of drug or until the blood pressure returned to the base line.

Heparin was given in the amount of 500 USP units per animal, to prevent coagulation.

In order to test the cholinergic effects of the tested compound, acetylcholine bromide at 2 mcg./Kg. was administered. After the characteristic hypotensive tracing had been obtained, acetylcholine bromide was administered a second time; however, this second injection was preceded by the tested compound.

A slight modification of the above procedures was used to prepare the cat for cardiovascular study. Because of the ready accessibility of the vessels, the left femoral artery and right femoral vein were used to measure blood pressure and to inject the tested drug, respectively.

Terminology—

Phenylquinone writhing test in mice:

good activity	>40% decrease of writhing movements as compared to untreated controls.
slight activity	10–40% decrease of the writhing movements as compared to the untreated controls.

hexobarbital-induced sleep in mice:

good potentiation	>40% increase in sleeping time over the untreated controls.

[1] Marketed as Artane by Lederle Labs, Pearl River, N. Y.

[2] Dial, Ciba Pharmaceutical Products, Inc., Summit, N. J.

slight potentiation	10–40% increase in sleeping time over the untreated controls.

Tremorine test in mice:
Induced Tremors (T), Lacrimation (L), and Salivation (S)

good activity	One or more factors (T, L, S) decreased by 75–100% as compared with untreated controls.
slight activity	One or more factors (T, L, S) decreased by 50–75% as compared with untreated controls.

Preliminary Results—Initial pharmacological screening of some of the compounds in this series has demonstrated the following:

Compound I exhibited a mild depressant effect, slight activity in the phenylquinone test, and slight antipyretic activity. In the hexobarbital-induced sleep test in mice, it demonstrated good potentiation of the barbiturate.

Compound II behaved in the manner of CNS depressant drugs, generally, and also produced tremor in some instances. This compound demonstrated a good sympathomimetic activity, transient hypotensive activity, and slight activity in the phenylquinone test.

Compound III displayed good sympathomimetic activity and produced a mild depressant response. Administration of the drug provoked transient lowering of the blood pressure. It also exhibited a slight analgesic effect with the typical "hot plate" test. Slight activity in the phenylquinone test was noted.

Compound V proved to be active as a sympathomimetic agent and produced a good effect in the phenylquinone writhing test. It decreased hexobarbital-induced sleeping time. It also exhibited a slight antagonism to tremorine-induced tremors and exerted a slight response as an antipyretic agent.

Compound VIII behaved as a mild depressant and exhibited cholinergic activity. It did not have an influence on the response of the organism to epinephrine. The compound also produced a mild hypothermia.

Compound X exhibited depressant qualities and demonstrated anticholinergic activity. It had no effect on body temperature and did not interfere with or potentiate the action of epinephrine. Some data obtained suggest that the compound is possibly a vasodilator. In general, this compound was less active than compound VIII in comparative tests.

Compound XI acted as a mild stimulant. It demonstrated atropine-like action, as well as ganglionic-blocking activity. A slight hyperthermic response was also observed.

EXPERIMENTAL[3]

3-Hexamethyleneiminopropyl α-(2-cyclohexene)-phenylacetate Hydrochloride—To the mixture of 345 mg. (0.015 mole) of sodium in 75 ml. of isopropanol was added 3.24 Gm. (0.15 mole) of α-phenyl-α-cyclohexene acetic acid. The mixture was refluxed for 30 min. and 2.42 Gm. (0.015 mole) 3-chloro-*N*-propylhexamethylimine was added. This mixture was refluxed 4 hr. The salt was removed by filtration and the residue evaporated to dryness. The residue was extracted with 75 ml. of ether and the extract acidified with hydrochloric acid. The crystals thus formed were separated by filtration; yield 3.0 Gm., m.p. 160–161°.

2 - Phenyl - 2 - cyclohexenyl - 1,3 - propanediol—Twenty grams (0.08 mole) of phenylcyclohexenediethylmalonate was dissolved in 250 ml. of anhydrous ether and 8.0 Gm. of $LiAlH_4$ was added in small portions. The reaction mixture was refluxed for 8 hr. and allowed to stand overnight. The excess $LiAlH_4$ was decomposed with water and the ether layer separated. The aqueous residue was extracted twice with 100-ml. portions of ether and the ether layers combined. The ethereal solution was dried over anhydrous calcium sulfate[4]; the ether was then removed to yield a residue; yield 14 Gm., m.p. 75–76°.

Ethyl - α - (2 - cyclohexenyl) - α - phenylacetate—Twenty-five grams (0.115 mole) of α-phenyl-α-cyclohexene acetic acid was refluxed 2 hr. with absolute ethanol in the presence of hydrochloric acid. The ester thus formed distilled in the range 117–130° (1.2 mm.); yield 17 Gm., n_D^{28} 1.519.

2 - (2 - Cyclohexenyl) - 2 - phenylethanol—Seventeen grams (0.08 mole) of the ethyl ester of α-phenyl-α-cyclohexene acetic acid was reduced with 6 Gm. of $LiAlH_4$ in 250 ml. of ether. After refluxing for 6 hr., the excess $LiAlH_4$ was decomposed with a water–ether mixture and the ether layer separated. The residue was extracted twice with 100-ml. portions of ether and the ether layers were combined; the ethereal solution was dried over anhydrous calcium sulfate and the ether was removed. The residual 12 Gm. distilled at 112–117° 0.3–0.35 mm., n_D^{27} 1.5447.

2-Phenyl-2-cyclohexenyl-1,3-propanediol Nicotinate—To 6.96 Gm. (0.03 mole) of 2-phenyl-2-cyclohexenyl-1,3-propanediol, 10.63 Gm. (0.06 mole) of nicotinylchloride hydrochloride was added and the mixture heated at 100° for 20 min.; the mixture was stirred constantly during this period. After cooling, the residue was dissolved in water and made strongly basic with concentrated ammonia water. The solid precipitate was extracted twice with 50-ml. portions of ether. The solution was dried over anhydrous calcium sulfate and then acidified with anhydrous hydrogen chloride. The product thus formed was collected by filtration; yield 16.5 Gm., m.p. 182–183°.

N-Methylpiperazino-N'-propyl α-(2-cyclohexene)-phenylacetate Dihydrochloride—To a solution of 6.5 Gm. (0.03 mole) of α-phenyl-α-cyclohexene acetic acid and 100 ml. of absolute isopropanol, 700 mg. (0.03 mole) of sodium was added. After the salt formation, 5.5 Gm. (0.03 mole) of α-chloropropyl-*N*-methylpiperazine was added and the mixture refluxed for 6 hr. The solvent was removed by distillation and the residue dissolved in 50 ml. of ether. The ether was then treated with anhydrous hydrogen chloride and the product was collected by filtration; yield 7.9 Gm., m.p. 222°.

N-Phenylpiperazinoethyl α - (2 - cyclohexene)-phenylacetate Dihydrochloride—Three grams (0.015 mole) of *N*-α-hydroxy-ethyl-*N*-phenylpiperazine was reacted with 300 mg. (0.015 mole) of sodium in 75

[3] Microanalysis was performed by Mr. G. Roberts, Jr., Florham Park, New Jersey. All melting points are uncorrected.

[4] Drierite, W. A. Hammond Drierite Co., Xenia, Ohio.

ml. of xylene; 3 Gm. (0.015 mole) of α-phenyl-α-cyclohexene acid chloride was added in small portions and the mixture was refluxed for 4 hr. The salt was removed by filtration and the residue distilled to dryness in high vacuum. The residue was dissolved in 60 ml. of ether, the solution decolorized with pulverized carbon and acidified with anhydrous hydrogen chloride. The product thus formed was collected by filtration and dried; yield, 5.0 Gm., m.p. 179–180°.

2 - Phenyl - 2 - cyclohexenyl - 1,3 - propanedinitrate—To 4.6 Gm. (0.02 mole) of 2-phenyl-2-cyclohexenyl-1,3-propanediol was added 20 ml. of 100% nitric acid at 0–5°. (The acid was previously prepared by distilling it over 100% sulfuric acid.) To the reaction mixture was added 20 ml. of 100% sulfuric acid and the mixture was left standing overnight. The solution was then poured into ice; at this point crystals were formed. They were collected by filtration and washed with water. The product was dissolved in methanol and 2% sodium bicarbonate solution added until the crystals separated. The crysals were collected again by filtration and dried; yield 4.1 Gm., m.p. 58–59°.

2 - Cyclohexenyl - 2 - phenylethoxy - 1 - ethylmethylsulfide Methiodide—Six grams (0.03 mole) of 2-(2-cyclohexenyl)-2-phenylethanol was reacted with 690 mg. (0.03 mole) of sodium in xylene. Three and four tenths grams (0.03 mole) of α-chloroethylmethyl sulfide was added over a period of 15 min. and the reaction mixture was refluxed for 12 hr. After filtering off the salt, the xylene was distilled and discarded. To the residue was added 20 ml. of methyl bromide, the mixture was allowed to stand for 2 days and then worked up at room temperature. Ten milliliters of absolute methanol was added and the mixture was refluxed for 2 hr. To this mixture 25 ml. of absolute ether was added; on cooling, the crystallized product formed; yield 3.6 Gm., m.p. 167–168°.

2-Cyclohexenyl-2-phenylethylcarbamate—To a solution of 2.4 Gm. (0.012 mole) of 2-(2-cyclohexenyl)-2-phenylethanol in 25 ml. of benzene was added twice the molar quantity of phosgene in 25 ml. of benzene. This mixture was placed in a pressure bottle and warmed to 50° for 4 hr. The excess phosgene was boiled off and the residue treated with dry ammonia gas. The reaction mixture was reduced to dryness under reduced pressure. The residue was dissolved in alcoholic ammonia and filtered. The clear solution was poured on ice; at this point fine crystals were formed. They were collected and washed with water.

The crystals were recrystallized from an ethanol–water mixture to give a compound, m.p. 100–101°; yield 2.4 Gm.

2-Phenyl-2-cyclohexenyl-1,3-propanediol Carbamate—To a solution of 12.0 Gm. (0.05 mole) of 2-(2-cyclohexenyl)-2-phenylethanol in 50 ml. of benzene, 150 ml. of 12% phosgene in benzene was added. The mixture was placed in a pressure bottle and kept 4 days in sunlight. The volume of the mixture was reduced by one-half and anhydrous ammonia was added. The precipitated crystals were filtered off and discarded. The benzene layer was then concentrated to dryness with the aid of high vacuum; to that residue 50 ml. of concentrated ammonia was added and the mixture was boiled for 1 hr. The solution was cooled and the ammonia was removed by blowing air over it. The crystals were separated and recrystallized from the ethanol–water mixture, m.p. 134°; yield 11.9 Gm.

Surfactant Effects on Spray-Congealed Formulations of Sulfaethylthiadiazole–Wax

By PHILLIP M. JOHN* and CHARLES H. BECKER

An investigation was undertaken to examine the effects of selected formulation and production variables on the physical characteristics and dissolution patterns of spray-congealed particles of sulfaethylthiadiazole (SETD)–wax. Melted suspensions of SETD in wax formulations contained various concentrations of the lipophilic surfactant, sorbitan monooleate. Particle size was found to correspond to the size of nozzle used; smaller particles were characterized by faster rates of SETD release. Depending upon the concentration employed, sorbitan monooleate may increase or depress the rate of SETD released from the particles in 0.1 *N* HCl; the surfactant consistently promoted faster release rates in alkaline pancreatin solution. A log–log dissolution model was used to predict the release patterns of the products, and the model showed good agreement with the experimental data.

VERY LITTLE WORK of a research nature has been done in the area of spray congealing. Although the technique of spray congealing is used by many industries, the pharmaceutical industry has not accepted this process as quickly as expected. This unit operation (prilling) offers an expedient method of producing a fairly uniformly sized particulate product from a melted wax suspension or solution of a medicament without the difficulties often encountered with a comminution step. Spray-congealed particles may be combined into a tablet granulation, encapsulated, or incorporated into a liquid suspension (1). A variety of suitable matrix materials have been spray congealed to produce essentially tasteless products of iron compounds (2) and water-soluble vitamins (3).

A very complete enumeration of available atomization techniques and equipment has been reported by Marshall (4) in the engineering literature. The particle-size relationships of centrifugal-disk atomizers have been examined by Scott *et al.* (5). Single-fluid pressure nozzles are frequently used to spray congeal drug and lipid material mixtures; Lantz and Robinson (6) used such a nozzle located at the top of a spray-dryer tower. Although less commonly used on a commercial scale, pneumatic atomizing nozzles are particularly useful for producing very fine powders. Such a two-fluid nozzle was used by Cox (7) in a study of the effects of wax matrix, siphon height, and air pressure.

The dissolution rates of spray-congealed products of sulfamethylthiadiazole (SMTD) and hydrogenated castor oil in 0.1 *N* HCl and alkaline pancreatin solution were determined by Robinson, Bondi, and Swintosky (8). They showed that the release in humans of a single 4.0-Gm. dose of the spray-congealed product was extended over a 12-hr. period. In a later work (9), the drug release of a SETD-hydrogenated castor oil spray-congealed product was compared to that of crystalline SETD administered to human subjects; this study showed that approximately 50% of the sustained-release dosage form was available for early absorption, with the balance being absorbed over a prolonged time.

The purpose of the present investigation was to determine the effects of wax matrix material, atomizing nozzle orifice size, and surfactant concentration on the resulting *in vitro* dissolution patterns of spray-congealed products of SETD–wax intended for sustained- or prolonged-release medication. Generalizations concerning the effect of these three treatment variables on rate of production, resulting particle size, density, and porosity were also sought. White wax USP, a synthetic wax-like ester,[1] and a 1:1 combination of these two waxes were used as matrices. These waxes were chosen to obtain a range of plasticity between the pliability of white wax and the brittleness of the synthetic wax-like ester. Three distinct particle-size ranges were obtained by using three sizes of fluid nozzle orifices. The effect of the nonionic lipophilic surfactant sorbitan monooleate[2] was studied over the range of concentrations from 0 to 10% by weight.

EXPERIMENTAL

Throughout this investigation analytical reagent chemicals were used for the assay procedures, and waxes of food grade were employed in the spray-

congealed samples. Sulfaethylthiadiazole (SETD) was obtained from American Cyanamid Co.

Manufacture of Spray-Congealed Samples—Ingredients totaling 2,000 Gm. for each formulation were combined and melted in a stainless steel beaker immersed in an 80 ± 0.5° constant-temperature oil bath. Suspension of the SETD was maintained through the use of a Lightnin model F laboratory-type mixer. A Teflon siphon tube wrapped with silicone-treated heater tape brought the melted wax mixture at the desired temperature from the beaker to the spraying nozzle. The 1/4 JCO pneumatic atomizing nozzle[3] was equipped with a specially designed nichrome wire heater and a copper-constantan thermocouple and monitor.[4] The nozzle was maintained at a temperature of 80 ± 3° throughout the spraying operation. Dry air at 60 p.s.i. provided the suction necessary to lift the melted formulation from the beaker through a constant siphon height of 30.5 cm. (12 in.) to the nozzle where atomization took place. The cloud of congealing wax droplets was directed into a galvanized steel collection chamber through the spraying port, and the product was collected from the base of the chamber's lower cone. A vortex was created during spraying operations by having the spraying port located 15 cm. (6 in.) left of center; the swirling flow of air inside the collection chamber helped to prevent the waxy particles from adhering to the walls of the chamber.

The assembled apparatus is shown in Fig. 1. The collection chamber was approximately 274.3 cm. (9 ft.) high. A cloth sleeve joined the atomizing nozzle to the spraying port, a cloth air-escape bag was attached to the upper cone, and a plastic collection bag was joined to the lower cone. The equipment was assembled as shown and preheated to 80° for 20 min. before atomization was begun. After a sufficient amount of product had been collected, the air and heaters were turned off. The product was then removed, weighed, and stored in glass jars. The remaining portion of the 2,000-Gm. formulation melt was allowed to cool in the beaker, then removed, weighed, and stored.

Problem Design—All formulations contained approximately 25% by weight SETD; the exact drug content of each product was determined by subsequent extraction and assay. Three wax bases were chosen that had been shown to release the drug favorably over an extended period of time (10). These bases were: white wax USP, a synthetic wax-like ester, and a combination of equal parts of these two waxes. Four levels of the surfactant sorbitan monooleate were used: 0, 1, 4, and 10% by weight. Each of these 12 different formulations was sprayed once through three fluid nozzle sizes; 0.02(~0.5 mm.), 0.04(~1 mm.), and 0.06(~1.5 mm.), in. diameter. This factorial design led to 36 samples, each with a unique set of the three treatment variables.

Particle-Size Analysis—Microscopic analysis, using a Zeiss filar ocular and a haemocytometer test cell, was selected as the best method of particle-size analysis. Mechanical sieving was not possible since the particles were too fine and too tacky in some instances to flow through the screens. Adequate deflocculation could not be maintained to enable the use of an electronic counter or a sedimentation technique.

Density Determinations—True density data were obtained from measurements made on the congealed portions of each formulation remaining in the beaker after spraying. Apparent bulk densities were determined by a standardized tapping method using a 100-ml. cylindrical graduate. Porosities and specific surfaces for each sample were then calculated from the results of the particle-size analysis and the density determinations.

Assay for SETD Content of Spray-Congealed Products—The test drug was extracted from the product by placing exactly 0.5000 Gm. of the spray-congealed sample in a 40-ml. portion of warm chloroform and washing several times with warm 0.1 *N* HCl, the washings being combined and made to volume in a 250-ml. volumetric flask with distilled water. An aliquot was assayed for SETD content by the Bratton-Marshall (11) colorimetric procedure for sulfonamides. The absorbance of the resulting solutions was determined on a Klett-Summerson colorimeter using a No. 54 filter and compared to a prepared standard curve. Duplicate extractions and assays were conducted on each spray-congealed sample.

Dissolution Studies—The release characteristics of the spray-congealed SETD–wax particles were examined by the method of Robinson and Swintosky (9). For the acid studies, 14 aliquots of the product were weighed and placed in 90-ml. glass vials. Each aliquot contained 0.1200 Gm. SETD, as determined by prior assay, and weighed between 0.4 Gm. and 0.5 Gm. Sixty milliliters of simulated gastric fluid (0.1 *N* HCl, pH 1.1) was added to each vial, and the vials were clamped into the rotating-bottle apparatus described by Souder and Ellenbogen (12). A constant-temperature water bath was used to maintain a temperature of 37 ± 1°, and filtered into 250-ml. conical flasks after 1/4, 1/2, 3/4, 1, 1 1/4, 1 1/2, and 2-hr. intervals. One milliliter of the filtered eluant was transferred to a 100-ml. volumetric flask and made to volume with distilled water. The samples were then assayed for SETD content by the Bratton-Marshall method. Duplicate samples were also eluted in the HCl for extended time periods from 20 to 60 hr. These later points were

[3] Manufactured by Spraying Systems Co., Bellwood, Ill.
[4] Built by the Bioelectronics and Instrument Dept., J. Hillis Miller Health Center, University of Florida.

used to estimate the amount of SETD that would eventually be released if extracted for an infinite period of time.

Similar studies were conducted in simulated intestinal fluid (alkaline pancreatin solution, pH 8.3) with the following differences: Each aliquot contained 0.6000 Gm. SETD and weighed between 2.2 and 2.5 Gm. Two samples were withdrawn from the rotating-bottle device after 1/4, 1/2, 3/4, 1, 2, 3, 4, and 6 hr. had elapsed. Two-tenths milliliter of the filtrate was transferred by pipet to 100-ml. volumetric flasks and made to volume with distilled water. In all other respects, the procedures for the acid and the alkaline dissolution studies were identical.

Mathematical Calculations for Estimating Drug Released—A log–log model first developed by Cox (7) for spray-congealed particles of white wax and the synthetic wax-like ester containing no surfactant showed good agreement with the experimental data of this investigation. It may be written in the following forms:

$$\log (1 - C/C_e) = -c \log (1 + t/d) \quad \text{(Eq. 1)}$$

$$C = C_e [1 - (1 + t/d)^{-c}] \quad \text{(Eq. 2)}$$

where C is the amount of drug released in time t, C_e is the equilibrium solubility, and c and d are parameters specific for a given formulation determined by minimizing the quantity $\Sigma(\hat{C} - C)^2$ utilizing the experimental data of a completed dissolution study. A least-squares solution in terms of $\log (1 - C/C_e)$ (from Eq. 1) would not be the solution of choice in terms of C. Since experimental errors were approximately of equal variance along the dissolution curve, it is best to find the least-squares fit in terms of C, Eq. 2. This second equation is not a linear function of the unknown constants; therefore, there is no explicit formula for the calculations of the least-squares estimates of the parameters. An iterative procedure must be used that will converge to the best-fitting values. A number of such procedures exist; the method used was a modified Gauss-Newton nonlinear least-squares procedure (13).

RESULTS AND DISCUSSION

Production Rates—Of the three treatment variables considered, nozzle orifice size almost entirely determined the rate of production. The average rate for the 0.02-in. nozzle was 3.9 Gm./min., for the 0.04-in. nozzle the rate was 54.0 Gm./min., and for the 0.06-in. nozzle, 127.4 Gm./min. The rate of production of the largest nozzle was approximately of the same order as those reported by Scott and co-workers (5) using a centrifugal-disk atomizer 5 cm. in diameter.

Frequent clogging occurred when the smallest nozzle was used, and almost continuous operation of a built-in nozzle clean-out needle was required to remove obstructions from the fluid nozzle orifice. These obstructions appeared to be congealed wax plugs which formed in the orifice. The 1/4 JCO nozzle operates on an external-mixing principle with the atomizing air passing through a small annular around the fluid nozzle orifice. It was impossible to heat the tip of the fluid nozzle sufficiently to compensate for the cooling effects of the atomizing air. Clogging seldom occurred with the two larger

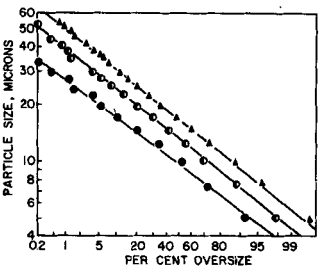

Fig. 2—Particle-size distribution comparison (by number) of spray-congealed products of SETD-white wax atomized through three different nozzles. Key: ●, 0.02-in. nozzle; ◐, 0.04-in. nozzle; ▲, 0.06-in. nozzle.

nozzles, and the greater amount of hot wax passing through the nozzle apparently heated the inner surfaces of the nozzle sufficiently to prevent congealing. The use of steam-jacketed nozzles and positive-pressure pumps would likely have eliminated the clogging problems experienced.

Surfactant concentration had no significant effect on the production rate, but the 1:1 combination wax matrices averaged production rates approximately twice those of synthetic wax-like ester matrices.

Particle-Size Analysis—The size of the nozzle used to atomize the melted wax formulations was found to largely influence the volume-surface mean diameter (d_{vs}) of the product; the type of wax matrix used was also found to be significant at the 5% level. The average d_{vs} was approximately linearly related to the nozzle size: 14.18 μ for the 0.02-in. nozzle, 21.23 μ for the 0.04-in., and 29.34 μ for the 0.06-in. nozzle. Figure 2 is a plot of the particle sizes obtained by spraying an identical formulation through three sizes of nozzles used in this investigation. Unusually close compliance with the log-normal distribution was found for each sample. Figures 3 and 4 are photomicrographs of the same formulation atomized through the 0.02-in. and the 0.06-in. nozzles, at the same magnification. The pronounced effect of the nozzle size can be seen in these photographs.

Synthetic wax-like ester formulations produced the smallest particles, and the 1:1 combination

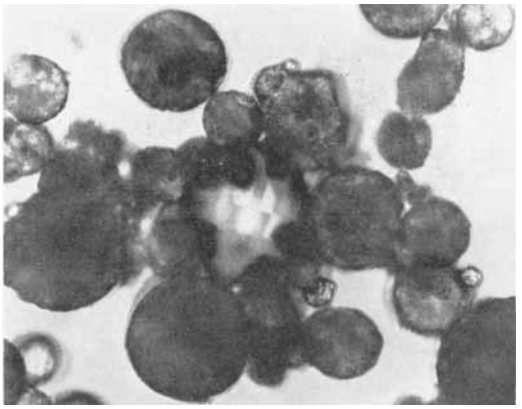

Fig. 4—Spray-congealed particles of SETD–white wax and a synthetic wax-like ester (1:1) containing 4% sorbitan monooleate atomized through a 0.06-in. pneumatic nozzle. Magnification, 210×.

matrix resulted in particles approximately 50% larger. The brittleness of synthetic wax-like ester was thought to be responsible for the small size of the particles since this wax shatters when stressed. The 1:1 combination matrix was more plastic than the synthetic wax-like ester alone and not as tacky as white wax alone. Sorbitan monooleate concentration had no significant effect on particle size.

Density Results—The true density of all formulations was almost the same: 1.063 average. Nozzle size and wax matrix were both important considerations in the bulk densities of the products. Bulk density increased with increasing particle size, as did flowability. White wax had the lowest bulk density as a result of its inherent tacky qualities, and the 1:1 combination had the highest.

Dissolution Studies in 0.1 N HCl—The amount of SETD released during the first 15 min. in 0.1 *N* HCl was taken as a measure of the partially exposed drug on the particles and possibly some free SETD. More drug was released in the first 15-min. period than in any later quarter-hour period, and it was found that all three treatment variables exerted a significant effect on this initial amount of released drug. The specific surface of the product was in part responsible for the amount of drug released in this initial period. Figure 5 shows the effect of the nozzle size on the dissolution patterns of the products; the largest nozzle produced particles with the lowest specific surfaces and lowest rates of dissolution.

White wax formulations released an average of half as much drug as either of the other two matrices within the first 15 min. of exposure to the acid fluid. White wax products tended to agglomerate more than the other matrices, thus presenting less surface to the eluant. Also, white wax, being very pliable, was thought to have insulated the drug particles from the eluting fluid through film formation around each particle. The addition of the brittle synthetic wax-like ester may have so reduced the pliability of white wax that such films were not formed, or were ruptured after formation, with the result that the drug was left exposed on the surface.

Sorbitan monooleate had a very pronounced effect upon the dissolution which occurred in the initial 15-min. period (Fig. 6). From this study, it appears that in concentrations up to 4%, this surfactant softens the particles, promotes wetting, and thus increases the amount of drug released. However, in 35 out of 36 samples prepared, 10% surfactant produced the lowest release. The particles were generally very tacky when this much surfactant was present. If the particles had agglomerated extensively, the total surface area exposed to the fluid would have been considerably reduced. Another possible explanation is that the w/o emulsion-forming tendencies of this lipophilic surfactant (HLB 4.3) may have entrapped the eluant and prevented the dissolved drug from being transported away from the wax particle into the solution.

The initial dissolution rate was obtained from the first derivative of Eq. 2 by setting $C = 0$ when $t = 0$. It was found that comparisons of the initial dissolution rate $(c/d)(C_e)$ closely paralleled the results of the 15-min. analysis. The initial dissolution rates of products atomized through the 0.06-in., 0.04-in., and 0.02-in. nozzles were in the ratios of 1:2:4, respectively. The average initial rate of synthetic wax-like ester formulations was twice that of white wax; the 1:1 combination rate was three times that of the white wax formulations. Increases in the surfactant concentration up to 4% resulted in higher initial rates of dissolution; at 10% concentration, the rate was about one-third that of products containing no surfactant.

There was little change in the effects of nozzle size, wax matrix, and surfactant concentration up

to 2 hr. in the acid fluid. After 22 hr., however, it was found that the synthetic wax-like ester formulations had released approximately 50% more drug than had the white wax formulations. As the drug was removed, the wax bead would likely become porous, channeled, and less able to resist the attritional forces of agitation in the vial. White wax, being pliable, would perhaps be more resistant to crumbling when used as a matrix than would the brittle synthetic wax-like ester. After 22 hr., sorbitan monooleate no longer exerted a significant repressant effect upon the total amount of drug dissolved.

Dissolution in Alkaline Pancreatin Solution—An examination of Fig. 5 shows that much more drug was released in a given time period to the alkaline pancreatin eluant than to 0.1 *N* HCl. This increase in dissolution was probably due to partial solubilization and disintegration of the wax particles by the surfactant action of bile and pancreatin, and by the alkalinity of the sodium bicarbonate. When the sample contained sorbitan monooleate, essentially complete solubilization or emulsification of the wax beads was noted after 24 to 48 hr.

After 15 min. in alkaline pancreatin solution, the effects of all three variables could be seen in the amounts of SETD released from the various samples. Products made with the largest (0.06-in.) nozzle released considerably less drug than the smaller particles. White wax showed the highest release, synthetic wax-like ester the lowest, and the 1:1 combination was intermediate. The acids present in white wax are believed to be responsible for the large release observed; synthetic wax-like ester was not as easily disintegrated and solubilized in the alkaline pancreatin solution due to the apparent lack of acids. In the alkaline medium, sorbitan monooleate promoted faster rates of release, and 10% surfactant concentration led to greater releases of drug in 6 hr.

Model Predictions—Figures 7 and 8 are compound log–log plots of $(C_e - C)$ against $(t + d)$. The lines and data points are derived from separate sources and do not represent a least-squares fit of the data in the usual sense. The lines were plotted using the estimated parameters from Eq. 2. Superimposed upon these lines are the data points of the indicated samples. The fit appears to be uniform, and the discrepancies are random. The slopes of the plotted lines $(-c)$ have been assigned no significance since c was determined through adjustment with trial values of C_e and d. Attempts to correlate these three parameters with the treatment variables or with other quantitated properties of the products were not successful.

Higuchi and Hiestand (14) proposed that diffusion-controlled systems released drug from the insoluble matrix according to the square root of time. A relationship to apparent zero- or first-order release patterns was demonstrated by Wagner (15) using previously published dissolution data. Considerable work has been done on idealized systems of solid drug dispersed in solid matrices. Higuchi (16) enumerated several complicating factors which must be considered before any dissolution model can be assumed to apply. He pointed out that break-up or dissolution of the matrix substances would result in erratically changing exposed surface area; also, the possibility of drug on the surface of the particle being released more rapidly than drug imbedded in the matrix must be considered.

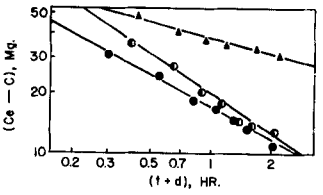

Fig. 7—Experimentally determined dissolution data for SETD in 0.1 N hydrochloric acid plotted on predicted lines for SETD–white wax and synthetic wax-like ester (1:1) formulations containing 1% sorbitan monooleate. Key: ●, 0.02-in. nozzle; ◐, 0.04-in. nozzle; ▲, 0.06-in. nozzle.

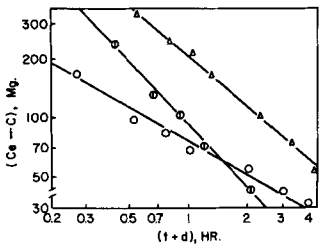

Fig. 8—Experimentally determined dissolution data for SETD in alkaline pancreatin solution plotted on predicted lines for SETD–white wax and synthetic wax-like ester (1:1) formulations containing 10% sorbitan monooleate. Key: ○, 0.02-in. nozzle; ◑, 0.04-in. nozzle; △, 0.06-in. nozzle.

This project dealt with wax particles which clumped, disintegrated, dissolved, and became emulsified; the exposed area was constantly changing. The surfactant concentration of the eluant continuously increased as sorbitan monooleate was extracted along with the drug from the wax particles. The parameters of the log–log model are likely related to the surface area, or to the rate of change of surface area; however, no relationship of this type was discovered during the course of the investigation.

SUMMARY AND CONCLUSIONS

1. Atomization through the use of a pneumatic nozzle and siphon tube was found to provide an expedient method of producing spray-congealed particles of drugs suspended in melted lipid materials.

2. Nozzle size largely determined the rate of production of the spray-congealed products.

3. The resulting particle size of the product was a function of the size of nozzle used for atomization; the particle-size distribution was found to be approximately log-normal.

4. The spray-congealed particles were discretely formed, apparently nonporous spheres; addition of sorbitan monooleate generally impaired flow properties and caused agglomeration.

5. In 0.1 *N* HCl, white wax matrices and large atomizing nozzles produced particles which had the slowest dissolution rates; sorbitan monooleate in concentrations up to 4% increased the solution rate; at 10%, the rate was markedly depressed. There was no noticeable surfactant effect upon the

total amount of drug dissoluted in a 22-hr. period.

6. In alkaline pancreatin solution, white wax matrices had the fastest rates of release, the largest particles had the slowest rates, and sorbitan monooleate consistently promoted faster release rates.

7. Good agreement was obtained between the model predictions and experimentally determined amounts of drug released from a formulation in a particular length of time. Determination of the model parameters adequately characterized the dissolution curve over the time period studied.

8. Sorbitan monooleate, when present in concentrations of 10%, was found to repress the dissolution rate of SETD in 0.1 *N* HCl, and to augment the rate in alkaline pancreatin solution. This behavior could be of use to formulators wishing to insure efficient release of the drug in the intestines after an initial delay.

Effect of Gibberellic Acid on the Growth, Alkaloid Production, and VLB Content of *Catharanthus roseus*

By A. N. MASOUD, L. A. SCIUCHETTI, N. R. FARNSWORTH, R. N. BLOMSTER, and W. A. MEER*

***Catharanthus roseus*, treated for 7 weeks with weekly doses of 100 mcg. of gibberellic acid (GA) and harvested biweekly, showed a significant increase in height and in stem dry weight. While GA treatment had a favorable effect on growth and did not affect the rate of flowering, it had an unfavorable effect on the concentration of total alkaloids in the plant organs. At final harvest the concentration of total alkaloids in the leaves was 55 percent of controls; that of the roots, 39 percent. Total alkaloid content per plant was greater than controls at the second harvest, but decreased at the fourth harvest. Detectable quantities of vincaleukoblastine (VLB) were not found in the stems or roots of both treated and untreated groups, but an increase of VLB concentration was noted in the leaves of the treated group. Gibberellic acid treatment had no affect on chlorophyll content, but markedly reduced the petroleum ether and ether extracts of plant organs.**

THE FOLLOWING GENERAL gibberellin effects have been reported in the solanaceous plants producing tropane alkaloids: increased internodal elongation, taller and spindlier plants, increased stem growth, variable effects on total plant growth depending upon the stage of the plant when treated and the concentration of growth hormone applied as well as environmental factors, chlorotic leaves and reduced chlorophyll content, an increased sugar content of the leaf tops, and a reduction in the concentration of alkaloids of the aerial parts (1–6). Many of these effects have been reported for other alkaloid pro-

Effect of Gibberellic Acid on the Growth, Alkaloid Production, and VLB Content of *Catharanthus roseus*

By A. N. MASOUD, L. A. SCIUCHETTI, N. R. FARNSWORTH, R. N. BLOMSTER, and W. A. MEER*

***Catharanthus roseus*, treated for 7 weeks with weekly doses of 100 mcg. of gibberellic acid (GA) and harvested biweekly, showed a significant increase in height and in stem dry weight. While GA treatment had a favorable effect on growth and did not affect the rate of flowering, it had an unfavorable effect on the concentration of total alkaloids in the plant organs. At final harvest the concentration of total alkaloids in the leaves was 55 percent of controls; that of the roots, 39 percent. Total alkaloid content per plant was greater than controls at the second harvest, but decreased at the fourth harvest. Detectable quantities of vincaleukoblastine (VLB) were not found in the stems or roots of both treated and untreated groups, but an increase of VLB concentration was noted in the leaves of the treated group. Gibberellic acid treatment had no affect on chlorophyll content, but markedly reduced the petroleum ether and ether extracts of plant organs.**

THE FOLLOWING GENERAL gibberellin effects have been reported in the solanaceous plants producing tropane alkaloids: increased internodal elongation, taller and spindlier plants, increased stem growth, variable effects on total plant growth depending upon the stage of the plant when treated and the concentration of growth hormone applied as well as environmental factors, chlorotic leaves and reduced chlorophyll content, an increased sugar content of the leaf tops, and a reduction in the concentration of alkaloids of the aerial parts (1–6). Many of these effects have been reported for other alkaloid pro-

ducing plants (1). Markiewicz (7, 8) reported that gibberellin treatment of *Catharanthus roseus* caused an increase in height but reductions in the weight of the aerial parts and the yield of root alkaloids.

The objectives of this research were: (*a*) to determine the effects of gibberellic acid (GA) on the growth of *Catharanthus roseus* (L.) G. Don (*Vinca rosea* L.) when the plant was grown under controlled greenhouse conditions during a 7-week observation period at which time periodic harvests were made; (*b*) to further ascertain the effects of GA on the concentration of alkaloids in the plant organs and the total alkaloid content of the plant; (*c*) to determine the effects of such treatments on the production of the antineoplastic alkaloid, vincaleukoblastine (VLB), during various growth phases of the plant; (*d*) to ascertain the effects of the growth regulator on other metabolic products.

EXPERIMENTAL

Procedure—*Catharanthus roseus* plants employed in this study were grown under greenhouse conditions from seeds obtained from a 1959 crop of mixed pink flowering and white flowering *C. roseus* (L.) G. Don grown in India from stock seed stored at the Department of Pharmacognosy, University of Pittsburgh. Germination was accomplished in flats containing a soil mixture of two parts of loam and one part of sand. About 50 Gm. of complete organic fertilizer[1] was incorporated into the soil of each flat. On July 24, 1964, the larger of the 10-day-old seedlings were transplanted from the flats into paper bands filled with the previously described soil mixture. These paper bands were arranged in flats, 80 per flat and a total of 12 flats were transplanted. One month later the plants were transplanted from the paper bands into individual 1-gal. metal containers that had been filled with the sandy loam mixture. Prior to transplantation approximately 15 Gm. of complete fertilizer had been thoroughly mixed into the soil of each container.

Plants of the pink-flowering variety, recognized by their pink stem were divided into two groups of 120 each. One group, numbered C-1 to C-120, served as the controls; the other, numbered GA-1 to GA-120, was the group treated with GA. These plants, numbered 111 through 120 for each group, were designated for height measurements and each group was further divided into subgroups of 30 plants each so that separate harvests at 2-week intervals could be performed. Plants were labeled according to the aforementioned treatment plan and randomized on two greenhouse benches.

Treatment was instituted on September 11 (zero time). At this time 0.1 ml. of a freshly prepared aqueous solution containing 100 mcg. of GA[2] was applied with a micropipet to the upper leaves of each plant of the GA group. Height measurements were also taken on the same date of the randomly arranged plants numbered 111–120 since these plants would be survivors throughout the whole experimental period. Height, in cm., was taken from the base of the stem at soil level to the apex of the highest leaf. Treatment and height measurements were performed at weekly intervals for 6 subsequent weeks. The 100-mcg. dosage was determined from a preliminary experiment employing dosage levels of 25, 50, and 100 mcg. of GA per group of three plants.

Four harvests were made at 2-week intervals. The first harvest was performed 5 days after the first treatment. Thirty plants were selected per harvest according to the following numbering plan: 1–30, first harvest plants; 31–60, second harvest plants; 61–90, third harvest plants; 91–120, fourth harvest plants. At harvest time each plant was thoroughly washed and excess moisture was removed with a towel. Plants were then divided into leaf, stem, and root portions; fresh weights were taken immediately, the respective plant parts were then dried in a circulating hot-air drier until dry weights were determined. The plant parts were pooled according to harvest and treatment, powdered to a No. 40 powder in a Wiley mill, and stored in air-tight glass containers until used for subsequent analysis.

Alkaloid Analysis—Samples of the pooled powdered material which had previously been dried in an oven at 100° for 24 hr. were assayed for total alkaloids in a manner similar to that of Szasz *et al.* (9). Five grams of the powdered crude drug was thoroughly moistened with 5 ml. of dilute ammonia soln. 58% (w/v), allowed to air dry and transferred, by washing with 75 ml. of chloroform, to a conical flask, stoppered, and allowed to macerate for 24 hr. This material was filtered through a Buchner funnel and the filtrate shaken with 100-ml. portions of 2% (w/v) sulfuric acid until it tested negative for alkaloids with modified Dragendorff's spray reagent. This acid solution was adjusted to pH 10 with dilute ammonia soln. 58% (w/v), and exhaustively extracted with chloroform. The resulting chloroform solution was dried over anhydrous sodium sulfate, filtered and concentrated to dryness, *in vacuo*, utilizing a methanol azotrope to assure complete removal of moisture. This residue was redissolved in chloroform, and adjusted to a volume of 25 ml. Three drops of indicator (0.5% w/v) solution of gentian violet in glacial acetic acid) and 12.5 ml. of glacial acetic acid were added, the mixture continuously stirred, and titrated to a visual green end point with 0.01 *N* perchloric acid in glacial acetic acid. Precautions were observed to assure that atmospheric moisture was not absorbed by the glacial acetic acid prior to its use in the titration procedure. The total alkaloid content was expressed as milligrams of perivine per gram of sample since this alkaloid is representative of the average molecular weight and structural type of alkaloids present in *C. roseus*. It is also the major alkaloid formed in the leaves of the plant (10).

The VLB content was determined from 1-Gm. samples of the pooled powdered plant material by a method devised in our laboratories and described in a recent publication (11).

[1] Organic Morcrop, Chas. Lilly Co., Seattle, Wash. (Analysis: 5% total nitrogen, 3% available phosphate, 2% available potash).

[2] Furnished through the courtesy of Dr. Edwin Alder, Agricultural Research Center, Eli Lilly and Co., Greenfield, Indiana.

Chlorophyll Content—The concentration of chlorophyll *a* and *b* was determined on 1/2-Gm. samples of powdered leaf material by a method previously described (4).

Selective Solvent Extraction—To determine the effects of the treatments on the formation of other types of metabolic products, duplicate 2-Gm. samples of the powdered dried leaves were selectively extracted in a Soxhlet apparatus in sequence with the following solvents: petroleum ether USP, absolute ether A.R., absolute alcohol A.R., and distilled water in a manner previously described (3).

RESULTS

A significant increase in height was induced by the GA treatment (Table I), and the maximal increase (61%) over controls occurred at the end of the second week. Just prior to the terminal harvest the GA-treated plants were 48% taller than controls. Analysis of variance of the height data (Table I) indicated that the height increases of the treated plants were statistically significant at the 1% confidence level. The rate of flowering was not affected by the gibberellin treatment.

A general favorable effect on plant growth was induced as indicated by dry weight data (Table II). Increases of 34, 20, and 14% were found in the total dry weight at the second, third, and fourth harvests, respectively. Stem dry weights were increased 11, 85, 93, and 40% over the controls at the first, second, third, and fourth harvests, respectively. The dry weight of the roots was increased except at the first harvest, but the weight of the leaves was not appreciably affected. Statistical analysis of the dry weight data indicated that there was significant increase in only the stem dry weights of the GA group. This increase was significant at the 5% level in only the second and third harvest plants. The marked increases in root and whole plant dry weights were not statistically significant.

First harvest samples were not assayed for the concentration of total alkaloids because insufficient amounts were available. Alkaloid concentration in the leaves of the controls increased with the age of the plant (Table III) and a reverse trend occurred in the GA group. In general, gibberellin treatment caused a reduction in leaf alkaloids, with the largest (45%) reduction occurring at the fourth harvest. Treated plants showed a lower alkaloid concentration in the stems than controls. In this case, both the treated and untreated groups demonstrated decreased alkaloid concentrations with age. Slight reductions were noted in the concentration of root alkaloids at the second and third harvest, and again the largest decrease (39%) occurred at the fourth harvest. It was observed that GA treatment generally induced a decrease in the concentration of alkaloids in all plant parts. This decrease was more pronounced in physiologically mature plants than in young plants. Alkaloid concentrations tended to increase with maturation in both leaves and roots, then leveled off at the final harvest.

Total alkaloid content in the leaves of treated plants was increased 31% at the second harvest but decreases of 20 and 45% were found at the third and fourth harvests (Table IV). This 31% gain was due both to increased growth and increased alkaloid concentration, while the reductions were due entirely to decreased alkaloid concentration. Total alkaloid content of the stems was increased at all three harvests (Table IV) and the increases were more pronounced at the early growth stages than during the more mature phases. These increases were due primarily to the effect GA had on increasing stem growth. Variable effects were noted on the total alkaloid content of the roots. The 32% decrease at the fourth harvest was due mainly to a significant reduction in the concentration of root alkaloids. The total alkaloid content per plant was increased 35% at the second harvest but decreased 39% at the final harvest, this latter effect was due

[a] VLB = vincaleukoblastine. [b] Calculated from dry weight and VLB concentration data.

entirely to the appreciable reductions in the concentrations of alkaloids found in the plant organs.

One-gram samples of the dried plant organs were analyzed for vincaleukoblastine (VLB) by the previously described procedure. The concentration of VLB was less than the minimum detectable concentration of 5 mcg./Gm. in both the stems and roots. It was concluded that in both the treated and control groups grown under the aforementioned greenhouse conditions, these organs either contained no VLB, or, if the alkaloid was present, it occurred in concentrations below the detectable concentration of 5 mcg./Gm. dry weight of plant material. Concentration of VLB generally was higher in the leaves of the treated plants than controls (Table V). In the treated plants the concentration of VLB decreased in the leaves as the plants matured. Even in the controls, the leaf concentration was much higher at the first harvest than the fourth harvest. Since gibberellin treatment did not significantly affect the dry weight of the leaves, the total VLB content of the leaves followed the pattern shown for the VLB concentration.

Due to the small quantities of plant material remaining, only the leaves of the fourth harvest plants were assayed for the concentration of chlorophyll *a* and *b*. The concentration of chlorophyll *a* in the controls was 3.76 mg./Gm. compared with 3.94 mg./Gm. in the treated group. Corresponding figures for chlorophyll *b* were 3.45 and 3.57. The GA treatment had no significant effect on chlorophyll concentration.

Selective solvent extraction was performed on the various organs of the final harvest only (Table VI) and the petroleum ether and absolute ether extracts of all organs were markedly less in the treated group. The absolute ether extract of the stems of the treated group was about one-third of the controls. A slight increase over controls was noted in the alcoholic extract obtained from the leaves of the GA group whereas marked reductions were found in the stems and roots. No significant differences were noted in the aqueous extracts of the organs between treated and nontreated groups.

DISCUSSION AND CONCLUSIONS

A typical gibberellin effect characterized by increased internodal elongation which resulted in taller plants was noted in the treated plants. Analysis of variance of the height data indicated that the increased height of the GA group was

GA	Stems	110	11	60	173
GA	Roots	110	14	86	154

[a] Expressed as mg./Gm. dry wt.

significant at the 1% confidence level. Treatment with GA did not affect the rate of flowering, but growth of the plants, indicated by total dry weight, was favorably affected. As could be expected most of the weight gain was concentrated in the stems. The pattern for stem dry weight (over controls) of 85 and 93% at the second and third harvests, respectively, were statistically significant at the 5% confidence level. In general the dry weight of the leaves was not materially altered while slight gains were noted in root dry weights.

There was a general unfavorable effect of the GA treatment on the concentration of alkaloids in the various plant organs. This is in agreement with other investigations (1–6). Several trends were noted during the experimental period. The concentration of alkaloids in the leaves of the control group increased with the age of the plant while the reverse trend was noted in the GA group. Both treated and untreated groups demonstrated decreased alkaloid concentration in the stems with increasing maturity. Alkaloid concentration tended to increase with maturation in both leaves and roots, then leveled off at the final harvest when all of the plants were in full bloom. In other words, the maximum concentration appeared during the flowering stage. The decreases in alkaloid concentration at the fourth harvest of 45% in the leaves and 39% in the roots were considered significant. Total alkaloid content of the leaves and roots generally followed the pattern exhibited with alkaloid concentration, however, the total alkaloid content of the stems was more directly related to the effect of GA on increasing stem growth. Due to significantly increased stem weight the total alkaloid content of this organ was markedly increased at all three harvests. The increases of 75% at the second harvest and of 52% at the third harvest were considered significant.

Of great interest was the disclosure of the effect of GA on the concentration of VLB and the total VLB content. It was concluded that the stems and roots of both groups either contained none of this alkaloid, or that this alkaloid, if present, was present below the minimum detectable concentration that could be demonstrated by the assay procedure. Treatment with GA generally increased the concentration and total content of VLB in the leaves. The concentration of VLB in the leaves of this group decreased with increased plant maturity. This pattern was the reverse of that noted with the concentration of total leaf alkaloids. Even in the control group the concentration of VLB in the leaves was about two-thirds that of the first harvest at the terminal harvest. These disclosures are in agreement with the observations by Noble (12) who found that extracts of leaves of young *C. roseus* plants showed a greater leukopenic activity than did the leaves of older plants. This was undoubtedly due to a lower concentration of the leukopenic alkaloid VLB in the older leaves. This suggests that VLB accumulates at a higher rate in younger leaves than in more mature ones. The total VLB content of the leaves followed a pattern similar to that of VLB concentration since gibberellin treatment did not markedly affect leaf growth.

The following pertinent observations were made concerning other types of metabolic products. Treatment with GA apparently did not affect the chlorophyll concentration. The synthesis and/or accumulation of lipids and resinous compounds was reduced in all of the organs of the treated groups as indicated by the decreased quantities of petroleum ether and ether extracts obtained by the selective solvent extraction. No significant differences were noted in the alcoholic or aqueous extracts.

Mechanism of Hypotensive Action of 2-(2,6-Dichlorophenylamino)-2-imidazoline Hydrochloride (ST-155) in the Cat

By R. D. MAGUS* and J. P. LONG

A study of the mechanism of hypotensive and bradycardic action of ST-155 in the cat revealed that this action is in part related to a centrally mediated bradycardia. Bradycardia and the hypotensive action of ST-155 were antagonized or abolished by hexamethonium, bretylium, decerebration, or by stellate ganglionectomy. The action of ST-155 does not appear to involve veratrine-sensitive pathways inasmuch as denervation of the carotid sinus or excision of the nodose and superior cervical ganglia were without effect on the action of ST-155. ST-155 in the dosage used (8 mcg./Kg.) potentiated the pressor responses to epinephrine and tyramine. It is presumed that reduced central sympathetic transmission to the heart from the cardiac sympathetic nerves is a major mechanism for the hypotension and bradycardia following ST-155 administration.

THE TOLAZOLINE ANALOG 2-(2,6-dichlorophenylamino)-2-imidazoline hydrochloride (ST-155) (Fig. 1) is currently being widely investigated in both animals and man as a possible antihypertensive agent. Studies in animals to date indicate that ST-155 administered intravenously exhibits a dose-dependent (1–100 mg./Kg.) reduction in heart rate and blood pressure in vagotomized dogs, an effect which is preceded by a brief pressor response (1). In addition,

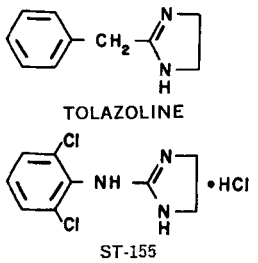

Fig. 1—Structures of ST-155 and tolazoline.

ST-155 has been shown to depress the carotid sinus reflex, reduce cardiac output with little change in peripheral resistance during the hypotensive phase, and exhibit a variety of sympathomimetic actions (*e.g.*, vasoconstriction in the isolated rabbit ear, splenic contraction in cats, increase in contraction amplitude of isolated spontaneously beating guinea pig atrial) (1). With relatively larger doses in rats ST-155 has been shown to increase urine volume and electrolyte excretion although such effects have not been seen in dogs receiving the drug in doses which produced marked hypotensive actions (1).

Clinical studies have thus far shown that ST-155 in microgram dosage is an orally effective antihypertensive agent in man with a low incidence of side effects (2–7) and toxicity (*loc. cit.*, 8). For example, orthostatic hypotension is a minor occurrence with therapeutically effective doses; however, fatigue, sedation, and anticholinergic effects have been repeatedly observed in humans receiving ST-155 (2–7).

To date, the mechanism of hypotensive action of ST-155 has not been elucidated (9). The present experiments were, therefore, undertaken in an attempt to provide a possible mechanism of hypotensive action of ST-155 in the anesthetized cat. The studies appear to indicate that a major component of the drug's hypotensive action is a centrally mediated inhibition of sympathetic cardioaccelerator nerves resulting in bradycardia.

EXPERIMENTAL

Animals—Thirty-five adult female mongrel cats weighing between 1.4 and 3.2 Kg. were used in this study. Anesthesia was performed by intrathoracic administration of sodium pentobarbital (30–35 mg./Kg.). All animals were tracheotomized and artificially respired on a Palmer respirator. Blood pressures were monitored, *via* a heparinized cannula inserted in the femoral artery, by a Statham arterial pressure transducer and recorded on an Offner RS dynograph. Heart rate was monitored with a stopwatch for 15-sec. periods at the intervals indicated on the charts. Injections of test drugs or infusion of additional anesthetic, when required, were made into the contralateral femoral vein either directly or through a cannula. Other operative procedures are described in the text where appropriate.

Key (Figs. 2–8): O, systolic blood pressure; ●, heart rates; S.E. = standard error of the mean; pressor areas are defined as the areas (mm. Hg × time) under the pressor phase of the systolic pressure curve. Statistical comparisons are made between the 0 time and 16-min. point.

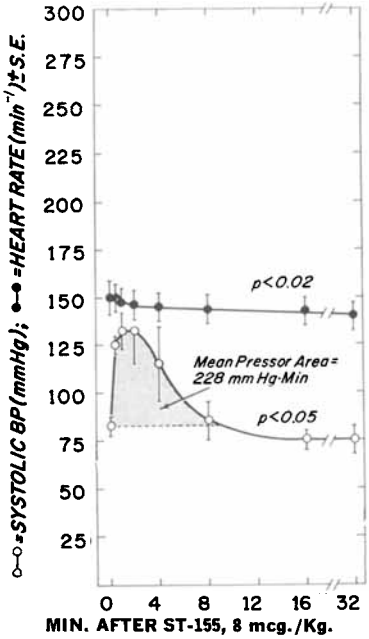

Fig. 3—Effect of hexamethonium pretreatment (10 mg./Kg.) on ST-155 action.

Drugs—ST-155 was administered as the water-soluble hydrochloride prepared in ampul form.[1] Tyramine hydrochloride (Eastman), hexamethonium chloride (Nutritional Biochemicals), and bretylium tosylate (Burroughs Wellcome) were administered in 0.9% saline solution. Epinephrine and isoproterenol were diluted before use from concentrated solutions (Parke-Davis). All dosages are expressed as the salt. Bretylium was administered by slow intravenous infusion; hexamethonium was similarly infused after an initial fraction of the administered dose was given intramuscularly. All other drugs were given by rapid intravenous injection.

In each experiment a total of five cats was used. All data are expressed as mean ± standard error; Student's 2-tailed *t*-test (paired comparison) was employed as described by Steel and Torrie (10).

RESULTS

Hypotensive Action of ST-155 in the Cat—The time course of pressor and depressor responses and bradycardia following 8 mcg./Kg. ST-155 administered intravenously is presented in Fig. 2. This dosage of ST-155 was selected from preliminary experiments as a dose which reduced heart rate and systolic pressure by approximately 20–25% and was used routinely in all subsequent experiments. The response to ST-155 in the cat (vagi intact) shown in Fig. 2 illustrates the initial transient pressor phase (30% increase in systolic blood pressure) concomitant with bradycardia. It will be noted that both the heart rate and arterial blood pressure 16 min. after administration of ST-155 are significantly different from preinjection values.

Effect of Hexamethonium Pretreatment on ST-155 Activity—In order to test the possibility that hypotension and bradycardia from ST-155 were reflexogenic, cats (vagi intact) pretreated with hexamethonium (10 mg./Kg.) were given ST-155 (8 mcg./Kg.) after the base line blood pressure following hexamethonium had become reasonably stable (20–30 min.).

The data in Fig. 3 indicate that hexamethonium pretreatment markedly reduced the bradycardia and hypotensive action of ST-155 and greatly potentiated its initial pressor action. Indeed, there is a ninefold increase in the pressor area (duration × pressure) when a comparison is made with cats not receiving hexamethonium pretreatment (Fig. 3 *versus* Fig. 2). A slight, albeit statistically significant change from pre-ST-155 values in heart rate and systolic blood pressure is seen at 16 min. However, since these changes vary only 7–8% from pre-ST-155 values and may be due to the action of hexamethonium, it may be concluded that bradycardia and hypotension due to the action of ST-155 are associated with a reflex. It would thus seem possible that hexamethonium abolished a depressor reflex which is otherwise triggered by ST-155.

Cardiovascular Response to ST-155 in the Decapitated Cat—That the hypotensive response to ST-155 was centrally mediated was tested by administration of the drug to cats that had a large press clamp placed tightly around the neck centrally to the tracheal cannula. This procedure effectively severed any functional connection of the head to the remainder of the animal. It was seen that such a maneuver abolished any depressor action of ST-155 (8 mcg./Kg.) although a transient bradycardia was seen (Fig. 4). However, no significant difference in both parameters was seen 16 min. after ST-155 administration. Whereas the pressor response to ST-155 showed a 30% increase in systolic pressure as in the intact cat (Fig. 4 *versus* Fig. 2), this action

[1] Catapres, Geigy.

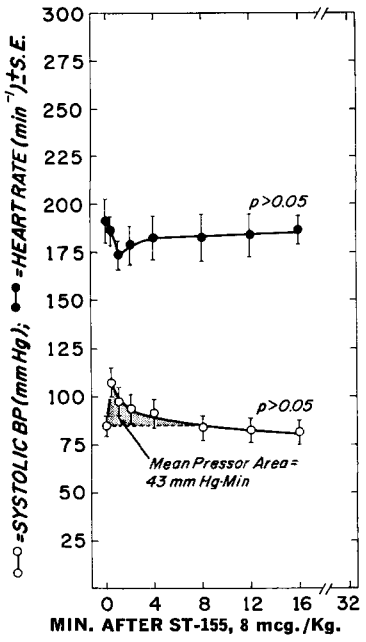

Fig. 4—Response to ST-155 in the headlamped cat.

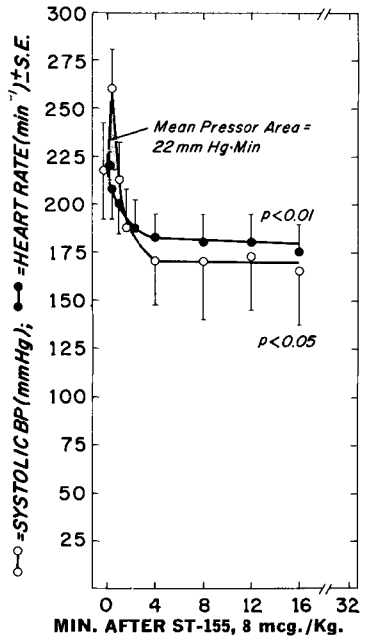

Fig. 5—Response to ST-155 following carotid sinus denervation.

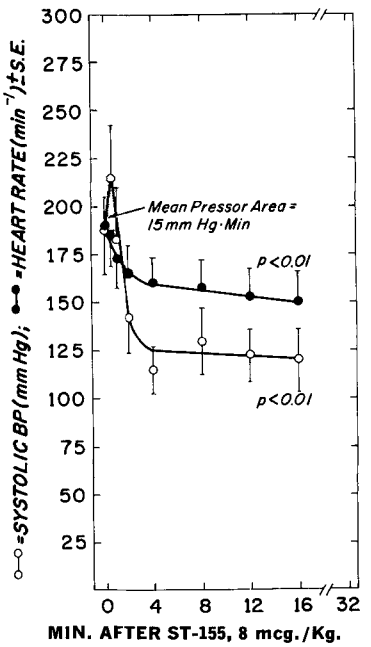

Fig. 6—Response to ST-155 following carotid sinus denervation and superior cervical and nodose ganglionectomy.

was of slightly longer duration in the headless cat (43 mm. Hg min. *versus* 29 mm. Hg min. pressor area). It would therefore appear that bradycardia and hypotension following ST-155 occur through centrally mediated pathways.

Effect of Carotid Sinus Denervation Alone or with Nodose and Superior Cervical Ganglionectomy on ST-155 Action—The possibility that ST-155 was activating reflex hypotension in a manner analogous to that of veratrum alkaloids (11, 12) was examined in the following experiments. Carotid sinuses were denervated bilaterally and painted with 1% lidocaine solution. Such a maneuver did not alter the action of ST-155 (Fig. 5 *versus* Fig. 2), nor did excision of the nodose ganglia and the superior cervical ganglia in addition to carotid sinus denervation (Fig. 6 *versus* Fig. 2). It was apparent, therefore, that the locus of action of ST-155 was unlike veratrum-like agents which appear to act reflexly *via* an action on the baroreceptor buffering mechanism and nodose ganglia (12).

Response to ST-155 After Bretylium Pretreatment or Stellate Ganglionectomy in Vagotomized Cats—It was speculated that a possible mode of action of ST-155 was *via* reflex inhibition of the cardiac sympathetic fibers emanating from the stellate ganglion. Pretreatment of bilaterally vagotomized cats with bretylium (15 mg./Kg.) (on the premise that if sympathetic nerve transmission was already inhibited by this means then ST-155 would not show hypotensive activity), potentiated the pressor action of ST-155 (8 mcg./Kg.), abolished the bradycardia, and markedly reduced the depressor action to a 10% change (at 16 min.) from pre-ST-155 values (Fig. 7). This effect of bretylium was much like that seen earlier with hexamethonium pretreatment (Fig. 3). Furthermore, administration of ST-155 (8 mcg./Kg.) to bilaterally vagotomized cats, in which the stellate ganglia were removed following a midline incision along the sternum, produced only a pressor response (Fig. 8). Again, the pattern of the response resembled that seen in the animals pretreated with hexamethonium (*cf.* Fig. 3).

Effect of ST-155 on Cardiovascular Reactivity to Tyramine, Epinephrine, and Isoproterenol—An investigation of the action of ST-155 was performed in order to examine its action at the adrenergic receptor level. Previous reports (1) indicated that with extremely high doses ST-155 may have adrenergic blocking activity. This would not be unexpected in view of its structural resemblance to tolazoline (Fig. 1). However, it was found that ST-155 in an 8 mcg./Kg. dose appeared to potentiate the pressor actions of epinephrine in both the intact and headless cat and of tyramine in the intact cat; the vasodepressor action of isoproterenol in the intact cat was not affected by ST-155 pretreatment

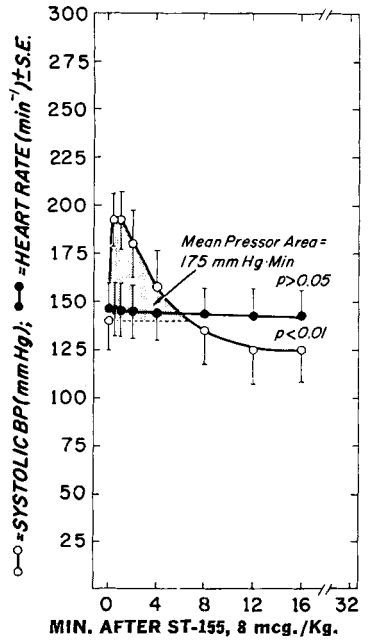

Fig. 7—Effect of bretylium pretreatment (15 mg./Kg.) on ST-155 action.

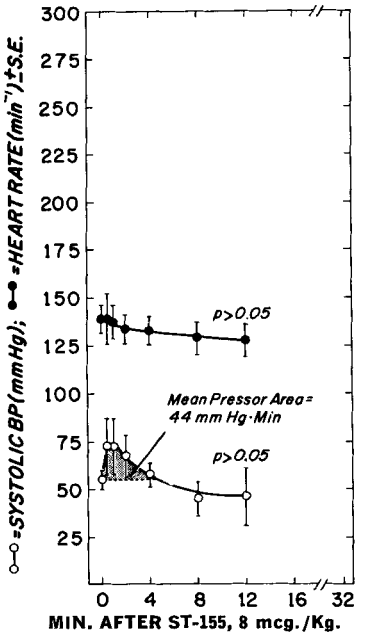

Fig. 8—Response to ST-155 following bilateral vagotomy and stellate ganglionectomy. No measurements were made beyond the 12-min. point.

(Fig. 9). It is apparent, therefore, that adrenergic blockade by ST-155 was not operative in the dosage used in this study.

DISCUSSION

If ST-155 were acting by central inhibition of the cardiac sympathetic fibers, the results obtained in this study would be in agreement with such a mechanism. Inasmuch as only a partial blockade of hypotension was obtained with bretylium and hexamethonium, it is difficult to state unequivocally that this is the mechanism of action. Such conclusions are further complicated by the possibility that hexamethonium and stellate ganglionectomy

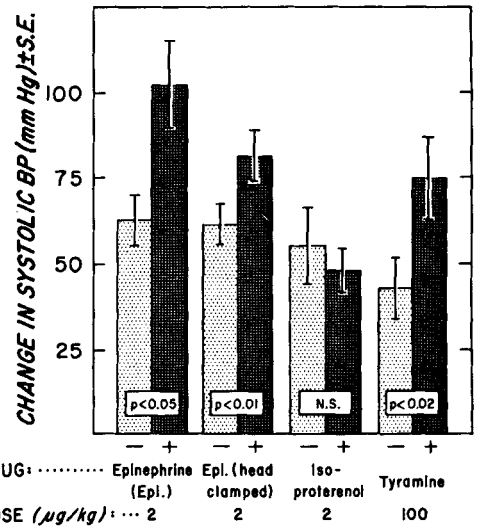

Fig. 9—Effect of pretreatment with ST-155 (8 mcg./Kg., i.v., 20 min.) on pressor responses to epinephrine and tyramine and vasodepressor response to isoproterenol and refer to ST-155.

lowered blood pressure to the extent that it could not be lowered further by ST-155 (Figs. 3 and 8). However, it must be emphasized that the "breakthrough" depressor responses to ST-155 after hexamethonium, *etc.*, were quantitatively minimal compared with the depressor activity seen in normal animals. It may be significant that whenever appreciable hypotension was seen, bradycardia was invariably present. Thus, it may well be that hypotension occurs as a result of a centrally mediated (reflex?) reduction in cardiac output (*cf.* 13). It is of interest to note that ST-155 appears to exert no bradycardia in the isolated spontaneously beating rabbit heart (Langenorff preparation) in doses of up to 100 mcg. (15).

Other studies in animals have shown that ST-155-induced hypotension is abolished by β-adrenergic blockade and by pentolinium (18), which is in agreement with the authors' interpretation of the action of ST-155 after hexamethonium or bretylium. Release of catecholamines by ST-155 would not seem to be involved since no change in cardiac norepinephrine occurs following high doses of ST-155 (1, 14). The sympathomimetic actions of ST-155 are abolished by tolazoline, phenoxybenzamine,[2] or phentolamine, but not by reserpine pretreatment (14, 17). It is thus likely that ST-155 has at least two components of action: an apparently "direct" musculotropic (α-adrenergic) action on blood vessels and nictitating membrane (1, 14, 17) and a centrally mediated bradycardia seemingly involving only the cardiac sympathetics.

The present studies pose a pertinent question of whether these findings can be extrapolated to explain the mechanism of hypotensive action of ST-155 in man. Significant reduction of cardiac output and heart rate was observed in a group of patients with essential hypertension receiving total doses of 150 to 300 mcg. of ST-155 intravenously (3). In these studies no appreciable change in peripheral

[2] Dibenzyline, Smith Kline and French Labs., Philadelphia, Pa.

resistance was noted. There have been reports of hypovolemia (7) and of redistribution of blood (*e.g.*, cutaneous vasconstriction) although these latter effects appear to be due to the vasoconstrictor action of ST-155 (16).

It cannot be stated at present if or how the supersensitization to the pressor actions of epinephrine and tyramine are related to the reflex hypotension or bradycardia. Moreover, that central inhibition of cardiac sympathetic nerve fibers by ST-155 does indeed occur must also remain an unresolved postulate until direct studies are made to test this hypothesis and to correlate this with the hypotensive action of ST-155. However, the authors of a related study which appeared shortly after the present investigation was completed, concluded that ST-155 owed its hypotensive action to a central inhibition of "medullary vasomotor and accelerator centers" (19).

Molecular Sorption on Ion-Exchange Resins: Studies with Coumarin

By R. S. HEGDE, M. J. MEHTA, R. A. BHATT, D. J. PATEL, and S. L. BAFNA

The sorption equilibrium of coumarin on ion-exchange resins of different degree of cross-linking, ionogenic groups, and counter ions in water and aqueous methanols has been studied and the results are discussed.

EARLIER, (1–3) the sorption and separation of coumarins on ion-exchange resins has been reported. This paper covers the study of the sorption equilibrium of coumarin on ion-exchange resins of different degrees of cross-linking, ionogenic groups, and counter ions in water and aqueous methanols at room temperature (~30°).

EXPERIMENTAL

Resins—(*a*) Styrene divinylbenzene copolymer-based sulfonic acid cation-exchange resins[1] of relative degree of cross-linking (% nominal divinylbenzene content) as 4, 8, and 12 (further referred to as X4, X8, and X12) of −100, +200 mesh; the resins were conditioned, regenerated, and moisture content and capacity were estimated (4, 5).

The different ionic forms of the resins were obtained by passing an excess of the salt or hydroxide solution through the resin bed. The resin was then washed, filtered, air dried, moisture content determined, and the capacity of the air-dried form of the resin calculated from the capacity of the oven-dried resin in the hydrogen form.

(*b*) Carboxylic acid cation-exchange resins[2] of relative degree of cross-linking (% nominal divinylbenzene content) X = 2.5, 5, 10, and 15 (further referred to as resin CX 2.5, CX 5, CX 10, and CX 15) of −40, +60 mesh; these are presumably based on acrylic acid divinylbenzene copolymers. The resins were conditioned, regenerated, and the moisture content and capacity were estimated as given before (5). The ionic forms of the resins were obtained by passing an excess of the corresponding hydroxide solution through the resin bed. The resins were then washed free of alkali, filtered, air dried, and the moisture content was determined. The capacity of the resins in different forms was calculated from the capacity of the oven-dried resin in the hydrogen form.

Molecular Sorption on Ion-Exchange Resins: Studies with Coumarin

By R. S. HEGDE, M. J. MEHTA, R. A. BHATT, D. J. PATEL, and S. L. BAFNA

The sorption equilibrium of coumarin on ion-exchange resins of different degree of cross-linking, ionogenic groups, and counter ions in water and aqueous methanols has been studied and the results are discussed.

EARLIER, (1–3) the sorption and separation of coumarins on ion-exchange resins has been reported. This paper covers the study of the sorption equilibrium of coumarin on ion-exchange resins of different degrees of cross-linking, ionogenic groups, and counter ions in water and aqueous methanols at room temperature (~30°).

EXPERIMENTAL

Resins—(*a*) Styrene divinylbenzene copolymer-based sulfonic acid cation-exchange resins[1] of relative degree of cross-linking (% nominal divinylbenzene content) as 4, 8, and 12 (further referred to as X4, X8, and X12) of −100, +200 mesh; the resins were conditioned, regenerated, and moisture content and capacity were estimated (4, 5).

The different ionic forms of the resins were obtained by passing an excess of the salt or hydroxide solution through the resin bed. The resin was then washed, filtered, air dried, moisture content determined, and the capacity of the air-dried form of the resin calculated from the capacity of the oven-dried resin in the hydrogen form.

(*b*) Carboxylic acid cation-exchange resins[2] of relative degree of cross-linking (% nominal divinylbenzene content) X = 2.5, 5, 10, and 15 (further referred to as resin CX 2.5, CX 5, CX 10, and CX 15) of −40, +60 mesh; these are presumably based on acrylic acid divinylbenzene copolymers. The resins were conditioned, regenerated, and the moisture content and capacity were estimated as given before (5). The ionic forms of the resins were obtained by passing an excess of the corresponding hydroxide solution through the resin bed. The resins were then washed free of alkali, filtered, air dried, and the moisture content was determined. The capacity of the resins in different forms was calculated from the capacity of the oven-dried resin in the hydrogen form.

[2] Zeo-karb 226, Permutit Co., London, England.

(*c*) IR-200[3] of −20, +60 mesh; this is presumably styrene divinylbenzene copolymer-based sulfonic acid cation-exchange resin of relative degree of cross-linking about 20 but has an expanded structure. The resin was conditioned, regenerated, and moisture content and capacity were determined.

(*d*) IRC-50[4] of −40, +60 mesh; this is presumably methacrylic acid divinylbenzene copolymer-based carboxylic acid cation-exchange resin of relative degree of cross-linking about 8. The resin was conditioned, regenerated, and the moisture content and capacity were determined and the ionic forms prepared as given in (*b*).

(*e*) Styrene divinylbenzene copolymer-based strongly basic anion-exchange resins[5] of relative degrees of cross-linking: 2, 4, and 8 (further referred to as 1X2, 1X4, and 1X8), of −20, +50 mesh; these have presumably trimethyl ammonium groups as ionogenic groups. The resins were conditioned, regenerated, and moisture content was determined. For the estimation of capacity weighed samples (∽0.5 Gm.) of air-dried resin were mixed with 100 ml. of 0.05 *N* hydrochloric acid in well-stoppered flasks with frequent shaking. The next day, the remaining hydrochloric acid was estimated by titrating the aliquots with standard sodium hydroxide solution and the capacity was then calculated. Chloride form of these resins was obtained by passing sodium chloride solution through the resin bed in an excess of, the resin was then washed, filtered, air dried, and the moisture content was determined. The capacity was calculated from an oven-dried capacity of the hydroxyl form of the resins.

(*f*) Styrene divinylbenzene copolymer-based strongly basic anion-exchange resins[6] of relative degrees of cross-linking as 4 and 8 (further referred to as 2X4 and 2X8) of −20, +50 mesh; these presumably have dimethyl methylol ammonium groups as ionogenic groups. The resins were conditioned, regenerated, the moisture content and capacity of the resins were determined, and the chloride forms prepared.

(*g*) Styrene divinylbenzene copolymer-based weakly basic anion-exchange resin G[7] of relative degree of cross-linking about 8 and −14, +52 mesh; the ionogenic groups are presumably diethylamino groups. The resin was conditioned, regenerated, and the moisture content was determined. For the estimation of capacity, a weighed sample (∽1 Gm.) of air-dried resin was mixed with 50 ml., 1 *N* in NaCl and 0.1 *N* in HCl of solution with frequent shaking. The next day, the remaining hydrochloric acid was estimated by titrating the aliquots with standard sodium hydroxide solution and the capacity was then calculated.

Chemicals and Solvents—Chemicals were of A.R. or C.P. grade. Aqueous methanols were prepared by volume; for example, 10% methanol was prepared by making 100 ml. of methanol to 1 L. with distilled water. The dielectric constant of each solvent was measured on Multi-Dekameter-type DK 06 (WTW) using 1.8 m./cs. frequency at room temperature (∽30°).

Procedure—Coumarin solutions of different concentration and of known volume were mixed with weighed amounts of air-dried resins in well-stoppered flasks, with frequent shaking at room temperature (∽30°). After sufficient time, after the equilibrium was reached, the initial and the equilibrium concentrations were determined by ultraviolet absorption (6) with a Beckman model DU spectrophotometer using 10-mm. quartz cells.

RESULTS AND DISCUSSION

The synthetic organic ion-exchange resins (7, 8) consist of an irregular, three-dimensional network of hydrocarbon chains, to which ionogenic groups are attached and the surplus electric charge is balanced by mobile counter ions. The hydrocarbon network is hydrophobic but the ionogenic groups are hydrophilic. Hence, when the resin particle is placed in water, it sorbs water and swells to a limited extent. The amount of water sorbed and the extent of swelling depend on the degree of cross-linking and the counter ions. If the external solvent contains a nonelectrolyte, it is also sorbed to a certain extent and after some time a state of equilibrium is reached. The amount sorbed will depend on several factors (7), which include the London (dispersion) interactions, the dipole–dipole interactions, the relative solubility of the solute in the medium inside and outside the resin particle, the solvent uptake and the volume of the swollen resin particle, the equilibrium concentration of the solute in the external solution, and the temperature. Besides these, there may also be specific interactions in a particular system.

A sorption equilibrium study involves three substances: the resin, the solvent, and the solute. For the resin, the variables may include the matrix structure, the relative degree of cross-linking, the type and the acid or base strength of the ionogenic group, and the charge, shape, size, and hydration of the counter ions. The solvent may be aqueous, mixed, or organic, it may be polar or nonpolar, and have different dielectric constants and solvation of the ionogenic groups and the solute molecules. For the solute, the variables may include the shape, size, polarity, and the relative solubility in the medium inside and outside the resin particle.

The amount of the solute sorbed per unit capacity of the resin at a given temperature will hence be determined by the overall effect and a complex behavior is to be expected; the systematic study of the variables may help toward better understanding of the phenomenon and with this object this study was undertaken.

The sorption equilibrium studies were carried out at room temperature, since the small variation in temperature did not make substantial change. The values of S were calculated from $S = (Co - Ce)/Cr$, where Co and Ce are the initial and equilibrium concentration of solute, gram moles per liter, and Cr is the capacity of air-dried resin (Table I) in equivalents added per liter of solution, and then S was plotted against Ce. The splots were linear. Figure 1 gives a typical example to illustrate this. The slope of such plots is termed as B (4).

Table II gives the values of B for the sorption of coumarin on sulfonic acid cation-exchange resins in hydrogen form in water and aqueous methanols. It is observed that with increase in the % methanol

TABLE I—CAPACITY OF ION-EXCHANGE RESINS

IR-200	4.78	...	...
CX 2.5	10.6	2X4	3.5
CX 5	9.77	2X8	2.67
CX 10	8.70	...	...
CX 15	6.84	G	4.0
IRC-50	10.4	...	...

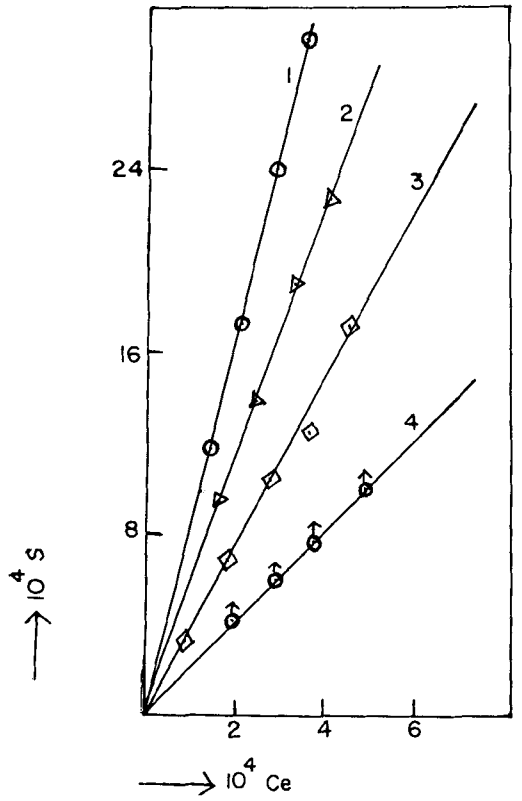

Fig. 1—Plots of S *against* Ce *for the resin X4 in hydrogen form in water* (1), *10% methanol* (2), *19% methanol* (3), *and 30% methanol* (4).

in the external solvent, B decreases. Figure 2 gives the plot of log B against log D (D is the dielectric constant of the external solvent) and the plots are linear; the values of slopes m, and the intercepts I are given in Table II. With the increase in the degree of cross-linking, X and m increase but I and B decrease.

For resin IR-200 (Table II) also, B decreases as the methanol content of the solvent increases, but the values of B are lower than what may be expected for 50W-type resin of $X = 20$. This implies that for sulfonic acid cation-exchange resins, the sorption is relatively less on a resin of expanded structure than that on a gel-type resin.

Table III gives the values of B for sorption of coumarin on the sulfonic acid cation-exchange resins of degree of cross-linking 4, 8, and 12 in H^+, Li^+, Na^+, K^+, and NH_4^+ forms. With the increase in X, for the hydrogen form of the resin, B decreases, but for Li^+, Na^+, K^+, and NH_4^+ forms, B increases. For resin X4, B is in the order $H^+ > Li^+ > Na^+ > K^+ > NH_4^+$, for resin X8 in the order $K^+ \backsim Na^+ > H^+ > Li^+ > NH_4^+$, and for resin X12 in the order $K^+ \backsim Na^+ > Li^+ > H^+ > NH_4^+$. Thus the order for H^+, Li^+, and Na^+ forms for resin X4 is reversed for resin X12. B for NH_4^+ form is always less than that for K^+ and Na^+ forms.

The sorption of coumarin was studied in water on resin X4 in different ionic forms. The values of B (Table IV) may be arranged in the order $H^+ > Fe^{+3} \backsim Al^{+3} > Ca^{+2} > Ni^{+2} \backsim Co^{+2} \backsim Li^+ > Na^+ > Fe^{+2} > Cu^{+2} > K^+ \backsim Sr^{+2} > Ba^{+2} > NH_4^+ > C_5H_5NH^+ > Ce^{+4}$.

Table V gives the values of B for sorption of coumarin on carboxylic acid cation-exchange resins of different X and ionic form. With increase in X, B first increases and then decreases for H^+, Li^+, Na^+, and K^+ forms, but for NH_4^+ form B increases with increase in X; for the ionic forms, B decreases in the order $H^+ > Li^+ > Na^+ > K^+ > NH_4^+$.

TABLE II—SORPTION OF COUMARIN ON SULFONIC ACID CATION-EXCHANGE RESINS IN WATER AND AQUEOUS METHANOLS

Resin	B in Solvent with Methanol % = 0	10	19	30	m	i
X4	8.5	5.8	3.8	2.1	7.6	−13.53
X8	7.3	4.3	2.6	1.2	9.6	−17.42
X12	6.3	3.5	2.0	0.9	10.6	−19.38
IR-200	1.8	0.8	0.41	...	...	...

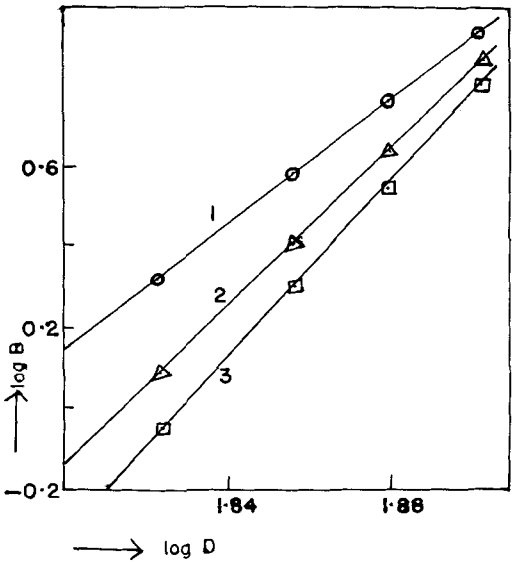

Fig. 2—Plots of log B *against* log D *for the resins X4* (1), *X8* (2), *and X12* (3) *in hydrogen form.*

TABLE III—SORPTION OF COUMARIN ON SULFONIC ACID CATION-EXCHANGE RESINS WITH DIFFERENT COUNTER IONS

Resin	B When Counter Ion is H^+	Li^+	Na^+	K^+	NH_4^+
X4	8.5	6.4	6.2	5.8	5.3
X8	7.3	6.8	7.9	7.9	6.8
X12	6.3	7.6	8.6	8.6	7.8

TABLE IV—SORPTION OF COUMARIN ON SULFONIC ACID CATION-EXCHANGE RESIN X4 WITH DIFFERENT COUNTER IONS (C.I.)

C.I.	B	C.I.	B	C.I.	B	C.I.	B	C.I.	B
H^+	8.5	Li^+	6.4	Ca^{+2}	6.6	Fe^{+2}	6.0	Fe^{+3}	7.4
NH_4^+	5.3	Na^+	6.2	Sr^{+2}	5.8	Cu^{+2}	5.9	Al^{+3}	7.4
$C_5H_5NH^+$	4.8	K^+	5.8	Ba^{+2}	5.1	Co^{+2}	6.4	Ce^{+4}	2.6
						Ni^{+2}	6.4		

TABLE V—SORPTION OF COUMARIN ON CARBOXYLIC ACID CATION-EXCHANGE RESINS WITH DIFFERENT COUNTER IONS

Resin	B when the Counter Ion is H^+	Li^+	Na^+	K^+	NH_4^+
CX 2.5	4.1	2.8	2.5	1.9	0.24
CX 5	9.0	5.9	4.2	3.7	0.71
CX 10	19.5	10.3	8.9	5.4	2.8
CX 15	9.1	9.0	6.9	6.4	5.8
IRC-50	6.7	2.9	1.7	1.3	0.74

For IRC-50, the same order is valid, but the values of B are relatively lower than those expected for carboxylic acid cation-exchange resin type resin of $X \backsim 8$. This implies that the sorption for acrylic and methacrylic acid-based resins is significantly different.

Table VI gives the values of B for the sorption of coumarin on anion-exchange resins in chloride form, with different X and type of ionogenic groups, in water and aqueous methanols. With increase in the methanol content and hence decrease in the dielectric constant of the solvent, B decreases. For 1X2, 1X4, and 1X8 resins, B increases with increase in the degree of cross-linking from 2 to 4 and is practically constant for increase in X for 4 to 8. For 2X4 and 2X8 resins, B increases when X increases from 4 to 8. B for 1X4 is greater than that for 2X4, but for 1X8 is lower than those for 2X8. B for the weak base anion-exchange resin G is greater than that for resin 1X8 but less than that for resin 2X8.

Table VII gives the values of B for sorption of coumarin on strong base anion-exchange resins in the hydroxyl form of different X in water and aqueous methanols. For 1X2, 1X4, and 1X8 resin, B increases with increase in X from 2 to 8 in water and 10% aqueous methanol; for 40% and 70% aqueous methanols, B first increases for increase in X from 2 to 4 and then decreases for increase in X from 4 to 8. For 2X4 and 2X8 resins, B varies in a similar manner for increase in X from 4 to 8. The values of B for 1X2, 1X4, and 1X8 resins are greater than those for the corresponding 2X4 and 2X8 resins of same X.

With increase in % methanol of the solvent and hence decrease in the dielectric constant of the solvent, B for resin 1X2 increases, for resin 1X4 decreases and then increases, and for resin 1X8 decreases. For resins 2X4 and 2X8, B decreases with increase in % methanol of the solvent. For the strong base anion-exchange resins, B for hydroxyl form is considerably greater than that for chloride form. This may be attributed to the strongly alkaline nature of the resins in the hydroxyl form and the relatively greater solubility of coumarin in alkaline medium; this comparison also suggests that in water 1X2, 1X4, and 1X8 resins should be more basic than the corresponding 2X4 and 2X8 resins of the same X.

TABLE VI—SORPTION OF COUMARIN ON ANION-EXCHANGE RESINS IN CHLORIDE FORM IN WATER AND AQUEOUS METHANOLS

Resin	B in Solvent with % Methanol = 0	10	20	30
1X2	9.0	6.1	5.0	2.9
1X4	21.0	12.5	9.2	6.2

Stability of Diosgenin

By G. BLUNDEN and C. T. RHODES

The decomposition of 25α-Δ⁵-spirosten-3β-ol (diosgenin) has been studied by various physical techniques in the solid state, in contact with both 2 *N* hydrochloric acid and 2 *N* sodium carbonate solution, and in solution in both chloroform and benzene. In contact with 2 *N* hydrochloric acid, about 40 percent of the diosgenin was found to decompose within 4 months, whereas in the other conditions, the amount of decomposition was found to be negligible, although decomposition products were detected on thin-layer chromatograms and by ultraviolet spectroscopy.

THE STEROIDAL SAPOGENIN, 25α-Δ⁵-spirosten-3β-ol (diosgenin), is of considerable importance as the main precursor of the pharmacologically active steroids, including the corticosteroids and oral contraceptives. Diosgenin is obtained commercially from the tubers of several species of *Dioscorea* by acid-hydrolysis of the naturally occurring saponins. This treatment with acid has been shown to produce products other than diosgenin. Peal (1) showed that when diosgenin was heated under reflux with ethanolic hydrochloric acid, a certain amount of 25α-spirosten-3,5-diene was formed, the amount varying with the acid concentration, being about 35% when refluxed with 2 *N* hydrochloric acid for 2 hr. Blunden, Hardman, and Morrison (2) found that when diosgenin was refluxed with 2 *N* aqueous hydrochloric acid for 2 hr., the quantity of 25α-spirosten-3,5-diene formed was about 6%. Yamagishi (3) found that the optimum procedure for obtaining diosgenin from the saponin dioscin with the least diene formation was refluxing for 2 hr. with 4 *N* sulfuric acid.

After boiling the *Dioscorea* tuber with acid in the extraction procedure for diosgenin, the acid-insoluble material is collected and washed, to free it from acid. Rothrock, Hammes, and McAleer (4) reported that if the residue were not washed free from acid, the diosgenin yield decreased when the residue was dried. Blunden and Hardman (5) found that if the acid-insoluble residue was stored in an acid condition, the diosgenin content decreased. To overcome this problem, Hershberg and Gould (6) neutralized the acid-insoluble material with a base. A similar technique using sodium carbonate solution was used by Blunden and Hardman (5). However, during the commercial extraction procedure of diosgenin, the process is sometimes continued until the acid-insoluble residue is produced this being exported for the final extraction of diosgenin. In certain cases, the shipped material has been distinctly acidic.

As indicated earlier, diosgenin is known to decompose when stored in contact with hydrochloric acid, but the authors are unaware of any published data concerning the stability of this steroid in the solid state or in solution in common organic solvents. The present investigation was undertaken to study the stability of diosgenin under these conditions over a 4-month period and determine the extent of decomposition compared with the total decomposition of diosgenin stored in contact with 2 *N* hydrochloric acid for the same period.

EXPERIMENTAL

The diosgenin used in this investigation was obtained from Steraloids Ltd. After three recrystallizations from acetone the material had a melting point of 204–205°. Decomposition of the sapogenin was studied over a 4-month period in the following environments: as solutions in chloroform and benzene and as solids, which were untreated or in contact with either 2 *N* hydrochloric acid or 2 *N* sodium carbonate solution. Suitable quantities of solutions or solids were packed in sealed glass ampuls at either 4, 20, or 37°, in light or in the dark. The solid samples and solutions in chloroform and benzene were examined at different time intervals, but only one sample of diosgenin in contact with 2 *N* hydrochloric acid and one sample in contact with 2 *N* sodium carbonate solution were prepared, both of which were stored at 20° in the light and examined after storage for 4 months. All the samples were examined by a number of different methods. (*a*) Optical rotations of diosgenin as solutions in chloroform were measured by a Bellingham and Stanley polarimeter using a cell of 1 ml. capacity and 10 cm. path length. (*b*) Infrared spectra of the diosgenin samples were obtained from Nujol mulls, using a Perkin-Elmer 257 spectrophotometer. (*c*) Nuclear magnetic resonance spectra of solutions of diosgenin in chloroform were determined using a Perkin-Elmer R10 spectrometer, utilizing a computer-assisted technique. (*d*) Thin-layer chromatograms were obtained on air-dried Silica Gel G (Merck) layers, 250 μ thick. Two-way chromatograms were prepared using chloroform-acetone (3:1 v/v) as the developing solvent for the first direction and *n*-hexane–ethyl acetate (3:1 v/v) for the second way. Development in each direction was for 15 cm. from the point of application of the test solution. The compounds were

Received September 25, 1967, from the School of Pharmacy, College of Technology, Portsmouth, Hampshire, England.
Accepted for publication December 20, 1967.
Presented to the Pharmacognosy Section at the 27th Congrés International des Sciencies Pharmaceutiques, Montpellier, France, September 1967.

detected by spraying the plates with a 300% w/v antimony trichloride solution in concentrated hydrochloric acid (7) and heating at 100° for 10 min. (*e*) Ultraviolet spectra of solutions of the sapogenin in chloroform were determined between 250 and 450 mμ using a Unicam SP.800 recording spectrophotometer. (*f*) Melting points were determined on dried material and were uncorrected. (*g*) Quantitative estimations of the diosgenin content of the samples were effected by the densitometric thin-layer chromatographic method of Blunden, Hardman, and Morrison (2). (*h*) Gas–liquid chromatograms were obtained by use of a Perkin-Elmer F11 instrument, stationary phase silicone gum rubber E-301, support A.W.-D.M.C.S. Chromosorb G 80-100 mesh $2^1/_2$: $97^1/_2$. The dual glass columns were maintained at 230°, the injection block temperature was 220°, and the nitrogen flow rate 55 ml. $min.^{-1}$. A standard Perkin-Elmer flame ionization detector was used. Signal amplification was 1×10^2, and sample volume 3 μl. of a 0.4% w/v solution.

RESULTS AND DISCUSSION

Of the techniques used to follow the decomposition of diosgenin, measurement of optical rotation proved of no utility, as no significant change in this property was detected in any sample. This indicates that groups immediately adjacent to the optical center are unaffected by the decomposition process.

The infrared and nuclear magnetic resonance spectra showed marginal changes in some samples, but in general, these techniques seem of little use in examining unresolved decomposition mixtures of diosgenin.

Thin-layer chromatography proved a most useful technique for following decomposition of the steroid. The diosgenin sample that had been stored in contact with 2 *N* hydrochloric acid, when examined by TLC, showed only two antimony trichloride positive spots, one being unchanged diosgenin and the second being a faint spot of high R_f value, which cochromatographed with 25α-spirosten-3,5-diene (Fig. 1). The chromatographic picture differed from that of a sample of diosgenin that had been refluxed with 2 *N* hydrochloric acid for 2 hr., before TLC examination (Fig. 2). These results indicate that the mechanism of decomposition resulting from refluxing diosgenin with acid may be different from that

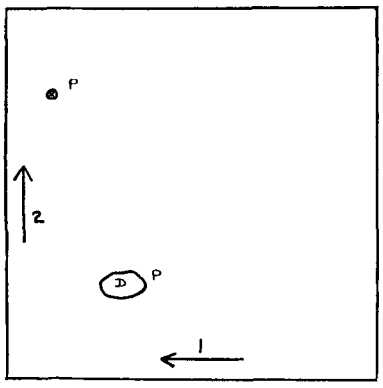

Fig. 1—TLC of diosgenin stored in contact with 2N HCl for 4 months. Solvent system: (1) chloroform–acetone (3:1 v/v; (2) n-hexane–ethyl acetate (3:1 v/v). Key: D, diosgenin; X, 25α-spirosten-3,5-diene; colors produced, p, purple.

operating when the compound is stored in acid at 20°. Moreover, these mechanisms appear to be different from that operating in the other test samples, in which no trace of 25α-spirosten-3,5-diene was detected. Thin-layer chromatograms prepared from diosgenin samples stored in the solid state and as solutions in chloroform and benzene were very similar (Fig. 3).

Further evidence of decomposition was obtained from the ultraviolet spectra. absorbance in the region of 250–350 mμ increasing during the storage period; no peaks were detected in the 350–450 mμ region During the decomposition process the absorbance in the 250 mμ and 285 mμ region increased. The ultraviolet spectrum of diosgenin stored in chloroform is markedly different from that of the drug stored in contact with acid or of pure diosgenin (Fig. 4). This is further evidence of differing decomposition routes. The ultraviolet spectrum of diosgenin with decomposition products is similar to that of 25α-spirosten, 3,5,-diene prepared synthetically. However, measurement in the critical 230–250 mμ region was not possible since the chloroform "cut-off" wavelength is about 245 mμ. The diene was not detected by thin-layer chromatography in diosgenin decomposition samples and thus its extent of formation may be presumed to be very low.

The melting point of decomposition samples de-

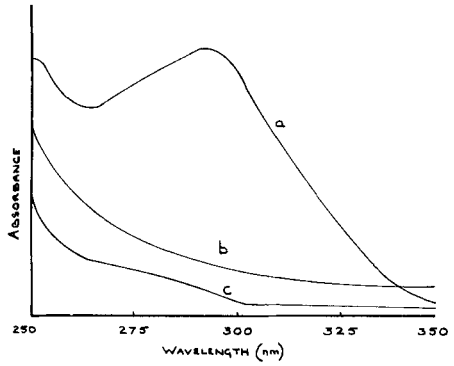

Fig. 4—Ultraviolet spectra of (a) *diosgenin stored in chloroform,* (b) *stored in contact with 2* N *hydrochloric acid, and* (c) *pure diosgenin.*

creased progressively from 204–205° to about 193°, but then remained stationary.

Quantitative TLC studies showed that, at the end of 4 months, the diosgenin had decomposed by an amount that was insignificant in all samples except the one that had been in contact with acid, of which approximately 40% had decomposed (Table I). The quantitative results obtained were subject to an experimental error of ±7% (2). At first sight this result is somewhat surprising, since all samples assayed after 4 months showed several decomposition compounds. However, antimony trichloride solution is a sensitive locating reagent for steroids, able to detect minute quantities of material. From this it was apparent that evaluation of qualitative thin-layer chromatograms of diosgenin for decomposition could be misleading since, even though several decomposition products may be present, the extent of the decomposition may be negligible.

Results obtained from GLC studies also indicated that the extent of decomposition was very low. Thus 4-month-old solid samples of diosgenin, as well as solutions in both chloroform and benzene, showed only two very small signals in addition to the diosgenin peak (Fig. 5). Apparent retention times were diosgenin 29 min. and decomposition peaks 18 and 38 min. Decomposition signals are obviously insignificant in comparison with the unreacted diosgenin.

The effect of temperature and light on the decomposition did not appear important. Qualitatively very similar chromatograms were obtained from all decomposition samples, and no evidence was obtained of photo or thermal effects on the rate of decomposition.

TABLE I—DIOSGENIN DECOMPOSITION AFTER DIFFERENT TIME INTERVALS

Diosgenin Samples	Diosgenin Yield—Percent of Original After 1 month	2 months	3 months	4 months
Solution in benzene[a]	98.9	100.5	98.5	99.1
Solution in chloroform[a]	100.3	100.8	98.7	97.6
Solid[a]	99.5	97.8	100.1	98.5
In contact with 2 *N* HCl[b]	...	...	...	60.0
In contact with 2 *N* Na_2CO_3[b]	...	...	...	101.1

[a] Samples stored in the light at 37°. [b] Samples stored in the light at 20°.

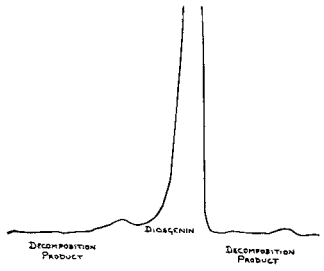

Fig. 5—GLC of diosgenin stored in chloroform for 4 months.

In this study it has been demonstrated that diosgenin rapidly decomposes in contact with hydrochloric acid. During the extraction process of diosgenin from plant sources, it is obvious that after hydrolysis of the naturally occurring saponins to liberate diosgenin, it is imperative to remove the excess acid before processing or transportation of the acid-insoluble residue. The process of neutralizing any residual acid with a base, such as sodium carbonate solution, is a sensible precaution as it does not cause any significant deterioration of diosgenin, even when the two are stored together for 4 months.

When the steroidal constituents of *Dioscorea* species have been studied by paper and TLC, many different spots have been detected. *Dioscorea* species contain both sterols and saponins and as sterols are known to decompose both in the solid state and in solution (8, 9), it will be certain that many of the spots produced on chromatograms of *Dioscorea* extracts will have been produced either during the acid treatment of the plant material to liberate the sapogenins or the subsequent decomposition of the steroidal constituents, in the solid state or in solution (10).

Interaction of 8-Hydroxyquinoline Sulfate with Components Present in a Tuberculin PPD Solution II

Effect of 8-Hydroxyquinoline on Metallic Impurities

By S. LANDI and H. R. HELD

The presence of 8-hydroxyquinoline sulfate (8-HQS) as a preservative in tuberculin purified protein derivative (PPD) solutions leads to the formation of a dark crystalline deposit. In this investigation it has been shown that the deposit was due to chelates resulting from the reaction of metals with 8-hydroxyquinoline (8-HQ) liberated from its sulfate. The metal impurities in tuberculin solution originate mainly from the buffer salts and the PPD. The removal of these metal impurities from the tuberculin PPD did not affect the potency of the preparation. Previous workers have shown the need to maintain the metal content within fairly narrow limits in order to render 8-HQ effective as a preservative. The necessity to keep the metal content within narrow limits in order to render the preservative effective, and to avoid the development of organo-metallic deposits, was considered an important drawback to its usefulness as a preservative.

8-HYDROXYQUINOLINE SULFATE (8-HQS)[1] is added to tuberculin solutions as an antimicrobial agent. These solutions are prepared by adding PPD (10, 50, or 1,000 TU[2]/ml.), polysorbate 80[3] (0.005%), and 8-HQS (0.01%) to a buffered solution of pH 7.38 (1). These solutions are perfectly clear when freshly prepared. However, upon storage at 5° in a 0.5 L. bulk, these solutions showed some turbidity which was accompanied by a dark deposit. Furthermore, after dispensing 1- and 5-ml. volumes of the original clear solutions in vials or ampuls, there was no turbidity, but on careful observation, a few tiny dark particles were present after approximately 6 months' storage at 5° or at 37°.

The authors wished to establish the reason for the appearance of this undesirable deposit and, therefore, attempted to determine which substances took part in its formation, and if the presence of such deposit would affect the biological potency of the tuberculin preparation.

MATERIALS AND METHODS

Reagents—8-Hydroxyquinoline sulfate (8-HQS) (Eastman Organic Chemicals, 1776); 8-hydroxyquinoline (8-HQ) (Fisher Scientific Co., 0-261); 8-hydroxyquinoline zinc salt (8-HQZn) (Eastman Organic Chemicals, 7884); polysorbate 80 (polyoxyethylene 20 sorbitan monooleate); chloroform (Fisher Scientific Co., C-298).

8-Hydroxyquinoline Iron Salt (8-HQFe)—8-HQFe was prepared by dissolving 4.35 Gm. of 8-HQ in 14 L. of distilled water and adding dropwise, while stirring, a solution of 2.70 Gm. $FeCl_3 \cdot 6H_2O$ in 50 ml. H_2O. The black precipitate was filtered on Whatman No. 1 paper and dried in a vacuum desiccator over $CaCl_2$.

8-Hydroxyquinoline Aluminum Salt (8-HQAl) and 8-Hydroxyquinoline Copper Salt (8-HQCu)—These metal chelates were prepared by adding an excess of 8-HQS (10% solution) to 1 L. of a millimolar aqueous solution of $AlCl_3$, respectively, $CuSO_4$ (reagent grade chemicals) and neutralization of the mixture at pH 7–8 by the dropwise addition of concentrated ammonia. The yellowish-green precipitates were filtered on a Millipore filter, washed thoroughly with distilled water, and vacuum dried over $CaCl_2$.

Tuberculin PPD (Trichloroacetic Acid Precipitate) and Tuberculin PPD (Ammonium Sulfate Precipitate)—Both methods of preparation and analysis of the tuberculin PPD preparations were previously carried out (2).

Buffer Solution (pH 7.38)—Isotonic phosphate-buffered solution, pH 7.38 (1.45 Gm. of KH_2PO_4, 7.60 Gm. of Na_2HPO_4, and 4.80 Gm. of NaCl in 1050 ml.). This buffer is also used as diluent for the preparation of tuberculin PPD solution (Mantoux) (1). Distilled water from a metal Barnstead still was used to prepare the buffer solution.

Isolation of a Dark Deposit from Tuberculin PPD Solution (0.01% 8-HQS; 0.005% polysorbate 80)—Five-hundred milliliters of a tuberculin PPD solution (1,000 TU/ml.) which had developed a dark deposit during 9 months' storage at 5°, was filtered through a Millipore TH filter[4] (pore size 0.45 μ).

Received April 5, 1967, from the Connaught Medical Research Laboratories, University of Toronto, Toronto, Ontario, Canada.

Accepted for publication November 13, 1967.

The authors wish to express their thanks to Mr. D. G. Glass for recording the infrared spectra and to Mrs. R. L. McClure for her cooperation in the statistical analyses of data. We also wish to thank Dr. H. D. Sharma, Department of Chemical Engineering, University of Toronto, for carrying out neutron activation analysis on the samples.

[1] Marketed as Chinosol.

[2] The biological potency of tuberculin is expressed in tuberculin units (TU). One TU is biologically equivalent to 0.00002 mg. of the international standard tuberculin PPD.

[3] Marketed as Tween 80 by Atlas Chemical Industries, Wilmington, Del.

[4] Obtained from Millipore Filter Corporation, Bedford, Mass.

The crystalline greenish black deposit was washed with distilled water and dried together with the filter in a vacuum desiccator over $CaCl_2$.

Twelve milliliters of a tuberculin PPD solution (2 mg. PPD/ml.) was prepared and sterilized by filtration. An aliquot of the solution was transferred into a glass-stoppered Pyrex tube and 8-HQS (0.01% final concentration) was added to the remainder of the solution. Both solutions were stored at 5° for 3 weeks. During this time a black deposit (0.3 mg.) had formed in the solution containing 8-HQS. The deposit was removed by filtration of the solution through a Gelman GA-6 filter[5] (0.45 μ) and the filtrate as well as the original solution without 8-HQS were tested for biological potency.

One-milliliter ampuls (capacity 1.5 ml.) filled with 1ml. tuberculin PPD solution (50 TU/ml.) and stored at 5° over a period of 3.5 years contained tiny black specks. The contents of 350 ampuls were filtered through a Gelman GA-6 filter, and the black specks retained on the filter were washed thoroughly with water containing 0.005% polysorbate 80. Filter and deposit were dried in a vacuum desiccator over $CaCl_2$. The weight of the greenish black deposit was 11 mg.

One-milliliter vials (capacity 1.7 ml.) filled with 1 ml. tuberculin PPD solution (50 TU/ml.) and closed with equilibrated[6] white rubber stoppers[7] and sealed with three-piece aluminum caps[8] were stored for 2.5 years at 10°. During storage a greenish dark deposit developed that was isolated by filtering the contents of 770 vials as described above for ampuls. The weight of the greenish black deposit was 11.4 mg.

Ultraviolet Spectrophotometry—The samples were dissolved in chloroform (approximately 4 to 8 mcg./ml.), and the ultraviolet absorption spectrum was determined with a Beckman model DU spectrophotometer using chloroform as a blank.

Infrared Spectrophotometry—KBr pellets of the samples were prepared and the infrared absorption spectra were recorded from 650 to 5,000 $cm.^{-1}$ using a Beckman model IR-4 spectrophotometer fitted with NaCl optics.

Neutron Activation Analysis—The Millipore filter with the dark deposit from tuberculin PPD solution (1,000 TU/ml.) and a Millipore filter used as a blank were sealed in quartz tubes and irradiated with neutrons for 2 days in an atomic reactor. After activation, the filters were taken out of the tubing and examined with a multichannel pulse height γ-ray spectrometer. γ-Ray spectra were taken at intervals, as the activated sample decayed during a 3-month period.

Biological Testing—The tuberculin preparations to be compared were diluted in a buffer solution (pH 7.38, containing 0.005% polysorbate 80) to give the following two concentrations, 0.004 and 0.001 mg./ml. The dose injected intradermally into 20 BCG-sensitized guinea pigs was 0.1 ml. at each of these concentrations as previously described by Landi (1). At 24 hr. after injection the diameter of each reaction zone was measured, and the result was recorded as the sum of two perpendicular diameters in millimeters. The estimate of potency was made by the method of Long, Miles, and Perry (4).

The dark deposit obtained from ampuls and vials was also tested for potency. A solution of the deposit was prepared by dissolving 1 mg. of the deposit in 1 ml. 0.02 *N* HCl and further diluting it to the following two concentrations, 0.004 mg./ml. and 0.001 mg./ml. by the addition of buffer (pH 7.38; 0.005% polysorbate 80); 0.1 ml. of these concentrations and 0.1 ml. of the buffer used to dilute the dark deposit were injected intradermally and at random into 16 BCG-sensitized guinea pigs.

RESULTS AND DISCUSSION

The deposit isolated from tuberculin PPD solutions containing 8-HQS (0.01%) was found to be soluble in chloroform and mineral acids. Microscopic examination of this deposit revealed that it consisted of tiny crystals and crystal fragments (Fig. 1). These crystals gave a bright yellow fluorescence under ultraviolet light (wavelength 360 mμ). In a tuberculin solution some of these crystals were invisible in daylight but their presence was easily revealed under ultraviolet light.

Figure 2 shows the ultraviolet spectra in chloroform of a deposit from tuberculin PPD solution (1,000 TU/ml.; 0.01% 8-HQS; 0.005% polysorbate 80) and for 8-HQFe, 8-HQZn, and 8-HQ. The steep absorption maximum at 260 mμ (Fig. 2, curve A) obtained with the deposit is in close agreement with the maximum at 256 mμ (8-HQFe), 258 mμ (8-HQZn) (Fig. 2, curves B and C, respectively), 260 mμ (8-HQAl), and 263 mμ (8-HQCu), while 8-HQ has a maximum in chloroform at 243 mμ (Fig. 2, curve D). The 8-HQ metal complexes served as controls. Other UV light absorbing substances such as tuberculoprotein with an absorption maximum at approximately 270 mμ and nucleic acid at approximately 260 mμ present in the tuberculin solution could not be considered as part of the deposit. These substances are insoluble in chloroform while the ingredients in the deposit were completely soluble in this organic solvent. The only other UV-absorbing and chloroform-soluble ingredient of tuberculin solution, which could be present in the deposit, was polysorbate 80; however, this nonionic surfactant has a very flat UV absorption maximum at a wavelength of 230 mμ. Therefore, polysorbate 80 certainly could not account for the steep absorption maximum of 260 mμ given by the deposit.

To verify these findings the infrared spectra (Fig. 3) of the following substances were compared: (A) the deposit which formed in a tuberculin PPD solution (1,000 TU/ml.; 0.01% 8-HQS; 0.005% polysorbate 80); (B) 8-HQFe; (C) 8-HQZn; (D) 8-HQ; (E) 8-HQS, (F) polysorbate 80; (G), nucleic acid from filtrate of *M. tuberculosis* var. *hominis*, (H) tuberculin PPD (trichloroacetic acid precipitation); (I) tuberculin PPD (ammonium sulfate precipitation). Figure 3 shows that only the IR spectra of 8-HQFe and 8-HQZn are similar to the IR-spectrum of the deposit. The substances D to I cannot constitute a major component of the deposit because their following distinct peaks are missing in the spectrum of the deposit (wave numbers in $cm.^{-1}$ Fig. 3): 897, 974, 1,900 for 8-HQ; 888, 993, 1,192, 1,400, 1,595, 3,000 for 8-HQS; 945, 1,000–1,200,

1,726, 2,920 for polysorbate 80; 1,000–1,150, 1,200–1,280, 1,580–1,730 for nucleic acid; 1,010–1,130, 1,200–1,260, 1,600–1,730 for tuberculin PPD (trichloroacetic acid precipitation); and 1,520–1,570, 1,600–1,680 for tuberculin PPD (ammonium sulfate precipitation).

The IR spectra (Fig. 3) do not give any clue as to which metals have taken part in the formation of the deposit, since the IR spectra of 8-quinolinolates of different metals are very similar to each other according to Charles *et al.* (5) and Stone (6). Due to the extremely small amount of residue collected on a Millipore filter the deposit was tested for metals on the filter itself by the neutron activation analysis technique. Among the metals which can be determined by this technique only iron, zinc, and sodium were found in appreciable amounts (7.0% Fe, 1.6% Zn, and 0.6% Na), whereas other metals (antimony, cobalt, copper, chromium, gold, lanthanum, manganese) were present in trace amounts only (Table I).

Sodium	0.62
Copper	0.36
Chromium	5.13×10^{-3}
Antimony	3.36×10^{-4}
Gold	2.97×10^{-4}
Cobalt	1.70×10^{-4}
Scandium	0.58×10^{-4}
Manganese	Trace
Lanthanum	Trace
Bromine	Trace

[a] The deposit had formed from 500 ml. tuberculin PPD solution (1,000 TU/ml.; 0.01% 8-HQS; 0.005% polysorbate 80) during 9 months' storage at 5°. [b] Looked for and not detected: Rb, Cs, Hg, Pt metals (all judged to be less than 1 p.p.m.); Cd, Mo, As, Ag, Ge (all judged to be less than 5 p.p.m.). The activation technique is not sensitive for the detection of Ca, Al, Pb, Si, S, P, I, Ni, Mg, and other light elements.

The above findings strongly suggest that chelation between 8-HQ and the metals present in tuberculin PPD solutions has taken place. In fact it is well known that traces of heavy metals are present in reagent grade chemicals (7, 8) and in the tuberculoprotein (2) used to prepare tuberculin PPD solutions. It is also known that when 8-HQS is added to a buffered solution (pH 7.38) it is dissociated into 8-HQ and H_2SO_4 (3, 9). 8-HQ is one of the best analytical reagents for metals (10–12) since it readily forms chelates which are of extremely low solubility. It is therefore not surprising that chelation could take place in tuberculin PPD solutions, when 8-HQS is employed as a preservative. Therefore, when tuberculin solutions, at pH 7.38, are stored in the bulk form (0.5 L. or more), chelation will at first render the solution slightly turbid and upon further storage a deposit will be formed which will settle at the bottom of the container. Magnusson and Bentzon (13) and Jensen *et al.* (14) reported a similar dark deposit which had formed in tuberculin PPD stock solution containing 8-HQS.

In order to verify to what extent the ingredients present in tuberculin PPD solutions contribute to the formation of the dark deposit, the following experiments were carried out. Solutions of phosphate-buffered saline (pH 7.38) containing 0.005% polysorbate 80 and 0.01% 8-HQS, and other solutions containing PPD in concentrations of 10, 50, and 1,000 TU/ml., respectively, in addition to polysorbate 80 and 8-HQS, were prepared. One liter of each solution was stored at 5° in glass-stoppered volumetric flasks. During a period of 9 months' storage, a deposit appeared in all the solutions. However, in those containing PPD the amount of deposit increased with increasing quantities of PPD. The distilled water used to prepare the buffered solution was only a minor contributor of metals. The distilled water from a metal Barnstead still may contain up to a total of 0.1 p.p.m. heavy metals according to Healy *et al.* (15). To determine if polysorbate contributed to the formation of the deposit, 0.01% 8-HQS was added to a buffered solution (pH 7.38) with 0.005% polysorbate 80 and without polysorbate 80. These two solutions were stored for 9 months at 37°. In both solutions an equal amount of dark deposit was formed indicating that the addition of polysorbate 80 had no noticeable influence on the amount of deposit present in these solutions.

Besides the metals present in the tuberculin PPD solution, a minor metal contribution could be made by the glass of the container and in the case of vials, by the rubber stopper and the metal seal. For instance when tuberculin PPD solutions are dispensed in multiple-dose vials sealed with equilibrated rubber stoppers (equilibrated against 100 p.p.m. 8-HQS) (3), these closures will influence the amount of deposit formed in these tuberculin solutions according to a "push-pull" mechanism engendered by the partition coefficients of the metal chelates between the tuberculin solutions and the rubber closures. As described previously (3), during equilibration of a rubber stopper against a buffered solution (pH 7.38) containing 100 p.p.m. 8-HQS, its base 8-HQ will distribute itself between rubber and aqueous solutions according to its partition coefficient. When 8-HQ enters the rubber, it reacts chemically with the heavy metal ions present in the rubber whereby the metals chelate with 8-HQ. These metal chelates have their own partition coefficients between the organic phase (rubber stopper) and the aqueous phase. Consequently, when rubber stoppers are used the chelates in the stopper and in the solution distribute themselves according to their partition coefficients until an equilibrium is reached. This may contribute to the formation of a deposit which may not necessarily be dark as the color of 8-HQ chelates from different metals varies from nearly colorless to black.

In order to find out if the removal of metals from tuberculin PPD would affect the potency of the preparation, the potency of a tuberculin solution (2 mg. PPD/ml. at pH 7.38) was compared with the potency of the same solution after removal of metal chelates which formed after addition of 8-HQS. It was found that the relative potency of the tuberculin solution after removal of metals and compared with the same tuberculin solution before removal of metals was 1.05 (0.89–1.24).[9] This relative potency is not significantly different from 1.00 and therefore there is no evidence of a loss or of an increase in potency when metal chelates are removed.

Skin tests were also carried out in BCG-sensitized guinea pigs using the dark greenish deposit isolated from vials and ampuls. No tuberculin skin reaction could be detected in the animals indicating that there was no tuberculin PPD present in either deposit.

Formation of an insoluble deposit is undesirable in pharmaceutical solutions and therefore represents a considerable drawback to the use of the preservative 8-HQS in tuberculin PPD solutions. The formation of such deposit could be avoided by (*a*) pretreating a stronger buffer solution (pH 7.38), for instance 10 times its usual strength with 0.01% 8-HQS, then filtering the metal chelates out and diluting the clear filtrate with distilled water containing 0.01% 8-HQS to the required buffer strength to be used to prepare tuberculin PPD solutions; the same treatment could be carried out on a more concentrated (2 mg./ml.) tuberculin PPD solution; (*b*) using closures with low metal content when dispensing tuberculin solutions into vials.

On the other hand, the complete exclusion of metals would not be desirable because 8-HQ is markedly antimicrobial only in the presence of

[9] Figures in brackets represent 95% confidence limits.

traces of certain heavy metals, *e.g.*, copper (Cu^{2+}), iron (Fe^{3+} or Fe^{2+}) while other metals such as cadmium, zinc, nickel, and especially cobalt antagonize the antimicrobial properties of 8-HQ (7, 16, 17).

These incompatibilities render this preservative (8-HQS) cumbersome to use in tuberculin PPD solutions.

SUMMARY

1. It has been shown that tuberculin PPD solutions to which 0.01% 8-HQS had been added as preservative, developed a crystalline deposit when stored for several months.

2. The deposit was found to consist of metal chelates of 8-HQ in which the metals involved were iron, zinc, sodium, and traces of some other metals.

3. The main sources of metals causing precipitation were found to be the reagent grade chemicals constituting the buffer and the PPD used to prepare the tuberculin solutions; a minor but still significant source was the distilled water.

4. The removal of metals from tuberculin PPD caused by the presence of the preservative 8-HQS did not affect the biological potency of the preparation and tuberculin PPD was not present in the deposit.

5. The tendency of the preservative, 8-HQS, to give rise to an organo-metallic deposit in tuberculin PPD solutions, is a considerable drawback. Especially so, since a trace of iron or copper has to be present in order to render this preservative effective.

Microbiological Evaluation of PCMX Complexes

By M. D. RAY*, K. E. AVIS, and C. C. FLANIGAN, JR.

The minimum inhibitory concentration of *p*-chloro-*m*-xylenol (PCMX) was established against *Bacillus subtilis, Pseudomonas aeruginosa,* and *Aspergillus niger,* using a serial dilution and a pour plate procedure. The inoculum size was standardized by absorbance of light at 450 mμ wavelength. The drug was subsequently complexed with methylcellulose, polyethylene glycol 6000, and polysorbate 80. A minimum inhibitory concentration for the drug against each of the microorganisms was established in the presence of varying concentrations of the macromolecules. The results demonstrated that in most cases the antimicrobial activity of PCMX was reduced in the presence of the macromolecules studied. Since it had been previously established that PCMX interacted with these molecules, it was concluded that the reduction in biological activity was a direct result of the molecular interaction.

PHENOL AND ITS DERIVATIVES have served a major function in antisepsis and disinfection since the introduction of phenol by Lister (1) in aseptic surgery. Although the value of these agents is widely acknowledged, there has been an extensive search in recent years for phenolic derivatives which have an increased spectrum of microbicidal activity with less toxicity to tissue. Considerable interest has been generated in this country and in Europe in the use of *p*-chloro-*m*-

xylenol (PCMX) as an antiseptic in external pharmaceutical products (2–14), as a disinfectant in cleaning solutions (15), and as a preservative for pharmaceutical and nonpharmaceutical commodities (16). Reports have also indicated that PCMX has a very low toxicity to tissue (17–22).

A recent investigation has shown, however, that PCMX reacts with various nonionic macromolecules often present in formulations to form complexes (23). The present investigation was undertaken to explore the effect of such interactions on the biological activity of the agent.

EXPERIMENTAL

Reagents—Recrystallized PCMX,[1] m.p. 115–115.5°; polyethylene glycol 6000[2]; methylcellulose 15 cps., USP[3]; polysorbate 80,[4] and Sabouraud medium.[5]

Microorganisms—*Bacillus subtilis* ATCC 6051, *Pseudomonas aeruginosa* ATCC 10145, and *Aspergillus niger* ATCC 6275.

Apparatus—Beckman spectrophotometer model DB, Bausch and Lomb spectronic 20, Thomas-Hoover melting point apparatus, Precision Scientific Company Thelco oven, constant-temperature water bath.

Procedures

Determination of Cell Count—The microorganisms used in this investigation—*B. subtilis*, *Ps. aeruginosa*, and *A. niger*—were selected because each had a previously reported sensitivity to PCMX and because they represented three general groups of microorganisms, Gram-positive bacteria, Gram-negative bacteria, and fungi, respectively. Sabouraud liquid medium and Sabouraud agar medium were employed as culture media throughout the investigation. The authors felt it advisable to use the same culture media for each organism so that any binding between the PCMX and culture media would be uniform throughout the study. Although, admittedly, bacteria do grow better in other media, Sabouraud media were selected in deference to the more fastidious *A. niger*. It was shown by controls that the bacteria used in this study did grow quite well in Sabouraud liquid medium and Sabouraud agar medium.

A rapid and accurate method for determining cell counts was adopted similar to the light absorption method reported by Guidry and Maier (24). In the author's investigation a loopful of each of the test organisms was transferred at zero time to 50 ml. of sterile liquid medium. Cultures of *B. subtilis* and *Ps. aeruginosa* were incubated at 37°, and the *A. niger* at 27°. After 48 hr. of growth, the suspensions were transferred to a sterile Waring blender bowl and subjected to a dispersion treatment for 30 sec. The dispersed cultures were diluted with a measured volume of nutrient medium, and percent transmittance readings were taken, employing a Bausch and Lomb spectronic 20, at wavelengths of 450 mμ and 500 mμ. Immediately thereafter, a measured aliquot from each dispersed culture was transferred to freshly prepared Sabouraud agar plates and incubated. After 48 hr. the plates were removed and the colonies counted. Several replicate tests were performed in this manner, and a relationship was established between percent transmittance and cell count (see Table I).

Determination of Standard Minimum Inhibitory Concentration (MIC)—An approximate MIC for PCMX against each of the test organisms was determined by inspecting for visible growth of the organisms in a series of concentrations of PCMX in nutrient medium. A standard MIC was subsequently determined by quantitating the growth of each organism in a series of solutions of PCMX having a range which extended above and below the approximate MIC. Replicate tubes of each concentration were inoculated with a measured volume of the standardized microbial suspensions. After incubation for 48 hr., aliquots from each tube were transferred to Sabouraud agar plates. Colony counts were made after a 48-hr. incubation period, comparing this count with the theoretical number that would have been present if all the cells initially introduced into the medium had survived. The effect of PCMX was then evaluated as lethal, inhibitory, or noninhibitory based upon whether the plates showed no growth, growth of fewer colonies than the theoretical cell count, or growth of considerably more colonies than were representative of the cell count of the initial inoculum.

Determination of MIC of Complexation Mixtures—The PCMX and macromolecule were weighed by difference into a dry volumetric flask. Sufficient liquid nutrient medium was added to attain a prescribed volume. The mixtures were transferred to conical flasks, capped with aluminum foil, and sterilized by autoclaving at 121° for 15 min. After cooling, the solutions were placed in a 30° chamber for 48 hr. to permit complexation to occur, after the manner described by Breuninger and Goettsch (23).

An exception was required for the methylcellulose solutions, because the heat of the sterilization process caused the methylcellulose to be partially dehydrated and precipitated from solution. To correct this, the samples containing methylcellulose were refrigerated for 8 hr. to rehydrate the methylcellulose prior to being placed in the 30° chamber.

A series of concentrations of each macromolecule was prepared, and the antimicrobial activity of PCMX at each of these concentrations was determined. The concentrations employed were: polyethylene glycol 6000–0.22, 0.33, 0.44, 0.88, and

TABLE I—CORRELATION BETWEEN PERCENT TRANSMITTANCE AND VIABLE CELL COUNT

Organism	Wavelength, mμ	Percent, T	Viable Cell Count[a]
Aspergillus niger	450	75	2×10^6
Aspergillus niger	500	87	2×10^6
Pseudomonas aeruginosa	450	35	2×10^7
Pseudomonas aeruginosa	500	42	2×10^7
Bacillus subtilis	450	78	1×10^8
Bacillus subtilis	500	86	1×10^8

1.32%; methylcellulose—0.5, 1.0, and 1.5%; and polysorbate 80—0.5, 1.0, and 1.5%. A known number of cells, as determined by optical density measurement, was added to each complexation mixture and incubated at the appropriate temperature for 48 hr. At the end of the incubation period an aliquot from each sample was transferred to Sabouraud agar plates. The inoculated plates were examined and the colonies counted after 48 hr. of incubation.

Controls were employed to establish the viability of the organisms, the ability of the nutrient to support the growth of each organism, and the ability of PCMX to inhibit growth of each organism in the absence of the macromolecule.

RESULTS AND DISCUSSION

Methylcellulose Complex—In the presence of methylcellulose, PCMX had less inhibitory effect on the growth of *B. subtilis* and *Ps. aeruginosa*, as reflected in an increase in the MIC (Figs. 1 and 2). The MIC for PCMX against *B. subtilis*, in all the concentrations of methylcellulose studied, was found to be 1:15,000 (0.007%). Against *Ps. aeruginosa* the intensity of the effect of methylcellulose varied with the concentration of the complexing agent. When PCMX was equilibrated with 0.5% methyl-

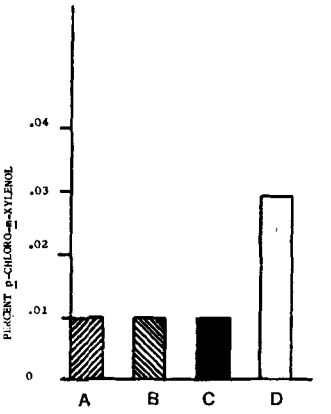

Fig. 3—Effect of complexation on the activity of p-*chloro*-m-*xylenol*—aspergillus niger. *See Fig. 1 for key.*

cellulose, a MIC of 1:400 (0.25%) was observed, as compared with an MIC of 1:1000 (0.1%) in the absence of a complexing agent. With a concentration of 1.0% and 1.5% an MIC of 1:200 (0.5%) was observed.

The activity of PCMX against *A. niger* was apparently unaffected by complexation with methylcellulose (Fig. 3). In all concentrations of methylcellulose studied, an MIC of 1:10,000 (0.01%) was noted, which was the same as the MIC of uncomplexed PCMX against *A. niger*. There was no apparent explanation for this lack of effect, since complexation had occurred in the work of Breuninger and Goettsch (23), although the metabolic effects of the organism on the complex may be a factor.

Through the use of controls it was shown that methylcellulose alone had no stimulatory or inhibitory effect, in the concentration range studied, on any one of the three organisms. Solutions of 0.5, 1.0, and 1.5% methylcellulose in water failed to support the growth of any of the organisms, but did not inhibit the growth in Sabouraud liquid medium. It was concluded therefore that any diminution in the activity of PCMX was a direct result of interaction with methylcellulose.

Polysorbate 80 Complex—The activity of PCMX against all three test organisms was considerably diminished in the presence of polysorbate 80, in the range of concentrations studied. Against *B. subtilis* the MIC of PCMX when complexed with 0.5% and 1.0% polysorbate 80 was found to be 1:10,000 (0.01%), and with 1.5% polysorbate 80 was found to be 1:7,500 (0.015%) (Fig. 2). The MIC for unreacted PCMX against *B. subtilis* was 1:26,000 (0.004%).

There was a uniform reduction in the activity of PCMX against *A. niger* (Fig. 3) at all three concentration levels of polysorbate 80 employed, to an MIC of 1:3300 (0.03%). The MIC of uncomplexed PCMX was 1:10,000 (0.01%).

Complexation of PCMX with 0.5% polysorbate 80 had no effect on the activity of the drug against *Ps. aeruginosa* (Fig. 1), showing an MIC of 1:1000 (0.1%). When equilibrated with 1.0% and 1.5% polysorbate 80, however, PCMX showed a marked reduction in activity, with an MIC of 1:200 (0.5%).

Through the use of suitable controls, it was demonstrated that polysorbate 80 contributed no

stimulatory or inhibitory activity of its own against the three test organisms. Therefore, where polysorbate 80 caused a reduction in the activity of PCMX, it was thought that the reduction was directly attributable to complexation between the agent and the macromolecule, thereby lessening the availability of the drug to exert its antimicrobial activity. Where no inhibition occurred there may have been insufficient polysorbate 80 present.

Polyethylene Glycol 6000 Complex—The activity of PCMX against both *B. subtilis* and *Ps. aeruginosa* was reduced when complexed with polyethylene glycol 6000 (Figs. 1 and 2). The MIC against *Ps. aeruginosa* was found to be 1:400 (0.25%), and against *B. subtilis*, 1:10,000 (0.01%). The MIC for unreacted PCMX against the two organisms was 1:1000 (0.1%) and 1:26,000 (0.004%), respectively.

Polyethylene glycol 6000 did not inhibit the activity of PCMX against *A. niger* in the range of concentrations studied (Fig. 3). This observation, coupled with the fact that methylcellulose had a like effect, suggested the possibility that *A. niger* was capable of disrupting the complex formed with these two macromolecules, thereby restoring the availability of PCMX to exert is antifungal activity, but not the complex formed with polysorbate 80.

Controls similar to those described above for methylcellulose were used to establish the fact that polyethylene glycol 6000 alone had no contributing effect on the growth of the organisms. It was assumed, therefore, that any reduction in the activity of PCMX when complexed with polyethylene glycol 6000 was a direct result of that interaction.

The studies of Breuninger and Goettsch (23) showed that the solubility of PCMX was decreased upon the addition of polyethylene glycol 6000 up to about 0.5%, and that a subsequent increase in the concentration of polyethylene glycol 6000 caused an increase in the solubility of PCMX. In our study, contrary to what might be expected, colony counts of *B. subtilis* and *Ps. aeruginosa* at a polymer concentration of 0.22% were lower than counts at higher concentrations. Polyethylene glycol 6000 had no apparent effect on the activity of PCMX against *A. niger*. Table II shows the effect of polyethylene glycol 6000 on the MIC of PCMX.

Comparison with Equilibrium Dialysis Studies—In the equilibrium dialysis studies of Breuninger and Goettsch, moles of bound PCMX were plotted against moles of unbound PCMX in the presence of 2% methylcellulose and 2% polysorbate 80. The slope for the plot in the presence of methylcellulose was found to be 0.14 and in the presence of polysorbate 80, it was 9.3. This comparison showed that polysorbate 80 had a much greater binding affinity for PCMX than did methylcellulose.

From our data the increase in the required MIC in the presence of the various concentrations of polysorbate 80 and methylcellulose as compared with PCMX alone was calculated. These percentages are shown in Tables III and IV.

A comparison of percent increase in MIC for PCMX–polysorbate 80 complex with PCMX–methylcellulose complex does not reveal a striking parallel with the greater binding affinity that Breuninger and Goettsch found for PCMX-polysorbate 80 complex as compared with PCMX-methylcellulose complex. However, there is a degree of correlation in that the percent increase for PCMX-polysorbate 80 against *B. subtilis* was 150 but only 81 with PCMX-methylcellulose, and against *A. niger* was 200 and 0, respectively. Thus it would appear that with these two organisms the greater binding effect between PCMX and polysorbate 80 resulted in a greater inhibition of activity than with PCMX and methylcellulose.

[a] MIC = Minimum inhibitory concentration.

SUMMARY AND CONCLUSIONS

In almost all cases the activity of PCMX against three microorganisms, *B. subtilis*, *Ps. aeruginosa*, and *A. niger* was shown to be diminished when allowed to interact with the three macromolecules, polyethylene glycol 6000, methylcellulose, and polysorbate 80, in the concentration ranges studied. Exceptions to this general observation were obtained

with *A. niger* when evaluating the effect of methylcellulose and polyethylene glycol 6000 on PCMX; and the result obtained with *Ps. aeruginosa* in evaluating the effect of polysorbate 80 at a concentration of 0.5% on PCMX. In these instances, no increase was observed. In all cases where a reduction in the antimicrobial activity of PCMX was demonstrated, the reduction was thought to be a direct result of the molecular interaction with the nonionic macromolecule, thereby diminishing the availability of the drug to exert its antimicrobial activity.

Studies on the Effects of Reserpine in Mice as Influenced by its Diluent

By W. VELDKAMP, G. A. JOHNSON, and H. H. KEASLING

The effects of dextroamphetamine sulfate and benzphetamine hydrochloride on locomotor activity in mice pretreated with reserpine varied depending on the reserpine preparations used. Pretreatment with reserpine suspended in aqueous 0.25 percent methylcellulose (pH 5.8) had little effect on the response to dextroamphetamine sulfate but decreased the response to benzphetamine hydrochloride. Pretreatment with a reserpine solution (pH 3.5) significantly enhanced the locomotor response to both compounds at the higher doses tested. The difference in effect produced by the reserpine preparations could not be explained on the basis of differences in brain amine levels at the time locomotor activity was measured since both preparations had depleted brain amines to the same extent. Further studies revealed that variations in pH of the reserpine diluent had a marked effect on brain reserpine levels, on brain amine levels when measured 1 hr. after reserpine administration, and on the rate of onset and intensity of ptosis produced in the mouse.

VAN ROSSUM *et al.* (1) and van Rossum and Hurkmans (2) have reported that reserpine pretreatment in mice has no effect on the locomotor activity response to dextroamphetamine sulfate while the effects of derivatives of amphetamine which have large substituents on the nitrogen atom, such as benzylamphetamine and benzphetamine hydrochloride,[1] are antagonized by pretreatment with reserpine. On the other hand, Smith (3) has reported an enhancement of the effects of dextroamphetamine sulfate on the locomotor activity of mice when pretreated with reserpine.

The present study shows that the effect obtained with dextroamphetamine sulfate and benzphetamine hydrochloride in reserpinized mice will vary depending upon the reserpine preparation used in pretreating the mice. A number of acids such as ascorbic, Burn and Rand, (4), acetic, Fleming and Trendelenberg, (5), and citric, Fleming, (6) have been used to dissolve reser-

pine in preparation for parenteral administration. In this study the results obtained when mice were pretreated with a reserpine preparation containing citric acid were compared with results from mice pretreated with reserpine suspended in aqueous 0.25% methylcellulose. The following parameters were measured in making these comparisons: locomotor activity after administration of dextroamphetamine sulfate or benzphetamine hydrochloride in the reserpinized mouse and the effects of pH of the reserpine diluent on the onset and intensity of ptosis, on the depletion of biogenic amines, and on brain levels of reserpine.

METHODS

Carworth Farms No. 1 male albino mice weighing between 20 and 25 Gm. were used. Each mouse was used only once.

Measurement of Locomotor Activity—Eight Metro Industries[2] circular actophotometers, each equipped with 6 light beams and 6 photoelectric cells connected to a digital counter, were used. A single mouse was placed in each actophotometer and the number of times the mouse crossed a beam of light was recorded. In determining the locomotor activity effects of dextroamphetamine sulfate and benzphetamine hydrochloride, groups of 8 mice were injected with various doses of the compounds and immediately placed in individual actophotometers. After a 10-min. acclimation period, locomotor activity was recorded for a 30-min. period. Each experiment was carried out using an 8 × 8 Latin square design balanced with respect to treatments, actophotometers and time of day.

Drugs—The reserpine solution used in the motor activity studies contained the following per ml. of solution: 0.25 mg. recrystallized reserpine, 0.20 mg. citric acid anhydrous, 9.0 mg. benzyl alcohol, 15.0 mg. *N,N*-dimethylacetamide, water, q.s., to make 1 ml. This solution had a pH of approximately 3.5. The reserpine suspension contained 0.25 mg. reserpine per ml. of aqueous 0.25% methylcellulose and had a pH of approximately 5.8. In the experiments where the effects of pH were studied, the stock reserpine solution was diluted with 0.25 volume of either distilled water or an 0.25% aqueous methylcellulose solution. The pH was adjusted to the desired pH with 0.1 *N* HCl or 0.5 *M* $NaHCO_3$. The final concentration of reserpine was 0.2 mg./ml. Dextroamphetamine sulfate and benzphetamine hydrochloride were dissolved in saline and the dosages expressed in terms of the salts. All injections were made intraperitoneally.

Reserpine Assay—Two mouse brains were pooled for each determination. Tissues were homogenized and reserpine was extracted by the methods reported by Hess *et al.* (7). The assay of reserpine was modified from that of Hess *et al.* by the omission of selenious acid from the assay mixture. The quantitative determination of reserpine was based upon the fluorescence of reserpine (0.2 mcg.) in duplicate internal standards in split brain homogenates. Fluorescence of reserpine in this assay was linear over the range 0.01–0.2 mcg.

[2] Metro Industries, Mineola, L.I., N.Y.

Biogenic Amine Assays—The extraction procedure of Shore and Olin (8) was employed for the extraction of dopamine (DA), norepinephrine (NE), and serotonin (5-HT) from paired mouse brains. Aliquots of the resulting 4-ml. aqueous extract were removed for the respective analyses with the noted modifications: NE, Shore and Olin (8); DA, Carlsson and Waldeck (9), with reduced volumes to increase the sensitivity and a final acid addition of 5 *N* acetic acid–5 *N* HCl, 2:3; 5-HT, Snyder *et al.* (10), with heating at 60° for 1 hr. All calculations of amine content were based upon tissue-containing internal standards and are expressed as mcg./Gm. wet weight of brain tissue. Results were not corrected for recovery of amines by the extraction procedure.

Ptosis Scoring—Ptosis was graded on a 4-point scale (1 = normal, 4 = complete ptosis) in groups of six mice, 1, 2, 3, and 18 hr. after intraperitoneal administration of reserpine, Rubin *et al.* (11).

RESULTS

Locomotor Activity in Mice Pretreated with Either a Reserpine Solution or a Reserpine Suspension—The effects of dextroamphetamine sulfate and benzphetamine hydrochloride on the 30-min. locomotor activity of mice pretreated once daily for 3 days with either saline or 1 mg./Kg. of reserpine suspension with motor activity run on the fourth day are shown in Fig. 1. Pretreatment with the reserpine suspension decreased the effect of benzphetamine hydrochloride on locomotor activity of both doses tested. Dextroamphetamine sulfate in similarly pretreated mice was less effective at the 0.625 mg./Kg. dose while the 2.5 mg./Kg. dose caused a slight but nonsignificant increase in motor activity compared to the effect in saline pretreated controls.

When the mice were pretreated with the reserpine solution, there was no quantitative difference between the effects of dextroamphetamine sulfate and benzphetamine hydrochloride. Figure 2 shows the results obtained with mice pretreated once daily for 3 days with 1 mg./Kg. of reserpine solution and 30-min. locomotor activity run on the fourth day. At the lower dose both dextroamphetamine sulfate and benzphetamine hydrochloride were less stimulant, while at the higher dose both caused a significantly greater increase in locomotor activity than in the saline pretreated controls.

Brain amine levels after 3 days pretreatment do not explain the difference in results obtained with the two reserpine preparations on motor activity with dextroamphetamine sulfate and benzphetamine hydrochloride. Groups of mice were injected once daily for 3 days with 1 mg./Kg. of either the reserpine solution or suspension and brain amine levels were determined on the fourth day. Results in Table I show that there was no significant difference between the reserpine preparations in their effect on brain amine levels under these conditions.

Effects of pH on Reserpine Activity—Since there was a difference in the pH of the reserpine solution (pH 3.5) and the reserpine suspension (pH 5.8) used in the above locomotor activity studies, the effects of pH on reserpine activity were investigated.

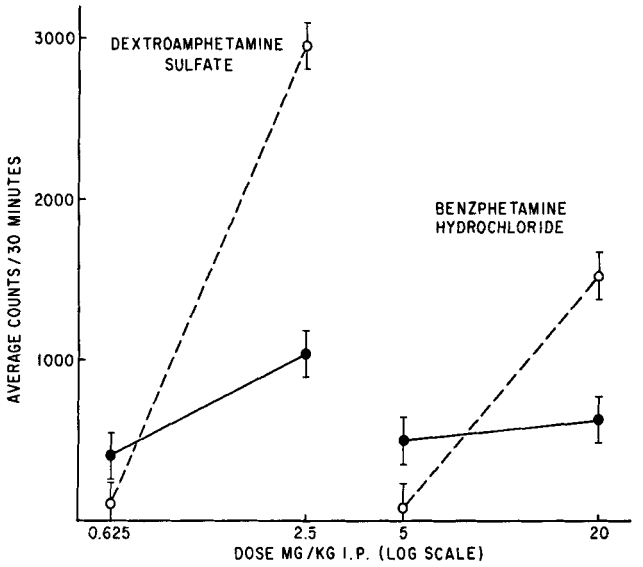

Fig. 2—Effect of reserpine solution (1 mg./Kg./day, 3 days) on locomotor activity response of mice to dextroamphetamine sulfate and benzphetamine hydrochloride. Key: I, represents ± S.E. of mean; O—O, reserpine solution, pretreatment; ●——●, saline, pretreatment.

TABLE I—BRAIN NOREPINEPHRINE AND SEROTONIN LEVELS IN MICE AFTER 1 mg./Kg. RESERPINE ONCE DAILY FOR THREE DAYS

	Norepinephrine			Serotonin		
Preparation	No. of Determinations	Concentration mcg./Gm. ± S.E.M.	% of Control	No. of Determinations	Concentration mcg./Gm. ± S.E.M.	% of Control
Saline control	5	0.50 ± 0.04	100	5	0.80 ± 0.07	100
Reserpine solution	4	0.05 ± 0.01	10	4	0.51 ± 0.04	64
Reserpine suspension	3	0.05 ± 0.01	10	3	0.46 ± 0.06	60

Effect of diluent pH on brain levels of reserpine at various intervals after its intraperitoneal administration is shown in Fig. 3. Maximal reserpine levels were detected with the pH 2.8, 3.5, and 4.5 solutions in the 10–20 min. interval after injection. Reserpine was not detected in the brain following intraperitoneal administration of the pH 5.7 preparation and only trace quantities were found with the pH 2.0 solution. Brain levels of reserpine after intraperitoneal administration of reserpine suspended in aqueous 0.25% methylcellulose at pH 3.7 are less than those obtained after the pH 3.5 reserpine solution.

Variations in diluent pH of the reserpine preparations also influenced the depletion of endogenous brain amines. The effects of diluent pH on the depletion of brain amines during the first hour after intraperitoneal administration of reserpine (5 mg./Kg.) are shown in Table II. The most marked depletion of norepinephrine, dopamine, and serotonin was noted with the reserpine preparation at pH 2.8. No decrease in amine content at 1 hr. was detected with the pH 5.7 and pH 7.0 preparations.

The onset and intensity of ptosis induced by reserpine (2 mg./Kg., i.p.) as influenced by the pH of its diluent is shown in Fig. 4. The reserpine preparation with pH 3.5 caused the greatest degree of ptosis. With all the preparations except the one at pH 7.0 maximum ptosis was detected at the 3-hr. reading. A moderate amount of ptosis was present at 18 hr. with the pH 7.0 preparation.

DISCUSSION

The results presented indicate that the effect of dextroamphetamine sulfate and benzphetamine hydrochloride on locomotor activity in reserpinized mice varies depending on the reserpine preparation

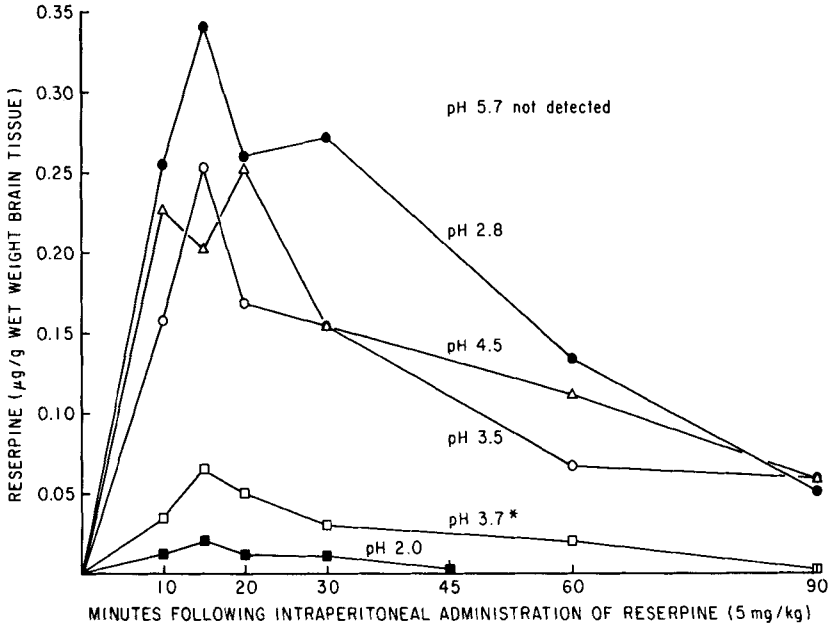

Fig. 3—Effect of diluent pH on brain reserpine content. Stock reserpine solution was diluted with 0.25 volume of distilled water and the pH adjusted as described in Methods. *At pH 5.7 no reserpine was detected. * The reserpine for these results was suspended in 0.25% aqueous methylcellulose and pH adjusted to 3.7.*

TABLE II—EFFECT OF DILUENT pH ON ENDOGENOUS MOUSE BRAIN AMINE LEVELS BY RESERPINE (5 mg./Kg., i.p.) AFTER ONE HOUR[a]

Diluent pH	NE	DA	5-HT
2.0	0.44 ± 0.14[b] (4)[c]	0.46 ± 0.27 (4)	0.69 ± 0.17 (4)
2.8	0.24 ± 0.04 (4)	0.23 ± 0.08 (4)	0.52 ± 0.05 (4)
3.5	0.31 ± 0.03 (4)	0.36 ± 0.14 (4)	0.56 ± 0.05 (4)
4.5	0.37 ± 0.17 (4)	0.51 ± 0.44 (4)	0.57 ± 0.17 (4)
5.7	0.51 ± 0.09 (6)	0.82 ± 0.13 (4)	0.88 ± 0.06 (6)
7.0	0.52 ± 0.13 (6)	0.85 ± 0.17 (4)	0.90 ± 0.07 (6)

[a] Brain amine levels from control animals in these five experiments were: NE, 0.52 ± 0.04 (7); DA, 0.83 ± 0.05 (4); 5-HT, 0.89 ± 0.07 (7). [b] All values are expressed as mg. amine/Gm. wet weight brain tissue ± S.D. [c] Number of determinations.

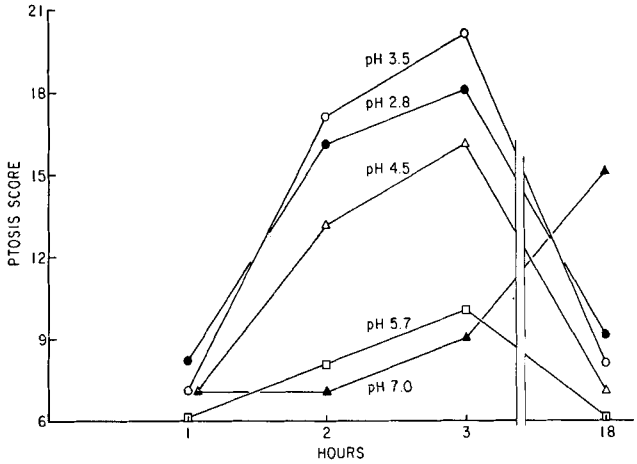

Fig. 4—Effect of diluent pH on reserpine (2 mg./Kg., i.p.) induced ptosis. Composition of the reserpine preparation is the same as described for stock reserpine solution in Fig. 3.

used in pretreating the mice. Pretreatment of mice with a reserpine suspension (pH 5.8) resulted in a decreased motor response to both the low (2.5 mg./Kg.) and high (20 mg./Kg.) dose of benzphetamine hydrochloride. The response to the low (0.625 mg./Kg.) dose of dextroamphetamine sulfate was depressed while there was a slight but non-significant increase at the high (2.5 mg./Kg.) dose. Mice pretreated with the reserpine solution (pH 3.5) had a decreased locomotor activity response to the low dose of both dextroamphetamine sulfate and benzphetamine hydrochloride but the high dose of both compounds caused a significant increase in activity.

The results presented here with dextroamphetamine sulfate in mice pretreated with reserpine solution are in agreement with those reported by Smith (3) who used reserpine solubilized with ascorbic acid to pretreat his mice. The results obtained with both dextroamphetamine sulfate and benzphetamine hydrochloride in mice pretreated with the reserpine solution do not agree, however, with those of van Rossum *et al.* (1, 2) who used acetic acid to solubilize the reserpine (personal communication). Only when the mice were pretreated with a reserpine suspension could the results reported by van Rossum *et al.* be repeated.

Brain amine levels after pretreatment with either the reserpine solution or suspension for 3 days at 1 mg./Kg./day do not explain the differences in results obtained on locomotor activity. These preparations both depleted measurable brain amine levels about the same extent.

The results shown in Fig. 3 indicate that whether the reserpine is in solution or suspension and the pH of the diluent influence the initial rate of reserpine uptake and the level of reserpine attained in the brain. This in turn is thought to influence the rate of decline in the brain amine levels. The pH of the reserpine solution used to pretreat the mice for the locomotor activity studies was 3.5 and therefore gave higher and more rapid reserpine levels in the brain and more rapid decline of brain amine than did the reserpine suspension which had a pH of 5.8. If the reasoning of Stein (12) is correct that reserpine pretreatment may cause supersensitivity to amines in the brain as well as in the periphery, and if the sensitivity is increased with time then the increased locomotor response in the mice pretreated with the reserpine solution may be due to the increased length of time these mice had to develop the supersensitivity.

Potassium Absorption—A Comparison of *In Vitro* and *In Vivo* Studies

By A. J. JOUHAR, E. S. GARNETT, and J. S. WALLINGTON

Some ^{42}K was released from a slow release preparation within 15 min. of ingestion and further potassium release continued for approximately 200 min. A similar absorption pattern was found from enteric-coated tablets of potassium chloride although a considerable initial delay occurred before potassium was released from this preparation. The *in vivo* behavior of the slow release preparation and enteric-coated tablets was similar to that seen in static solution experiments but differed considerably from that found in the B.P. disintegration apparatus. There was no evidence that sudden release and absorption of potassium took place from enteric-coated tablets.

LONG CONTINUED ADMINISTRATION of thiazide diuretics reduces exchangeable potassium, and the need for potassium supplements is well recognized (1, 2). These may be given separately or in a compound tablet, such as the film-coated, two-layered slow release preparation.[1] In this preparation crystals of potassium chloride (KCl) are coated with a polymeric material and compressed to form one layer, and the other layer contains bendrofluazide. The KCl layer is intended to dissolve gradually and so release potassium ions (K^+) continuously. Since it has been

shown radiologically that this preparation passes down the gut (3), localized high concentrations of K^+, which induce gastric irritation and are believed to cause intestinal ulceration (4–6), may be prevented. Such slow release preparations are formulated with the help of *in vitro* control methods which should ensure uniform behavior in the gastrointestinal tract. In this investigation, the authors have compared the results of such *in vitro* experiments with *in vivo* ^{42}K absorption studies in man.

MATERIALS AND METHODS OF MANUFACTURE

Tablets for *in vivo* studies were made containing ^{42}KCl, after it was shown by microscopy that irradiation to give a specific activity at the time of administration of 70–80 μc. per dose did not produce any change in the crystals of KCl. The radiochemical purity of ^{42}KCl was 100% at the time of administration.

The usual production process for the slow release preparation of granulating KCl crystals to form a damp mass was not possible because of difficulty in manipulating 2 ft. 6 in. long hand-operated tongs behind a screen of 1 in. perspex. Instead, a remotely controlled microstirrer was used to mix the ^{42}KCl crystals into a slurry with a granulating solution of coating materials dissolved in excess solvent.

The slurry was dried over an electrically heated mantle at 70° and the solid residue was forced through 8- and 16-mesh sieves with a large glass stopper. Weighed quantities of granules were fed into a hand-operated tablet machine, with a small glass weighing boat designed so that it could be easily picked up with the tongs. After adding inert granules in place of bendrofluazide to form the second layer, the tablet was ejected from the machine. The tablets were film-coated by dipping in warm film-coating solution, and allowing them to dry on a pin bed in a warm air stream.

Enteric-coated tablets of ^{42}KCl were made by directly compressing the weighed crystals in the hand-tablet machine. Each tablet was coated by dipping into cellulose acetate phthalate/vinyl acetate copolymer/solvent solution several times. The slow release tablets and the enteric-coated tablets both contained 630 mg. KCl (8.4 meq. K^+).

Similar quantities of ^{42}KCl were made into solution for the *in vivo* studies. Nonradioactive preparations were used for the *in vitro* work.

In Vitro Studies—(*a*) *Static Solution*—The extent of release of KCl from the tablets was measured at intervals of 20 min. for 7 hr. by the following method: 120 ml. of the double-distilled water or buffered solutions (pH 7.9 and 8.9) at 20° were placed in each of 40 polythene pots. One tablet of the slow release preparation or an enteric-coated KCl tablet was placed in each of two pots at 20-min. intervals for 400 min. Twenty minutes after the last tablets had been placed in the pots, all the tablets were removed. The potassium chloride concentration of the solution remaining was then measured with a Pye conductance bridge, and the rate of release plotted.

(*b*) *Solution in the B.P. Disintegration Apparatus*—Three tablets of the slow release preparation or three enteric-coated KCl tablets were placed in a B.P. disintegration apparatus and agitated according to the B.P. monograph (8). The amounts of KCl released in periods of 5 min. were measured with a Pye conductance bridge.

In Vivo Studies—Male volunteers were fasted overnight and then given a solution of ^{42}KCl, two radioactive slow release tablets, or two enteric-coated ^{42}KCl tablets. Blood samples, each of 20 ml., were taken from an uncuffed arm vein at intervals of 5 to 100 min. for the next 320–540 min.

The plasma from each sample was separated at once and the ^{42}K content of 10-ml. aliquots was measured in a M64 Geiger-Müller liquid counter connected to an EKCO Automatic Scaler Type N530F through an EKCO N558 probe unit with the dead time set at 300 μsec. The background count rate of this system was 12 counts per minute (c.p.m.). The plasma samples were counted for 50 min. or until 3,000 counts had been accumulated (whichever was the shorter). Samples were recorded as containing a significant amount of ^{42}K provided they gave a count rate of at least twice background. The maximum count rate achieved in any one experiment was approximately 50 times background. After subtracting background count and correcting for radioactive decay using a ^{42}K half-life of 12.5 hr., the c.p.m. from each sample were expressed as a percentage of the c.p.m. obtained from that sample containing the maximum radioactivity in each subject.

RESULTS

In Vitro Studies—Figure 1 shows the rate of release of KCl from each of the formulations studied.

After 200 min. in static distilled water, 50% of the available KCl had been released from the slow release preparation and after 420 min. 70% of the KCl had been released.

Because the rate of release of KCl from enteric-coated preparations depends upon pH, tests were carried out in static solutions at various pH levels. Thus at pH 7.9, the rate of release of KCl became maximal after 150 min. and was complete after about 420 min. At pH 7.0 and at pH 8.9 the solution rates were faster than at pH 7.9 and were immediately maximal, slowing after 120 min. The release of KCl was complete after about 420 min.

In the B.P. disintegration apparatus all the potassium was made available from the slow release preparation within 80 min. in acid pepsin solution and within 50 min. in alkaline pancreatin solution.

Release of KCl from the enteric-coated preparation in the B.P. disintegration apparatus in alkaline pancreatin solution was delayed for 10 to 15 min. but was complete at 30 min.

In Vivo Studies—Fig. 2 shows the appearance of $^{42}K^+$ in the plasma after ingestion of a solution ^{42}KCl. In all cases, peak activity occurred within 35 min. Figure 3 shows the appearance of $^{42}K^+$ in the plasma from the radioactive slow release preparation. ^{42}K was detected soon after ingestion, but a peak plasma level was not obtained until about 200 min. Figure 4 shows the appearance of $^{42}K^+$ in the plasma after giving enteric-coated ^{42}KCl; no radioactivity was detected in the plasma for at least 120 min. Thereafter, the pattern of absorption paralleled that obtained from the slow release preparation.

DISCUSSION

The use of radioactive materials in pharmaceutical formulations presents manufacturing problems as only a few tablets must be specially produced for each investigation. Nevertheless, it has been possible to make radioactive potassium chloride tablets with high specific activity at the time of preparation by using special handling and screening procedures, and with these radioactive preparations it has been possible to study the *in vivo* behavior of a variety of formulations.

The first studies showed that ^{42}K is rapidly absorbed after oral administration of ^{42}KCl in solution. It is assumed that this early absorption occurs in the upper small bowel since activity appeared in the blood within 5 min. of ingestion and peak activity occurred within 30 min. It is unlikely that gastric absorption of ^{42}K contributes significantly to the early uptake curves as Code *et al.* (7) have shown that potassium is absorbed only slowly from the stomach.

When ^{42}KCl was given as the slow release preparation, activity appeared in the plasma within 20 min. indicating that some ^{42}K had been absorbed from the upper small bowel. These results might be expected from the B.P. disintegration experiments which showed that potassium is released early from the slow release preparation both in acid pepsin and alkaline pancreatin solution. They do not, however, give any information about the possible release of ^{42}K from the formulation in the stomach with subsequent absorption from the jejunum.

Following the early appearance of ^{42}K in the plasma after administration of the slow release preparation, the concentration of ^{42}K rose slowly to a maximum at about 220 min. This suggests that ^{42}K was slowly released into the gut, since ^{42}K in solution produced an early peak in plasma activity. The apparent pattern of release is quite different from results obtained in the B.P. disintegration studies in which all of the potassium had been released by 60 min. The pattern accords more nearly to that seen in the static solution experiments in which potassium was released for about 300 min.

The pattern of absorption, once established, from enteric-coated ^{42}KCl tablets was very similar to that seen with the slow release preparation and again, static solution studies seem to give a more realistic measure of tablet breakdown in the intestine. It will be noted however that although the pattern of absorption of ^{42}K from enteric-coated tablets and the slow release preparation is similar, ^{42}K does not appear in the plasma for at least 100 min. after the administration of the enteric-coated preparation. The observed variation in delay probably results from such factors as gastric emptying time and the pH and motility of the small bowel. Thus in one study ^{42}K appeared in the plasma only after 212 min.

It is appreciated that serial measurements of plasma concentration of ^{42}K may not necessarily give a true impression of intestinal absorption since the plasma is only one of at least three compartments between which ^{42}K is distributed. However, since there was no evidence of electrolyte imbalance in any of the subjects, the pattern of ^{42}K redistribution from plasma can be assumed to be qualitatively similar in all of the subjects; thus the pattern of ^{42}K appearance in the plasma reflects uptake from the intestinal tract.

In conclusion, it has been shown that the *in vivo* behavior of the slow release preparation and the enteric-coated tablets is similar to that seen in static solution experiments, and differed considerably from that found in the B.P. disintegration apparatus. Further, there was no evidence for an explos've release of potassium from the enteric-coated tablets.

Urinary Excretion of Pheniramine and Its *N*-Demethylated Metabolites in Man—Comparison with Chlorpheniramine and Brompheniramine Data

By PETER KABASAKALIAN, MARILYN TAGGART, and EDWARD TOWNLEY

The *N*-demethylated metabolites of pheniramine, *N*-desmonomethylpheniramine and *N*-desdimethylpheniramine, were found in the urine of a male subject using a repetitive dosage schedule. A comparison of the urinary excretion data of pheniramine and its halogenated derivatives indicated the compounds to be metabolized in the following order: pheniramine < chlorpheniramine < brompheniramine. This is inverse to the order of total free and *N*-demethylated drug excreted in the urine.

ALTHOUGH THE URINARY EXCRETION of chlorpheniramine (1, 2) and brompheniramine (3) have been studied, no such study has been made on the urinary excretion of pheniramine.[1]

The present investigation was undertaken to further determine the substituent effect of the halogens in the *p*-halobenzyl group of the pheniramines on urinary excretion.

EXPERIMENTAL[2]

Protocol—A male subject [used in the previous chlorpheniramine study (2)] under a normal diet with no urine pH or fluid intake control was used in this study.

Single Dose Regimen—The subject orally took a single dose of 74 mg. of pheniramine maleate in tablet form (two 37-mg. pheniramine maleate tablets). Urine was collected normally for 6 days and combined into 24-hr. samples.

Multiple Dose Regimen—The same subject orally took 37 mg. of pheniramine maleate in tablet form daily for 21 days. Urine was collected normally for 25 days and combined into 24-hr. samples.

Analytical Methods—A gas chromatographic method previously described (2, 4) was used. The column was operated at 170°. A 2.5-ft. column exhibited 1,500 theoretical plates for pheniramine.

Free pheniramine had a retention time of 7.0 min. Quantitative determinations were made using a pheniramine reference standard. Isolation by thin-layer chromatography on alumina (5) and subsequent mass spectroscopy (6) showed an *m/e* value of 58 for $CH_2{=}N(CH_3)_2$ indicative of a tertiary amine and *m/e* values of 169 and 83.5 which are characteristic of the benzyl-2-pyridyl group. It did not form derivatives either with cyclopentanone or acetone using the procedure of Capella and Horning (7).

Metabolite *X* had a retention time of 13 min. Quantitative determinations *via* the area technique were made using pheniramine as a calibration standard. Isolation by thin-layer chromatography on alumina (5) and mass spectroscopy (6) showed *X* to be a secondary amine with an *m/e* of 44 for $CH_2{=}NH(CH_3)$ and the *m/e* values of 169 and 83.5 for the benzyl-2-pyridyl group. It formed a derivative (retention time > 60 min.) with cyclopentanone (indicative of primary and secondary amines), but none with acetone (indicative of the absence of a primary amine).

Metabolite *Y* had a retention time of 18 min. Quantitative determinations *via* the area technique were made using pheniramine as a calibration standard. Isolation by thin-layer chromatography on alumina (5) failed to separate metabolite *Y* from the fiftyfold excess of metabolite *X*, consequently no mass spectral data could be obtained. It formed derivatives with cyclopentanone (retention time > 60 min.) and with acetone (retention time, 22 min.), indicative of a primary amine.

Lipid-Water Distribution—The procedure of McMahon (8) was used to determine the partition coefficient of pheniramine, chlorpheniramine, and brompheniramine for the heptane and pH 7.4 aqueous phosphate buffer system.

RESULTS AND DISCUSSION

Single Dose Regimen—The urinary excretion of free pheniramine by the subject on the single dose regimen is shown in Table I.

The amount of unchanged pheniramine excreted by the single subject in the first 24 hr. was 16.6% of the ingested dose. The total excretion of free pheniramine (over the 6-day period) was 22.6% of the ingested dose.

TABLE I—URINARY EXCRETION OF FREE PHENIRAMINE BY SUBJECT WHO RECEIVED ONE DOSE OF TWO 37-mg. PHENIRAMINE MALEATE TABLETS

Time After Drug Taken,[a] Days	Combined Volume of 24-Hr. Urine, ml.	pH of 24-Hr. Urine	Pheniramine[b] Excreted in 24-Hr. Urine, mg.
0	...	...	...
1	1420	6.2	12.26
2	1465	6.2	3.17
3	1065	5.9	0.90
4	970	6.0	0.25
5	1080	5.9	0.10
6	760	5.9	0.02

[a] Experiment started at 7:30 p.m. [b] Reported as pheniramine maleate.

Received November 15, 1967, from the Research and Development Division, Schering Corporation, Bloomfield, NJ 07003

Accepted for publication December 19, 1967.

[1] Pheniramine is *dl*-2-[α-[2-(dimethylamino)ethyl]-benzyl] pyridine.

[2] All gas chromatograms were obtained on a F and M model 400 gas chromatograph with a flame ionization detector and a Minneapolis Honeywell recorder. The mass spectra were obtained on a Consolidated Electrodynamics Corporation model CEC-103C mass spectrometer.

Multiple Dose Regimen—The urinary excretion of free pheniramine by the subject on a multiple dose regimen is listed in Table II.

The 24-hr. urinary excretion rate did not form a gradually increasing pattern as in the case of chlorpheniramine (2) and brompheniramine (3), indicating that pheniramine is not building up in the body.

The calculated *average* daily excretion rate (for the first 21 days) of free pheniramine was 9.0 mg., or 24.3% of the repeated 37-mg. pheniramine dose. This compares favorably with the 22.6% which was obtained in the single dose experiment. Large fluctuations (coefficient of variation of 32%) were observed in the daily excretion rate which could not be accounted for by variance in daily urine pH and volume.

The average daily urine volume was 1,020 ml. (range: 655–1495 ml.) while the average daily urine pH was 6.1 (range: 5.5–6.6).

On termination of the drug intake regimen, the pheniramine excretion rate decreased. From the total amount of free pheniramine excreted after the last dose is taken on day 20 and using the average 9.0-mg. pheniramine excreted per 37-mg. dose, one can calculate the equivalent amount of pheniramine maleate present in the subject immediately after the last dose. This calculation yields a figure of 47 mg. of pheniramine maleate (equivalent to 1.3 tablets, each containing 37 mg. of pheniramine maleate). Since this is well within the daily urinary excretion variance, there is no evidence of drug build-up in the body under this multiple dosage regimen.

Metabolites *X* and *Y*—The metabolites *X* and *Y* were found to be *N*-desmonomethylpheniramine and *N*-desdimethylpheniramine, respectively (Table III).

During the first 21 days an average of 9.3 mg. *N*-desmonomethylpheniramine and 0.17 mg. *N*-desdimethylpheniramine were excreted daily (26.1% and 0.5% of the repeated 37-mg oral dose). Together with the free pheniramine excreted daily, this accounts for 51% of the dose leaving the fate of the remaining 49% still unaccounted for.

TABLE IV—COMPARISON OF URINARY EXCRETION OF PHENIRAMINE, CHLORPHENIRAMINE, AND BROMPHENIRAMINE AND THEIR *N*-DEMETHYLATED METABOLITES IN MAN

Drug	% of Ingested Dose Excreted in Urine			
	Unchanged	*N*-Desmonomethyl-	*N*-Desdimethyl-	Total
Pheniramine	24.3	26.1	0.5	51
Chlorpheniramine	12.6	13.2	5.8	32
Brompheniramine	5.3	6.3	5.8	18

COMPARISON OF BROMPHENIRAMINE AND PHENIRAMINE WITH CHLORPHENIRAMINE

A comparison of the urinary excretion of pheniramine, chlorpheniramine, and brompheniramine and their *N*-demethylated metabolites is given in Table IV. The total urinary excretion of free pheniramine (24.3%) is greater, while that for free brompheniramine (5.3%) is less than that for chlorpheniramine (12.6%). This indicates that these drugs are metabolized (if one assumes that they are all well absorbed and there is no excretion of free drug *via* feces) in the following increasing order: pheniramine (76%), chlorpheniramine (87%), and brompheniramine (95%).

This difference in percentage metabolized may be due to differences in the degree of reabsorption from the kidney tubules by nonionic diffusion (9). Since the base strength of these amines are nearly identical (10), their lipid-water partition coefficient determines the degree of reabsorption. Using the heptane-water (pH 7.4) model, the distribution coefficients of these compounds were experimentally determined and tabulated in Table V. The drug with the highest lipid-water partition coefficient was brompheniramine followed by chlorpheniramine and pheniramine. These data are consistent with the amount of unchanged drug excreted in the urine.

TABLE V—COMPARISON OF LIPID-WATER DISTRIBUTION OF BROMPHENIRAMINE, CHLORPHENIRAMINE, AND PHENIRAMINE

Compd.	Heptane-Water Partition Coefficient[a]
Pheniramine	0.20
Chlorpheniramine	1.71
Brompheniramine	2.23

[a] 25°, water at pH 7.4.

It can be noted from Table IV that the amount of unchanged drug and *N*-desmonomethylated drug excreted are approximately equal for each of the three drugs. The reason for this is not obvious. The total amount of free drug plus *N*-demethylated metabolites excreted in the urine declined in the following order: pheniramine (51%), chlorpheniramine (32%), and brompheniramine (18%).

Urine pH and flow rate have been reported (1) to influence the renal excretion of chlorpheniramine. During the "steady state" period, the daily brompheniramine excretion rate was found to be dependent on the daily (24 hr.) urine pH and urine volume (3). These two variables (assuming a linear relationship) could account for 80% of the fluctuations in the daily free brompheniramine excretion rate. In the present study daily urine pH and urine volume could only account for about 25% of the fluctuations in the daily urinary excretion rate.

Repetitive daily oral dosage regimen appears to cause the build-up of brompheniramine in the body similar to the behavior of chlorpheniramine. However, in the case of pheniramine there is no evidence of drug build-up in the body.

SUMMARY AND CONCLUSIONS

A repetitive dosage regimen has been successfully used to identify two metabolites of pheniramine, *N*-desmonomethylpheniramine and *N*-desdimethylpheniramine, in the urine of a human.

The substitution of hydrogen for chlorine in chlorpheniramine evidently results in a molecule which is less extensively metabolized while the substitution of bromine for the same chlorine results in a molecule which is more extensively metabolized.

Bubble Size Analysis of High Consistency Aerosol Foams and Its Relationship to Foam Rheology

Effects of Container Emptying, Propellent Type, and Time

By LARRY L. AUGSBURGER and RALPH F. SHANGRAW

A photographic technique for the analysis of bubble size in "aerosol" foams is presented and the relationship between bubble size and foam rheology discussed. Within the same formulation, small bubbles are associated with high consistency. Container emptying gives rise to foams of lower consistency due to decrease in bubble density which more than offsets a decrease in bubble size. Synergistic consistency effects resulting from blends of fluorochlorohydrocarbon propellents are due to bubble size. Flammable propellents give rise to foams of lower consistency and decreased stability.

THE PAST few years have seen the introduction of a number of pharmaceutical and cosmetic foams which utilize the unique properties obtained from pressurized systems. These include contraceptives, hand creams, anogenital antiseptics, and antitussive products. The increased interest in foams as a dosage form makes it imperative that a more detailed investigation of basic foam systems be conducted in order that the formulation, packaging, and stability problems may be approached theoretically as well as empirically.

A review of foam formation and evaluation has been presented by Richman and Shangraw (1). These authors investigated the usefulness of rheological measurements in foam evaluation and found them to be extremely informative and reproducible (2–4). Studies were made on the effect of propellent type, propellent concentration, soap type, soap concentration, and additives on foam consistency and stability. In addition, a detailed study was made of the loss of consistency which occurs on container emptying, and a mathematical model was presented which predicted propellent concentrations at different stages and rates of container emptying.

All changes in foam consistency and stability should be relatable to the surface area of the foam bubbles and surface viscosity. The object of the present investigation was to study the effect of formulation, time, and can emptying variables on the bubble size of foams produced by pressurized systems, and to relate these studies to foam rheology.

EXPERIMENTAL

Formulation and Preparation—The same basic formulation suggested by Richman and Shangraw (2) was selected for this study because it combines relative simplicity with significant practical importance in regard to a typical high consistency foam such as shaving cream. This basic formulation consists of: soap concentrate 8%, stearic acid 5 parts; coconut oil fatty acids 3 parts, triethanolamine 5 parts; additive q.s.; distilled water q.s. ad. 100%. Total—90%; propellant 12/114 (57:43) 10%.

The soap concentrate was prepared by adding, with constant stirring, an aqueous solution of triethanolamine, which had been heated to 80° to a mixture of the stearic acid and coconut oil fatty acids which had also been heated to 80°. The mixture was held at 80° for 20 min. and then allowed to cool to room temperature with agitation. Any additives to be included were added, and the mixture was brought to the desired final weight by dilution with a suitable quantity of distilled water. Temperature, time, and rate of mixing were reproduced as closely as possible, as they may influence the properties of the resultant products.

The soap preparation was weighed into "six ounce" standard coated Spra-Tainer[1] cans which had previously been purged with a few drops of the liquid propellent and Precision 0.020/0.080 valves (Precision Valve Corporation, Yonkers, N. Y.) were crimped into place. As previous work in our laboratories has shown that the presence or absence of normal dip tubes does not affect foam properties; dip tubes were nevertheless omitted because the inversion of cans facilitates the filling of test vessels. The propellent was pressure filled into the test cans by weight. The finished products were then shaken vigorously and placed in a 40° bath water for 20 min. to test for leakage and can distortions. Although water bathing is routinely carried out in aerosol. production to check for leakage and can distortion,

[1] Spra-Tainer, Crown Can Co., Philadelphia, Pa.

little attention has been paid to the effects of time and temperature on the final product, which may be considerable for some formulations. After removal from the water bath, the cans were allowed to remain at room temperature for 3 days prior to testing. All testing was completed on a given batch of test products within 2 weeks of their preparations so as to minimize any possible aging factor.

Bubble size analysis was carried out utilizing an American Optical series 682 apparatus and a Polaroid camera. Foams were placed in a chamber which was formed by gluing a parallel pair of polyethylene strips ($^5/_{16} \times {}^5/_{16} \times 1$ in.) one-half in. apart onto a standard glass slide and covering with a cover slip. The $^5/_{16}$-in. deep chamber allows excess foam to flow freely out of the open ends, eliminating bubble distortion and at the same time providing greater protection against the heating effects of the illuminating lamp. Illumination was provided by an American Optical No. 735C microscope illuminator provided with heat absorbing glass. Exposure times up to 3 sec. were required through the first 5 min. elapsed time. Thereafter, as the foams aged, exposures of less than 1 sec. were sufficient.

Bubble size analysis was made by comparing bubbles against a scale made from a photograph of an object micrometer at the respective magnification used. Measurements were facilitated by performing the operation under the low power of an American Optical (Spencer) Cycloptic series 58 stereoscopic microscope. Bubbles were classified into 10-μ intervals and the average bubble radius was computed. An attempt was made to draw 100 bubble samples. However, in rare instances, it was necessary to take as few as 75 bubbles because of the limitations of magnification ranges available, field size, and actual bubble size.

Foam Rheology—Foam rheology was carried out in the manner of Richman (2) using the Haake Rotovisco rotational viscometer (Brinkmann Instruments, Inc., Westbury, N. Y.). All foams evaluated were studied using the MV III system, consisting of a smooth surface stainless steel rotor with a radius of 1.520 cm. and a height of 6.0 cm., and a stainless steel cup with a radius of 2.10 cm. Use of the 500 Gm. cm. torsion spring gave a working range in shearing stress of 27–5900 dynes cm.$^{-2}$ through a rate of shear range of 1–210 sec.$^{-1}$. Although this smooth rotor has proven to give excellent results with our experimental foams, some slippage was observed whene valuating commercial foam products of still higher consistency. For this reason the MV II P profiled bob system was used which gives a narrower gap between cup and rotor and has a serrated surface which reduces slippage.

Each pressurized container was shaken 15 sec. before filling the cup. The foam was introduced directly into the cup through a 5-in. extension of 0.25-in. polyethylene tubing attached to a Precision foam actuator No. SP115. All samples were removed with the valve in its maximum open position. In order to fill the cup uniformly, the cup was filled from the bottom up by slowly withdrawing the tube during actuation. All measurements were made at 28° so that they might better correlate with bubble data. Except in stability studies, readings were begun 1 min. after the cup had been filled. In operation, the time spent at each shear rate was limited to that necessary to make a dial reading, approximately 5 sec.

The need for reproducible technique in regard to evaluating any foam system cannot be overstressed. Such points as can shaking, rate of discharge, filling of evaluation vessels, time of setting before measurements are run, and temperature are critical. However, once such techniques have been mastered, reproducible results can be obtained. One other caution might be interjected at this point. If the formulation of a product is such that significant sputtering occurs when the foam is discharged, no meaningful physical measurements can be obtained. Sputtering means loss of entrapped propellent, which leads to an increase in foam density and a decrease in foam consistency. Although the literature is full of such data, it is impossible to interpret it even relatively.

Experiment I—The first experiment was designed to determine if bubble sizes and foam aging could be correlated with foam rheology. At the same time it was hoped to determine how these parameters are affected by the well-known can emptying effect. To accomplish these objectives, rheograms and bubble size measurements were made on foams after 1, 5, 10, 20, 30, 60, 90, and 120 min. of standing at room temperature (28 ± 1°). These determinations were made at 1, 10, 20, 40, 60, and 80 percentages of can emptying. Separate cans were used for each time increment. Can emptying was accomplished by removing approximately 5-Gm. samples at 15-min. intervals. Before removing samples the cans were shaken uniformly for 15 sec. Two formulations were studied. The first formulation was the basic formulation without additives, while the second formulation included 1.5% methylcellulose 400. The methylcellulose had previously been shown to have a marked effect on foam consistency and its effect on foam stability was of interest. Generally speaking, foam consistencies and bubble sizes decreased with increasing can emptying as did bubble rates of decay.

Experiment II—This experiment was designed to elucidate the effect of propellents on consistency and stability. Foams were prepared containing 10% of propellents 12, 114, or 12/114 (57:43) in two formulations: plain soap and plain soap with 10% propylene glycol. In addition, a formulation containing the hydrocarbon propellent A-46 with a vapor volume identical to the 57:43 blend of the fluorochlorohydrocarbons (*i.e.*, at 3.99% concentration) was included. This equivalent concentration was obtained using the equation of Gorman and Hall (5). In order to show the variation in bubble data, replicates of the plain soap formulation were studied. Bubble analysis and rheograms were determined for each product at 5% and 75% can emptyings. It was felt that the choice of 75% rather than 80% can emptying would ensure a higher degree of success in obtaining a sufficiently large and uniform sample. Of the fluorochlorohydrocarbon products, those prepared from plain propellents 12 and 114 showed the largest bubble sizes and the poorest consistencies at 5% can emptying. Products using the propellent blend were superior in consistency and showed the smallest bubbles. The addition of propylene glycol generally enhanced consistency, reduced bubble sizes, and reduced their rate of growth. Propellent A-46

generally produced foams with lower consistencies and less uniformity than those obtained using equivalent amounts of the fluorochlorohydrocarbons.

DISCUSSION

The choice of propellent and propellent concentration for use in an aerosol product has traditionally been governed by empirical evaluation of the initial product, stability, and economics. In most cases it has been difficult to ascertain subtle influences of formulation and packaging components and propellent changes due to the lack of sensitive quantitative tests on the final properties of the foam. Rheological evaluation has proven to be an effective means of determining changes in foam consistency, which is certainly one of the most important properties of foams. Furthermore, changes in foams which occur upon aging are reflected in such measurements. It has also been known that the changes in foam properties which occur during use of the product due to can emptying effects may be monitored by rheological measurements. The discovery of the discrete changes in consistency which can be brought about by relatively small changes in formulation raised the interesting question as to what physical-chemical phenomenon these changes could be attributed. It seemed obvious, and later work has borne this fact out, that changes in consistency can be attributed to changes in surface area or changes in viscosity of the interbubble film, probably as reflected in surface viscosity. Taking these influencing factors one at a time, a comprehensive study of the effect of formulation variables on bubble size was undertaken.

The effect of aging of a plain foam on the average bubble diameter at various stages of can emptying is shown in Fig. 1. The same effects on a formulation including methylcellulose can be seen in Fig. 2. Initial bubble radii for both formulations were in the general region of 10 μ. Bubble growth during the first 20 min. was rapid and essentially exponential. However, after 20 min., average bubble diameter seemed to be directly proportional to time.

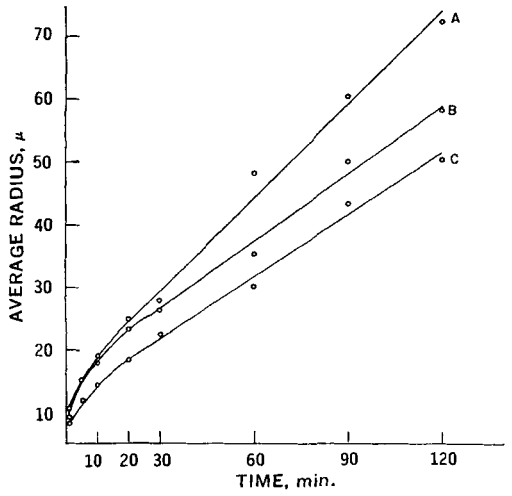

Fig. 1—Bubble growth curves: effect of can emptying (basic soap formulation without additive). Curve A, 10% empty; curve B, 40% empty; curve C, 80% empty.

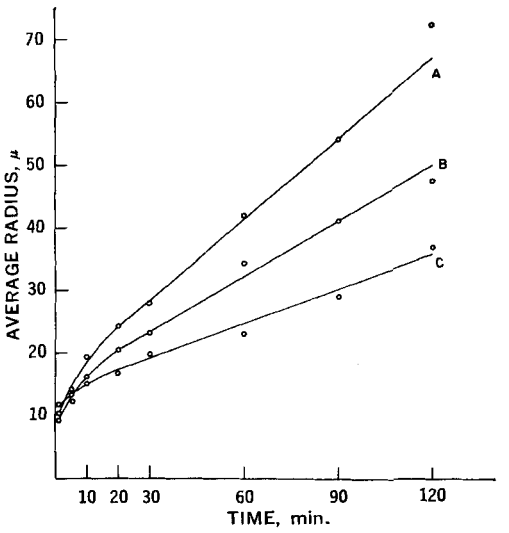

Fig. 2—Bubble growth curve: effect of can emptying (basic soap formulation with 1.5 % w/w methylcellulose 400). Curve A, 10% empty; curve B, 40% empty; curve C, 80% empty.

The initial apparent rapid growth in bubble size can be attributed to the presence of many very small bubbles which would have disappeared after a few minutes. Other factors which may play a role include (*a*) residual vaporiziation of propellent, (*b*) increase in vapor volume as the system equilibrates from cooling effects of propellant vaporization, and (*c*) higher kinetic energy in the initial system and possible greater initial permeability of interbubble films.

One very striking fact can be noted in almost all studies of bubble size *versus* can emptying. The average bubble size decreases as can emptying increases. At the same time the rate of coalescence of bubbles decreases. This means that foams produced at later stages of can emptying are more stable. Smaller bubble size would indicate a larger surface area and thus an increased consistency. However, these results are misleading in regard to the actual consistency of foams, which is known to substantially decrease during container emptying (2). This is due to the fact that although the bubble size decreases, the number of bubbles is also substantially smaller. This lower bubble density results in a much lower surface area which is then reflected in the decreased consistency. The decrease in bubble density helps also to explain the decrease in rate of coalescence of bubbles produced at later stages of emptying. Interbubble films are thicker and diffusion of vapor is thus retarded. These results are consistent with the conclusions of DeVries, who points to the thickness of bubble lamellae as being one of the most important factors in the rate of bubble coalescence (6). The works of DeVries along with that of Clark and Blackman (7) offer an indispensable background for all workers interested in bubble size analyses.

With regard to formulation variables, the plain soap formulation appeared to age more rapidly than the one containing methylcellulose, and this becomes more evident with can emptying. This

can be explained as the result of both a retardation of film drainage and a retardation of drying due to film formation on the surface of the bubbles. As expected, these effects are more significant at later stages of can emptying where the foam is denser.

Foam consistencies decrease with container emptying. Previous works by Richman and Shangraw, and Fong and Shangraw (8) confirmed in this study, show that this decrease in consistency is not directly proportional to can emptying but plateaus in the general region of 40–60% can emptying. It was hoped that bubble size analysis data would show a similar pattern, as it is difficult to envision anything but bubble size playing an important role. However, correlation did not materialize. The plateauing in consistency which occurs in can emptying is thought to be related to the fractionation of propellent blends which occurs as the propellent vaporizes into the headspace. The need for a better understanding of these effects led to the experiment in which the type of propellent was varied.

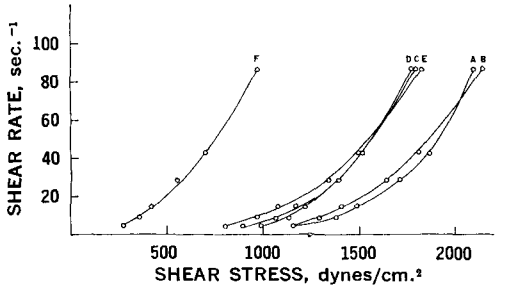

Fig. 3—Pressurized foam flow curves: effect of can emptying on 1 min. rheology (basic soap formulation with 1.5 % w/w methylcellulose 400). Curve A, 1% empty; curve B, 10% empty; curve C, 20% empty; curve D, 40% empty; curve E, 60% empty; curve F, 80% empty.

Bubble analysis can generally be correlated with foam rheology when the formulation remains constant. The effect of can emptying on the methylcellulose formulation may be seen in Fig. 3. As expected, the foam containing the methylcellulose exhibited higher consistencies but the relative drop in consistencies on container emptying remained constant. As initial bubble sizes of the two formulations are very similar, consistency changes are obviously due to viscosity effects, either in the bulk of the liquid, or, more probably, in the surface of the bubbles.

Photomicrographs of a typical shaving cream foam at different times of aging can be seen in Fig. 4. Initially, a shaving cream foam looks more like a gas emulsion since bubbles are essentially spherical. It is only after these high consistency foams have aged for a period of time and the interbubble films have drained, that the classical pentagonal dodecahedrons begin to form.

An interesting insight into the variabilities which can occur in bubble patterns of two high consistency commercial vaginal foams used in contraception is shown in Fig. 5. While one foam appears to be similar to the shaving cream, the other is much more polydisperse and seems to be of poorer quality. The polydisperse foam with thick lamellae shows little change on aging (Fig. 6). The few small bubbles have disappeared as would be expected, but the other bubbles have shown little growth. This photomicrograph points up the basic dynamics of bubble distribution in foams which occurs on aging, *i.e.*, small bubbles become smaller and larger bubbles grow. This is due to the increased curvature of a small bubble which results in higher relative pressure.

The results of the bubble size analysis conducted on foams prepared using different fluorochlorohydrocarbon propellent systems at two stages of can emptying can be found in Tables I and II. Two formulations were employed, one containing

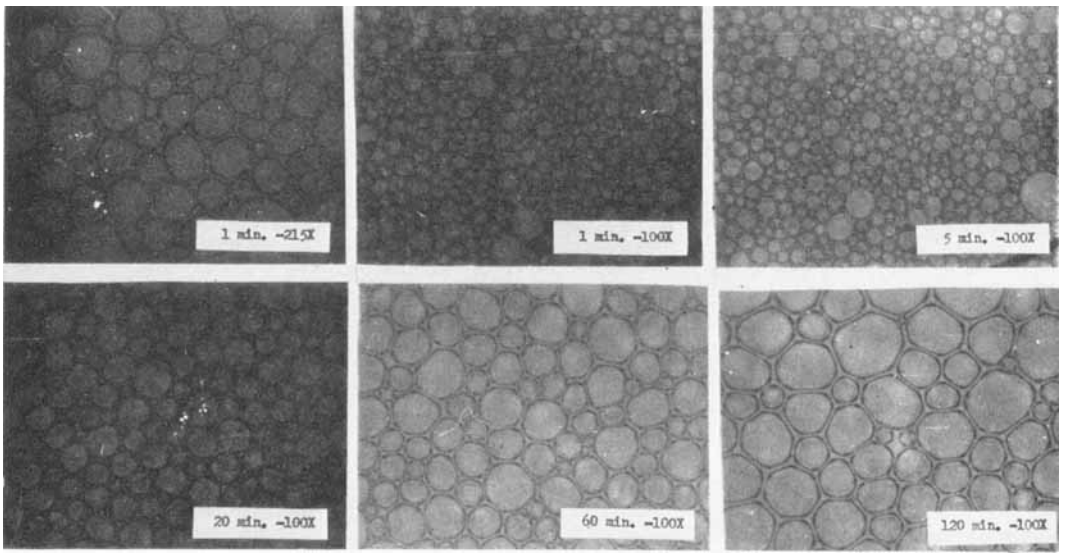

Fig. 4—Photomicrographs illustrating the effect of aging on a typical pressurized shaving foam.

plain soap (with replicate) and one containing 10% propylene glycol. The corresponding flow curves are presented in Fig. 7.

Bubble size data corresponded to consistency curves in all systems, *i.e.*, as bubble size decreased, consistency increased. However, there were some unusual results obtained in regard to bubble sizes produced by each propellent system.

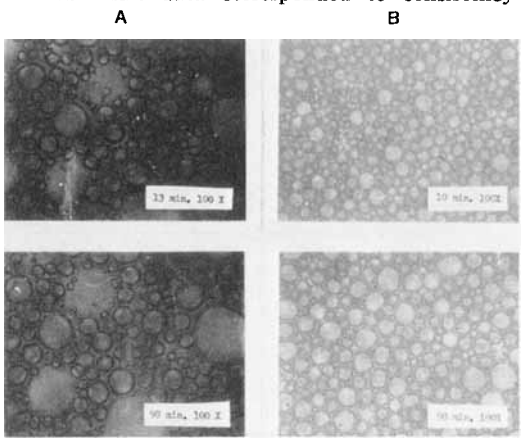

Fig. 5—Photomicrographs comparing commercial pressurized vaginal foams.

Propellent 12 gave smaller bubble sizes and higher consistencies than 114. These consistency data were not in agreement with the preliminary work done by Richman (2), but were reproducible and in line with bubble size measurements. However, the synergistic effect that propellent blends have on foam consistency was apparent in both studies. The reason for this increased consistency can now be seen to be due to the overall decrease in bubble size exhibited by foams prepared from blends. The reason for this decrease in bubble size is not immediately obvious but must be connected to the propensity for solubilized or emulsified molecules of propellent to associate into a single bubble of vapor when pressure is reduced during expulsion of foam.

The changes in bubble size which occur in foam aging can be seen in Fig. 8. Foams containing propellent 12 age extremely rapidly and would be expected to have sharp decreases in consistency.

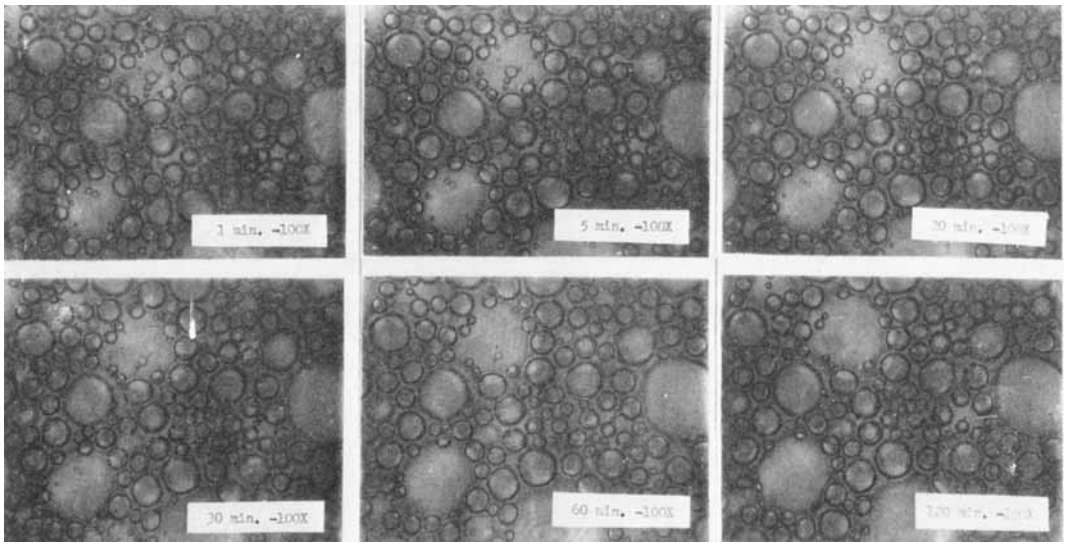

Fig. 6—Photomicrographs illustrating the effect of aging on a commercial pressurized vaginal foam.

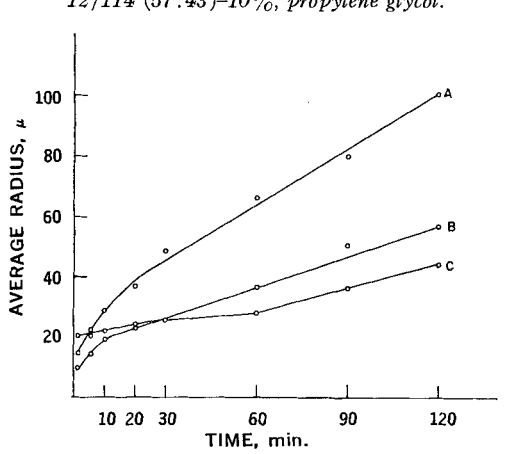

Fig. 8—Bubble growth curves: effect of different nonflammable propellent systems (basic soap formulation without additive—5% can emptying). Key: A, 10% 12; B, 10% 12/114 (57:43); C, 10% 114.

On the other hand, foams prepared from propellent blends and plain propellent 114 have identical bubble sizes after 30 min. All foams containing only propellent 114 age extremely slowly. It seems apparent that propellent 114 does not diffuse as rapidly through the interbubble walls as does propellent 12. The presence of propylene glycol in the formulation gives rise to smaller bubble sizes and slower aging in those foams utilizing propellent 12 or propellent blends. On the other hand, foams produced with propellent 114 have a much larger initial bubble size but show extremely little aging over a 2-hr. period. In all cases, addition of propylene glycol resulted in a decrease in the slopes of the linear portions of the time-radius plots.

One unusual effect is that wherein the propylene glycol formulation actually gives a lower consistency foam than the plain soap when propellent 114 is employed. The effect was so unexpected that additional samples were tested with confirming results. Although the relatively low boiling point and longer time required for vaporization equilibrium to be achieved makes data obtained from propellent 114 less reliable, the effects noted are real and reproducible.

The 75% can emptying data presented in Table II point up the characteristic decrease in bubble size and lower rate of coalescence which occurs in foams produced from the latter part of a pressurized container. This effect is particularly striking in the case of propellent 114 in which the average

bubble size is now the smallest of the three propellent systems studied. On this basis, it would be expected that consistency of the 114 foams would not decrease as much as would be expected. The consistency curves shown in Fig. 9 bear out this assumption with the effects in the propylene glycol formulation being particularly striking. The foam obtained at 75% can emptying from propellent 114 in the presence of propylene glycol exhibits a higher consistency than any of the other 114 curves at either level of can emptying. These results have to be relatable to bubble size. Although the reason for this is not clear, the propellent 114 appears to be better emulsified or solubilized in the presence of a large excess of soap. The fact that fractionation of propellents upon can emptying favors the retention of propellent 114 in the concentrate combined with the above effects might serve as a basis for improving foam quality at latter stages of container use. Unfortunately, propellent 114 alone is not energetic enough to serve as the sole propellent in a foam system.

Because it was felt that nonflammable propellents would have a greater application to pharmaceutical foam systems, a great deal of the experimental work was devoted to the investigation of the fluorochlorohydrocarbon propellents. However, the fact remains that economics have resulted in the widespread use of the flammable propellents (isobutane, propane) in cosmetic foams such as shaving creams. A recent analysis of shaving creams of 10 major companies indicates that only two are using nonflammable propellent systems.

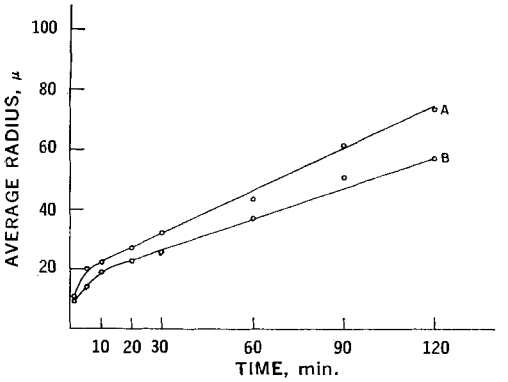

Fig. 10—Bubble growth curves: comparison of flammable and nonflammable propellent systems with matched vapor volumes (basic soap formulation without additive—5% can emptying). Key: A, 3.99% A-46; B, 10% 12/114 (57:43). Slope of linear portion (μmin.$^{-1}$): A, 0.476; B, 0.345.

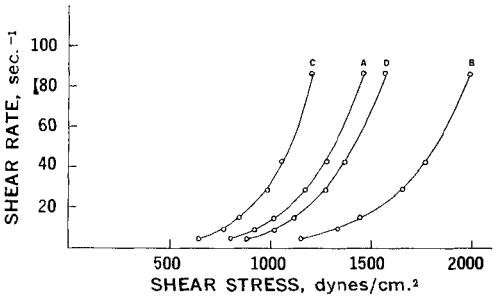

Fig. 11—Pressurized foam flow curves: comparison of flammable and nonflammable propellent systems with matched vapor volumes (5% can emptying). Key: A, plain soap + 10% 12/114 (57:43), B, same as in A + 10% w/w propylene glycol; C, plain soap + 3.99% w/w A-46; D, same as in C + 10% w/w propylene glycol.

A summary of the bubble size data obtained from foams produced from the two propellent systems with matched vapor volumes is shown in Table III. Initial bubble sizes appear to be quite similar but bubble growth is more rapid in the A-46 systems. This increased rate of aging which occurs in the flammable propellent system is illustrated in Fig. 10. It would appear that the flammable propellents diffuse more rapidly through the interbubble walls than do the nonflammable propellents, indicating a slightly lower degree of stability.

The consistency curves shown in Fig. 11 obtained from the two propellent systems indicate the existence of a much greater difference between the foams than was obvious from the bubble data. The A-46 foams gave significantly lower consistencies for both concentrate formulations studied. This decreased consistency in light of fairly equal average bubble diameters can best be explained by looking at a bubble size frequency distribution, as is shown in Fig. 12. The much wider distribution of bubble

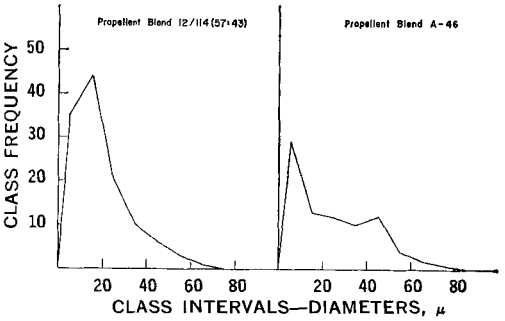

Fig. 12—Initial (1 min.) bubble size frequency distributions: Comparison of flammable and nonflammable propellent systems with matched vapor volumes (basic soap formulation without additive—5% can emptying).

sizes and resultant decrease in total surface area in the A-46 foam helps to explain the lower consistencies. This lack of bubble size homogeneity would seem to indicate that emulsification of A-46 propellent is more difficult. A great deal of work remains to be done on characterization of foams from flammable propellent systems.

SUMMARY AND CONCLUSIONS

(*a*) A photomicrographic technique is described for the determination of the growth of bubbles in aerosol foams which yields a reasonably good degree of reproducibility.

(*b*) Within the same formulation and propellent concentration, smaller bubbles are associated with higher consistencies.

(*c*) As a container is emptied, bubble sizes and growth slopes tend to decrease due to a higher ratio of soap to propellent and thicker interbubble films. Consistency also decreases.

(*d*) The addition of methylcellulose increases foam consistency and decreases the rate of bubble coalescence.

(*e*) Initially, propellent 114 yields larger bubbles than propellent 12. Blends yield smaller bubble sizes than either single propellent. These results are consistent with foam rheology at both 5% and 75% can emptying.

(*f*) The addition of propylene glycol tends to decrease bubble sizes and increase foam consistency except in cases of plain propellent 114 where unusual effects are noted, particularly at 75% can emptying.

(*g*) When vapor volumes are matched, flammable propellents give rise to foams of lower consistency and decreased stability. This is not always obvious when observing average bubble size alone, as bubble sizes are more disperse when A-46 propellents are used.

Determination of Free Salicylic Acid in Buffered Aspirin Tablets

By JOSEPH LEVINE and JOHN D. WEBER

Aspirin and free saliyclic acid are quantitatively released from buffered aspirin tablets, with a negligible degree of hydrolysis of aspirin, by briefly wetting the sample with 98–100 percent formic acid, followed by immediate dilution with chloroform. The salicylic acid is isolated and determined as previously described.

SALICYLIC ACID can be quantitatively separated from aspirin by trapping it as the complex formed with ferric ion on a partition chromatographic column, using ferric chloride (1) or ferric chloride-urea (2) solutions as the immobile phase.

In the application of this procedure to analytical samples, it is essential that the entire amount of aspirin and salicylic acid be dissolved in the mobile phase before the chromatographic treatment, and that the aspirin is not hydrolyzed during the preparation of that solution. These

Determination of Free Salicylic Acid in Buffered Aspirin Tablets

By JOSEPH LEVINE and JOHN D. WEBER

Aspirin and free saliyclic acid are quantitatively released from buffered aspirin tablets, with a negligible degree of hydrolysis of aspirin, by briefly wetting the sample with 98–100 percent formic acid, followed by immediate dilution with chloroform. The salicylic acid is isolated and determined as previously described.

SALICYLIC ACID can be quantitatively separated from aspirin by trapping it as the complex formed with ferric ion on a partition chromatographic column, using ferric chloride (1) or ferric chloride-urea (2) solutions as the immobile phase.

In the application of this procedure to analytical samples, it is essential that the entire amount of aspirin and salicylic acid be dissolved in the mobile phase before the chromatographic treatment, and that the aspirin is not hydrolyzed during the preparation of that solution. These

Received October 5, 1967 from the U. S. Department of Health, Education, and Welfare, Food and Drug Administration, Bureau of Science, Division of Pharmaceutical Sciences, Washington, DC 20204
Accepted for publication December 15, 1967.

two requirements are not readily achieved in the case of buffered aspirin tablets (2). Chloroform solutions of aspirin, in the presence of basic materials such as those which comprise the buffering components of the tablets, undergo hydrolysis together with aspirin anhydride formation (1). Boric acid stabilizes the solution, at least with respect to the hydrolysis of aspirin, but does not achieve the necessary release of the aspirin and salicylic acid from the buffer components to permit their complete solution in chloroform.

A preliminary acid treatment of the buffered tablet will release the aspirin and salicylic acid. The acid may, however, concurrently hydrolyze the aspirin. In designing a valid assay procedure, the acid which is used must: (*a*) produce only minimal hydrolysis of aspirin under the conditions of the assay; (*b*) rapidly and completely release aspirin and salicylic acid from the buffer components of the tablet; (*c*) be soluble in chloroform; and (*d*) be readily removed from the chloroform, so that the ferric-salicylic acid complex will not be dissociated during the following step of the analysis.

These requirements are fulfilled by 98–100% formic acid. The common 90% reagent is not suitable because it is immiscible with chloroform. The distribution of formic acid between chloroform and inorganic acids is greatly in favor of the aqueous phase; therefore, the formic acid is removed from the chloroform solution by passage over dilute hydrochloric acid.

In the analysis the powdered sample is thoroughly wetted with the formic acid and then immediately diluted with chloroform to sharply decrease the hydrolytic action of the acid.

The extent of hydrolysis during the period of contact of the sample with the formic acid before dilution was gauged by a direct determination of the rate of the hydrolysis. Although this increase varies somewhat for various brands of buffered aspirin, it lies in the range of 0.01–0.02%/min. The procedure specifies a period of 30–45 sec. for this step; the average time of contact will be shorter since a part of this time is consumed in the wetting of the sample. The total extent of hydrolysis in this step will therefore be in the order of 0.01%.

After dilution, hydrolysis is sharply decreased to an average of only 0.03%/hr., and thus a negligible amount occurs during the 10-min. period specified for dissolving the aspirin and salicylic acid.

The degree of completeness of solution is established by direct examination of the residual solid tablet components. After vigorous treatment of the residue with hydrochloric acid, the spectrum of a chloroform extract indicated the presence of both aspirin and salicylic acid. In view of the hydrolytic effect of the acid treatment, these results indicate that perhaps the major portion of the residual acidic material is aspirin, rather than salicylic acid. In any event, the total amount of the residual material, whatever its original identity, was about 0.02%, calculated as salicylic acid.

EXPERIMENTAL

The ferric chloride-urea reagent, salicylic acid standard, and chromatographic tubes are prepared as previously described (2).

Column A—Pack a plug of cotton about 15 mm. deep in the base of the chromatographic tube to absorb any stationary phase which may bleed off column. Mix 5 Gm. of diatomaceous earth[1] with 3 ml. of 0.05 *N* hydrochloric acid to a uniform mixture, transfer, and pack the mixture in three portions, lightly enough to obtain a 12 ml./min. flow of chloroform.

Column B—Pack a plug of glass wool[2] in the base of the chromatographic tube for support. To prepare the lower state, mix 1 Gm. of diatomaceous earth with 0.5 ml. of 30% phosphoric acid to retain any ferric chloride which may be removed during the elution of larger quantities of salicylic acid (3), as are often found in buffered tablets. Transfer the mixture to the tube and tamp to a uniform mass. For the upper stage, mix 3 Gm. of diatomaceous earth with 2 ml. of ferric chloride-urea solution, transfer to the column directly above the phosphoric acid layer, and tamp. Cover with a pad of cotton about 20 mm. thick to insure uniform distribution of the solvent over the column cross section. Mount column A above column B.

Procedure—(Use water-saturated solvents throughout.) Determine the average weight of a representative number of tablets. Grind to a fine powder rapidly, and immediately weigh an amount equivalent to about 500 mg. of aspirin. Transfer to a 100-ml. volumetric flask and immediately add 5 ml. of 98–100% formic acid. Agitate to wet the sample thoroughly; then within 30–45 sec. add 75 ml. of chloroform. Shake for 10 min., and adjust to volume with chloroform. Filter through a loose plug of glass wool. Pass 20.0 ml. of the sample over the columns, and then wash with three 25-ml. portions of chloroform, allowing each portion to pass through both columns before the successive addition. Discard the eluate and column A, and rinse the tip of column B with a stream of chloroform.

Place as receiver under column B a 100-ml. volumetric flask containing 10 ml. of methanol and 2 drops of hydrochloric acid. Pass a solution of 1 ml. of glacial acetic acid in 10 ml. of ether through the column and follow with 1% acetic acid–chloroform (v/v) to volume.

Concomitantly determine the absorbance of this solution and of the standard at the maximum at about 306 mμ.

[a] Analysis by extrapolation of hydrolysis rate curve. [b] Separate bottle of same brand. [c] Analyzed 1 mo. after bottle was opened.

Determination of Rate of Hydrolysis—Weigh portions of sample equivalent to about 100 mg. of aspirin into individual 150-ml. beakers. Add 1 ml. of 98–100% formic acid to each beaker and agitate to wet the sample thoroughly. Immediately add 2 Gm. of diatomaceous earth to one beaker, mix thoroughly, transfer to column A, and tamp. Pass 25 ml. of chloroform through the columns, recording the interval between the addition of the formic acid and the addition of the chloroform as the period of contact. Continue the analysis as described above. Add the diatomaceous earth to the other samples at proper intervals to provide contact periods of 5, 10, 20, and 30 min.

RESULTS AND DISCUSSION

A number of commercial samples of buffered aspirin tablets purchased from local retailers were analyzed for their salicylic acid content. Results are shown in Table I.

The total extent of hydrolysis of aspirin during an actual assay is shown in the values obtained in the analysis of pure aspirin by the original procedure (2) and by the proposed procedure, using formic acid. The original procedure gave a salicylic acid value of 0.025% and the current procedure 0.036%, an increase of only 0.011%. Although a slightly larger increase may result during the analysis of buffered tablets, since the rate of hydrolysis of aspirin in these tablets is somewhat greater than that for pure aspirin (Fig. 1), it remains at a level close to the precision of the determinative steps (2), and therefore does not constitute a significant source of error. This is substantiated by the fact that the values obtained by extrapolation of the hydrolytic rate series to zero time agreed well with those obtained by the method as proposed.

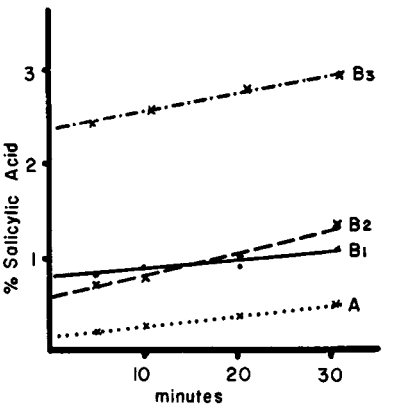

Fig. 1—Rate of hydrolysis of (A) aspirin tablets and (B 1–3) buffered tablets.

Atmospheric humidity can cause an appreciable degree of hydrolysis before the analysis. A freshly opened bottle of buffered tablets gave a value of 0.70% salicylic acid. One month later the salicylic acid content had increased to 0.77%. For this reason, the procedure requires assay immediately after the sample is ground.

The very small amount of salicylic acid found on analysis of residual tablet material demonstrates the effectiveness of the procedure in completely releasing aspirin and salicylic acid from the buffering materials. It has not been resolved whether the free salicylic acid is present as such adsorbed on the buffering components or has been converted to its metallic salts. The formic acid treatment readily recovers salicylic acid from its calcium or magnesium salt, but the aluminum salt is quite refractory to the treatment. Hence, if a metallic salicylate is formed, it must be other than aluminum salicylate.

Chemical Determination of the Potency of Thyroid Preparations

By JOSEPH E. MOODY, JR., JOHN R. HOHMANN, and GILBERT B. KAPLAN

Several methods for the chemical analysis of thyroid have been reported in recent years, but none has been adopted by the official compendia. In an attempt to meet the need for a new official chemical assay, a procedure has been devised, and is reported in this paper for the quantitative determination of triiodothyronine (T_3) and thyroxine (T_4). Results for some of the samples tested are compared to the biological assay. The thyroid is hydrolyzed with barium hydroxide and the digest is extracted with *n*-butanol. The iodoamino acids are separated by thin-layer chromatography on cellulose plates and the T_3 and T_4 zones are scraped separately from the plates and ignited in oxygen flasks. The iodine is subsequently released and determined spectrophotometrically in benzene. Commercial thyroid preparations with different biological activities were analyzed and a chemical potency determined for each. The results correlated well with those obtained by biological assay.

THE USP requires that thyroid contain not less than 0.17% and not more than 0.23% of iodine in thyroid combination. This 50-year-old standard does not truly reflect the physiological activity of the drug (1–3). Numerous samples of thyroid meet the official iodine requirement but have little or none of the desired activity.

Many attempts have been made to develop an analytical procedure for thyroid that will more accurately reflect its physiological activity. The complexity of this proteinaceous substance has until recently defeated these efforts. Hydrolysis of thyroid yields a number of iodinated derivatives of tyrosine and thyronine (4–7). However, only four of these, thyroxine, 3,3′,5-triiodothyronine, 3,3′,5′-triiodothyronine, and 3,3′-diiodothyronine, have biological activity. A quantitative method for thyroxine and 3,3′,5-triiodothyronine would suffice to estimate the potency of thyroid since the diiodo compound is present in only trace amounts and the 3,3′,5′-triiodothyronine has negligible activity (8).

Recently several methods have been presented for the determination of thyroxine (T_4) and 3,3′,5-triiodothyronine (T_3) in thyroid (2, 7, 9–14). Most of these procedures use the following scheme: (*a*) hydrolysis of the thyroprotein with sodium hydroxide or barium hydroxide, or by enzymatic action; (*b*) extraction of the released iodoamino acids with *n*-butanol; (*c*) separation of these iodoamino acids by paper, thin-layer or column chromatography, or by gel filtration; (*d*) quantitation of the separated active compounds either by direct determination or by destruction of the compound and determination of the released iodine.

Some of these published methods of thyroid assay have been studied in this laboratory, but the consistent results necessary for routine analysis could not be achieved. Lemieux and Talmage (11) discuss many of the disadvantages and inadequacies of some of the earlier methods. The general scheme of their procedure contains some steps which, with modifications, were adapted to our method. Enzymatic hydrolysis with pronase and alkaline hydrolysis with barium hydroxide were compared in the present study. Devlin and Watanabe (12) reported that hydrolysis with pronase yielded more T_3 and T_4 in a shorter time than hydrolysis with the other enzyme studies. The present data agree with their report with regard to enzymatic hydrolyses, but show that more T_4 is released by hydrolysis with barium hydroxide.

In our procedure the released components of the hydrolyzed thyroprotein are separated by thin-layer chromatography on cellulose plates, with a solution of *p*-toluenesulfonic acid and formic acid as the developing solvent. This procedure releases a significant amount of a component between T_3 and T_4 on the chromatogram which is not usually reported. The compound has been shown to be 3,3′,5′-triiodothyronine.

Received August 21, 1967, from the U. S. Department of Health, Education, and Welfare, Food and Drug Administration, Division of Pharmaceutical Chemistry, Washington, DC 20204

Accepted for publication October 12, 1967.

The authors express deep appreciation to Frieda M. Kunze and Charlotte A. Brunner of the Chromatographic Research Branch of this Laboratory for their assistance and advice in the development of the chromatographic step in this procedure.

The authors also wish to thank Miss Mae E. Biesemeyer and Mrs. Sandra Harvey for their invaluable assistance in the laboratory. Thanks are also expressed to Stanley Srensek, Division of Pharmacology, who performed all of the bioassays.

The areas of the chromatogram containing T_3 and T_4 are scraped from the plate and ignited in an oxygen flask to convert the iodine, after intermediate treatment, to iodate. The final step in the procedure is the spectrophotometric measurement of iodine in benzene.

EXPERIMENTAL

Apparatus—A Cary 14 or Beckman DK recording spectrophotometer was used for these studies. The 10-cm. cylindrical silica cells for the absorption measurements and the Thomas-Ogg oxygen ignitor were purchased from Arthur H. Thomas Co., Philadelphia, Pa. Glass chromatography tanks were 30 × 30 × 10 cm.; the chromatoplates were 20 × 20 cm.

Reagents—All reagents and solutions were prepared from analytical grade chemicals and with water redistilled from an all-glass still. The following reagents were used: $Ba(OH)_2.8H_2O$; 30% formic acid, diluted from 90% analyzed reagent; *n*-butanol; *n*-butanol equilibrated with 0.1 *N* sodium thiosulfate solution; ammoniacal methanol, 5% v/v solution of ammonium hydroxide in methanol; phosphoric acid solution, 260 ml. of 85% H_3PO_4 diluted to 1 L. with water; benzene, "distilled in glass," b.p. 80–81°, Burdick and Jackson Laboratories, Inc., Muskegon, Mich.; bromine water, USP; *p*-toluenesulfonic acid, 40% w/v; NaOH, 2% w/v; freshly prepared potassium iodide, 7.5% w/v; sodium carbonate, half saturated.

To prepare the diazotized sulfanilamide (15), mix 5 ml. of a 1% sulfanilamide solution in 10% v/v hydrochloric acid with 5 ml. of 5% w/v sodium nitrite solution in a 50-ml. glass-stoppered graduated cylinder for 1 min. Add *n*-butanol to 50 ml. and shake for 1 min. Let stand 4 min. and decant the butanol layer to be used as the spraying solution. Prepare just before use.

The cellulose was MN cellulose powder from Macherey Nagel and Co. (distributed by Brinkmann Instrument Co., Great Neck, N. Y.). The gelatin capsules (No. 0 and 00) were obtained from Eli Lilly & Co., Indianapolis, Ind.

To facilitate transferring the cellulose containing the T_3 nd T_4 to capsules, a funnel rack and a capsule holder were devised (Fig. 1).

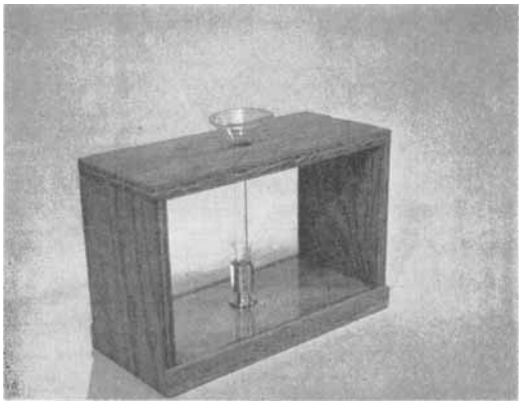

Fig. 1—Device to transfer cellulose from chromatoplates to capsules for oxygen ignition.

Preparation of Samples—*Tablets*—Weigh 20 tablets and grind to a fine powder. Transfer the equivalent of 200 mg. of USP thyroid, accurately weighed, to a 50-ml. centrifuge tube or appropriate test tube to fit a centrifuge and heating block. Add 6 ml. of water, mix well on a vortex mixer, and centrifuge for 15 min. Remove the supernatant with a syringe fitted with a large blunt needle and discard the washings. Repeat with a second 6 ml. of water. Fit the tube with an air condenser at least 10 in. long.

Bulk Powders—Place an accurately weighed sample of thyroid powder equivalent to about 400 mcg. of iodine in a test tube of appropriate size that is fitted with an air condenser.

Total Iodine Determination—Weigh accurately a No. 0 gelatin capsule and a sample of ground tablets or bulk powder equivalent to about 8.4 mg. of USP thyroid. Ignite the capsules as described under *Oxygen Ignition* and continue the procedure from there to completion. Calculate as follows:

$$\% \text{ total iodine} = \frac{(\text{mcg. iodine from standard curve})\ (100)}{(\text{wt. of thyroid in sample in mcg.})\ (6)}$$

Hydrolysis and Extraction—To the tubes containing the accurately weighed samples add 3 Gm. of $Ba(OH)_2.8H_2O$ and 6 ml. of water (16). Mix well and place the air condensers in the tubes. Heat the tubes in an aluminum heating block at 100° or in a boiling water bath for 16–18 hr. Swirl the tubes occasionally to mix the contents. After the hydrolysis, allow the mixture to cool and add about 3.5 ml. of dilute hydrochloric acid (1:1) to a pH of 0.8 or 0.9 as determined with a pH meter. Transfer the acidified solution to a 60-ml. separator. Wash the hydrolysis tube with three 5-ml. portions of water and add the washings to the separator. Extract the hydrolysate solution with 10, 5, and 5 ml. of *n*-butanol previously equilibrated with 0.1 *N* sodium thiosulfate. Wash the combined butanol extracts with 25-ml. portions of butanol-saturated water until the washings are neutral to pH indicator paper. Filter the butanol through a medium sintered-glass funnel into a 50-ml. round-bottom flask. Rinse the separator with three 2-ml. portions of butanol and pass the rinsings through the separator. Add a small quantity of ethanol to the filtered butanol solution to dissolve any droplets of water present. Remove the butanol at 55° under reduced pressure. The dried residue may be stored for at least 1 week in the cold under nitrogen (13).

Chromatography—To prepare five 20 × 20 cm. plates homogenize 15 Gm. of cellulose powder in a fast blender with 90 ml. of water. Spread the cellulose slurry on the plates in a 0.6 mm. (±0.05 mm.) layer, and dry the plates overnight at room temperature. Scratch a line across a plate about 3 cm. from the top. Make two lines, each 6 cm. long, of pin-point dots 0.5 cm. apart, about 1.5 cm. from the bottom of the plate and separated by 3 or 4 cm.

Dissolve the hydrolysate residue in 1.0 ml. of ammoniacal methanol, and transfer as much of the solution as possible to a 1-ml. stoppered flask or tube to reduce evaporation. Spot 200 µl. of the ammoniacal methanol solution uniformly along each of the 6-cm. dotted lines. Scrape a vertical band of

cellulose from top to bottom with a narrow flat-edged spatula on both sides of the spotted areas in parallel lines almost touching the lines of sample application (see Fig. 2). These borders will aid in the development of straight horizontal zones.

Line glass chromatography tanks on one side with filter paper. Pour a mixture of 50 ml. of the 40% *p*-toluenesulfonic acid solution and 50 ml. of the 30% formic acid solution down the paper into the tank. Place the chromatoplate in the developing tank leaning on the unlined side and cover the tank with a glass plate. Allow the chromatograms to develop until the solvent front reaches the line across the top of the plate (about $2^1/_2$ hr). Air dry the plates in a fume hood.

Spray the plate with the freshly prepared diazotized sulfanilamide solution (15). Dry the plate in a current of air for 5 min. and then spray with half-saturated sodium carbonate solution. The zones containing the amino acids will be visible as pink areas on the chromatogram. Allow the plate to air dry in a fume hood.

Place the plate in a chromatogram viewing cabinet and observe with a long-wave ultraviolet light. The pink areas will appear as dark zones (Fig. 3). Mark the T_3 and T_4 zones with a dissecting needle or other sharp instrument. Scrape the marked T_3 and T_4 zones from the plate and place the cellulose in No. 0 or 00 gelatin capsules. Clean the glass in the scraped zones and the instruments used with small pledgets of cotton and add the cotton to the capsule.

Oxygen Ignition—All glassware used from this point on should be extensively rinsed with the redistilled water. Oxygen ignition is carried out in a Thomas-Ogg oxygen igniter. Ignite the capsules in 1-L. flasks containing 30 ml. of 2% sodium hydroxide solution as the scrubbing solvent, and a small strip of black ignition paper as the igniting point. After the flasks are cooled, invert and shake them for 5 min. Quantitatively transfer the solution to well rinsed 250-ml. conical flasks, collecting a total of about 150 ml. from repeated rinsings. Run a reagent blank starting with the addition of 30 ml. of the sodium hydroxide solution to a 250-ml. conical flask and continuing through the assay.

Assay—Slowly add 5 ml. of the dilute phosphoric acid solution to each flask, then 1 ml. of USP bromine water. Do not reverse this order of addition of reagents; otherwise high and irregular blanks and samples may result. Mix by swirling the flasks gently, and add a few boiling chips. Boil the solutions on a hot plate until all the excess bromine is removed as shown with starch-iodide test paper, and until the solutions are between 75 and 100 ml. Do not let the solutions boil down below 75 ml. Wash down the sides of the flasks with a stream of water and boil for an additional 5 min. Cool the solutions to room temperature and transfer to well-rinsed 125-ml. separator. Extract the solutions with 25 ml. of benzene and discard the benzene. Add a second 25-ml. portion of benzene to each separator and 3 ml. of the freshly prepared 75% solution of potassium iodide. Stopper the separators and shake for 1 min. Allow the layers to separate and collect the benzene layer in benzene-rinsed 50-ml. volumetric flasks. Extract the samples with additional 15-ml. and 9-ml. portions of benzene and add the extracts to the volumetric flasks. Bring

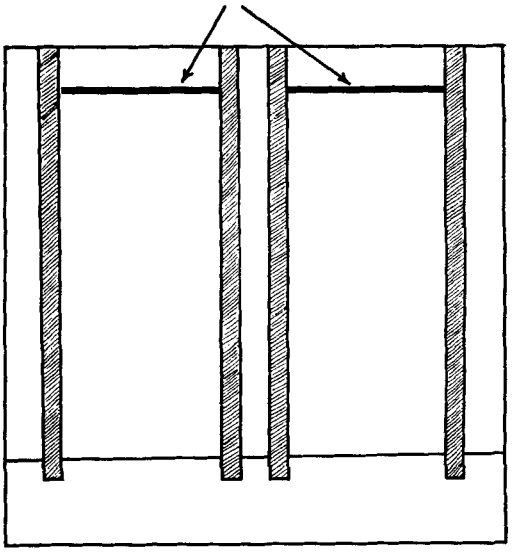

Fig. 2—Diagram of chromatoplate before development. Arrows point to lines of sample application.

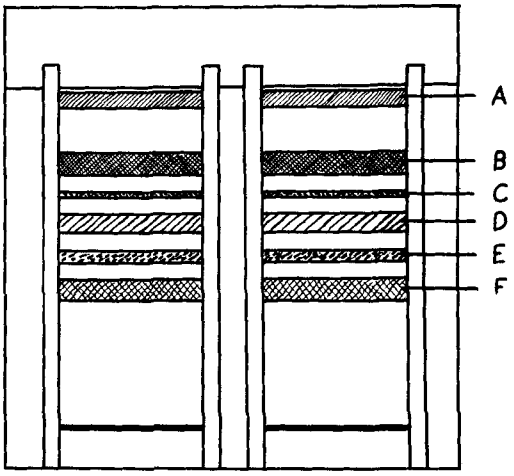

Fig. 3—Diagram of chromatoplate after development. A = solvent front; B = DIT, MIT, T_3; C = iodide; D = T_3; E = T_3-iso; F = T_4.

the solutions to volume with benzene and mix well. Record the absorbance of the benzene solutions at the minimum (400 mμ) and the maximum (295 mμ) in the 10-cm. cylindrical cells with benzene as the reference. Subtract the absorbance at the minimum wavelength from the absorbance at the maximum wavelength. Subtract the difference, if any, in absorbance at the maximum and minimum of the blank from the sample value to give the corrected absorbance. Prepare a standard curve in the same manner for solutions of iodine in benzene of at least 5 different dilutions ranging from about 20 to 100 mcg. in 50 ml. of benzene (Fig. 4).

Calculations—Determine the mcg. of iodine in the 50-ml. benzene solutions from the standard curve, using the corrected absorbances of the sample solutions.

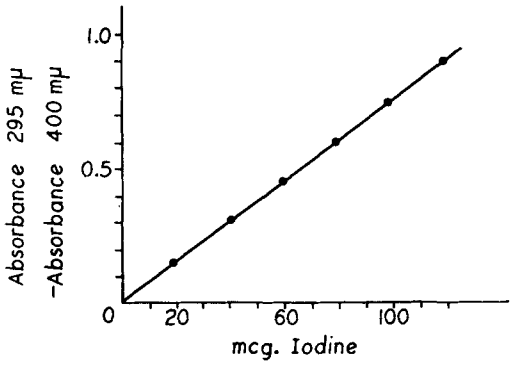

Fig. 4—Standard curve of iodine in 50 ml. benzene.

$$\%\ T_3 \text{ in sample} = \frac{(\text{mcg. of I})\ (1.425)\ (100)}{\text{wt. of sample in mcg.}}$$

$$\%\ T_4 \text{ in sample} = \frac{(\text{mcg. of I})\ (1.275)\ (100)}{\text{wt. of sample in mcg.}}$$

The factors (1.425 and 1.275) in the calculation equations are derived from the percentages of iodine in T_3 and T_4, respectively, as given below. The full equation without using factors is:

$$\%\ T_3 \text{ in sample} = (\text{mcg. of I from std. curve}) \times \frac{(5)}{(6)} \times \frac{(100)}{(58.48)} \times \frac{(100)}{(\text{wt. of sample in mcg.})}$$

where: (5) = multiplication factor due to the use of 200 μl. from 1 ml. of solution for spotting plates;

(6) = oxidation of iodide to iodate and release of iodine with potassium iodide to give six times the iodine in the original iodide; and

$\frac{(100)}{(58.48)}$ = percent factor for iodine in T_3.

$$\frac{(5)}{(6)} \times \frac{(100)}{(58.48)} = 1.425$$

Similarly for T_4: $\frac{(100)}{(65.34)}$ = percent factor for iodine in T_4.

$$\frac{(5)}{(6)} \times \frac{(100)}{(65.34)} = 1.275$$

RESULTS

Table I shows the T_3 and T_4 content of several commercial thyroid powders and tablets as determined by this method. Some of the powders were marketed as USP thyroid and some as triple strength thyroid. The tablets were all labeled as 1-grain USP thyroid tablets.

The total iodine content in thyroid combination agreed with the labeling as to USP and triple strength for all samples tested. Sample A is a USP thyroid powder that was used as the standard.

In Table II, the chemical potency and biological activity are set at 100% for the standard and the other results are compared to it. Assuming T_3 to have five times the antigoitrogenic activity of T_4, a chemical potency was derived for each sample, using the formula $5 \times (\%\ T_3) + \%\ T_4$. These figures were compared with the one calculated for sample A, the standard, to obtain the percent chemical potency. A preliminary biological assay showed that samples B, G, I, J, and K have less activity than the standard. Samples C, D, and F show greater activity. The biological activity was not determined for samples E and H. Sample E is an undiluted porcine thyroid powder purchased directly from the manufacturer. The total organically bound iodine content of this sample is 3.7 times that of the standard sample and the percent chemical potency found is 3.6 times that of the standard. Sample H is a 1-grain tablet from the same manufacturer as sample E and the total organically bound iodine and the chemical potency are, respectively, 1.10 and 1.07 times the corresponding figures for the standard.

Table II shows that the chemical potency gives a good indication of the physiological activity of the samples tested. The biological potency figures are based on a single determination.

A representative sampling of several brands of thyroid tablets was collected from various areas of the United States and the tablets were assayed by this procedure. The results are compared to our standard thyroid powder and are shown in Table III.

The accuracy of the assay procedure was checked with National Bureau of Standards 2-iodobenzoic acid. Recovery results starting with the oxygen ignition step were 101.5% and 99.96%. Recovery results starting with spotting 200 μl. of a 2-iodobenzoic acid solution on a cellulose plate and scraping the area of application from the plate were 101.1% and 100.7%.

DISCUSSION

Sample Preparation—The ground tablets are prewashed with water to remove water-soluble tablet ingredients, especially lactose. Lactose, which is present in many tablets, caramelizes during the alkaline hydrolysis, and the resulting dark color obscures the chromatogram. The use of a second wash with chloroform-methanol (1:1) as reported by Lemieux and Talmage (11) was investigated but resulted in considerably lower recoveries of T_3 and T_4.

Hydrolysis—The pronase hydrolysis was an improvement over the earlier reported trypsin-erepsin treatment (13), because a better yield of T_3 and T_4 was obtained and the time required for hydrolysis was considerably reduced. In general, more T_4 was released by the 50% barium hydroxide solution than by pronase, while the quantity of T_3 released was about equal for both procedures. Some samples of thyroid powder yielded very little T_3 or T_4 with pronase hydrolysis, but gave a good yield of these compounds when hydrolyzed with 50% barium hydroxide. Hydrolysis with an 8% solution of $Ba(OH)_2 \cdot 8H_2O$ for 6 hr. was attempted but was less complete and the extracts gave diffused and dirty chromatograms.

Chromatography—Roche *et al.* (17) reported that the 3,3′,5′ isomer of T_3 is a normal constituent of thyroid protein. The majority of systems used in the separation of the components of thyroid digests disregard this isomer. As shown in Fig. 2, this compound is located between T_3 and T_4 on the chromatogram developed by our procedure. T_3, T_3-iso, and T_4 were chromatographed by some paper chromatographic procedures. With formic acid and water (1:5) as the developing solvent, the T_3-iso accompanies the T_3, while with 6 *N* ammonium hydroxide and tertiary amyl alcohol, the T_3-iso accompanies the T_4.

Roche *et al.* (8) compared the antigoitrogenic activity of some of the iodothyronines in propylthiouracil-treated rats to that of thyroxine. DL-3,3′,5′-Triiodothyronine (T_3) was 5–10 times as active as DL-thyroxine and the 3,3′,5′-triiodothyronine (T_3-iso) was only about 5% as active as DL-thyroxine. The extremely low activity of the T_3-iso makes it imperative that this compound be separated from T_3 and T_4 before quantitation.

The cellulose must be removed from the plate on

both sides of the sample line if horizontal zones and good resolution of the components are to be obtained. Without this treatment, the solvent front curves around the ends of the sample line and produces a cone-shaped chromatogram because the developing solvent moves up the plate faster in areas where there is no sample. The plates must be dried thoroughly before spraying to dispel as much formic acid as possible. The color development will occur only when the plate is made basic, and if too much Na_2CO_3 is needed to neutralize the formic acid, some of the color formed is obscured by a coating of sodium carbonate.

Quantitation of T_3 and T_4—The oxygen-ignition procedure has proved to be a direct and accurate method for quantitatively transforming organic iodine to inorganic iodide for subsequent assay. The oxidation of iodide to iodate with bromine does not require the addition of other chemicals to remove excess oxidant as is necessary when potassium permanganate is used.

Some very important precautions must be observed in the procedural operations. The iodide solutions must always be acidified before the bromine is added. If the bromine is added to the alkaline solution, hypobromites, bromates, *etc.*, may be formed (18). High and irregular blanks and samples result from the liberation of iodine if residual amounts of these bromine compounds are present. When the bromine is added to the acidified solutions, these compounds are not formed.

The data in Table II show that the samples marketed as USP all have the necessary amount of iodine in thyroid combination to meet the official requirements. The triple strength samples have a proportional amount of iodine. Many of these samples, though passing the official assay, do not have a corresponding physiological activity. The chemical potency determined for these samples follows the same pattern as the biological activity. The authors believe that this chemical assay procedure can be used to establish standards for ranges of T_3 and T_4 content and ratios of these two compounds that will be meaningful in expressing relative biological activity.

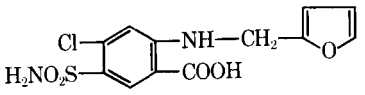
Qualitative and Quantitative Tests for Furosemide

By E. F. SALIM*, A. HAUSSLER†, and J. B. VAUGHAN‡

Provisional, unofficial monographs are developed by the Drug Standards Laboratory, in cooperation with the manufacturers of the drug concerned, for publication in the *Journal of Pharmaceutical Sciences*. The ready availability of this information affords discriminating medical and pharmaceutical practitioners with an added basis for confidence in the quality of new drug products generally, and of those covered by the monographs particularly. Such monographs will appear on drugs representing new chemical entities for which suitable identity tests and assay procedures are not available in the published literature. The purity and assay limits reported for the drugs and their dosage forms are based on observations made on samples representative of commercial production and are considered to be reasonable within expected analytical and manufacturing variation.

4-CHLORO - *N* - FURFURYL - 5 -SULFAMOYLANTHRANILIC ACID; $C_{12}H_{11}ClN_2O_5S$; mol. wt. 330.75. The structural formula of furosemide may be represented as:



Physical Properties—Furosemide occurs as a white to slightly yellow crystalline, odorless powder. It is practically insoluble in water, sparingly soluble in alcohol, soluble in methanol, very slightly soluble in chloroform, and slightly soluble in ether. It is freely soluble in acetone, in dimethylformamide, and in solutions of alkali hydroxides.

Identity Tests—Dissolve about 5 mg. of furosemide in 10 ml. of methanol. Transfer 1 ml. to a flask, add 10 ml. of 2 *N* hydrochloric acid, and reflux for 15 min. on a steam bath. Cool, add 15 ml. of sodium hydroxide T. S. and 5 ml. of sodium nitrite solution (1 in 1000). Allow the mixture to stand 3 min., add 5 ml. of ammonium sulfamate solution (1 in 200), mix well, and add 5 ml. of *N*-(1-naphthyl)-ethylenediamine dihydrochloride solution (1 in 1000): a red to red-violet color is produced.

A 1 in 200,000 solution of furosemide in methanol exhibits ultraviolet absorbance maxima at about 234 mμ, 274 mμ [absorptivity (*a*) about 66], and 338 mμ and absorbance minima at about 247 and 293 mμ. The spectrum is shown in Fig. 1.

The infrared spectrum of a 0.5% dispersion of furosemide in potassium bromide, in a disk of about 0.82 mm. thickness, is shown in Fig. 2.

Purity Tests—Dry about 1 Gm. of furosemide, accurately weighed, at 105° for 3 hr.: it loses not more than 1% of its weight.

Char about 1 Gm. of furosemide, accurately weighed, in a tared crucible, cool the residue, add 1 ml. of sulfuric acid, heat cautiously until evolution of sulfur trioxide ceases, ignite, cool, and weigh: the residue does not exceed 0.1%.

Determine the heavy metals content of furosemide by the USP heavy metals test, method II: the heavy metals limit for furosemide is 20 p.p.m.

Assay—Transfer about 600 mg. of furosemide, accurately weighed, to a 125-ml. conical flask, and dissolve in 50 ml. of methanol. Add 3 drops of bromothymol blue T. S. and titrate with 0.1 *N* sodium hydroxide to a blue end point. Perform a blank determination, and make any necessary correction. Each milliliter of 0.1 *N* sodium hydroxide is

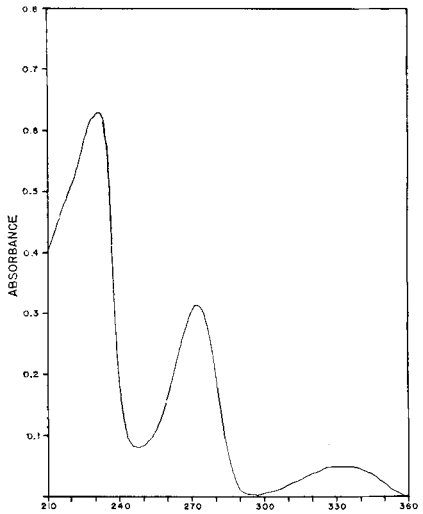


Fig 1—Ultraviolet absorption spectrum of furosemide in methanol (5 mcg./ml.); Beckman model DK-2A spectrophotometer.

Received September 26, 1967, from the *Drug Standards Laboratory (cosponsored by the American Medical Association, American Pharmaceutical Association, and United States Pharmacopeia Convention), of the APhA Foundation, Washington, DC 20037

Accepted for publication December 1, 1967.

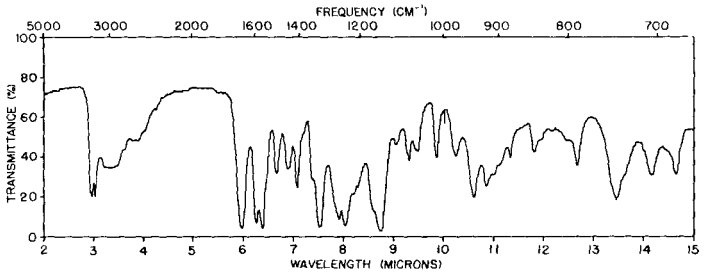

Fig 2—Infrared spectrum of furosemide in potassium bromide disk (0.5%); Perkin-Elmer model 21 spectrophotometer, sodium chloride prism.

equivalent to 33.07 mg. of $C_{12}H_{11}ClN_2O_5S$. The amount of furosemide found is not less than 98% and not more than 101% of the weight of the sample taken.

DOSAGE FORMS OF FUROSEMIDE

Furosemide Tablets—Identity Test—The final solution prepared from the tablet sample in the *Assay* exhibits ultraviolet absorbance maxima and minima at the same wavelengths as the furosemide standard solution.

Assay—Weigh and finely powder not less than 20 furosemide tablets. Weigh accurately a portion of the powder, equivalent to about 200 mg. of furosemide, and transfer to a 100-ml. volumetric flask. Add about 50 ml. of 0.1 *N* sodium hydroxide and shake mechanically for 1 hr. Dilute to volume with the alkaline solution, and mix. Filter the solution, discarding the first portion of filtrate, and transfer 10.0 ml. into a small separator. Add 1 ml. of diluted hydrochloric acid and extract with four 25-ml. portions of a mixture of chloroform–acetone (4:1), filtering each portion through chloroform-washed paper into a suitable beaker. Evaporate the combined extracts on a steam bath in a current of air to dryness. Transfer the residue quantitatively with the aid of about 100 ml. of methanol to a 200-ml. volumetric flask, dilute to volume with methanol, and mix. Dilute 10.0 ml. of this solution to 200.0 ml. with methanol, and mix. Concomitantly determine the absorbance of this solution and of a standard solution of furosemide, in the same medium at a concentration of about 5 mcg./ml., in 1-cm. cells, at the maximum at about 274 mμ, with a suitable spectrophotometer, using methanol as the blank. Calculate the quantity, in milligrams, of $C_{12}H_{11}ClN_2O_5S$ in the portion of tablets taken by the formula $40\ C \times (A_U/A_S)$, in which C is the exact concentration of the standard solution, in mcg./ml., A_U is the absorbance of the sample solution, and A_S is the absorbance of the furosemide standard solution. The amount of furosemide found is not less than 90% and not more than 110% of the labeled amount.

DISCUSSION

USP and NF terminology for solubility, melting range, reagents, *etc.*, has been used wherever feasible

Furosemide[1] is an oral diuretic agent which is useful in the treatment of edema associated with congestive heart failure, cirrhosis of the liver, and renal disease, including the nephrotic syndrome. Chemically, it is distinct from organomercurials, thiazides, and other heterocyclic compounds employed as diuretics.

Identity Tests—Furosemide has been observed to melt between 205° and 207° [lit. (1) m.p. 206°] with decomposition (USP class Ia). Acid hydrolysis of furosemide yields a primary aromatic amine which is diazotized and coupled with Bratton-Marshall reagent to produce a red to red-violet color. This reaction which has been included as an identification test for furosemide has been reported by Hajdu and Haussler as a quantitative determination of the compound (2).

Quantitative Methods—Titration of furosemide with sodium hydroxide using bromothymol blue T.S. gave an average value of 100.1 ± 0.4%.[2] This determination involves neutralization of the carboxylic acid group in the molecule. A solution of furosemide in ethylenediamine titrated with 0.1 *N* sodium methoxide using azo violet indicator exhibits two acidic groups, the carboxylic acid and an acidic hydrogen. The latter is too weak an acid to titrate in aqueous solution but the acidity is promoted in a strongly basic nonaqueous medium so that titration is routine.

Analysis of commercial furosemide tablets (40 mg.) by the spectrophotometric method gave an average value of 99.2 ± 1.0%[2] of the labeled amount of furosemide. The fluorescence of furosemide in 0.01 *N* hydrochloric acid has been utilized as the basis of quantitative measurement by Hajdu and Haussler (2). Concentrations of 0.03–0.5 mcg./ml. of furosemide can be determined at the wavelength of maximum fluorescence at 410 mμ.

Separation and Determination of Polymyxin B in Formulations

By EUGENE IVASHKIV

A method for the separation and the determination of polymyxin B in formulations is described. It is based on the absorption of the antibiotic on a cation-exchange resin with subsequent elution with methanol–aqueous sodium chloride solution and the reaction of polypeptide with ninhydrin.

NUMEROUS microbiological methods (1, 2, 6–9) have been described for the determination of polymyxin B but little work has been carried out on the chemical assay of the antibiotic. In the fractionation of polymyxins, a spectrophotometric measurement at 259 mμ has been used (4). A gravimetric method has been described for the determination of polymyxin B by precipitation as phosphotungstate (3). The biuret reaction has been suggested for the determination of polymyxin in fermentation broths (5).

In formulations, in addition to polymyxin B, there frequently are substances present which interfere in a spectrophotometric or colorimetric determination of polypeptides. In these cases, it is essential to separate polymyxin B from impurities and other ingredients of a protein character. The proposed method is based on the separation of polymyxin B by means of a cation-exchange resin and the determination of the antibiotic with the ninhydrin reagent.

EXPERIMENTAL

Method

Reagents and Equipment—*Amberlite IRC-50 resin*, pH 7.0, sodium form; *methanolic aqueous sodium chloride solution*, 10% sodium chloride (10 Gm.) is dissolved in methanol–water (1:1); *Polymyxin B standard solution*, polymyxin B equivalent to about 100,000 units is dissolved in 25 ml. water; *Sodium acetate buffer*, pH 5.5 sodium acetate trihydrate (680 Gm.) is dissolved in 0.5 L. of distilled water and to the cooled solution 125 ml. of glacial acetic acid is added. The volume is made up to 1 L. with water. The reagent is stored at 5°; *Ninhydrin reagent*, ninhydrin (0.2 Gm.) and 25 mg. of hydrindantin are dissolved in 12 ml. of methyl cellosolve. Sodium acetate buffer 5.5 (2.5 ml.) is added and the reagent is stored in a low actinic flask. The reagent is prepared daily; *Chromaflex column*, size A-3, made by Kontes, catalog No. K-42082.

Procedure—A sample equivalent to 100,000 units of polymyxin B is weighed in a 100-ml. beaker. About 15 ml. of water is added and the solution is mixed. The solution is filtered through a sintered-glass filter of medium porosity having a diatomaceous earth[1] precoat of a 1/8 in. thickness. The beaker and filter are washed with 10 ml. of water and the wash is combined with the sample. Two columns are packed with wet IRC-50 resin until a height of 12.7 cm. is obtained. Water is withdrawn from the columns to about 0.6 cm. above the resin and the standard and sample solutions are transferred quantitatively to the corresponding columns. The flow of the effluent is regulated to 1 ml./min. After all of the solutions have been passed through the columns, the resin beds are washed with 100 ml. water at the rate of 5 ml./min. Polymyxin B is eluted with methanolic aqueous sodium chloride solution at the rate of 1 ml./min. until 100 ml. of the eluate is obtained.

Some samples may require the following purification: samples and standard solutions (25 ml.) are transferred to suitable flasks and methanol is evaporated *in vacuo* at about 5 mm. Hg and 60°. The remaining aqueous solutions are transferred quantitatively to separators and polymyxin B is extracted with 15 ml. and 2 × 5 ml. of butanol. One milliliter of butanol solution is taken for the ninhydrin reaction.

One milliliter of methanolic sodium chloride solution or 1 ml. of butanol solution (blank), 1 ml. of sample, and 1 ml. of standard eluates are transferred to 17.9 cm. test tubes. To each tube, 1 ml. of ninhydrin reagent is added and the tubes are incubated in a boiling water bath for exactly 15 min. To each tube 15 ml. of ethanol–water (1:1) is added and the solutions are mixed. The absorbance is measured at 570 mμ on a spectrophotometer using 1-cm. cells against the reagent blank.

The polymyxin B content is calculated as follows:

$$\frac{A \times C \times P \times S}{B \times D} = \text{polymyxin B, units/ml.}$$

where:

A = absorbance of sample
B = absorbance of standard
C = weight of standard, mg.
D = weight of sample, Gm.
P = potency of standard, units/mg.
S = specific gravity

DISCUSSION AND RESULTS

In formulations, in addition to polymyxin, other various organic and inorganic substances are usually present. For the quantitative determination of

2	4780	4890

polymyxin, it is essential to separate the antibiotic from impurities, especially from those of a proteinaceous nature. In this study, an experimental formulation consisting of neomycin, amphotericin B, polymyxin B, ethylenediamine, and other ingredients was assayed. No chemical methods for the determination of polymyxin B in the presence of neomycin and other amines have been found in the literature. Methods used in the isolation and the purification of polymyxin on a preparative or commercial scale have not been previously applied to analytical procedures.

Polymyxin B and neomycin are adsorbed on cation-exchange resin and their separation by means of ion exchange techniques was investigated. Various solvents were investigated for their efficiency in the elution of polymyxin from the resin. Aqueous hydrochloric acid solutions elute about 80% of the polymyxin, but also about 80% of the neomycin. With methanolic solution of hydrochloric acid, 100% elution of polymyxin and 85% of neomycin is obtained. With ammonium hydroxide only 60% of the polymyxin is eluted and 100% of the neomycin. With the 10% methanol aqueous sodium chloride solution, polymyxin B can be eluted quantitatively from a column while neomycin remains on the resin. With 5% methanol aqueous sodium chloride, only 40% of the polymyxin was eluted.

In the separation of polymyxin B and neomycin in an experimental suspension formulation stored at room temperature for 2 years, an incomplete purification of the polymyxin was obtained. A further purification was attained by the extraction of polymyxin from aqueous solutions with butanol.

Only a limited study has been carried out on the correlation of the proposed chemical assay and the standard microbiological assay. The results of this correlation are shown in Table I.

The correlation of the chemical method with the biological assay was studied by the degradation of polymyxin B in 0.1 *N* NaOH and 0.5 *N* NaOH at room temperature (25°). The samples were withdrawn periodically over 96 hr. and assayed by both the chemical and microbiological methods. About 50% of polymyxin B was degraded in 0.1 *N* NaOH in 24 hr. No further degradation was observed over the period of 72 hr. The degradation of polymyxin B in 0.5 *N* NaOH was rapid. After 24 hr. no polymyxin B activity was found by the microbiological method. About 45% polymyxin was found by the chemical method over the period of 72 hr. It appears that the chemical method does not correlate with the microbiological assay when polymyxin B is degraded in 0.5 *N* NaOH.

When a known amount of polymyxin B was added to the formulation samples, an average recovery of 98% was obtained.

This method is useful as a labeling assay of polymyxin in pharmaceutical formulations. The use of this assay as a stability method has not been explored.

Spectrophotometric Determination of Acetaminophen, Phenylephrine Hydrochloride, Codeine Phosphate, and Pyrilamine Maleate in Tablets or Powder

By FABRIZIO DE FABRIZIO

An ultraviolet spectrophotometric method has been developed for the determination of acetaminophen, phenylephrine hydrochloride, codeine phosphate, and pyrilamine maleate after a partial separation of them by means of column chromatography using alginic acid; codeine phosphate and phenylephrine hydrochloride are both eluted with 0.01 *N* HCl and determined simultaneously while acetaminophen and pyrilamine maleate are determined separately.

NO STANDARD ANALYTICAL PROCEDURE exists for acetaminophen, codeine phosphate, phenylephrine hydrochloride, and pyrilamine maleate in this common pharmaceutical combination[1]; however, various assays were reported for each of the components alone or in other combination (1–4). To achieve the separation of the components, the author employed a chromatography technique using alginic acid 40–100 mesh prepared after the process of Foster and Murfin (5). This cation-exchange medium has been used largely to determine many organic bases, to separate codeine phosphate from aspirin and phenacetin in APC tablets B.P. (6), strychnine from nux vomica (7), and to determine thiamine nicotinamide, and pyridoxine in vitamin B complex tablets (8). In this investigation it was found that acetaminophen was not held by the alginic acid used, as was foreseen in a previous theoretical study of the problem, but passed through the prepared column; codeine phosphate and phenylephrine hydrochloride are both eluted with 0.01 *N* HCl and simultaneously determined at two different wavelengths. Finally, pyrilamine maleate is eluted with 0.1 *N* HCl and determined at 316 mμ.

EXPERIMENTAL

Apparatus—Spectrophotometer, Beckman DB, and 1-cm. square fused silica cells were used. Glass column 35 × 2 cm. with stem (5 cm.) was fitted with a buret key.

Reagents—Cation-exchange resin alginic acid, 40–100 mesh, available from British Drug House (B.D.H.): hydrochloric acid 2 *N* in water; 0.1 *N* hydrochloric acid in water; 0.01 *N* hydrochloric acid in water; 0.01 *N* hydrochloric acid in 80% ethanol in water. Except where otherwise specified all reagents were of B.D.H. analar quality.

Received June 2, 1967, from the Control Pharmaceutical Laboratory, Propan Pharmaceutical Ltd., Germiston, South Africa.
Accepted for publication December 19, 1967.
[1] Marketed as Mepacod.

Standard Solutions—The following solutions were prepared with suitable reference standard: (*a*) acetaminophen, 0.75 mg./250 ml. in 0.1 *N* hydrochloric acid in 80% ethanol in water; (*b*) codeine phosphate, 8.1 mg./250 ml. in 0.01 *N* hydrochloric acid in water; (*c*) phenylephrine hydrochloride, 5 mg./250 ml. in 0.01 *N* hydrochloric acid in water, (*d*) codeine phosphate and phenylephrine hydrochloride in a mixture in 0.01 *N* hydrochloric acid in water; (*e*) pyrilamine maleate, 20 mg./250 ml. in 0.1 *N* hydrochloric acid in water.

Column Preparation—Alginic acid, about 4 Gm. is slurried in water and allowed to soak 4 hr. The slurry is poured into a glass column that has been fitted with glass wool plug and allowed to settle. The column is washed with 2 *N* hydrochloric acid until the absorbance of the eluate (pathlength 1 cm.) is less than 0.005 at 250 mμ and 273 mμ, and then washed with distilled water until the eluate is neutral to litmus solution.

Sample Treatment—Powder 20 tablets and weigh an amount of powder equivalent to one tablet. Place this in a 50-ml. volumetric flask, add water to volume, and mix. Allow to stand for 30 min., shaking occasionally, then centrifuge about 40 ml. of solution. Pipet 20 ml. of the clear solution onto the prepared alginic acid column; place a 1-L. volumetric flask under the column and start collecting the eluate at the rate of 1 ml./min. Then add 200 ml. of water and allow to pass through at the same rate. Adjust the rate to 2 ml./min. and pass more water through the column to the 1-L. mark. Remove and shake. This eluate contains the acetaminophen. Bring the layer of the liquid in the column to just above the glass wool pledget. Elute the column with 0.01 *N* HCl at the rate of 2 ml./min. Discard the first 15 ml. of eluate and collect the rest in a 100-ml. volumetric flask to volume. This solution contains codeine phosphate and phenylephrine hydrochloride. Again allow the level of the liquid in the column to drop to just above the glass wool pledget. Elute the column with 0.1 *N* HCl at the rate of 2 ml./min., collecting the eluate in a 250-ml. volumetric flask. This solution contains pyrilamine maleate.

Determination—Following the base-line technique compare the absorbances of the standard solutions passed through the column with those of the samples. Quantitatively adjust the claimed concentrations of the sample eluates as closely as possible to the corre-

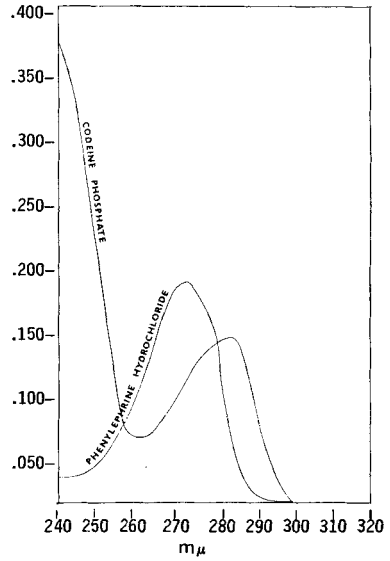

Fig. 1—Spectra of 0.0324 mg./ml. of codeine phosphate and of 0.02 mg./ml. of phenylephrine hydrochloride in 0.01 N HCl.

sponding standard solutions. Calculate the amount of acetaminophen in the sample from the value of the absorptivity of the corresponding standard at 249 mμ. Similarly calculate pyrilamine maleate at 316 mμ and codeine phosphate and phenylephrine hydrochloride at both wavelengths of 250 and 273 mμ.

RESULTS AND DISCUSSION

The first step in the chromatographic procedure was the determination of the "breakthrough" point of each component separately and in a mixture. As previously mentioned, acetaminophen and pyrilamine maleate are separated by the column and their spectrophotometric determination does not present any difficulty. Further study was necessary to choose two different wavelengths where the interferences of codeine phosphate and phenylephrine hydrochloride, contained in the same solution, were as low as possible. In a series of 40 determinations the most favorable system was to be found at the wavelengths of 273 mμ and 250 mμ. However at 250 mμ, the corresponding point lies on the steep part of the curve (see Fig. 1). The error using this wavelength gave a value much lower than the one computed at 248 (the peak), 240, and 245 mμ. The results of 10 determinations of mixtures of codeine phosphate and phenylephrine hydrochloride at 250 and 273 mμ are shown in Table I.

Five mixtures prepared in this laboratory containing acetaminophen, codeine phosphate, phenylephrine hydrochloride, and pyrilamine maleate gave mean values as shown in Table II.

TABLE I—DETERMINATIONS OF MIXTURES OF CODEINE PHOSPHATE AND PHENYLEPHRINE HYDROCHLORIDE

Material	Mean of 10 Determinations, % of Theoretical	S.D. of 10 Determinations, % of Theoretical
Codeine phosphate	98.8	±2.1
Phenylephrine hydrochloride	98.4	±1.0

TABLE II—MEAN VALUES OF FIVE MIXTURES

Material	Taken	Found, % of Amt. Taken
Acetaminophen	150 mg.	99.85
Codeine phosphate	8.1 mg.	98.70
Phenylephrine hydrochloride	5.0 mg.	98.50
Pyrilamine maleate	10.0 mg.	98.97

The total error was about −4 mg. and the mean relative deviation ±2.6%. As can clearly be seen, the proposed method yields results acceptable for routine analysis. In the spectrophotometric determination of pyrilamine maleate, slight differences between the absorbance observed in the standard solution as is and the one passed through the column were taken into account. Finally some water-soluble excipients and dyes, generally used in the manufacture of tablets and powder, pass through the alginic acid column together with acetaminophen; they do not affect the results at 249 mμ as they are in such high dilution.

Quantitative Determination of Diethylstilbestrol by Thin-Layer Chromatography

By LOUIS N. JONES, MURRY SEIDMAN, and B. C. SOUTHWORTH

A thin-layer chromatographic procedure has been developed for the analysis of diethylstilbestrol at the 0.01 percent level in a water-dispersible suppository base. Following a preliminary separation on an alumina column, the diethylstilbestrol is isolated on a silica gel chromatoplate. A color is then produced *via* the Folin-Ciocalteu procedure for phenols and the blue spot evaluated densitometrically directly on the chromatoplate. The standard deviation is 3.4 percent. Effects of variations in the operating parameters are discussed and evidence is presented to indicate that only intact diethylstilbestrol is measured.

WHILE BOTH biological and chemical methods are available for the determination of diethylstilbestrol [3,4-bis(*p*-hydroxyphenol)-3-hexene] in pharmaceutical preparations, no rapid assay procedure for this estrogen in combination with nitrofurazone in a water-dispersible suppository base has been reported. Biological procedures (1) require a minimum of 8 days to complete. Nitrofurazone interferes in the official USP XVII procedure (2) for diethylstilbestrol (DES) suppository, and any modification of this procedure would necessitate extensive purification before the irradiation analysis could be used.

Michels *et al.* (3) were able to separate DES from nitrofurazone and the suppository base in sufficiently pure form so that the Folin-Ciocalteu procedure could be used for its determination. Although the total procedure was fairly time consuming, their preliminary separation was rapid and served to separate the DES from the bulk of the suppository base. Lisboa *et al.* (4) have developed a thin-layer chromatographic classification system for a series of estrogens. After separating the DES from the bulk of the suppository base *via* the above-mentioned preliminary separation, Lisboa's system was found to be adequate for the purification and isolation of the DES. Having isolated the DES in pure form, densitometric determination directly on the chromatoplate was found to be feasible.

Lisboa *et al.* used the Folin-Ciocalteu reagent to visualize DES on a chromatoplate. Their techniques were designed for qualitative purposes so that refinements were necessary before a quantitative determination was possible. The stability of the color produced by the Folin-Ciocalteu reagent is very much dependent on the final pH adjustment. This pH adjustment may be obtained by observation of an indicator (thymolphthalein) color change as a base is sprayed on the plate. Alcoholic potassium hydroxide was chosen as this reagent, the base simply for its solubility characteristics; the alcohol for its volatility. After the pH adjustment has been completed, the alcohol evaporates and the color is "fixed." Attempts to use ammonia vapor (5) were not successful in that a wide background variation was noted in the final densitometric determination.

The recommended procedure calls for a sample size calculated to contain 0.5 mg. of DES. After an initial clean-up this 0.5 mg. is contained in 10 ml. of chloroform. The final determination requires four spots of 2 mcg. each for an accurate determination. The ultimate sensitivity of the procedure is about 0.1 mcg. of DES.

EXPERIMENTAL

Apparatus—Photovolt densitometer model 520 A, equipped with an automatic TLC stage, a Varicord recorder No. 42, and an Integraph integrator No. 49.

Reagents—Potassium hydroxide alcoholic solution, 0.5 *N*, V.S.; thymolphthalein solution, 0.1% in alcohol, T.S.; alcohol, 80%, R.

Developing Solvent—Ethyl acetate R., petroleum ether R., glacial acetic acid R., and alcohol R. (72:13.5:10:4.5, respectively).

Folin-Ciocalteu Reagent—Use the procedure according to Folin (6) or use Harleco item 2690.

Preparation of Standard DES Solution—Transfer exactly 100 mg. of USP reference standard diethylstilbestrol to a 200-ml. volumetric flask, dissolve it, and dilute to the mark with chloroform. Further dilute 10.0 ml. of this solution to 100 ml. with chloroform for use in the assay.

Preparation of Chromatoplates—Slurry together Silica Gel G and distilled water in the ratio of 1:2, apply the slurry uniformly to 20 × 20-cm. glass plates to a thickness of 750 μ and allow the plates to air-dry for 30 min. Activate the plates at 105° for 1 hr. and store under desiccation until used. Immediately before use, check the background of the chromatoplate according to the parameters to be used for the final spot measurement. Any variation should not exceed ±0.05 absorbance units.

Received June 5, 1967, from the Quality Control Department, The Norwich Pharmacal Company, Norwich, NY 13815

Accepted for publication November 30, 1967.

Preparation of Developing Chamber—Line the walls of the developing chamber (30.48 cm. × 10.16 cm. × 27.94 cm.) with filter paper. Add 100 ml. of the developing solvent, close the chamber tightly and allow at least 30 min. for complete saturation of the chamber atmosphere. Prepare this tank fresh daily.

Preparation of Column—Place a glass-wool pledget at the bottom of a 1-cm. i.d. chromatographic column and pack it to a height of 10 cm. with basic alumina. Add the adsorbent in small portions with horizontal tapping and gentle bouncing until no further settling occurs (7). Lot to lot variations in adsorptive capacity of the alumina have been noted. The following test is, therefore, recommended. Dissolve about 10 mg. of nitrofurazone in 100 ml. of dehydrated alcohol. Add 10 ml. of this solution to a prepared column. The nitrofurazone should remain at the top of the column in a narrow yellow band. Elute the band with 80% alcohol in water. The band should follow the solvent front. The characteristics of DES are similar to nitrofurazone under these conditions.

Assay Procedure—Melt and mix suppositories to be assayed and weigh accurately sufficient sample to contain 0.50 mg. of DES. Add 10 ml. of chloroform to the sample, warm gently to dissolve, then transfer with the aid of additional chloroform to the alumina column. Wash the column with 100 ml. of chloroform and discard the $CHCl_3$. Elute the DES from the column with 50 ml. of 80% alcohol collecting the eluate in a 150-ml. beaker. Evaporate the eluate to dryness on a steam bath using a stream of air to aid the evaporation. Dissolve the residue in chloroform, transfer it to a 10-ml. volumetric flask, and dilute to volume with chloroform. To an activated chromatoplate apply alternately 40-μl. spots of the reference standard DES solution and the sample solution. Repeat this operation three times (8 spots total). Transfer the plate to the developing chamber, chromatograph 100 mm., remove, and air-dry for 30 min. At a point in line with the 100-mm. mark, place a spot of thymolphthalein solution near each edge of the plate. Dilute the Folin-Ciocalteu reagent 1 to 4 with distilled water just prior to use and spray the plate evenly with about 5 ml. of the diluted reagent, using the spray procedure described by Stahl (8). In a similar manner, spray the plate with the alcoholic potassium hydroxide solution until the thymolphthalein spot remains a permanent blue color. The DES will be visualized as a blue spot (R_f approximately 0.9). Measure the density of the DES in the reference standard and the sample spots with the densitometer. Determine the areas under the recorded curves from the integrator pen traces. The following instrument parameters were used for the Photovolt densitometer: range setting 3; recorder response 4; 610 mμ filter (Photovolt No. 5408), and slit width, 1 × 7 mm.

Calculation—

$$\frac{\Sigma \text{ area of sample spots}}{\Sigma \text{ area of standard spots}} \times \frac{0.05}{\text{sample wt. (Gm.)}} = \% \text{ DES.}$$

RESULTS

Linearity of Results—Chloroform solutions containing 0.5, 1.0, 1.5, 2.0, and 2.5 mcg. of DES per 40 μl. of solution were prepared and treated according to *Experimental* starting at the thin-layer chromatographic step. Results are given in Table I.

TABLE I—LINEARITY OF SPOT DENSITY *Versus* CONCENTRATION

Plate	Regression Line	Correlation Coefficient (γ)	Standard Deviation (σ)
1	$y = 1.7 + 49.4x$	0.9990	1.7
2	$y = -0.3 + 41.0x$	0.9995	1.0
3	$y = -2.5 + 45.8x$	0.9997	0.8

The result of a given plate is given in the form $y = a + bx$ where y is the area of a spot in terms of integrator count, a is the y intercept, b is the slope of the line, and x is the quantity of DES in a spot. The remainder of the table is self-explanatory.

Recovery of Standard DES—To test the reproducibility of the above procedure, portions of standard DES equivalent to what would normally be found in a medicated suppository were treated as indicated in *Experimental*. Results are given in Table II.

The average areas of the sample spots and of the standard spots are given in columns $\bar{X}$ and $\bar{Y}$, respectively, as integrator counts. The average recovery was 98.4% with a standard deviation of 3.5%.

The statistical treatment is as follows: the area figures used in the calculations for the sample spots and for the standard spots are each an average of four essentially independent observations. The variance of an average result is:

$$\text{Var}\{\bar{X}\} = \sigma^2/n$$

or

$$\bar{\sigma}^2 = \frac{1}{n^2(n-1)}[n\Sigma X^2 - (\Sigma X)^2]$$

The value of σ^2 is then converted to a percentage coefficient of variance:

$$V^2 = (\sigma^2)\left[\frac{100}{\bar{X}}\right]^2$$

The variance for the result is:

$$V_T^2 = V_{\bar{X}}^2 + V_{\bar{Y}}^2$$

and the standard deviation is the square root of the variance.

Recovery of DES from a Suppository Mixture—A mixture of 0.3% nitrofurazone and 0.0125% DES in a water-dispersible base of glyceryl monolaurate and sorethytan (4) monostearate was prepared to simulate a commercial vaginal suppository.[1] Portions of the mixture were treated as indicated in *Experimental*.

Results are given in Table III. Data are treated as indicated above. The average recovery was 98.7% with a standard deviation of 3.4%.

Another suppository mixture[2] containing 0.2% nitrofurazone, 2% diperodon hydrochloride, and

1	0.1	0	0.098	98
1	0.25	0	0.25	100
2	0.1	0	0.093	93
2	0.5	0	0.47	94
3	0.1	0	0.075	75
3	0.1	0.1	0.177	177

0.0077% DES in the above base was also studied. The diperodon hydrochloride was eluted in the preliminary chloroform wash and discarded. Otherwise, results were comparable to the above results.

Assay of Commercial Suppositories for DES—The DES present in five different dosage forms (commercially available units) from three different manufacturers was determined by the above procedure. Results are given in Table IV. The validity of the low recovery of DES from manufacturer 3 was confirmed by the addition of a known amount of DES. As an additional check, the insoluble portion of suppository base was extracted with chloroform *via* the Soxhlet procedure for 4 hr. No additional DES was found.

DISCUSSION

Effects of Variations in Column Parameters—It was ascertained (the alumina meeting the above criterion) that 75 ml. of chloroform was sufficient to elute interfering substances from the column. As much as 200 ml. of chloroform can be passed through the column without eluting any DES. The DES can be quantitatively eluted with 20 ml. of 80% alcohol. The DES can be satisfactorily eluted with 75–90% alcohol. Alcohol concentration of less than 70% or more than 95% is unsatisfactory for the elution. The column can handle a threefold increase in sample size without overloading.

Effects of Variations in the TLC Procedure—Using good technique, the only problem area in the TLC procedure is the spray pattern. A uniform spray must be laid down on the plate. The volume of the Folin-Ciocalteu reagent must be held to between 4 and 6 ml. The alkaline spray must also be uniform and close attention must be given to the indicator color change. The spots produced are then stable for about 4 hr.

Intact DES—In order to determine that the DES was not degraded by the assay procedure, DES was eluted from the plate and an infrared spectrum recorded. The spectrum compared favorably with that of standard DES.

Portions of a suppository mass were exposed to ultraviolet radiation from a germicidal lamp. The apparent decomposition approximated a first-order degradation. At 15 cm. from a 17-w. lamp 30% of the DES was decomposed in 10 min. The ketonic product formed was found to have an R_f of 0.7 and did not undergo the Folin-Ciocalteu reaction.

Similar Phenolic Compounds—Compounds with structures similar to DES can also be determined by the above procedure. Dienestrol, hexestrol, and 4,4′-dihydroxystilben will behave the same as DES. If present in admixture an additional separation would be necessary before the determination.

Common suppository base materials such as polyethylene glycol or theobroma oil do not interfere with the above procedure.

CONCLUSION

This method is sufficiently rapid for use as a routine quality control procedure and necessary technical skills can be readily learned. The high degree of selectivity demonstrated also indicates that the method is useful for a stability program. A further use of the method might be as a referee method or as an official procedure for the determination of diethylstilbestrol.

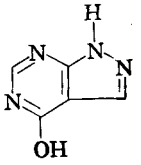
Qualitative and Quantitative Tests for Allopurinol

By EDWARD F. SALIM* and JAMES E. MURPHY†

Provisional, unofficial monographs are developed by the Drug Standards Laboratory, in cooperation with the manufacturers of the drug concerned, for publication in the *Journal of Pharmaceutical Sciences*. The ready availability of this information affords discriminating medical and pharmaceutical practitioners with an added basis for confidence in the quality of new drug products generally, and of those covered by the monographs particularly. Such monographs will appear on drugs representing new chemical entities for which suitable identity tests and assay procedures are not available in the published literature. The purity and assay limits reported for the drugs and their dosage forms are based on observations made on samples representative of commercial production and are considered to be reasonable within expected analytical and manufacturing variation.

1H-PYRAZOLO [3,4-*d*]-pyrimidin-4-ol; $C_5H_4N_4O$; mol. wt. 136.11. The structural formula of allopurinol may be represented as



Physical Properties—Allopurinol occurs as a white to off-white, practically odorless powder and melts above 300°. It is very slightly soluble in water and in alcohol, and practically insoluble in chloroform and in ether. It is soluble in dimethylformamide and in dilute solutions of alkali hydroxides.

Identity Tests—A 1 in 100,000 solution of allopurinol in 0.1 *N* hydrochloric acid exhibits an ultraviolet absorbance maximum at about 250 mμ [absorptivity (*a*) about 56] and a minimum at about 231 mμ. The spectrum is shown in Fig. 1.

The infrared spectrum of a 0.3% dispersion of allopurinol in potassium bromide, in a disk of about 0.82 mm. thickness, is shown in Fig. 2.

Purity Tests—Dry about 1 Gm. of allopurinol, accurately weighed, in vacuum at 105° for 5 hr.: it loses not more than 1% of its weight.

Dissolve about 10 mg. of allopurinol in 1 ml. of 0.1 *N* sodium hydroxide. Arrange for ascending

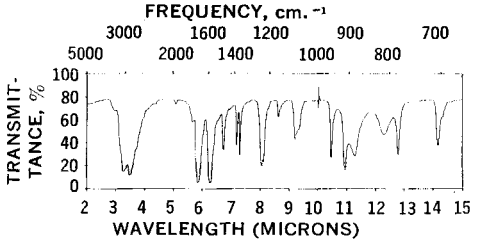

Fig. 2—Infrared spectrum of allopurinol potassium bromide disk (0.3%); Perkin-Elmer model 21 spectrophotometer, sodium chloride prism.

paper chromatography using a strip of paper (Whatman No. 1 filter paper) about 40 cm. in length. Spot 0.005 ml. on the starting line of the chromatographic paper, and suspend the paper in a chromatographic chamber equilibrated with a mobile solvent consisting of ammonium sulfate solution (1 in 20)-isopropanol (95:5). Proceed with the chromatography until the solvent front has advanced about 25 cm., remove the paper, dry, and examine under ultraviolet light: only one spot is visible in the chromatogram.

Assay—Transfer about 300 mg. of allopurinol, accurately weighed, to a 125-ml. conical flask, and dissolve in 60 ml. of dimethylformamide. Add 5 drops of thymol blue T. S., and titrate with 0.1 *N* sodium methoxide, using a magnetic stirrer and taking precautions against absorption of atmospheric carbon dioxide. Perform a blank determination, and make any necessary correction. Each milliliter of 0.1 *N* sodium methoxide is equivalent to 13.61 mg. of $C_5H_4N_4O$. The amount of allopurinol found is not less than 97% and not more than 102%, calculated on the dried basis.

DOSAGE FORMS OF ALLOPURINOL

Allopurinol Tablets—Identity Test—The final solution prepared from the tablet sample in the *Assay* exhibits an ultraviolet maximum and minimum at the same wavelengths as the allopurinol standard solution.

Assay—Weigh and finely powder not less than 20 allopurinol tablets. Weigh accurately a portion of the powder, equivalent to about 100 mg. of allopurinol, and transfer to a 100-ml. volumetric flask. Add 10 ml. of 0.1 *N* sodium hydroxide, shake for about 5 min., dilute to volume with 0.1 *N* hydrochloric acid, and mix. Filter the solution, discarding the first portion of filtrate, and dilute a portion of the clear filtrate quantitatively and stepwise with 0.1 *N* hydrochloric acid to obtain a solution having a concentration of the equivalent of 10 mcg. of allopurinol/ml. Concomitantly determine the absorbance of the final solution and of a standard solution of allopurinol, in the same medium, at a concentration of about 10 mcg./ml., in 1-cm. cells, at the maximum at about 250 mμ, with a suitable spectrophotometer, using 0.1 *N* hydrochloric acid as the blank. Calculate the quantity, in milligrams, of $C_5H_4N_4O$ in the portion of tablets taken by the formula $10\ C \times (A_u/A_s)$, in which C is the exact concentration of the standard solution, in mcg./ml., A_u is the absorbance of the sample solution, and A_s is the absorbance of the allopurinol standard solution. The amount of allopurinol found is not less than 93% and not more than 107% of the labeled amount.

DISCUSSION

USP and NF terminology for solubility, melting range, reagents, *etc.*, has been used wherever feasible.

Allopurinol[1] is an oral uricosuric agent effective in the treatment of hyperuricemia associated with gout and other conditions. Its action differs from that of other uricosuric agents which lower the serum uric acid level by increasing urinary excretion of uric acid. Allopurinol reduces both the serum and urinary uric acid levels by blocking the formation of uric acid.

Identity Tests—An additional identification test for allopurinol is obtained by comparing absorbances of the hydrochloric acid solution at 231 mμ (minimum) and at 250 mμ (maximum). The ratio A_{231}/A_{250} is between 0.5 and 0.62. A ratio of 0.57 was calculated from absorbance data in the ultraviolet absorption identification of allopurinol tablets. A 1 in 100,000 solution of allopurinol in pH 11 buffer solution exhibits an ultraviolet absorbance maximum at about 262 mμ and a minimum at about 235 mμ.

Quantitative Methods—Nonaqueous titration of allopurinol with sodium methoxide using thymol blue T.S. gave an average value of 98.5 ± 0.4%.[2] Spectrophotometric analysis of commercial allopurinol tablets (100 mg.) gave an average value of 100.3 ± 0.6%[2] of the labeled amount.

[1] Marketed as Zyloprim by Burroughs Wellcome & Co., Inc., Tuckahoe, N. Y.

Determination of DMSO in Solutions and Ointments by NMR

By T. C. KRAM and J. W. TURCZAN

An NMR method for the determination of DMSO in ointments and solutions is presented, using methanol as an internal standard. Samples containing from 20 to 0.05 percent (v/v) DMSO were successfully analyzed with this technique.

DIMETHYL SULFOXIDE (DMSO) is readily analyzed by NMR because it produces a single absorption peak of relatively great intensity and is miscible with a wide variety of solvents. NMR spectroscopy has been used to determine DMSO in a mixture with glycerol and water by measuring total hydrogen in the sample and in that fraction due to DMSO (1). This report discusses the determination of DMSO in solutions and ointments with methanol as an internal standard.

Although volatile liquids are not generally recommended as internal standards, methanol was found to be useful because of the chemical shift of its methyl peak, its low equivalent weight, and its wide miscibility range. Its use simplifies sample preparation and calculation of results for a series of determinations.

Sample and standard were mixed with suitable solvent, NMR spectra were obtained, and the amount of DMSO in the sample was calculated from the integration of the sample and standard peaks of interest (2–4).

Serial dilutions of a mixture of DMSO standard and methanol were similarly analyzed. The use of peak heights (5) as a means of estimation was investigated for solutions too dilute to produce integral presentations of any reasonable reproducibility.

PROCEDURE

Sample Preparation—Liquid—Pipet sample equivalent to 4–5 ml. of DMSO into a 50-ml. glass-stoppered conical flask. If the sample is too viscous to be pipeted accurately, accurately weigh a portion, determine the density of the material, and calculate the volume of the weighed portion ($V = W/d$). Add 5.0 ml. of methanol. Dilute with 10 ml. of water, stopper, and mix thoroughly.

Semi-Solid—Weigh sample equivalent to 4–5 Gm. of DMSO into a 50-ml. glass-stoppered conical flask, add 5.0 ml. of methanol and 15 ml. of water stopper, and mix thoroughly. If material is not soluble in water, use chloroform as diluent.

Received October 5, 1967, from Food and Drug Administration, 850 Third Avenue, Brooklyn, NY 11232
Accepted for publication December 19, 1967.

Transfer approximately 0.4 ml. of solution to an analytical NMR tube. Prepare an NMR spectrum on the Varian A-60, adjusting settings for optimum integration. Each sample is integrated 10 times.

Calculations:

$$\% \text{ DMSO in sample (v/v)} = \frac{A \text{ DMSO}}{A \text{ CH}_3\text{OH}} \times \frac{E \text{ DMSO}}{E \text{ CH}_3\text{OH}} \times \frac{d \text{ CH}_3\text{OH}}{d \text{ DMSO}} \times \frac{V \text{ CH}_3\text{OH}}{V \text{ sample}} \times 100$$

$$\% \text{ DMSO in sample (w/w)} = \frac{A \text{ DMSO}}{A \text{ CH}_3\text{OH}} \times \frac{E \text{ DMSO}}{E \text{ CH}_3\text{OH}} \times \frac{d \text{ CH}_3\text{OH}}{W \text{ sample}} \times V \text{ CH}_3\text{OH} \times 100$$

in which:

A DMSO = area of DMSO peak (2.7 p.p.m. δ)
A CH_3OH = area of methanol CH_3 peak (3.3 p.p.m. δ)
d = density (Gm./ml.)
V = volume (ml.)

$$E \text{ DMSO} = \text{equivalent weight of DMSO} = \frac{78.13}{6} = 13.02$$

$$E \text{ CH}_3\text{OH} = \text{equivalent weight of methanol} = \frac{32.04}{3} = 10.68$$

W sample = weight of sample in Gm.

If a series of determinations is made, the combination of repeated values will greatly simplify the calculations; *e.g.*, in determining % DMSO (v/v) in various solutions, equal volumes of methanol and sample were taken; the densities of methanol and DMSO at room temperature, 74° F., were determined to be 0.7863 and 1.0915, respectively. Combining terms, the calculation becomes:

$$\% \text{ DMSO (v/v)} = 87.83 \times \frac{A \text{ DMSO}}{A \text{ CH}_3\text{OH}}$$

DISCUSSION

A solution containing known amounts of DMSO and methanol in water was prepared. Aliquots were diluted to obtain concentrations ranging from 20% to 0.05% (v/v) DMSO. Table I shows recoveries obtained for concentrations of 2–20% DMSO.

Since integration was not feasible for the more dilute solutions, peak heights of CH_3 (DMSO) and

TABLE I—DMSO DETERMINATION OF STANDARD PREPARATIONS[a]

Solution	DMSO Added, ml.	DMSO Found, ml.	Relative Error, %
1	20.00	20.14	0.7
2	10.00	9.99	0.1
3	5.00	4.94	1.2
4	2.00	1.98	1.0

[a] Equal volumes of DMSO and methanol were diluted to approximately 100 ml. in each case.

TABLE II—EFFECT OF CONCENTRATION OF PEAK HEIGHT RATIO OF DMSO/CH_3OH[a]

Solution	Concn. DMSO, % (v/v)	Mean $\frac{H \text{ DMSO}}{H \text{ } CH_3OH}$	Standard Deviation	Relative Standard Deviation, %
1	20	1.494	0.019	1.3
2	10	1.313	0.009	0.7
3	5	1.226	0.015	1.2
4	2	1.164	0.011	0.9
5	1	1.177	0.016	1.4
6	0.2	1.234	0.040	3.2
7	0.05	1.235	0.066	5.4

[a] H DMSO = height of DMSO peak. H CH_3OH = height of CH_3 peak in methanol. Results are based on 5 scans per solution.

$CH_3(CH_3OH)$ were measured on spectra of the aforementioned solutions, and the ratio of the two peaks was calculated for each spectrum. Table II shows mean ratios and standard deviations for 5 scans of each dilution. Reproducibilities of the mean peak height ratios for concentrations of 2% down to 0.05% were deemed adequate to suggest this procedure for estimating DMSO present as a contaminant in human and veterinary drugs. If any of the usual components of the drug produce an interfering spectrum, they may possibly be kept out of solution by a change of solvent.

As may be noted, there is a marked trend in peak height ratios of DMSO to the methyl in methanol as the concentrations increase from 2% up to 20%. This may be due to differential line broadening effects on the CH_3 peaks of methanol and DMSO resulting from increased viscosity. However, the importance of this phenomenon is only academic, as solutions of greater concentration may be determined satisfactorily by integration.

The DMSO peak is prominent down to a concentration of 0.01%; at this level the signal-to-noise ratio was found to be approximately 7:1 at a spectrum amplitude of 100 and a filter band width of 0.4 Hz.

Water is the solvent of choice; nearly all commercial DMSO preparations analyzed in this laboratory were found to be soluble in it, and its chemical shift (4.6–4.7 p.p.m. δ) is far removed from those of DMSO (2.7 p.p.m. δ) and the methyl peak of methanol (3.3 p.p.m. δ). Certain preparations produced a heavy precipitate upon the addition of water but were soluble in chloroform (7.3 p.p.m. δ). In these cases the addition of a small amount of hydrochloric acid eliminated spin-spin coupling between the methyl and hydroxyl groups of methanol. In either case, the use of a deuterated solvent is unnecessary.

In a series of commercial samples analyzed recently, results were in good agreement with the declared values (Table III).

TABLE III—DMSO CONTENT OF COMMERCIAL PREPARATIONS

Comparison of Iron Assays in Multivitamin Products Using an Automated Chemical Procedure and an X-Ray Emission Method

By WILLIAM F. BEYER and KARL G. ZIPPLE

Two methods are described for the determination of iron in multivitamin preparations, formulated with either ferrous sulfate, ferrous fumarate, or ferrous gluconate. In the first procedure, an automated colorimetric procedure, iron is determined with 2,4,6-tripyridyl triazine in a buffered solution. In the second procedure, an X-ray emission spectrometer is used. Samples, analyzed as solutions, are placed in liquid sample cells and counted for 100 sec. Following sample preparation, approximately 20 samples can be assayed per hour with the automated procedure as compared to four (in duplicate) by X-ray emission.

THE DETERMINATION of iron in multivitamin preparations requires the use of assay procedures that are not affected by other minerals, vitamins, or formulation excipients. In achieving this, X-ray emission spectroscopy has given satisfactory results in our laboratories over a long period of time. Requests for large numbers of iron assays in formulation studies and in single tablet or unit dosage assays, however, prompted the use of an automated chemical assay procedure.

This report describes two methods for the determination of iron in multivitamin preparations, formulated with either ferrous sulfate, ferrous fumarate, or ferrous gluconate. In the first procedure, an automated colorimetric procedure, iron is determined with 2,4,6-tripyridyl triazine in a buffered solution essentially as described by Zak *et al.* (1).

In the second procedure, a General Electric X-ray emission spectrometer is used. Samples, analyzed as solutions, are placed in a liquid sample cell and are counted for 100 sec.

METHODS AND MATERIALS

Automated Chemical

Instruments—Automatic analyzer components[1]: Sampler I, proportioning pump I, colorimeter, linear recorder, chart reader, assorted tubing, and glass fittings.

Reagents—Double distilled water used throughout the procedure; hydrochloric acid, A.R.

Acetate buffer, pH 4, 1.0 *M*, 27.22 Gm. of sodium acetate trihydrate is dissolved in approximately 200 ml. of water in a 1,000-ml. flask, 45.79 ml. of glacial acetic acid is added and the solution is made up to volume with water.

2,4,6-Tripyridyl triazine (TPTZ)[2]; 200 mg. of anhydrous TPTZ is dissolved in 0.5 ml. of HCl and transferred to a 1,000-ml. volumetric flask with the aid of 200 ml. of acetate buffer. After dilution to volume with water, the contents are thoroughly mixed and allowed to stand several days with periodic shaking. The solution is filtered before use and stored in light-resistant bottles.

Ascorbic acid, 2% aqueous solution. When refrigerated, it is stable for several days.

Iron Standard—Stock solution; 200 mcg./ml. 1.4045 Gm. of ferrous ammonium sulfate hexahydrate is placed in a 1,000-ml. volumetric flask with 1.0 ml. of HCl, gently mixed, and diluted to volume with water. The standard is stable indefinitely in a tightly closed, glass container.

Working Solutions; The iron stock solution is used to prepare solutions containing 0.75 mcg., 1.0 mcg., 1.25 mcg., and 1.50 mcg. iron/ml. in water. The diluted standards are kept in tightly closed volumetric flasks. The standards appear to be stable indefinitely; however, new standards should be prepared periodically.

Multivitamin Sample Preparations—For single-tablet assays, individual tablets are placed in 10.0 ml. of concentrated HCl and approximately 5 ml. of water. After shaking for approximately 4 hr., or placing on a steam bath for approximately 1 hr., the solutions are diluted to 100.0 ml. with water. An aliquot is transferred to a suitable volumetric flask and diluted with water to a theoretical iron concentration of approximately 1.0 mcg./ml. If

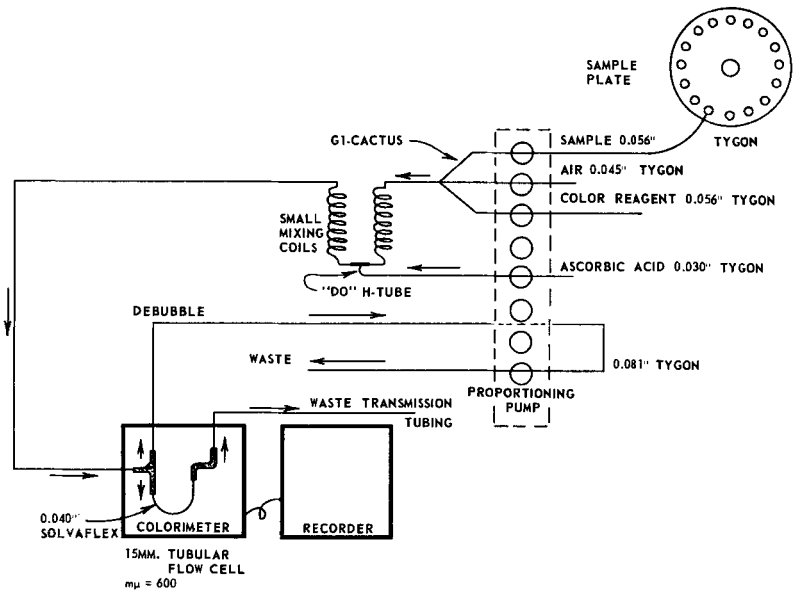

Fig. 1—Manifold-flow diagram for iron (ferrous) with the automatic analyzer.

necessary, the solutions are filtered prior to filling the automatic analyzer cups.

When a specified number of tablets are required in the initial sample preparation, the same ratios of tablet, acid and water are maintained as for single-tablet assays. For example, if a procedure calls for the assay of 10 tablets, they are placed in a 1,000-ml. volumetric flask with 100 ml. of concentrated HCl and 50 ml. of water. Following disintegration of tablets, the volume is adjusted to 1,000 ml. with water and an aliquot is further diluted to the desired concentration of iron.

Procedure—The automatic analyzer is standardized using the manifold-flow system of Fig. 1. As the figure shows, a 15-mm. flow cell is used in the colorimeter and measurements are made at a wavelength of 600 mμ. Standardization is achieved by pumping water through the tubes to establish a 99% transmittance base line, substitution of reagents for water, and adjusting to a new 99% transmittance base line. A known iron solution is continuously sampled to establish initial stability of the automated system. The four levels of iron standards (0.75, 1.0, 1.25, and 1.50 mcg./ml.) are placed in alternate sample cups followed by test preparations. The analysis is set at 40 samples/hr. with a water washout cup between each iron sample, standard as well as test preparation. At regular intervals a 1.0 mcg./ml. iron standard is inserted to compensate for the effect of instrumental or reagent variations.

Calculations—A transmission curve is plotted on the chart reader using recorded peak heights of the iron standards. The mcg./ml. of iron in each test preparation is determined from its corresponding transmittance peak using the chart reader and the iron standard curve. An adjustment factor, determined from standards placed periodically, is applied if necessary. The iron content of each product is obtained by multiplying the mcg./ml. by the proper dilution factors. To express results in terms of the proper ferrous salt (fumarate, gluconate, or sulfate), an additional factor based on the ratio of molecular weights is applied.

X-Ray Emission

Instruments—The General Electric XRD-5 spectrometer, equipped with a lithium fluoride analyzing crystal and a tungsten target X-ray tube operated at 50 kvp. and 45 ma., was used in the study. The flow proportional counter (GE No. SPG4) was operated at 2.100 kv. The spectrometer was equipped with a General Electric large sample holder. General Electric liquid sample cells, closed with 1/4-mil Mylar were used to hold the samples. The liquid sample holder is shown in Fig. 2.

Reagent—Hydrochloric acid, A.R., concentrated and 1:1000.

Iron Standard—A 1.0 mg./ml. iron standard is prepared by dissolving 7.0217 Gm. of ferrous ammonium sulfate hexahydrate in 1,000 ml. of 1:1000 HCl.

Multivitamin Sample Preparation—Sufficient tablets to provide approximately 100 mg. of iron are placed in a 250-ml. volumetric flask with 4 ml. of HCl and 20 ml. of deionized water and left at room temperature for at least 1 hr. or, if convenient, overnight. Another 180 ml. of water is added, the sample is heated on a steam bath for an hour; the solution is then cooled to room temperature and made to volume with water. This solution contains 0.4 to 0.5 mg. of iron per ml.

Procedure—Three separate GE liquid sample cells are used for the following solutions: (*a*) *Blank*, 6.0 ml. of 1:1000 HCl; (*b*) *Sample*, 4.0 ml. of multivitamin test preparation and 2.0 ml. of 1:1000 HCl; and (*c*) *Sample with iron standard*, 4.0 ml. of multivitamin test preparation and 2.0 ml. of iron standard (1.0 mg./ml.). The cells are sealed with 1/4-mil Mylar and the contents are mixed by gentle shaking.

If a thick syrup is to be assayed, a suitable aliquot of the product is transferred with a syringe into two glass-stoppered centrifuge tubes and 1:1000 HCl is added to give an iron concentration of approximately 0.3 mg./ml. An aliquot of iron standard is added to one of the tubes to make the total iron concentration approximately 0.6 mg./ml. An equal volume of 1:1000 HCl is added to the other tube. Six-milliliter aliquots are then pipeted

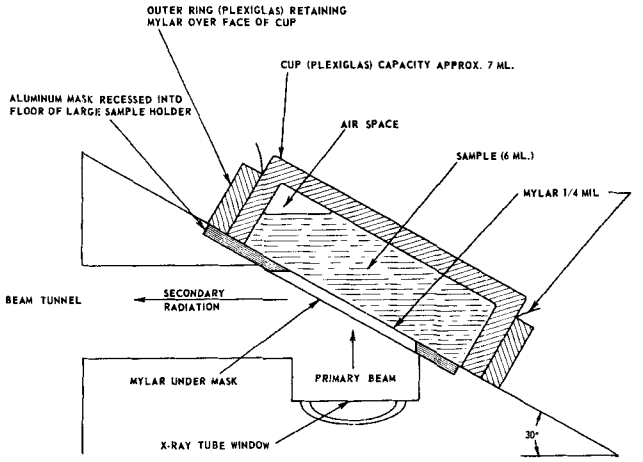

Fig. 2—Liquid sample holder used in X-ray emission analysis.

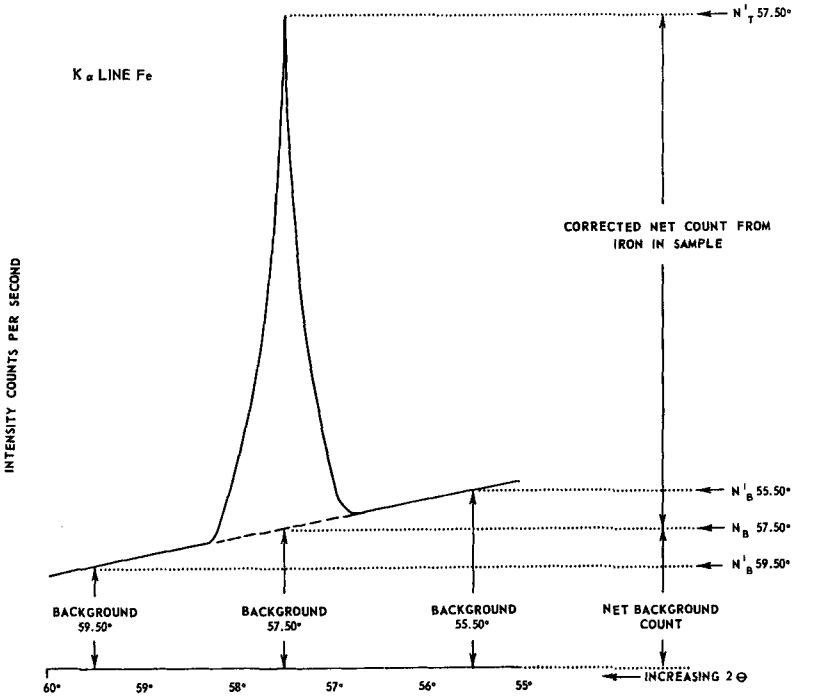

Fig. 3—Spectrum of the analytical line for iron showing background corrections.

into the GE liquid sample cells and sealed with 1/4-mil Mylar.

The cells are gently shaken, inverted, and placed in the large sample holder. Counts are made on each cell for 100 sec. with the spectrometer set for 2θ 55.50° (background), 57.50° (Kα emission line of iron), and 59.50° (background). A representative spectrum of the analytical line for iron showing background corrections is shown in Fig. 3. The average of the background counts taken 2° 2θ each side of the Kα emission line of iron at 2θ = 57.50° is the assumed background at this line and this value is subtracted from the count at 2θ = 57.50° to give the net count due to iron present.

The diluent blank cell gives a net count over background which is a measure of the iron present in the X-ray tube, holder, mask, and cell. This blank is subtracted from the net count for the "sample" and "sample with standard" to give corrected net counts. A schematic of the procedure is shown in Fig. 4. The diluent blank is not counted for each sample; once a day is sufficient.

Calculations—The amount of iron present in the sample aliquot is calculated by applying the straight line-slope equations:

$$\text{Slope } (m) = \frac{\Delta y}{\Delta x} = \frac{\text{corr. net count sample with standard} - \text{corr. net count sample}}{\text{mg. Fe added to sample with standard} - \text{mg. Fe added to sample}}$$

and

$$\text{mg. Fe present in sample aliquot} = \frac{b}{m} = \frac{\text{corr. net count sample}}{m}$$

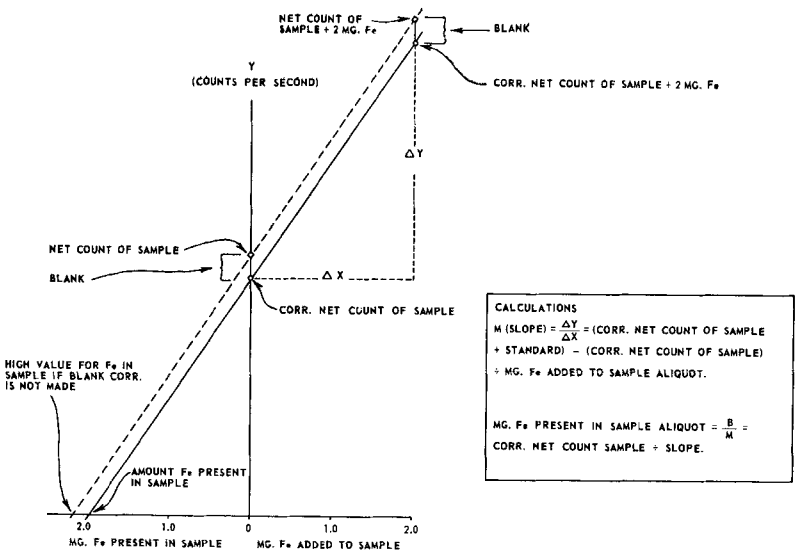

Fig. 4—Calculations used in X-ray emission analysis for iron.

RESULTS AND DISCUSSION

Initial experiments with the automated colorimetric procedure using a standard 10-mm. flow cell and dialysis gave satisfactory results for iron standards; however, product results were extremely variable from day to day. This was thought to be due to variable efficiency of the dialysis membrane or less than optimal sample preparation.

Installation of a 15-mm. tubular flow cell, elimination of dialysis, and the use of initially strongly acid solutions for sample preparation led to a satisfactory assay procedure. Because product excipients caused initial solutions to become basic when using water, the addition of acid was required; however, the volume of acid had to be regulated so that the capacity of the pH 4 acetate buffer was not exceeded.

A linear relationship exists for the log of transmittance and iron concentration in the range of 0.25 mcg. to 2.0 mcg./ml. with the automatic analyzer procedure. The assay has a percent coefficient of variation $\left(\frac{\text{standard deviation}}{\text{mean value}} \times 100\right)$ of approximately 1%.

To test the efficiency of the automated procedure, iron standards in varying amounts, were added to tablet sample preparations containing ferrous sulfate. Results of the study are shown in Table I, an average recovery of 100.3% was obtained, varying from a low of 98.8% to a high of 102.2%.

Table II gives automated assay results of individual multivitamin tablets containing ferrous sulfate. The average iron content was 10.33 mg., with an average tablet weight of 308.8 mg. Ten tablets of the same lot were assayed as a combined sample with an average iron value of 10.50 mg./tab. The average value compares favorably with the value of 10.33 mg./tab. for the single-tablet assay.

X-ray emission analysis (also called X-ray fluorescence analysis) provides a rapid procedure for the determination of iron in pharmaceutical materials. Approximately 25,000 counts are recorded in the 100-sec. period for each mg. of iron present in the cell. Total iron is measured without regard to valence or sample color and there is little interference from other elements. Tedious acid digestion of fluid samples containing sugar is unnecessary. The use of an internal standard for each sample minimizes absorption effects of various excipients. The assay has a coefficient of variation of approximately 1.2%. Four samples can be

assayed in duplicate in an hour; however, it is possible to automate the assay with accessories now available commercially.

A large number of single-tablet assays of multivitamin tablets from studies involving formulation and tableting process changes were carried out using X-ray emission. Data from a study of this nature are shown in Table III. The coefficients of variation for both tablet weight and iron content are lower than that found with an earlier lot of tablets assayed by the automated colorimetric procedure (Table II). Sixteen additional tablets from the same lot were individually weighed and assayed on each of 2 days with the X-ray emission method. The coefficients of variation were 0.82 and 1.05% for tablet weight and 1.94 and 2.34% for iron content, respectively. These data indicated that a uniform tablet had been produced, from the standpoint of weight and iron content.

Assay results of pulverized tablets obtained by both procedures are shown in Table IV. Weighed amounts of the ground tablets approximating the average tablet weight were analyzed. More deviation in iron content was found with the X-ray procedure than with the automated colorimetric method; however, the average of the results agree quite favorably. Satisfactory assays with the two

procedures have been performed on numerous additional multivitamin preparations, including capsules, tablets, syrups, and powder mixes.

SUMMARY

An automated chemical method and an X-ray emission procedure have been described for the determination of iron in multivitamin preparations. Following sample preparation, approximately 20 samples can be assayed per hour with the automated procedure as compared to four (in duplicate) by X-ray emission.

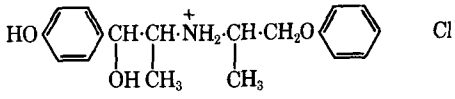
Single-Tablet Assays

Automated Assay of Single Tablets of Isoxsuprine Hydrochloride

By RHYS BRYANT, D. E. MANTLE, D. L. TIMMA, and D. S. YODER

An automatic analyzer system was used to determine the amount of isoxsuprine hydrochloride in single tablets. The intensity of the ultraviolet absorbance of isoxsuprine hydrochloride was a measure of its concentration in the tablet.

ISOXSUPRINE HYDROCHLORIDE[1] (I) is a myovascular relaxant that acts directly and specifically on the smooth muscle of the blood vessels and the myometrium to increase blood flow in vascular disorders, and to reduce uterine hypermotility (1, 2). Isoxsuprine hydrochloride is readily assayed in tablets by means of its characteristic ultraviolet spectrum: $\lambda_{max.}$ 218 mμ (0.1 *M* H_3PO_4) (*a*, 42.2).



The literature on the application of automated analyses to pharmaceutical formulations, including tablets, is extensive, and several comprehensive literature compilations exist (3–5). The application of an automated ultraviolet assay to single tablets of isoxsuprine hydrochloride is now reported. Using this method the probability of meeting the USP test for content uniformity (6) was found to be greater than 99%.

EXPERIMENTAL

Apparatus—The analytical train consisted of the following modules: (*a*) Solidprep Sampler, proportioning pump, and dialyzer, from Technicon Instruments; (*b*) Hitachi Perkin-Elmer spectrophotometer, model 139; (*c*) Microflow cell 9120 No. 5; and (*d*) Sargent model TR-05 recorder.

Reagents—(*a*) Phosphoric acid (H_3PO_4), 0.1 *M*; and (*b*) phosphoric acid (0.1 *M*) containing 0.01% polysorbate 20.[2]

Standards—Aqueous solutions of isoxsuprine hydrochloride were made up at three levels of concentration (0.871, 1.09, and 1.31 Gm./L.) (Table I). Ten-milliliter aliquots of each solution were equivalent to an 8-mg., 10-mg., or 12-mg. tablet, respectively, when they had been diluted with 110 ml. 0.1 *M* H_3PO_4 in the Solidprep sampler. This correction was necessary to compensate for volume differences.

Samples—Production lots of tablets were obtained at both front and back punches of the tableting machine. Theoretical content of each tablet was 10 mg. of isoxsuprine hydrochloride.

Procedure—A schematic of the automatic analyzer[3] system is shown in Fig. 1. Each tablet was individually disintegrated in the presence of 0.1 *M* phosphoric acid. An aliquot of the resulting suspension was dialyzed to remove extraneous solid and the dialyzate passed through the spectrophotometer where its ultraviolet absorbance was measured and recorded (Fig. 2).

Approximately 120 tablets could be analyzed in an 8-hr. day.

The three standard solutions were analyzed several times during the day to check the variation of absorbance. No significant variation was found.

Calculation—The average absorbance for each level of standard was determined. A standard curve [average absorbance *versus* tablet equivalent (mg.)] was prepared. Reference to the standard curve gave for each sample the mg. of isoxsuprine hydrochloride per tablet.

TABLE I—CONCENTRATION AND AVERAGE ABSORBANCE OF STANDARDS

Concn. of Standard, Gm./L.	10 ml. of Standard Equivalent to	Av. Absorbance at 220 mμ
0.871	8 mg. Isoxsuprine HCl	0.253
1.09	10 mg. Isoxsuprine HCl	0.311
1.31	12 mg. Isoxsuprine HCl	0.369

DISCUSSION

Interference at the dialysis stage due to dibasic calcium phosphate (a tablet excipient) was overcome by the use of phosphoric acid. Other acids (*e.g.*, sulfuric acid, hydrochloric acid) were found unsuitable. Sulfuric acid resulted in anomalous dialysis rates; hydrochloric acid attacked the automatic analyzer's stainless steel.

RESULTS

Standard Curve—The average absorbance for each of the three standards was determined. A plot of the values (see Table I) gave a straight line, indicating adherence to Beer's law.

Reproducibility of Standards—The reproducibility of the method was checked by the analysis of 10 standards (Table II).

Reproducibility of Sample Suspension—The precision of the method was checked by the analysis of nine aliquots of a sample suspension (Table II).

Statistical Results[4]—The results of nine lots of 50 tablets have been evaluated. The data are presented in Table III.

Evaluation of Factors Affecting the Encapsulation of Powders in Hard Gelatin Capsules I

Semi-Automatic Capsule Machines

By G. REIER, R. COHN, S. ROCK, and F. WAGENBLAST

A useful model has been developed which relates particulate properties, capsule size, and the operating rate of semi-automatic filling equipment to filled capsule characteristics. The mean capsule fill weight is dependent on machine speed, capsule size, and specific volume. The weight variation as expressed by the standard deviation is a function of machine speed, capsule size, specific volume, flowability, and the presence of a glidant. Particle size considerations of moderately coarse powders (USP designation) are not directly a part of the model because they are reflected in the other evaluated particulate properties. The model is applicable to powder systems other than those from which it was derived. Mean gross capsule weights of such systems may be calculated with an accuracy often exceeding 95 percent. The utility of the model lies in its ability to provide information concerning the relationship of machine speed, capsule size, powder specific volume, and flow to mean capsule fill weight from simple evaluations of small samples of the formulation to be encapsulated.

HARD GELATIN capsules have been known since 1848. They were first prepared in London (1), and quickly attained popularity in the United States where capsule manufacturing and filling operations were carried out manually (2). Hard gelatin capsules are today an important part of solid dosage form drug presentation. A variety of useful, elegant capsule products are available to the physician.

Curiously, the literature is devoid of any reports dealing with the encapsulation of dry powders on an industrial scale. The absence of reported works on this subject is even more marked when one considers the detailed investigations published, for example, by Higuchi *et al.* (3, 4), on the physical factors affecting the tableting process.

Current formulation of powders for encapsulation is carried out on an empirical basis and, while this method has apparently met the needs of the pharmaceutical industry, it would be extremely valuable to have a mathematical model which quantitatively defines the variables encountered in capsule filling. Once these variables are known and quantitated, their application to formulations can be assessed before laboratory work is begun.

The present work was conducted to develop a mathematical model which describes the effect of selected physical powder properties as well as mechanical operating conditions on the capsule filling operation, and to ascertain the relationships of these variables on the encapsulation process.

The industrial pharmacist encounters drugs of widely differing physical natures, some of which require previous densification before encapsulation can be accomplished. Powders of this sort were not included in this study. Further, there are presently available both semi-automatic and automatic capsule filling machines. This report deals only with the semi-automatic type. The areas of encapsulating densified powders and the effect of variables associated with automatic filling equipment will be the basis of future reports.

EXPERIMENTAL

In order to describe adequately any process, one must have parameters which define that process. Often these parameters are evaluations of the resultant end product. A case in point occurs with capsule production. Mean capsule weight and weight variation are properties which define the completed encapsulation process.

Of the variables affecting encapsulation, those imposed by the filling equipment itself are the speed of operation and the capsule size being filled. Formulation variables include powder particle size and particle size distribution, specific volume, and flowability. The presence or absence of a glidant in the formulation may be expected to have an effect on powder flow. Classically, glidants have been thought to improve flow but recently this concept has been challenged (5).

In order to prepare powder blends varying in mean particle size, particle size distribution, specific volume, and flowability, the following materials were chosen as blend components: microcrystalline cellulose NF,[1] dicalcium phosphate dihydrate unmilled,[2] lactose USP, magnesium stearate USP, and talc USP. Microcrystalline cellulose and dicalcium phosphate dihydrate, unmilled have widely different physical properties, particularly with regard to specific volume and flowability. They were used to vary these properties of the powder blends as desired. Lactose was included as a component because of the need for a filler and its common use as such. A lubricant is necessary for mechanical capsule filling, and magnesium stearate served that purpose. Talc was the glidant.

Three operating speeds, the slowest and the most rapid of which the machine was capable, as well as an intermediate speed, were chosen for study. Three capsule sizes were included in the study.

An experimental design defining the formulation of 42 powder blends from the infinite number that could be formulated was prepared. The lubricant level was maintained throughout at 1%. One-half of the formulations contained no talc, the others 3%. The formulas are given in Tables I and II.

When the two machine operating variables (speed and capsule size) and the three conditions for each are included with the 42 formulations, 378 experimental capsule filling runs are possible. By taking one-third replicates of the operating conditions, the experimental effort was considerably reduced. Each formulation was filled into capsules at one of the nine possible combinations of speed and capsule size, with half of them being studied at two combinations

to maintain a balanced design. Table III shows the operating conditions at which each blend was filled.

EXPERIMENTAL

Particulate Properties—*Specific Volume*—Approximately 50 ml. of powder was placed into a tared 100-ml. graduate. The graduate was tapped 15 times mechanically by means of a Numinco Tap-Pak Volumeter.[3] The volume of the powder after tapping was divided by the weight of the powder to give the specific volume in ml./Gm.

Flowability—Powder was allowed to flow gently through a glass funnel by means of a mechanical feeding device[4] onto a calibrated vibrationless flat surface where it formed a cone. The funnel had an orifice of 2.58 mm. and was placed 2.40 cm. above the flat surface. When the apex of the cone reached the funnel orifice powder flow was stopped, and the diameter of the base of the cone determined. The area of the base was calculated (in square inches) rather than the angle of repose. The result was termed "flowability" although the authors realize that such experimental procedures may be measuring interparticle friction rather than flow.

Mean Particle Size and Particle Size Distribution—Particle size determinations were made by sieve analysis using 70, 80, 120, 170, and 325 screens. The Ro-Tap testing sieve shaker[5] was used, and powder samples of 100 Gm. were shaken for 10 min. The best linear plot of percent retained *versus* screen size (in microns) was made on log-probability paper. From the plot the geometric mean diameter and the coefficient of variation were obtained.

Capsule Filling Machine Properties—Throughout the study a Lilly model 8 capsule filling machine[6] was used.

Capsule Size—In order to obtain a meaningful computer analysis it is necessary to have absolute numbers available for data input. This was accomplished in the case of capsule size by measuring the volume in ml. of alcohol USP needed to completely fill the bodies of empty No. 0, No. 1, and No. 2 capsules.

Capsule Machine Speed—A tachometer placed on the turntable spindle yielded r.p.m. data directly.

Filled Capsule Properties—Preliminary work showed that the elimination of ring-to-ring capsule weight differences could be obtained by discarding the first three rings of capsules. There was no statistical difference as measured by a *t* test between the net weights of capsules selected at random from the fourth, fifth, or sixth rings. Also, further study showed that capsule shells do not vary in weight to a statistically significant extent. To simplify analytical weighings, gross capsule weights are reported throughout.

After filling of the powder hopper, the first three rings were filled and discarded, the hopper refilled, and 15 capsules taken at random from the combined fourth, fifth, and sixth rings and individually weighed on an analytical balance. The mean, standard deviation, and coefficient of variation were calculated.

RESULTS

Tables IV and V list the evaluated physical properties of the powder blends.

The machine speed r.p.m. values and the capsule size volume measurements are given in Tables VI and VII.

Filled capsule characteristics are shown in Tables VIII and IX.

A multiple stepwise regression analysis of the dependent variables was made with the aid of an IBM 1620-II computer. A full second-order (quadratic) model with all possible two-factor interactions was employed. The stepwise regression method offers the advantage of including only those variables, quadratic terms, and interactions which demonstrate statistically significant effects on capsule weight and weight variation responses.

During the initial data processing it became evi-

dent that a degree of internal correlation existed between the particle size responses and specific volume and/or flowability. Correlation coefficients calculated with and without particle size factors present showed little difference. It was, therefore, possible to eliminate these factors from further analysis since they had no practical effect on capsule characteristics.

The equations below are the result of the computer analysis.

$$Y_1 = 630.71 - 34.37(X_1) + 1.92(X_1)^2 + 1185.99(X_2) + 561.99(X_2)^2 - 421.46(X_3) + 110.34(X_3)^2 - 11.20(X_4) - 24.31(X_1X_2) + 8.27(X_1X_3) - 433.57((X_2X_3). \quad \text{(Eq. 1)}$$

[a] Excessive binding at 2.2 r.p.m., No. 0 capsule.

where

Y_1 = mean gross capsule weight, mg.,
Y_2 = capsule weight standard deviation, mg.,
Y_3 = capsule weight coefficient of variation, %,
X_1 = machine speed, r.p.m.,
X_2 = capsule size, ml.,
X_3 = specific vol., ml./Gm.,
X_4 = flowability, sq. in.,
X_5 = presence of talc (+1) or absence of talc (−1).

It is obvious from the complexity of the equations that the measured responses are dependent on many factors and interactions between factors. Since no simple relationship exists for each of the evaluated properties, particulate or mechanical, with capsule characteristics, the equations as such are difficult to use for data analysis. Response surface contours, however, may be generated from Eqs. 1–3.

The shape, or contour, of the solid geometrical surface generated by changes in a response produced by continuous variations in values of two interacting factors is known as a response surface contour. Response surface contours may be plotted two dimensionally as contour charts (6). While only two interacting factors can be accommodated on a single contour chart, the preparation of a number of such charts allows for the analysis of the effect of many factors on a response.

DISCUSSION

Mean Capsule Fill Weight—The computer supplied contour charts for all combinations of capsule size and machine speed, including, in the latter case, intermediate machine speeds not a part of the

original experimental data. Thus, 24 contour charts (8 machine speeds × 3 capsule sizes) were drawn, of which Fig. 1 is representative.

It was seen from these contour charts that, for a given capsule size and machine speed, specific volume almost solely determines the mean capsule weight. A decrease in specific volume (increase in density) increases mean weight. Aside from the obvious fact that dense powders weigh more per unit volume, the weight of the powder head in the hopper above the capsule during filling is increased with dense powders thus increasing the pressure on the material being filled. Of course, the size of the capsule shell and the machine operating speed have a direct effect on capsule weight.

Standard Deviation—Equations 2 and 3 indicate that the presence of talc acts to decrease the filled capsule weight variation. Such a decrease cannot be attributed to improved powder flow as it was measured. The average flowability of powders containing talc was 2.81 sq. in. while that of powders in which talc was not present was 2.94 sq. in. A possible explanation for the decrease in weight variation when talc is present may be that powder flow is more uniform in the presence of a glidant.

In a tableting study, Augsberger and Shangraw (7) reported the opposite result, an increase in weight variability with the addition of a glidant. They also reported a decrease in mean tablet weight in the presence of talc. In the present work, however, there was no such glidant effect on mean capsule weight as evidenced by the absence of a term for talc in Eq. 1.

Two types of contour charts were constructed for studying the interactions of factors contributing to the weight variation of filled capsules. The first type is the result of fixing machine speed, capsule size, and the presence of talc while allowing specific volume and flow to vary. Figure 2 is representative of the charts of this type that were generated showing standard deviation as an estimate of the weight variation. A minimum standard deviation is obtained at intermediate flow values and medium to high specific volumes. Fixing flow at a medium value and increasing specific volume decreases the weight variation. Fixing specific volume and increasing flow results first in a lowering and then an increasing of the standard deviation.

The second type of contour chart results from fixing specific volume, the presence of talc, and capsule size and plotting machine speed *versus* powder flow. Figure 3 is typical. It can be seen that the interaction of machine speed and flow results in a three-dimensional figure, sections of which are ellipse-like in shape. The center area at the top of the figure is the point where the standard deviation is at a minimum. Moving from this area along either the machine speed or flow axis results in an increase in standard deviation. For each capsule size and specific volume combination there are optimum values of machine speed and flow that produce a minimum standard deviation.

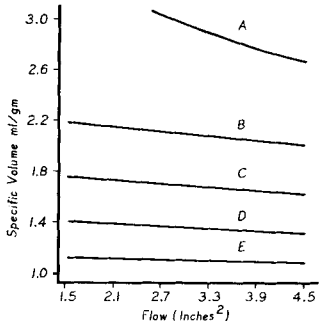

Fig. 1—Mean gross fill weights of No. 0 capsules as a function of specific volume and flow at a machine speed of 4.8 r.p.m. Key: A, 400 mg.; B, 500 mg.; C, 600 mg.; D, 700 mg.; E, 800 mg.

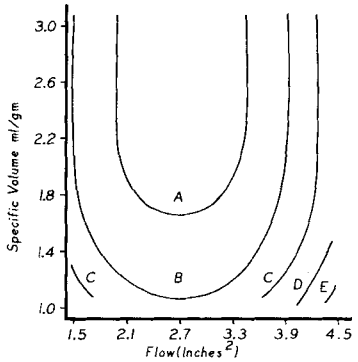

Fig. 2—The standard deviation of filled No. 2 capsules as a function of specific volume and flow at a machine speed of 4.8 r.p.m. Key: A, 3.0 mg.; B, 6.0 mg.; C, 9.0 mg.; D, 12.0 mg.; E, 15.0 mg. (Talc present.)

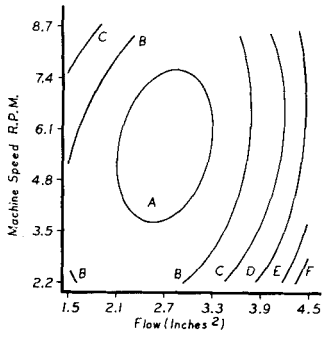

Fig. 3—The standard deviation of filled No. 2 capsules as a function of machine speed and flow at a specific volume of 2.0 ml./Gm. Key: A, 3.0 mg.; B, 6.0 mg.; C, 9.0 mg.; D, 12.0 mg.; E, 15.0 mg.; F, 18.0 mg. (Talc present.)

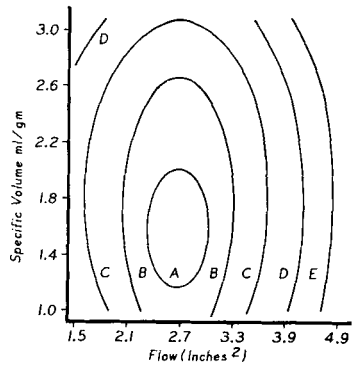

Fig. 4—The coefficient of variation of filled capsules as a function of specific volume and flow at a machine speed of 4.8 r.p.m. Key: A, 1.4%; B, 1.6%; C, 1.8%; D, 2.2%; E, 2.6%. (Talc present.)

Coefficient of Variation—A similar analysis may be made of the influence of the variables on the weight variation as estimated by the coefficient of variation with one exception. Equation 3 states that the coefficient of variation is independent of the capsule size.

Figure 4 is representative of the contour charts generated in which machine speed and the presence of talc are fixed. There is one area in which the coefficient of variation is at a minimum. Any change in specific volume or flow will move the response from the minimum area.

Of the contour charts illustrating the effect of machine speed and flow on the coefficient of variation when the presence of talc and the specific volume are fixed, Fig. 5 is typical. A minimum area occurs at one particular value of machine speed and flow.

Fit of the Model to the Data—The fit of the mathematical model to the data is evidenced by the ability of Eq. 1 to estimate the weights of capsules filled with powders of the same system used in the experimental work but under different filling conditions. The results of this interpolation are shown in Table X where calculated and actual weights of capsules filled with powder blend N7 are compared. Excellent agreement is obtained.

Applicability of the Model—To demonstrate the applicability of the model to other powder systems,

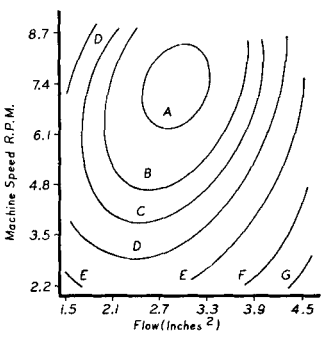

Fig. 5—The coefficient of variation of filled capsules as a function of machine speed and flow at a specific volume of 2.0 ml./Gm. Key: A, 1.2%; B, 1.4%; C, 1.6%; D, 1.8%; E, 2.0%; F, 2.6%; G, 3.2%. (Talc present.)

Specific volume = 1.62 ml./Gm.
Flowability = 2.99 sq. in.

Using the specific volume and flow values, capsule weights to be expected at various machine speeds were calculated from Eq. 1. A comparison of calculated and actual weights is given in Tables XI and XII. In three cases the percent difference exceeds 5% but in no case does it exceed 6%.

The utility of the model as a capsule formulation aid is to be found in the use of Eq. 1. From an evaluation of specific volume and flow properties of a small sample of the powder to be encapsulated, the equation can be used to predict fill weights at various machine speed and capsule size combinations. In a similar manner, the capsule size necessary for the encapsulation of a powder can be determined from the equation without the necessity of a trial. Further, the equation reveals that the alteration of specific volume is necessary if the desired capsule fill weight cannot be obtained from capsule size and machine speed combinations.

SUMMARY

A model has been developed which defines and quantitates the factors affecting the encapsulation of powders in hard gelatin capsules using semiautomatic capsule filling equipment. The model reveals that the mean capsule fill weight is dependent on specific volume, flowability, machine speed, and capsule size. The weight variation as estimated by the standard deviation is a function of machine speed, capsule size, specific volume, flowability, and the presence of a glidant. The coefficient of variation as an estimate of the weight variation is a function of machine speed, specific volume, flowability, and the presence of a glidant but independent of capsule size. Particle size considerations of moderately coarse particles (USP designation) are not directly a part of the model because they are reflected in other measured particulate properties.

The model expresses through equations and contour charts useful information for capsule formulation development. For example, from the contour charts it may be seen that the particulate property influencing fill weight to a major extent at a fixed capsule size and machine speed is specific volume. The interaction of specific volume and powder flowability produces an area where weight variation is at a minimum. The mean capsule fill weights that may be expected for any given powder blend may be calculated with an accuracy often exceeding 95% from simple capsule size, machine speed, and particulate property evaluations on small samples of formulation.

Savings in time and material needed to prepare and evaluate trial formulations are a direct result of the use of this model.

Powder Flow Studies III

Factors Affecting the Flow of Lactose Granules

By G. GOLD, R. N. DUVALL, B. T. PALERMO, and J. G. SLATER

In an attempt to provide a better understanding of the variables affecting the flow of tablet granulations, the effects of different granulating agents and techniques, particle size distribution, fines, and glidants on the flow of lactose granules were studied. Flow rates were measured with a recording powder flowometer. In binary mixtures the addition of increasing proportion of finer particles to 10/20 mesh granules increased the flow rate to a maximum followed by a decrease. Flow rates of granulations were found to vary considerably, depending upon the particular granulating agent used. For granulations and blended systems of various particle size distributions, a strong negative correlation existed between flow rate of granules and proportion of particles less than 100 mesh in size. The particle size of the granules influenced considerably the effect of glidants.

AN IMPORTANT requirement of tablet formulations is that the powder or granular material possess uniform and free flowing properties. The ability of particulate matter to flow into the dies in a reproducible manner results in uniform tablet weights and uniform doses of active ingredients, as well as increased production rates (1). Using an instrumented rotary tablet machine, Knoechel *et al.* (2) reported that when good flowing formulations were tableted, compression and ejection force levels became more uniform and weight deviations decreased. To achieve better flowability and desirable compression characteristics, it is often necessary to use a granulating technique in the manufacturing procedure. The most common granulating method is wet granulation which involves the moistening of a powder mixture with a granulating solution containing a binder to form a plasticized mass. The mass is then forced through a sieve, dried, and resieved. The finished granulation is a mixture of various size particles and contains some finely powdered material often referred to by industrial pharmacists as "fines." Some finer particles are necessary in limited amounts for producing smoother tablets and for proper functioning of the tablet press. While 10–20% fines has occasionally been set as the maximum amount permissible, it has been pointed out that there is no general limit to the amount of fines that can be present in a granulation and that excessive fines should be determined for each specific formulation (3). Usage of the term fines is rather widespread, yet there is no general agreement as to what mesh size constitutes fines and much confusion exists in the literature due to varying usage of this term.

Hammerness and Thompson (4) observed that the flow rate, ascertained by timed delivery through an orifice, of a tablet granulation increased with added fines to an optimum flow rate, after which additional fines caused the flow rate to decrease. However, fines in this study were particles smaller than 40 mesh. An increase in the amount of lubricant also increased the flow rate, and the combination of fines and lubricant appeared to have a synergistic action. Crosby (5) reported that surface roughness may be reduced by the presence of fines which serve to fill in the depressions or irregularities in the surface of the particles and, thereby, increase the rate of flow. Nelson (6), using angle of repose measurements, found that the addition of fines smaller than 100 mesh to sulfathiazole granules caused an increase in repose angle and concluded that fines increase interparticle friction and are responsible for difficulty in granulation flow. According to Neumann (7) stickiness is produced by the presence of particles smaller than 10 μ. When these "fines" are removed or adsorbed onto larger particles, the powder becomes free flowing.

In many literature reports (8–10) dealing with investigations concerning flow of solid materials, angle of repose measurement was used with assumed correlation to flow. A recent report including a statistical evaluation from this laboratory (11) indicated that angle of repose measurement was not a reliable method to evaluate flow of materials. In view of this and the lack of reports in the literature dealing with factors affecting the flow of tablet granulations, the present work was undertaken in an effort to evaluate the variables

affecting the flow of granules. Lactose granules were used as the model system and the effects of finer particles were ascertained by adding various size particles to 10/20 mesh granules. The effects of different granulating agents and techniques on the flow rate of the resultant granules were also determined. A final objective was to study the effects of commonly used glidants on the flow of lactose granules of varying particle size distribution to ascertain similarities or differences in effects between glidants and granule fines.

EXPERIMENTAL

Materials—Methylcellulose,[1] cornstarch, polyvinylpyrrolidone,[2] gelatin, magnesium stearate, talc, and fumed silicon dioxide[3] were either USP or pharmaceutical grade materials. Glidants were used as supplied by the manufacturers and were finer than 100 mesh. However, cornstarch, when used as a glidant, was dried at 140° F. for 24 hr.

Lactose granulations were prepared in 15 Kg. batches by the following standard procedure: USP lactose powder was passed through a No. 12 screen on an oscillating granulator and placed in a 1.8 cubic foot total capacity Stokes' mixer. The granulating solution, at room temperature, was added in three equal volumes at 2-min. intervals until 1,000 ml. was added. The wet mass was mixed for 20 min., wet sieved through a No. 6 screen on an oscillating granulator, dried at 120° F. for approximately 20 hr., and dry sieved through a No. 12 screen. Moisture content of the granules was determined by the Karl Fischer method and all granules were found to contain moisture corresponding to 1 mole of water of hydration (5.00%) for lactose and 0.3% or less free moisture.

Particle Size Separation and Analysis—Separation of granules into different particle size ranges was accomplished by a Ro-Tap testing sieve shaker with U. S. standard sieves in series 20, 40, 60, 80, 100, and 200 mesh sizes. For particle size analysis of granulations, a 100-Gm. sample was placed in the shaker for 5 min.

Flow Rate Determinations—The Recording Powder Flowometer described in a previous report (12) was modified to contain four strain gauges and a built-in transistorized power supply. The potential across the bridge circuit was adjusted so that each horizontal chart division represented 6.25 Gm. of powder. Flow rates, expressed in Gm./sec., were calculated from the recorder tracing resulting from the flow of 300 Gm. of material passing through a conical stainless steel hopper which measured 20 cm. top diameter, 30 cm. in length, and 10 mm. orifice diameter.

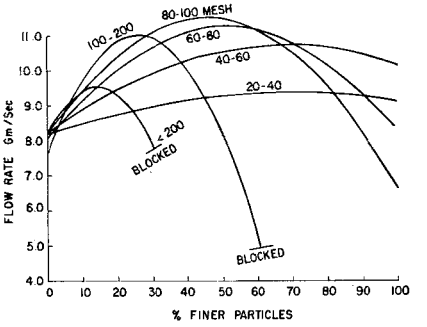

Fig. 1—The effect of finer particles on the flow rate of 10/20 mesh lactose granules.

RESULTS AND DISCUSSION

A 2% methylcellulose granulation (formulation 10—Table I) was sieved into 7 fractions and the effect of finer particles added to 10/20 mesh granules was determined in 5% increments up to 50% and 10% increments thereafter. The flow rates of each system, Fig. 1, are shown in a multiple regression plane (13). From Fig. 1, it will be noted that, as the proportion of the smaller particle sizes increased, the flow rate of 10/20 mesh granules attained a maximum and then decreased. This maximum flow rate was specific for each binary component system and varied with the concentration and size of the added particles. The data indicate that the smaller the particle size, proportionately less was necessary to reach the maximum flow rate. Also, the maximum flow rates did not reflect the flow rates of the individual sieve fractions but did indicate synergistic effect from their combination. The effect of 100/200 and <200 mesh particles was rather surprising, especially in

view of the fact that neither would flow through the funnel orifice used in the study. High concentrations of the 100/200 and <200 sieve fractions did adversely affect flow as concentrations exceeding 30% for <200 and 60% for 100/200 mesh stopped the flow of powder. Jones and Pilpel (14) in evaluating the flow of binary systems of granular magnesia also noted that the percentage of fine component required to produce the maximum flow rate, increases with the size of the fine component. With granular magnesia, however, increased concentrations of 300/350 mesh granules did not block the flow of either 22/36 or 52/72 mesh granules through an 8.98 mm. orifice.

Few guidelines are available for developing tablet granulations having good flow characteristics. Experiments were, therefore, devised to determine the effects of the granulating process on the flow rate. Table I lists the granulating agents and techniques that were evaluated. By using the 1,000 Gm. aqueous granulating solution as the standard for comparing the effectiveness of the various binders and comparing flow rates for significant differences by the method of analysis of variance (15), it may be concluded that the flow rate decreased with the use of 10% starch paste and increased with 2% methylcellulose, 10% PVP, 10% gelatin, and 10% methylcellulose. A significant increase resulted when the concentration of methylcellulose increased from 2–10%. Maximum flow rates were obtained by increasing the quantity of water. However, free moisture content of the resulting granules indicated no relationship between flow rate and free moisture. Flow rates of the 10/20 mesh sieve fractions are also indicated in Table I and suggest that it is risky to characterize the flow properties of a granulation with a separated sieve fraction. It is evident from the mesh analysis data in Table I that increased flow rates are associated with higher concentrations of 10/60 mesh and lower concentrations of <100 mesh particles. The coefficient of correlation (16) has been used to statistically measure the extent of the linear relationship between flow rates and 10/60, 60/100, and <100 sieve sizes. A correlation coefficient close to 0 indicates a weak or nonexistent relationship; whereas, a value close to +1 or −1 indicates a strong relationship between the two variables. The percent dependence (17), a measure of the percentage of the variation in flow rate related to variation in concentration of mesh sizes, has also been calculated. These statistics (Table II) indicate a fairly strong positive correlation between flow rate and proportion of 10/60 mesh particles ($r = +0.88$). A weak or nonexistent correlation exists for the 60/100 size (−0.20) and a strong negative correlation for <100 mesh granules (−0.92). Increasing the degree of wetness was effective in reducing the concentration of <100 mesh particles and, consequently, produced a faster flowing granulation.

To study the effects of particle size distribution, 5 formulations were prepared with varying concentrations of the 7 sieve fractions used in the binary system study. Table III gives the composition of each formulation and its corresponding flow rate. It will be noted that the flow rates ranged from a low of 4.07 Gm./sec. to a high of 10.19 Gm./sec. A high negative correlation coefficient (Table II) was obtained between flow rate and concentration of particles smaller than 100 mesh (−0.99). The 10/60 mesh fraction had a lower positive correlation coefficient of +0.77 while 60/100 particles had a weak correlation (+0.24). The data obtained from this experiment indicate that the proportion of particles smaller than 100 mesh is the main factor influencing the flow rate.

It was noted in binary mixtures that a linear relationship existed on each side of the composition of maximum flow; whereas, the relationship was nonlinear over the entire range. A negative linear relationship between flow rate and proportion of particles less than 100 mesh was obtained in the concentration range of 12–59% for granulations and 13–44% for blended systems. This negative linear relationship is, therefore, apparently representative of mixtures to one side of the composition of maximum flow.

Various materials commonly referred to as glidants are fine particles. As such, the effects of cornstarch, magnesium stearate, fumed silicon dioxide, and

TABLE II—CORRELATION COEFFICIENTS AND PERCENT DEPENDENCE VALUES SHOWING RELATIONSHIP BETWEEN FLOW RATES AND SIEVE SIZES

	Granulations[a]		Blended Granules[b]

<200	14.3	23.6	5.0	23.6	5.0
Flow rate (Gm./sec.)	7.54	4.07	10.19	5.62	8.58

talc were also studied for comparative purposes. These glidants were added to the following lactose granule fractions: 10/60 mesh; 50% 10/60, 50% 60/100; and 50% 10/60, 25% 60/100, and 25% <100. To compare flow rates, a flow factor "f" (18) which is the ratio of the flow rate of discharged granulate and glidant to the flow rate of the discharged granulate without glidant was calculated. A "f" value greater than 1.0 indicates increased flow; whereas, a value below 1.0 indicates decreased flow. It can be seen from Figs. 2–6 that the effectiveness of added particles is dependent upon the particulate size of the granules to which they are added. For example, lactose fines (Fig. 2) and cornstarch (Fig. 3) were effective when added to 10/60 mesh granules, but their effectiveness

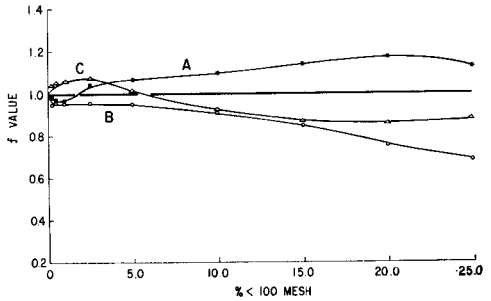

Fig. 2—The effect of <100 mesh particles of the same material on the flow rate of lactose granules. Key: A, 10/60 mesh granules; B, 50% 10/60, 50% 60/100; C, 50% 10/60, 25% 60/100, 25% <100.

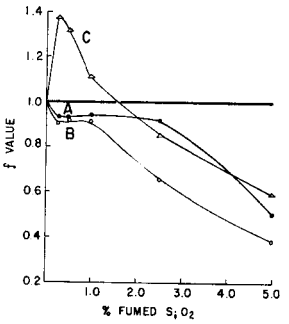

Fig. 5—The effect of fumed silicon dioxide on the flow rate of lactose granules. Key: A, 10/60 mesh granules; B, 50% 10/60, 50% 60/100; C, 50% 10/60, 25% 60/100, 25% <100.

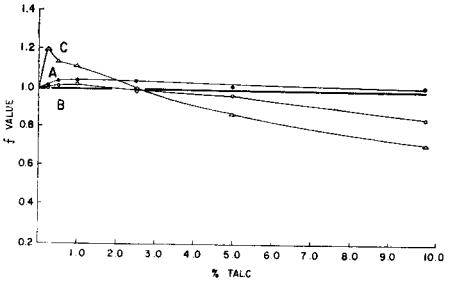

Fig. 6—The effect of talc on the flow rate of lactose granules. Key: A, 10/60 mesh granules; B, 50% 10/60, 50% 60/100; C, 50% 10/60, 25% 60/100, 25% <100.

decreased markedly when added to the other 2 systems which already contained finer particles. Both the fine fraction of the same material and cornstarch appeared to act in a similar manner. In contrast, the optimum concentrations of fumed silicon dioxide, talc, and magnesium stearate were 0.5% or less. All three were more effective in the mixture containing 25% of <100 mesh particles suggesting that these materials act by a different mechanism than fines or cornstarch which were more effective with coarse particles. Both fumed silicon dioxide and magnesium stearate caused sharp decreases in flow rate when used above their optimum concentration.

Jones and Pilpel (14) have classified glidants into two categories: (*a*) those reducing van der Waal's type interparticle cohesive forces and (*b*) those reducing surface rugosity and hence coefficient of interparticle friction. Another possible mechanism is that glidants act by filling void spaces between particles. It appears that fines and cornstarch which were more effective with coarse particles acted either by filling surface irregularities or void spaces; whereas, silicon dioxide, talc, and magnesium stearate possibly acted by reducing interparticle cohesive forces since they were more effective with finer particles and interparticle attraction forces of the van der Waal's type increases as particle size is reduced (19).

SUMMARY

(*a*) In binary mixtures the addition of finer particles increased the flow rate of 10/20 mesh

granules to a maximum, following which a decrease was obtained upon addition of more finer particles. The maximum flow rate was specific for each binary component system and varied with the concentration and size of the added particles.

(*b*) Flow rates of granulations were found to vary considerably, depending upon the degree of wetness and upon the granulating agent used. Granulating agents in order of increasing effectiveness were: 10% starch, 2% methylcellulose, 10% PVP, 10% gelatin, and 10% methylcellulose.

(*c*) Faster flow rates of granulations and blended systems of various particle size distributions were associated with an increase in proportion of 10/60 mesh granules and a decrease in proportion of <100 mesh granules.

(*d*) Effectiveness of glidants was found to be dependent upon particle size of the granules to which they were added. Cornstarch and <100 mesh particles of the same material were found to be more effective for coarse particles; whereas, fumed silicon dioxide, talc, and magnesium stearate were more effective with finer particles.

Rheologic Studies on Dermatologic Lotions

By IVO SETNIKAR, GIUSEPPE GÁL, and SERGIO FANTELLI

The rheologic properties of some dermatologic lotions were studied. The changes in the viscosity, thixotropy, and yield value of the lotions during storage and following various degrees of agitation were recorded. The relevance of these phenomena to production processes and to therapeutic use are discussed. The range of optimum viscosity values of dermatologic lotions is indicated.

DERMATOLOGIC LOTIONS are milky, fluid pharmaceutical preparations consisting of a disperse phase of liquid or solid particles in a predominantly aqueous phase.

The rheologic properties of lotions are generally of non-Newtonian type. Indeed, their viscosity often depends upon the shear rate and may be of the dilatant, pseudoplastic, plastic, or Bingham type. They may even exhibit an isothermic reversible decrease in viscosity after an imposed shear rate (thixotropy) or an increase in viscosity (rheopexy).

It is important to know the rheologic properties of a lotion, and the changes they undergo during preparation and during storage in order to adapt the manufacturing operations to these properties and ensure that the lotion possesses the most suitable rheologic properties when it is used therapeutically; few studies on these lines have been published. Woodman and Marsden (1) described the thixotropic properties of a lotion they had prepared. They used "Rheomat" and "Rotovisco" viscosimeters, which involve decanting the lotion into the viscosimeter vessel to measure the viscosity, an operation that alters the rheologic status of a sample with pronounced thixotropic or rheopexic properties.

The ideal instrument for defining the rheologic properties of lotions should (*a*) permit measurement at various shear rates, and (*b*) not require decanting, so that the viscosity of a lotion is not altered before measurement. The latter point is

Rheologic Studies on Dermatologic Lotions

By IVO SETNIKAR, GIUSEPPE GÁL, and SERGIO FANTELLI

The rheologic properties of some dermatologic lotions were studied. The changes in the viscosity, thixotropy, and yield value of the lotions during storage and following various degrees of agitation were recorded. The relevance of these phenomena to production processes and to therapeutic use are discussed. The range of optimum viscosity values of dermatologic lotions is indicated.

DERMATOLOGIC LOTIONS are milky, fluid pharmaceutical preparations consisting of a disperse phase of liquid or solid particles in a predominantly aqueous phase.

The rheologic properties of lotions are generally of non-Newtonian type. Indeed, their viscosity often depends upon the shear rate and may be of the dilatant, pseudoplastic, plastic, or Bingham type. They may even exhibit an isothermic reversible decrease in viscosity after an imposed shear rate (thixotropy) or an increase in viscosity (rheopexy).

It is important to know the rheologic properties of a lotion, and the changes they undergo during preparation and during storage in order to adapt the manufacturing operations to these properties and ensure that the lotion possesses the most suitable rheologic properties when it is used therapeutically; few studies on these lines have been published. Woodman and Marsden (1) described the thixotropic properties of a lotion they had prepared. They used "Rheomat" and "Rotovisco" viscosimeters, which involve decanting the lotion into the viscosimeter vessel to measure the viscosity, an operation that alters the rheologic status of a sample with pronounced thixotropic or rheopexic properties.

The ideal instrument for defining the rheologic properties of lotions should (*a*) permit measurement at various shear rates, and (*b*) not require decanting, so that the viscosity of a lotion is not altered before measurement. The latter point is

Received June 13, 1967, from the Research Division, Recordati s.a.s., Milano, Italy.
Accepted for publication October 12, 1967.

especially important when checking after an interval of time, for the viscosity of a lotion is liable to undergo considerable change during storage. Not even the thixotropic effect can be determined correctly if the lotion has been subjected to shear, *e.g.*, as with decanting. Of the various types of instruments, reviewed by Bottoni (2), neither capillary viscosimeters (Ostwald, Ubbeldholde) nor falling (Hoeppler) or ascending sphere viscosimeters (Cochins) comply with either of the requisites specified above. Brebender, MacMichael, or Ferranti-Shirley viscosimeters permit the study of viscosity in very precisely defined geometric and dynamic conditions, but they require decanting of the liquid and so do not comply with requirement *b*. Brookfield's viscosimeter does not allow the strict definition of geometric and dynamic conditions and so yields conventional viscosity values; on the other hand, it does not require decanting of the liquid, and so it complies with condition *b*.

The authors used Brookfield's viscosimeter for their investigations, as it was felt that it was more important to define thixotropy or rheopexy and changes in viscosity after a long storage than it was to obtain viscosity values that are only formally more accurate using other viscosimeters.

EXPERIMENTAL

Rheologic Determinations—The Brookfield RVF viscosimeter was used, calibrated with Brookfield L-3 standard fluid (10 poise at 25°).

The determinations were made at 24° on 600 ml. of lotion in containers with a diameter of 9 cm. To alter the physical status of the sample as little as possible, the spindle was introduced edgeways and very gently into the sample, thus ensuring the minimal shear and the absence of air bubbles on the undersurface of the spindle. The spindle was then screwed on to the apparatus and readings were taken, starting at the lowest speed (2 r.p.m.). The maximum shear stress value shown on the instrument was recorded and readings were taken in the same way at 4, 10, and 20 r. p. m. ("up" curve). Immediately after the sample was subjected in the same container, for 3 min., to the action of a stirrer with two blades (each of 45 × 25 mm.) spinning at 100 r.p.m. The viscosimeter readings were then taken again at decreasing spindle speeds, from 20 to 2 r.p.m. ("down" curve).

The "initial yield value," that is, the maximum stress value required before shear starts, was determined by extrapolating the rheograms up to the intersection with the abscissa (shear rate = 0).

Composition and Method of Preparing the Lotions—The compositions are specified in Table I. Lotions 1 and 2 were prepared by melting at 70° and mixing stearic acid, esters of saturated fatty acids, sorbitan monopalmitate, and polyoxyethylene sorbitan monolaurate and dissolving the propyl-*p*-oxybenzoate in this mixture. The deionized water was heated in another container to 70° and the methyl-*p*-oxybenzoate was dissolved therein. The oily phase was poured into the aqueous phase and this mixture was passed through an ALM-O homogenizer (Auguste and Moutis, Paris). The lotion was cooled while stirring and, at 30°, the propylene glycol was added.

TABLE I—COMPOSITION OF LOTION BASES

Constituents	Gm./100 ml. Lotion 1	Lotion 2	Lotion 3
Stearic acid	1.00	1.00	...
Esters of saturated fatty acids	6.00	6.00	...
Sorbitan monopalmitate	4.50	6.00	...
Polyoxyethylene sorbitan monolaurate	2.00	2.00	...
Cetostearyl alcohol	...	...	3.00
Cetylpolyglycol ether	...	...	0.60
Propylene glycol	5.00	5.00	5.00
Methyl-*p*-oxybenzoate	0.15	0.15	0.15
Propyl-*p*-oxybenzoate	0.03	0.03	0.03
Deionized water *q.s.* to:	100 ml.	100 ml.	100 ml.

"Farmomac" Metering-Bottling Machine—Some samples of the lotions were put through the metering-bottling machine used in manufacturing, with a view of studying the effects of this machine on the rheologic properties of the lotions. The metering-bottling machine was the "Farmomac F 37," made by Messrs. Farmomac of Bologna. Basically it is a syringe by which a certain volume of lotion is sucked, and through an inlet-outlet valve is injected into the final containers. Suction and filling, advancement, and container closure is automatic and may be performed under sterile conditions. The measured volume can be regulated between 0 and 100 ml. and the advancement speed up to 4,500 bottles/hr. From the hydrodynamic point of view the maximum shear of the liquid is reached in the valve and in the bottling needle, with shear rates depending on the delivered volume and on the advancement speed. Under these working conditions the maximum shear rate was approximately 2000 sec.$^{-1}$ with a duration of 0.5 sec.

RESULTS

Influence of the Number of Revolutions of the Spindle on the Viscosity of the Sample—When the viscosimeter is set in motion the pointer quickly marks the maximum value and then begins to fall back because of the thixotropy of the lotion (Fig. 1). The maximum viscosity value found is thus the closest value to the true viscosity of the sample before it is affected by thixotropy. The viscosity readings were therefore always compared to this maximum value obtained by noting the position of the pointer during the first revolutions of the spindle and stopping the viscosimeter when the pointer reached the highest position on the dial (usually at the third revolution).

Rheologic Properties of the Lotions Being Tested—The consistency curves before and after stirring

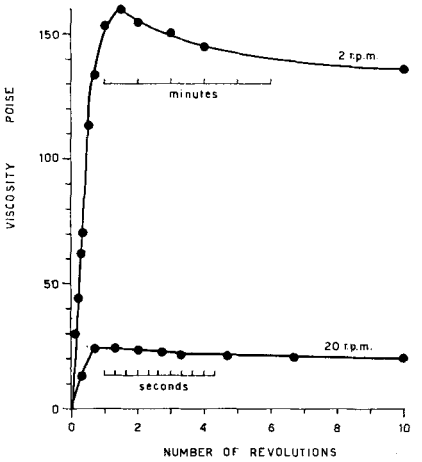

Fig. 1—Changes of viscosity during measurement. Spindle No. 2, 24°, at 2 r.p.m. (approx. 0.6 sec.$^{-1}$ shear rate) and at 20 r.p.m. (approx. 6 sec.$^{-1}$ shear rate). Viscosity appears related to the number of revolutions of the spindle.

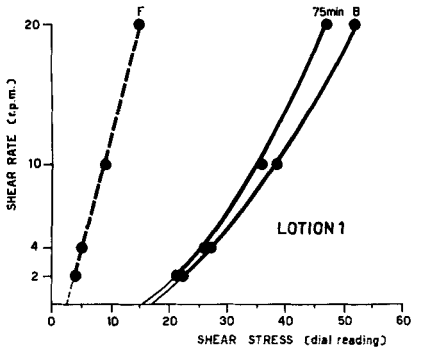

Fig. 2—Lotion 1, spindle No. 2, 24°. Rheogram before (B) and after 75 min. (75) stirring. The dash-line curve (F) is the rheogram after the run through the Farmomac. B is the up curve, the others are down curves.

are given in Figs. 2–4. The viscosity tends to decrease as the shear rate increases and the consistency curve extrapolates to a defined stress value (yield value). The behavior is characteristic of a Bingham-type non-Newtonian liquid.

Stirring diminishes the viscosity and the yield value. The lotions thus show evidence of thixotropy.

Certain types of agitation, such as occur in the Farmomac, may on occasion produce a viscosity which is higher than the lowest viscosity reached by "gentle" stirring.

Dependence of Thixotropy Upon the Type and Duration of Agitation—Figures 2–4 show that the degree of thixotropy depends upon the intensity (*cf.* the F curves) and upon the duration of shear. The two factors must therefore be distinguished and accurately defined when analyzing the thixotropic phenomena. This distinction was drawn by Green and Weltmann (3), who quantified the thixotropic breakdown "by time" and "by velocity."

With traditional methods the thixotropic breakdown measurement is based on the shear imposed by the viscosimeter itself (*cf.* 4) and evaluated by the difference between the "up" and the "down" curve.

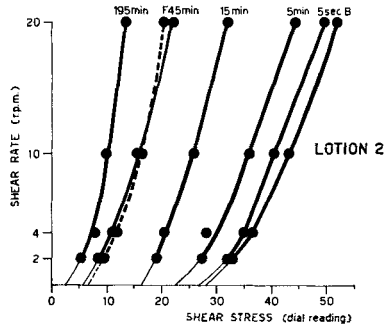

Fig. 3—Lotion 2, spindle No. 2, 24°. Rheogram before (B) and after different times of stirring. The total time of stirring to which the sample was subjected is shown. The dash-line curve (F) is the rheogram of the lotion after the run through the Farmomac. B is the up curve, the others are down curves.

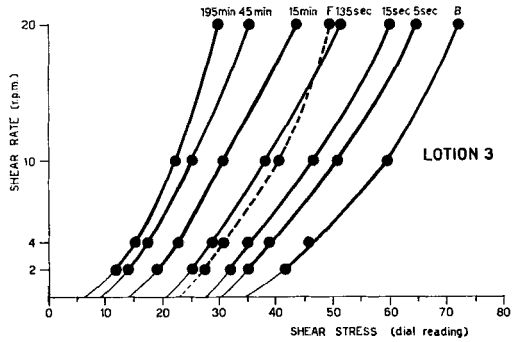

Fig. 4—Lotion 3, spindle No. 2, 24°. Rheogram before (B) and after different times of stirring. The total time of stirring to which the sample was subjected is shown. The dash-line curve (F) is the rheogram of the lotion after the run through the Farmomac. B is the up curve, the others are down curves.

The total shear thus gradually increases from beginning to end of the determination and is not constant in intensity. The result is a loop expressing a superposition of time and intensity of shear that is difficult to analyze.

If a defined quantity of shear is interposed between the consistency measurements, distinct and nearly parallel curves are obtained instead of loops (Figs. 2–4). The distance between the initial (up) curve and the curves after shears of different duration (down curves) expresses thixotropy by time.

The curves obtained differ from those worked out by Green and Weltmann (3) for other types of fluids, because there is also a decrease in yield value [thixotropic coefficient of Goodeve (5)]. Perhaps the difference is due partly to our method, which results in determinations that are less biased by initial thixotropic phenomena, since the operations preceding the determination are less destructive on the structure of the samples.

Effects of the Composition of the Lotion—An alteration of the quantities of the constituents obviously alters the rheologic properties of the lotion, including the thixotropic phenomena. This is illustrated by Figs. 2 and 3, referring to lotions with a different quantitative composition, and by Fig. 4, referring to a lotion with a different qualitative composition.

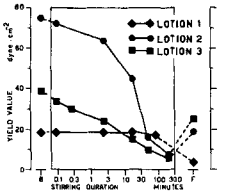

Fig. 5—Yield values at 24° observed for 3 lotions before (B) stirring, after stirring for various periods, and after passage through the Farmomac (F). The values were obtained by extrapolating on the abscissa the consistency curves of Figs. 2–4.

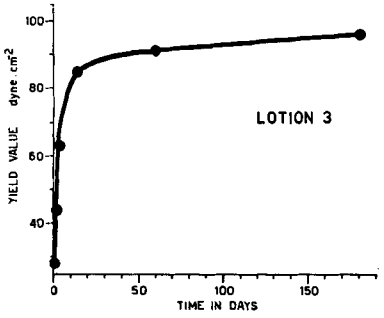

Fig. 6—Lotion 3. Yield values at 24° observed after storage for various periods. This batch of lotion 3 differs from that of Fig. 4.

In Fig. 2 the thixotropy, as a result of 75 min. stirring, is less evident than in the case of Fig. 3. Passage through the bottling machine considerably lowers the viscosity. In Figs. 3 and 4 the thixotropy is marked and the run through the bottling machine determines, in contrast to what happens in Fig. 2, a viscosity intermediate between the initial viscosity and the minimum obtainable with gentle stirring. This effect could be due to a change in particle size or shape or to rheopexic phenomena.

Yield Value—The yield value estimates obtained by means of the Brookfield viscosimeter are represented by a torque and must be referred to the spindle used. To obtain the yield value in dynes·cm.$^{-2}$, the following formula may be used:

$$Y = \frac{m}{2\pi r^2 \cdot r \sqrt[3]{1/2}} = \frac{m}{4{,}986 \cdot r^3} \quad \text{(Eq. 1)}$$

where Y = yield value in dynes·cm.$^{-2}$; m = torque measured in dynes·cm., referred to the intercept of the consistency curves with the shear stress axis; and r = radius of the spindle in centimeters.

Figures 2–4 show that the lotions considered always exhibit a yield value greater than zero.

The yield value changes as a result of stirring. Figure 5 shows the decreases in yield value for the three lotions after different periods of stirring and after passing through the Farmomac.

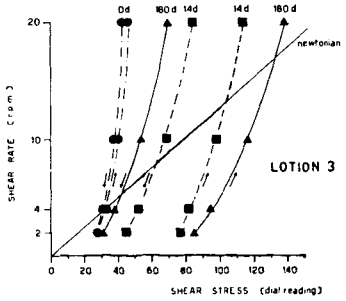

Fig. 7—Lotion 3 (different batch from that of Fig. 4). Consistency curves at 24°. The initial (0 d) up and down curves and the up and down curves after 14 days (14 d) and after 180 days (180 d) are shown. The straight line represents the consistency curve of a Newtonian liquid. As a rule, spindle No. 2 was used. For the 14-day and 180-day samples, spindle No. 3 was used as well. The values were then referred to spindle No. 2 by extending the scale of the abscissas beyond the value 100.

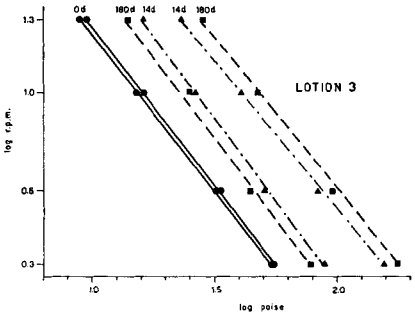

Fig. 8—Results of Fig. 7 plotted on a diagram in which the ordinate is log r.p.m.; the abscissa log poise. By this means the experimental points are on a straight line.

The yield value of a lotion may increase during storage. An example of this is shown in Fig. 6 which refers to lotion 3.

Changes in Viscosity and Thixotropy During Storage—Five samples of lotion 3 were stored in sealed containers at 24° and not moved until viscosimetry. The viscosity and thixotropy values are given in Table II and in Fig. 7.

The viscosity increases considerably with time, *i.e.*, about threefold after 6 months' storage. The thixotropy increases also: evaluated as average percentile decrease of viscosity after standardized stirring it is about 6% in the freshly prepared lotion and rises to 55% after 6 months' storage.

The Fig. 7 viscosity data are drawn in Fig. 8 on a diagram with poise and r.p.m. values in logarithmic

	B[a]	A[a]	Δ[b]	B	A	Δ	B	A	Δ
Batch									
1	23	22	1	50	34	16	2.8	3.3	−0.5
2	19	17	2	53	33	20	4.8	4.5	−0.3

[a] Columns B and A show the values before (B) and after (A) agitation at 100 r.p.m. for 3 min. [b] Columns Δ give the difference between A and B, an index of thixotropy.

scales. By this means the experimental points can be aligned in straight lines and described empirically by

$$\ln v = -A \ln s + B \qquad \text{(Eq. 2)}$$

where v = viscosity; s = shear rate; and A and B = two constants.

By imposing a defined quantity of shear a different line is obtained, in which constant A of Eq. 2 does not change and in which constant B decreases. In these conditions the decrease of B quantitizes empirically the thixotropy.

These conclusions do not agree formally with the measurement of thixotropy by coefficient M of Schulte and Kassem (4). It should be noted, however, that in coefficient M thixotropic breakdown by time is superposed on thioxotropic breakdown by shear, whereas our method permits a separate measurement of thixotropic breakdown by shear.

Effects of Initial Agitation on Changes in Viscosity and Thixotropy Occurring Through Time: Role of the Metering-Bottling Machine—A given quantity of lotion was passed through the Farmomac, an operation equivalent to violent agitation. The changes in viscosity during storage of the lotions thus treated were measured and compared with the changes in viscosity of samples of the same lotion not passed through the Farmomac.

Table III shows the results observed on 4 batches of lotion 1. The run through the Farmomac resulted in a considerable decrease of viscosity. Further, during storage, in the samples not passed through the Farmomac viscosity increased greatly (up to 2.5-fold in 75 days) along with thixotropy (up to 8-fold in 75 days, *cf.* Table IV). Both phenomena did not occur in the samples run through the Farmomac. Thus, as a result of the run through this machine an irreversible change in the rheologic properties of the lotion occurred.

Since the implications of these phenomena for lotion manufacture are important, the authors studied one of them. Observations on the performance of the Farmomac showed that the maximum shear rate occurs at the level of the bottling needles, where it may be estimated as high as 2000 sec.$^{-1}$. Viscosity changes due to the bottling process on some lotions using bottling needles with bores of 6 and 3 mm. were therefore studied. The former yielded shear rates of up to 120 sec.$^{-1}$ and the latter up to 2000 sec.$^{-1}$. Table V shows the viscosity values observed for two lotions before and after passage through the Farmomac in these conditions. As suspected, the decrease under viscosity was greater in the samples run through the smaller bore.

TABLE V—VISCOSITY IN POISE MEASURED AT 2 r.p.m. AND AT 24° ON TWO BATCHES OF LOTION 1 BEFORE AND AFTER THE RUN THROUGH THE FARMOMAC FITTED WITH BOTTLING NEEDLES OF DIFFERENT BORE

Batch	Initial	6-mm. Needles	3-mm. Needles
1	23	4	2.5
2	19	4.8	3.3

DISCUSSION

We have already discussed the ways in which thixotropy recorded by the method used in this study differs from that recorded by traditional methods, such as those used by several authors (6–9). Briefly, the thixotropic breakdown obtained by traditional methods depends on the relatively small shear imposed by the measuring instrument itself and is represented by a loop, formed by the up and down curves, in which thixotropy by time and thixotropy by velocity are mingled. The dimensions and shape of the loop depend upon instrumental factors and on the speeds at which the measurements are taken. The very shape of a loop is solely due to the fact that the apical closing point of the loop is the only one to be unaffected, at a given shear rate level by differences in shearing quantity and duration.

Instead of determining immediately the down curve, the authors interposed a set quantity of shear between the initial (up) and the final (down) consistency measurement, and imposed this shear by means that are independent of the measuring instrument. In these conditions the consistency curves before and after shear are almost parallel and may be expressed by Eq. 2.

"Thixotropic hysteresis loop" is an unhappy misnomer, too, as it implies some resemblance to elastic or magnetic hysteresis. The latter have defined physical dimension and meaning and are independent of measuring instruments. The thixotropic loop has neither, and the magnitude of its area supplies no more information than the average decrease in thixotropy between the two consistency curves.

Since thixotropy depends on the type, degree, and duration of shear, no absolute definition of it is possible, and the study of the phenomenon must be approached keeping in mind the actual conditions which may provoke thixotropic phenomena, and the reasons for which thixotropy may be relevant.

Thixotropy also alters the shape of the consistency curve, since any measurement is affected by the shear imposed by the measurement instruments and by the history of the sample (3). This drawback may to some extent be overcome by using Brookfield's "helipath," by which the spindle shifts vertically in the course of measurement so that it keeps changing its position in the sample. For the lotions considered, the helipath did not prove to have advantages over the method adopted, partly because the bars of this instrument are not designed to register the relatively low viscosities of the authors' lotions and partly because, by the authors' method, thixotropy can be prevented from interfering seriously with viscosity measurement.

For the physical stability of a lotion, an important property is that shear does not begin until a stress of some magnitude is applied (Bingham's yield value). Before the stress applied attains this value, the sample behaves as a solid, "imprisoning" the suspended particles, which thus can neither come to the top nor sediment (11). It is even possible to calculate a critical yield value below which the particles separate out into layers. For example, for the lotions studied, it may be assumed that the particles in suspension are spherical, have a diameter of 4 μ, and a density of 0.9, and that the density of the continuous phase is 1.0. In these conditions every particle receives an upthrust of $3.4 \cdot 10^{-9}$ dynes and, as every particle has a surface of $5 \cdot 10^{-7}$ cm.^{2}, the fluid must possess a yield value of at least $6.9 \cdot 10^{-3}$ dynes. cm.$^{-2}$ to prevent the particles from coming to the top. This value is much lower than the actual yield values of our lotions, which are 100–1000 times greater and which thus ensure good stability during storage. It should be noted, however, that the rheologic properties of a lotion are the properties of the fluid as a whole, that is of the continuous phase together with the particles in suspension, and so the foregoing calculations can not be considered very rigidly.

The yield value increases during storage and this improves the physical stability of a lotion. It decreases if the lotion is stirred. If the agitation is very violent the yield value may be abolished altogether and so the stability of the lotion may be affected.

The passage of the lotion through the metering-bottling machine, which is usually the final step in the pharmaceutical process, imposes on the lotion a heavy shear of short duration. This is not comparable to a more gentle stirring of longer duration, since viscosity and yield values may be influenced differently in the two conditions. In fact the violent shear may modify some qualities of the emulsion such as increase of surface area of the internal phase, size and shape of the particles, *etc.*, which may decrease or increase viscosity or yield value, and therefore also the physical stability of the lotion.

Storage increases also the viscosity of the lotions under consideration, thereby slowing down the rate at which the particles come to the top or sediment. An undue increase in viscosity has its snags, however. First, it cancels out the advantages of lotions over creams as regards therapeutic use, second, the lotion becomes more difficult to get out of its container, and third, lotions of different ages exhibit different rheologic properties, a fact that is likely to worry the consumer.

Optimum Viscosity for a Dermatologic Lotion—Although the rheologic definition is an essential technologic datum for dermatologic lotions, the pharmacopeias make no reference to it. The USP XVII, the NF XII, and the BP 1963 simply carry a few examples of lotions without describing their physicochemical properties or specifying methods for determining them.

It is highly desirable for the rheologic properties of lotions to be stated and studied, as knowledge of these properties is indispensable: (*a*) for checking that the formula adopted yields the degree of viscosity suited to the therapeutic use for which the lotion is intended; (*b*) for adjusting the production and bottling equipment to the rheologic properties of the product in the various stages of production, and (*c*) for checking and ensuring the physical stability of the lotion over a period of time.

With regard to point *a*, lotions are usually preferred to creams when the area to be treated is painful or the skin very delicate, in which case the process of rubbing to spread the cream would be painful. Lotions are also preferable when the areas to be treated are large or there are skinfolds or hairy areas or when the lesions are scabbed or chapped, that is when the lotion reaches the target more easily than a cream. For all these reasons viscosity should be kept as low as possible. On the other hand, a liquid with low viscosity tends to run off easily from skin surface, which is never perfectly horizontal. Hence, one has to seek a compromise between these opposite requirements.

This problem does not yet seem to have been approached. We have therefore carried out acceptance tests with lotions of varying viscosity on normal subjects and on patients suffering from skin diseases. The results showed that the extreme range of acceptable viscosity, determined at 20 r.p.m. with a No. 2 spindle at 24°, is between 1 and 20 poise and that the optimum range of viscosity is between 2 and 5 poise. To generalize this indication to other vicosimeters it may be added that the above shear rate corresponds to about 6 sec.$^{-1}$. This shear rate is at the lower levels of those actually applied to lotions when rubbed on skin. In fact the layers of lotion may be estimated between 0.02 and 0.3 cm., the velocity of rubbing between 1 and 5 cm. · sec.$^{-1}$. This is to say that shear rates between 3 and 250 sec.$^{-1}$ may be involved during therapeutic use.

Thermodynamic Effects in the Compression of Solids

By EDWARD J. HANUS* and LOUIS D. KING

The temperature changes of solids undergoing compression were determined. Compounds of known heat capacity were compressed into tablets at varying speeds and pressure and collected into thermally insulated vessels containing a suitable liquid. The resulting increase in temperature of the liquid was measured after equilibrium was established, and it was found that the increases in temperature were directly related to speed of compression and to compression pressure. Extrapolation of the data provided a technique for predicting tablet temperatures at time of compression. Thermal energy was converted to its mechanical equivalent thus providing a means for estimating the energy expended in the tablet compression process. The use of thermochromic indicators qualitatively supported the validity of the conclusions and quantitative confirmation was obtained by direct heating of samples.

MEASUREMENT OF thermal energy developed in a dynamic operation such as the compression of solids with a tablet machine is a difficult and challenging problem. The reasons are numerous: (*a*) the heat content of a compressed compact is very quickly dissipated to its environment, (*b*) the high pressures applied during compression would crush ordinary temperature measuring devices such as thermometers or thermistors, and (*c*) during compression, the granulation is virtually encased within a steel chamber consisting of the die and punches, and thus is not physically accessible at the moment when temperatures are at a maximum.

In the compaction of powders, the following processes contribute to the total energy of compression (1, 2).

(*a*) Packing—Initially within a bed of powder there is essentially only one point of contact between two neighboring particles. As pressure is applied, consolidation takes place by the particles sliding one over the other and heat is generated. The extent to which this occurs is influenced to a large degree by the frictional properties of the two sliding surfaces (3, 4).

(*b*) Elastic and plastic deformation—In this phase of compression, most of the energy is consumed in the deformation of particles and by die-wall friction.

(*c*) Cold working with or without fragmentation—When fragmentation occurs, the specific surface area of tablets increases directly with pressure to a maximum and then decreases (5).

(*d*) Removal of the upper punch from the die after compression.

(*e*) Tablet ejection.

Nelson *et al.* (2), using an instrumented single punch tablet machine, found it possible to estimate the energy expended in the tablet compres-

Thermodynamic Effects in the Compression of Solids

By EDWARD J. HANUS* and LOUIS D. KING

The temperature changes of solids undergoing compression were determined. Compounds of known heat capacity were compressed into tablets at varying speeds and pressure and collected into thermally insulated vessels containing a suitable liquid. The resulting increase in temperature of the liquid was measured after equilibrium was established, and it was found that the increases in temperature were directly related to speed of compression and to compression pressure. Extrapolation of the data provided a technique for predicting tablet temperatures at time of compression. Thermal energy was converted to its mechanical equivalent thus providing a means for estimating the energy expended in the tablet compression process. The use of thermochromic indicators qualitatively supported the validity of the conclusions and quantitative confirmation was obtained by direct heating of samples.

MEASUREMENT OF thermal energy developed in a dynamic operation such as the compression of solids with a tablet machine is a difficult and challenging problem. The reasons are numerous: (*a*) the heat content of a compressed compact is very quickly dissipated to its environment, (*b*) the high pressures applied during compression would crush ordinary temperature measuring devices such as thermometers or thermistors, and (*c*) during compression, the granulation is virtually encased within a steel chamber consisting of the die and punches, and thus is not physically accessible at the moment when temperatures are at a maximum.

In the compaction of powders, the following processes contribute to the total energy of compression (1, 2).

(*a*) Packing—Initially within a bed of powder there is essentially only one point of contact between two neighboring particles. As pressure is applied, consolidation takes place by the particles sliding one over the other and heat is generated. The extent to which this occurs is influenced to a large degree by the frictional properties of the two sliding surfaces (3, 4).

(*b*) Elastic and plastic deformation—In this phase of compression, most of the energy is consumed in the deformation of particles and by die-wall friction.

(*c*) Cold working with or without fragmentation—When fragmentation occurs, the specific surface area of tablets increases directly with pressure to a maximum and then decreases (5).

(*d*) Removal of the upper punch from the die after compression.

(*e*) Tablet ejection.

Nelson *et al.* (2), using an instrumented single punch tablet machine, found it possible to estimate the energy expended in the tablet compres-

sion process by considering the magnitude and relation between compression variables (upper and lower punch force, ejection force, upper punch displacement), and the linear dimension of the die cavity. Using granulations of sulfathiazole, Nelson calculated a probable temperature rise of about 5° by constructing force–displacement curves and measuring the area under the curve with a planimeter. However, there appears to be a need for a relatively simple and inexpensive method for determining the total heat generated by solids undergoing compression in order to study the tableting process. It was for this reason that the current study was initiated.

The simplest approach to the problem originally appeared to be to include some material in the tablet granulation that would change color in such a way as to give a true indication of the maximum temperature produced during compression. However, results from this portion of the study were only qualitative in nature and a more precise thermometric method was developed.

EXPERIMENTAL

Thermochromic Method—Samples of Thermochrom temperature indicating crayons[1] and Detecto Temp temperature indicating pigments[1] were obtained for evaluation. The exact chemical identity of these highly complex metallic salts could not be provided. When the specified temperature is maintained for 1 or 2 sec. a gas, such as carbon dioxide, ammonia, sulfur dioxide, or water vapor is liberated and the chemical structure and color of the salts undergo changes (6). Eighteen Thermochrom crayons provide temperature measurements from 65°–670°. Thirty-six pigments cover a measurement range from 40 to 1350°; accuracy is estimated to be ±5°. Reportedly changes in air pressures affect all compounds in that the color change temperature thresholds are displaced upward or downward (7). At 5–10 mm. mercury, the materials change color from 5–20% below the temperatures they would indicate under normal atmospheric pressure and when used under vacuum or pressure, suitable calibrations are recommended.

The lowest available temperature indicating crayons of Thermochrom 915–1015 (65°) and 915–1016 (75°) were shaved with a razor blade to small fragments, passed through a No. 40 sieve, added to separate samples of sodium chloride (40/60 mesh) at a concentration of 1%, and mixed for 15 min. by tumbling in a wide-mouth glass bottle. Three-gram tablets were then prepared using a hydraulic press at a pressure of 10,000 lb. Duplicate runs revealed no change in color from gray to blue (65°) or gray to green (75°) in either sample, therefore, it was tentatively concluded that the average temperature of the sodium chloride tablet was less than 65°. However, it was noted that the crayons appeared to contain a waxy base which would undoubtedly act as a lubricant and possibly alter experimental results. For this reason, the Thermochrom crayons were abandoned and attention was directed toward the Detecto Temp pigments which were available as fine powders and could readily be incorporated in tablet granulations.

The first pigment to be examined was Detecto Temp 915–0900 which was reported to change from pink to blue after 2 sec. at 40°. A 5% triturate of sodium chloride (40/60 mesh) was prepared and then compressed into 3-Gm. tablets of $^3/_4$ in. diameter using a flat-faced upper tablet punch and a smooth flat stainless steel plate as a support for the die in lieu of a lower tablet punch. Tablet pressure was brought up rapidly and maintained at 10,000 lb. for 15 sec. and then quickly released. It was noted that tablets made in this manner changed in color from pink to blue indicating that an average tablet temperature of approximately 40° or higher had been attained.

The pigment available at the next higher temperature was Detecto Temp 915–0923 which was reported capable of undergoing two color changes, *i.e.*, pink to lilac at 55° and lilac to blue at 85°. Tablets prepared in the manner described above showed a very faint lilac color which was difficult to distinguish with certainty from the original pink color of the pigment. In order to establish confidence in the observations, tablets were prepared at pressures of 5,000, 10,000, and 30,000 lb. on the basis that increasing pressures might produce higher tablet temperatures. This was borne out in the experimental results which showed no color change at 5,000 lb. pressure, a very faint color change at 10,000 lb., and a definite color change at 30,000 lb.

The experiment was repeated with Detecto Temp 915–0901 which changes from light green to blue at 60°. Pressures of 10,000 and 30,000 lb. were employed; no change in color was observed indicating that a temperature of 60° was not reached regardless of pressure. Tablets containing the 60° pigment (915–0901) were placed in an oven at 80° for $1^1/_2$ hr. A pronounced color change from green to blue was noted indicating that the pigment was operative.

Thus, using a pressure of 30,000 lb., sodium chloride tablets were found to rise in temperature to about 55°, and an increase in thermal energy appeared to be directly related to an increase in pressure.

The temperature developed at points in the compress was probably much higher than the indicated temperature. However, no measure of the maximum temperatures which may have developed was possible because of the time required for the pigments to undergo changes and the possible reversibility of the reactions. Only average temperature changes for the total compress were observed.

Effect of Reduced Pressure—A vacuum pellet die, usually used with infrared procedures, was employed to prepare $^1/_2$-in. flat-faced tablets under reduced pressure. One-gram tablets of sodium chloride were compressed at a pressure of 3,000 lb. while a vacuum of 2 mm. mercury was maintained for 30 min. Two pigments were tested at a concentration of 5%, *i.e.*, 915–0901 (60°) and 915–0924 (65°) and no color change was noted with the 65° pigment while a nonuniform color change from green

to blue was observed with the 60° pigment. The sides of the tablets were mostly blue whereas the upper and lower face of the tablet still showed some evidence of the original green color. Reducing the time period for applying vacuum from 30 min. to 2 min. resulted in no color change in tablets prepared with either one of the pigments. This indicates that the thermochromic materials change color significantly below the temperatures that they would under normal atmospheric pressure. A summary of the above findings is presented in Table I.

Dynamic Compression—The behavior of the thermochromic materials under dynamic conditions of compression using a Stokes model E single punch tablet machine equipped with 1/2-in. flat-faced punches was studied. Two pigments, 915–0900 (40°) and 915–0293 (55°) were added at a level of 5% to a number of common pharmaceutical compounds; no tablet lubricant was used. Approximately 10 to 50 tablets were compressed depending on the severity of binding or capping experienced because of the absence of lubrication. In all cases, the tablets were made as hard as practical. However, hardness, tablet weight, and thickness measurements were not attempted because the resulting tablets were not satisfactory *per se.*

As shown in Table II, sodium bicarbonate, alumina, citric acid, lactose, and sodium chloride attained average temperatures of about 40°, representing a temperature rise of about 16° above room temperature (24° ± 2°); polyethylene glycol did not exhibit a comparable rise in temperature which is not unexpected considering its lubricating properties (low coefficient of friction) and its relatively low yield value.

Thermometric Method—A single punch Stokes Tablet Machine model E as shown in Fig. 1 was converted to a variable speed tablet press by the use of appropriate pulley arrangements. Other modifications included the use of 1/8 in.-Teflon laminated to the bottom of the feed shoe in order to reduce friction and heat transfer between the feed shoe and die table. In addition, the hopper and die table were ringed with a combination of copper and rubber tubing, covered with aluminum foil and then connected to a constant temperature bath. The granulation, die table, punches, and die were maintained at constant temperature by circulating water through the system. The hopper was covered and a thermometer was inserted into the granulation with the bulb centered 1 in. from the bottom of the hopper. An additional thermometer was attached to the die table in close proximity to the punches and die in order to monitor possible temperature changes in that area of the tablet machine which was critical to the operation. A closed chute was prepared of cardboard and polyethylene and attached to the tablet machine in order to permit transfer of tablets to a Thermos bottle with a minimum loss of heat. Flat-faced punches of 1/2 in. diameter were used throughout the study.

Granulations—Calcium carbonate and sodium chloride, two common materials of known heat capacity, were selected for study. The first was formulated into granules by a wet granulating technique whereas the latter, which can be compressed directly into tablets, was used in its pure form. The calcium carbonate granulation was prepared as follows:

Calcium carbonate USP	10.000 Kg.
Magnesium stearate	0.105
Cellulose acetate phthalate	0.465
Acetone USP	2.068
Methanol	6.204

The cellulose acetate phthalate (CAP) was slowly added with stirring to the acetone. After solution was effected, the methanol was added with stirring until the solution was homogeneous and the solution was then filtered through gauze.

The calcium carbonate was weighed, transferred to a pony mixer, and the granulating solution was added slowly with blending until the mixture was sufficiently wet. The wet mass was forced through a No. 8 mesh screen, air-dried for 18 hr., and then dried at 40° for a period of 40 hr. The dry granules were forced through a No. 14 screen and transferred to a steel drum. Magnesium stearate was added to an equal weight of 60 mesh fines, blended for 15

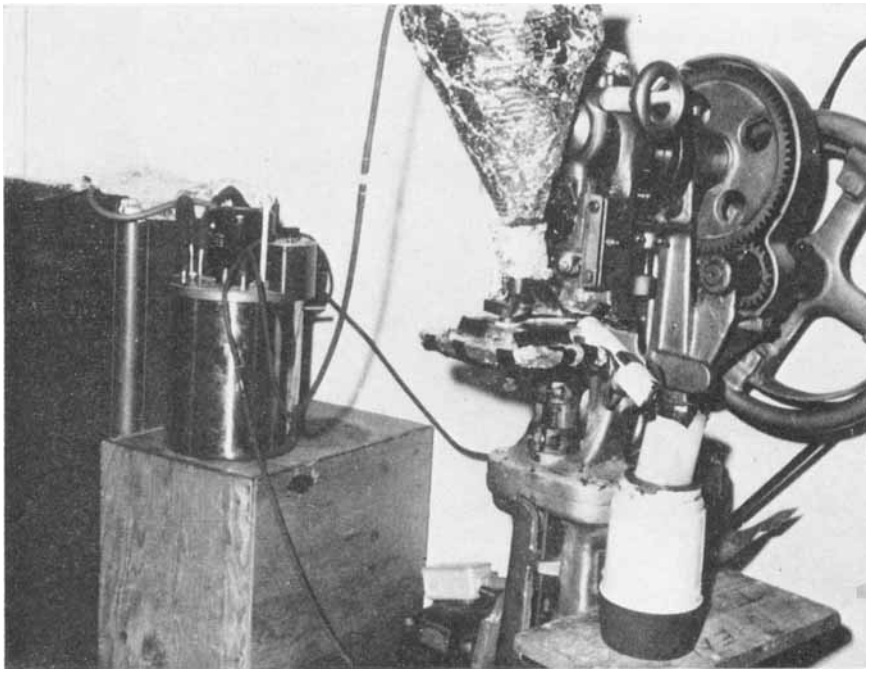

Fig. 1—Modified Stokes model E tablet machine.

min., and then added to the calcium carbonate granulation and mixed for 30 min. to form a homogeneous mixture.

One 25-lb. lot of sodium chloride was used throughout this study. Results of particle size analyses are recorded in Table III.

All operations were conducted in a sealed, air-conditioned room in which a constant temperature of 24° ± 1° was maintained at all times. Wide-mouth Thermos bottles were tared and 160 Gm. of distilled water was added. The bottles were capped and allowed to come to equilibrium for a period of time not less than 15 min. The speed of the tablet machine was then checked with a stopwatch, and the tablets collected were checked for initial weight, thickness, and hardness. Ten tablets were weighed to obtain an average weight; thickness was measured with a pair of vernier calipers and hardness was determined with the Monsanto tablet hardness tester. The plastic cap was removed from one of the Thermos bottles and quickly replaced with a square of Lucite (5 × 5 × ½ in.) to prevent any changes of temperature. A Beckman differential thermometer was inserted through a hole in the Lucite cover into the water to a point ½ in. from the bottom of the container. The temperature of the water was measured after allowing a period of 5 min. for equilibration. The Thermos bottle was then transferred to the tablet machine and inserted snugly under the tablet chute equipped with a round plastic adapter. The tablet machine was activated and approximately 350 tablets each weighing 500 mg. were collected directly into the Thermos. The bottle was immediately capped and allowed to come to equilibrium for 30 min. Exact tablet weight was determined by weighing the Thermos again at this point. At the end of a 30-min. period, the container was gently tumbled for 1 min. and the temperature of the mixture measured. All determinations were made in triplicate at machine, speeds of approximately 27, 40, 60, 80, 100, 120, and 140 tablets/min. Temperatures of the granulation, the room, and the die table were recorded at the beginning and end of each run.

As a control, tablets prepared as previously described were allowed to cool, and then stored at 24° for 15 hr. in preweighed quantities of exactly 175 Gm. The stored tablets were quickly added to the Thermos bottle containing 160 Gm. of distilled water. Temperature changes were measured using the exact procedure described above.

To check the accuracy of tablet temperatures predicted, 175 Gm. of preweighed 500-mg. tablets were stored in sealed glass bottles and heated in a constant temperature oven at a mean temperature of 45.60°. The heated tablets were quickly transferred to the Thermos bottles following precisely the procedure described above and appropriate temperature measurements made.

The procedure employed with sodium chloride was identical to that reported above for calcium carbonate with the following exceptions: (*a*) Two hundred 700-mg. sodium chloride tablets weighing 140 Gm. were compressed and collected in each

Table III—Particle Size Analysis of Calcium Carbonate and Sodium Chloride Granulations

Particle Size, μ	Calcium Carbonate, %	Sodium Chloride, %
840	24.0	5.1
420–840	33.3	65.2
177–420	21.4	29.6
177	21.3	0.1

Thermos bottle containing 150 Gm. of carbon tetrachloride. (*b*) In checking the accuracy of the method, the sodium chloride tablets were heated at a mean temperature of 32.06°.

Effect of Pressure—Although an instrumented tablet press, equipped with a strain gauge for measuring pressure was not available, it seemed desirable to determine the effect of pressure on thermal effects developed during tablet compression. In this connection, the pressure adjustment screw was measured; the circumference was calculated and found to be 8.3254 cm. The screw was then suitably calibrated so that each quarter turn of the screw would move through a distance of 2.0814 cm. Using sodium chloride as the test material, tablets were compressed at 8 different pressure settings ranging from 0 to 2.5 turns of the pressure adjustment set screw. All determinations were conducted in triplicate using the process detailed heretofore.

CALCULATIONS

The temperature of a tablet at a given machine speed was calculated from the thermal capacities of the tablet material and the liquid to which the tablets were added. Heat capacity values utilized are listed below (8):

Calcium carbonate granulation	0.206
Sodium chloride	0.220
Distilled water	1.000
Carbon tetrachloride	0.202

The following equation was used for calculating the increase in thermal energy of the compressed solid.

$$\Delta T = \frac{\Delta T_L W_L C_L}{W_t C_t}$$

where ΔT is the measured increase in temperature (°C.) of the tablets as a result of compression, ΔT_L is the increase in the temperature of the liquid (°C.), W_L the weight of the liquid, C_L the heat capacity of the liquid, W_t the weight of tablets, and C_t the heat capacity of the tablet granulation.

The calculated temperature (T) of the tablet just before striking the surface of the liquid was determined by summing ΔT and T_f and making a correction for the heat of wetting, mixing, dissolution, *etc.* (T_w) as follows:

$$T = (\Delta T + T_f) - T_w$$

where T_f represents the final temperature of the tablet-liquid mixture after equilibrium is established.

It was not feasible to collect a predetermined exact weight of tablets because of normal tablet weight variations, and practical counting difficulties. Thus, temperature readings were adjusted for a common weight, *i.e.*, 175 Gm. for the calcium carbonate granulation and 140 Gm. in the case of the sodium chloride. Temperature increases obtained with the unheated control tablets (T_w) were subtracted from the calculated temperature (T) in the case of the calcium carbonate granulation only since the T_w for the sodium chloride was found to be insignificant. This correction factor was 4.90° for the $CaCO_3$.

RESULTS AND DISCUSSION

Tables IV and V present a summary of the results obtained with the calcium carbonate and sodium chloride granulation, respectively. These data show that as the speed of the tablet machine increases, the temperature of the tablets collected also increases. In all cases, temperature ranges were not more than 1.61° indicating excellent reproducibility of results considering the nature of the experiments.

As can be observed, tablet hardness was reasonably well maintained throughout the study since variation in pressure imparts significant effects on tablet temperature. The relationship of tablet temperature to machine speed, Fig. 2, is almost

linear at low speeds, whereas at high speeds the temperature values tend to become constant. This indicates that a limiting value was approached and that relatively little thermal energy is lost to either the tablet press or atmosphere at the highest attainable machine speed.

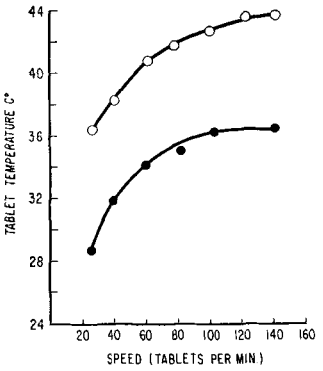

Fig. 2—Tablet temperature as a function of machine speed. Key: ●, 700-mg. sodium chloride tablets; ○, 500-mg. calcium carbonate tablets.

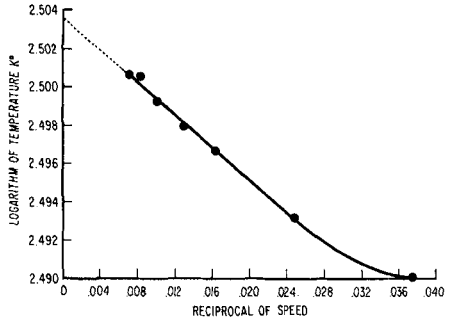

Fig. 3—Relationship of the logarithm of tablet temperature in degrees Kelvin (K.°) and the reciprocal of machine speed for tablets of calcium carbonate.

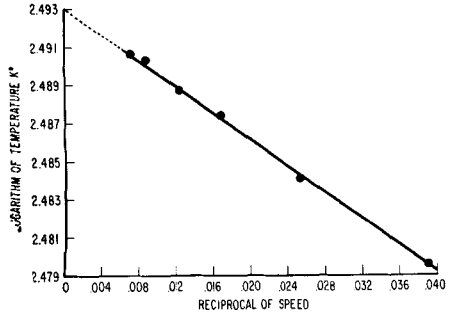

Fig. 4—Relationship of the logarithm of tablet temperature in degrees Kelvin (K.°) and the reciprocal of machine speed for tablets of sodium chloride.

Plotting the logarithm of the tablet temperature in degrees Kelvin (°K.) against the reciprocal of machine speed produced a linear relationship as shown in Figs. 3 and 4. Extrapolation of the plot to the y axis gave the predicted temperature of the solid at the instant of maximum compression. At this theoretically infinite speed, losses in thermal energy by conduction to the tablet machine or radiation to the atmosphere approached zero. Thus, were it possible to run a tablet press at infinite speed, the enthalpy of the compressed compact would be completely transposed to the liquid in the thermally insulated collecting vessel. Some slight departure from linearity was noted only in the case of the calcium carbonate granulation at a slow speed of 27 tablets/min. The temperature of the compressed sodium chloride and calcium carbonate tablets was then determined at time of compression from their respective plots and is reported in Table VI.

The average increase in temperature as a result of the tablet compression process was found to be 20.9° for calcium carbonate and 14.2° for sodium chloride. The local temperatures in the granulation at the points of contact during compaction may momentarily be several hundred degrees, thus the temperatures reported above actually represent the mean tablet temperature immediately after compression.

In order to establish further confidence in the procedure, tablets were first heated to an exact temperature and subjected to the experimental method detailed above. Predicted and observed temperatures were compared and are reported in Table VII. The observed and predicted temperatures for calcium carbonate are in good agreement. However, there is a difference of approximately 9% between the 2 values for sodium chloride. This difference appears to be due to difficulty in obtaining exact values for the specific heat in the indicated temperature range and slight inherent errors in the experimental methods. Variability within individual experiments was not more than 0.16° in all cases.

Pressure has a profound thermodynamic effect on materials undergoing compression as can be deduced from Table VIII. At a low pressure mea-

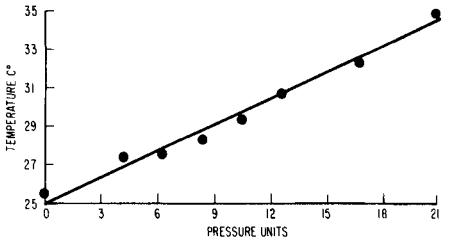

Fig. 5—The relationship of tablet temperature and applied pressure during the compression of sodium chloride tablets.

sured as 0 "cm." the tablet formed was observed to be extremely fragile however its shape was retained; the temperature increase noted was only 1.51°. On the other hand, when the pressure was grossly increased to a near maximum at 20.814 "cm." pressure, the increase in thermal energy was more than seven fold. Plotting pressure as represented by calibrated pressure adjusting screw *versus* temperature, produced a linear relationship as shown in Fig. 5. The reproducibility of the individual experiments at various pressure was excellent with the range of results being not more than 0.91° in all cases. As expected, tablet thickness was found to be inversely related to pressure and tablet hardness directly related.

Having determined tablet temperature as a result of compression, the heat in calories input, was then obtained from the following relationship:

$$Q = \Delta TCM$$

where Q is calories of heat, ΔT the increase in temperature, C the heat capacity, calorie/degree/Gm. of the granulation, and M the weight of one tablet in Gm. As shown in Table IX, it was found that the increase in heat per tablet for the calcium carbonate and sodium chloride tablet was 3.0 and 2.0 cal., respectively. Observing the law of conservation of energy and assuming that all the useful energy expended in the compression process appeared as heat, the mechanical equivalents of heat appearing in Table IX were derived from the following relationships: (9)

$$1 \text{ cal.} = 4.1858 \times 10^7 \text{ ergs} = 4.1858 \text{ abs. joules}$$

Thus by determining the increase in thermal energy in powdered solids as a result of compression, it has been possible to estimate the total useful energy expended in the tablet compression process.

SUMMARY AND CONCLUSIONS

The thermal changes occurring in powdered solids undergoing compression have been studied. Granulations of calcium carbonate and sodium chloride were compressed into tablets at varying machine speeds and pressures and collected into a thermally insulated vessel containing a suitable liquid. The resulting increase in temperature was measured after equilibrium was established. It was found that the increases in temperature were directly related to speed of compression and to the applied pressure. Plotting the reciprocal of time *versus* the logarithm of the temperature provided a linear relationship. An extrapolation provided techniques for predicting tablet temperature at the time of compression. Good agreement was observed between predicted tablet temperatures and results obtained by heating tablets by direct means. Further qualitative confirmation was obtained by the use of thermochromic materials which changed color at predetermined temperatures.

The measured thermal energy was converted to its mechanical equivalent thus providing a means for determining the useful work required for the tablet compression process. It is felt that the techniques reported here should find future utility as a tool in more quantitatively evaluating various parameters in tabletting technology related to the study of lubricants, excipients, glidants, particle size, moisture, and hardness.

TABLE IX—ENERGY REQUIREMENTS PER TABLET FOR THE COMPRESSION OF CALCIUM CARBONATE AND SODIUM CHLORIDE GRANULATIONS

Tablet Identification	Temperature Increase,[a] °C.	Thermal Energy Increase, Cal.	Mechanical Energy Expended ergs × 10^{-7}	Mechanical Energy Expended abs. joules
Calcium carbonate tablets, 500 mg.	20.9	3.0	12.6	12.6
Sodium chloride tablets, 700 mg.	14.2	2.0	8.5	8.5

Synthesis of Several Dibasic Acid Esters of 3-Quinuclidinol as Potential Pharmacological Agents

By HILLEL LIEBERMAN and SAMUEL ELKIN

Eight new dibasic acid esters of 3-quinuclidinol have been synthesized and isolated as their free bases using an alcoholysis reaction. A ninth compound, 3-quinuclidinyl hydrogen homophthalate, could not be isolated with sufficient purity to obtain an elemental analysis. However, this compound showed characteristic ester bands and gave a positive hydroxamic acid test. In a preliminary pharmacological evaluation in dogs, 3-quinuclidinyl hydrogen phthalate and 3-quinuclidinyl hydrogen 2,3-pyridinedicarboxylate gave a substantial increase in blood pressure and produced central stimulation as evidenced by a marked increase in respiration. Five compounds showed varying degrees of local anesthetic activity.

SERIES OF ESTERS of 3-quinuclidinol have been prepared by Sternbach and Kaiser (1) and by Mikhlina and Rubtsov (2). All of these esters produced marked spasmolytic activity. Of great interest was the observation that many of these esters showed a much higher antiacetylcholine activity than the analogous esters derived from diethylaminoethanol and other generally used basic alcohols. One of the most active of the series was 3-diphenylacetoxyquinuclidine.

Many other therapeutically active quinuclidine derivatives have been synthesized and pharmacological activity has been found in both mono- and disubstituted products. Several 3-substituted derivatives of quinuclidine have been reported by Grob (3) to stimulate the central nervous system. A series of 2-aminomethyl quinuclidines has been prepared and tested by Rubtsov *et al.* (4). Some members of the series were found to have strong ganglionic blocking activity while one member, diethylaminoethylquinuclidine-2-carboxylate (5), was found to be a good hypotensive. Ganglionic blocking was also noticed with 2,3-disubstituted derivatives (6). Perrine (7) has synthesized a series of 4-phenyl substituted compounds for investigation as possible analgesics.

The research involved in this work devotes itself to the synthesis of a series of dibasic acid esters of 3-quinuclidinol and the preliminary pharmacological testing of these products. These compounds evoked one or more of the following pharmacological responses: local anesthetic activity, respiratory and vasomotor stimulation.

Eight new compounds were synthesized and are represented by the general formula, I. All products

Received July 19, 1967, from Temple University School of Pharmacy, Philadelphia, PA 19140

Accepted for publication October 23, 1967.

Abstracted, in part, from a thesis presented by Hillel Lieberman in partial fulfillment of the requirements for the Master of Science degree.

The authors thank Dr. David Mann, Temple University School of Pharmacy, for his guidance in the pharmacological studies.

Synthesis of Several Dibasic Acid Esters of 3-Quinuclidinol as Potential Pharmacological Agents

By HILLEL LIEBERMAN and SAMUEL ELKIN

Eight new dibasic acid esters of 3-quinuclidinol have been synthesized and isolated as their free bases using an alcoholysis reaction. A ninth compound, 3-quinuclidinyl hydrogen homophthalate, could not be isolated with sufficient purity to obtain an elemental analysis. However, this compound showed characteristic ester bands and gave a positive hydroxamic acid test. In a preliminary pharmacological evaluation in dogs, 3-quinuclidinyl hydrogen phthalate and 3-quinuclidinyl hydrogen 2,3-pyridinedicarboxylate gave a substantial increase in blood pressure and produced central stimulation as evidenced by a marked increase in respiration. Five compounds showed varying degrees of local anesthetic activity.

SERIES OF ESTERS of 3-quinuclidinol have been prepared by Sternbach and Kaiser (1) and by Mikhlina and Rubtsov (2). All of these esters produced marked spasmolytic activity. Of great interest was the observation that many of these esters showed a much higher antiacetylcholine activity than the analogous esters derived from diethylaminoethanol and other generally used basic alcohols. One of the most active of the series was 3-diphenylacetoxyquinuclidine.

Many other therapeutically active quinuclidine derivatives have been synthesized and pharmacological activity has been found in both mono- and disubstituted products. Several 3-substituted derivatives of quinuclidine have been reported by Grob (3) to stimulate the central nervous system. A series of 2-aminomethyl quinuclidines has been prepared and tested by Rubtsov *et al.* (4). Some members of the series were found to have strong ganglionic blocking activity while one member, diethylaminoethylquinuclidine-2-carboxylate (5), was found to be a good hypotensive. Ganglionic blocking was also noticed with 2,3-disubstituted derivatives (6). Perrine (7) has synthesized a series of 4-phenyl substituted compounds for investigation as possible analgesics.

The research involved in this work devotes itself to the synthesis of a series of dibasic acid esters of 3-quinuclidinol and the preliminary pharmacological testing of these products. These compounds evoked one or more of the following pharmacological responses: local anesthetic activity, respiratory and vasomotor stimulation.

Eight new compounds were synthesized and are represented by the general formula, I. All products

Received July 19, 1967, from Temple University School of Pharmacy, Philadelphia, PA 19140

5	HOOC—
6	HOOC—
7	—$CH_2CH(C_{10}H_{21})COOH$
8	—$CH_2CH(C_{16}H_{33})COOH$

All compounds were prepared by alcoholysis, an acylation reaction between an anhydride and an alcohol (8). All types of alcohols are acylated by anhydrides. Cyclic anhydrides of dibasic acids are cleaved by alcohols to the monoester of the corresponding dibasic acid (9). The method employed for the preparation of the aforementioned compounds was a modification of that used by Eliel and Burgstahler (10).

The dibasic cyclic anhydrides were dissolved in boiling dry benzene containing varied amounts of pyridine. 3-Quinuclidinol, dissolved in hot dry benzene, was added to a refluxing solution of the anhydride and the mixture was allowed to reflux for 12 hr. In the case of the phthalic acid ester and the 2,3-pyridinedicarboxylic acid ester, white precipitates appeared during the reflux. These were filtered and subsequently purified. In all other cases, a clear solution was obtained at the end of the reflux period from which the product precipitated upon cooling. All yields were greater than 70%.

One of the compounds, 3-quinuclidinyl hydrogen, homophthalate was very hygroscopic. Attempts were also made to prepare the hydrochloride and methiodide salts. The methiodide salt was prepared by adding excess methyl iodide dropwise to an isopropanol solution of the ester and precipitating the methiodide salt with anhydrous ether. The gummy residue which formed was extremely hygroscopic and could not be crystallized. The hydrochloride salt was prepared by bubbling dry HCl into an alcoholic solution of the ester and precipitating the hydrochloride salt with anhydrous ether. This gummy precipitate could not be crystallized; however, it gave a positive hydroxamic acid test and the IR spectrum showed a characteristic ester band at 5.8 mμ.

EXPERIMENTAL

All melting points are uncorrected. Analyses were performed by Schwarzkopf Microanalytical Laboratory, Woodside, N. Y., and Clarke Microanalytical Laboratory, Urbana, Ill.

Preparation of 3-Quinuclidinyl Hydrogen Succinate—Into a 3-necked flask equipped with a stirrer, dropping funnel, and condenser were added 7.5 Gm. (0.075 mole) succinic anhydride and 100 ml. of dry benzene. This mixture was heated and 15 ml. of pyridine was added. Then 9.6 Gm. (0.075 mole) of 3-quinuclidinol[1] dissolved in 50 ml. of hot dry benzene was added all at once. Upon addition, the solution immediately turned greenish yellow. The mixture was refluxed for 12 hr. whereupon a clear, colorless solution resulted. The solution was distilled at atmospheric pressure to remove 100 ml. of benzene. The remaining solution was then allowed to stand at room temperature for 36 hr. at the end of which time a white precipitate had separated. The precipitate was filtered and recrystallized three times from isopropanol and ether to yield 14.1 Gm. (82.8%) of a white, crystalline product; m.p. 141–143°.

Anal.—Calcd. for $C_{11}H_{17}NO_4$: C, 58.13; H, 7.54; N, 6.16. Found: C, 58.24; H, 7.92; N, 5.90.

Preparation of 3-Quinuclidinyl Hydrogen Phthalate—Into a 3-necked flask equipped with a stirrer, dropping funnel, and condenser were added 11.1 Gm. (0.075 mole) of phthalic anhydride and 75 ml. of dry benzene. This mixture was heated and 5 ml. of pyridine was added. Then 9.6 Gm. (0.075 mole) of 3-quinuclidinol dissolved in 50 ml. of hot dry benzene was added all at once. The mixture was refluxed for 5 hr. whereupon a white precipitate formed. The mixture was cooled to room temperature and filtered with suction. This precipitate was recrystallized three times from hot isopropanol to yield 18.0 Gm. (85.9%) of a white, crystalline product; m.p. 253–255°.

Anal.—Calcd. for $C_{15}H_{17}NO_4$: C, 65.44; H, 6.22; N, 5.09. Found: C, 65.70; H, 6.41; N, 4.99.

Preparation of 3-Quinuclidinyl Hydrogen Maleate—Into a 3-necked flask equipped with a stirrer, dropping funnel, and condenser were added 7.5 Gm. (0.075 mole) of maleic anhydride and 75 ml. of dry benzene. This mixture was kept at room temperature and 9.6 Gm. (0.075 mole) of 3-quinuclidinol dissolved in 50 ml. of hot dry benzene was added all at once. Upon addition, the solution immediately assumed a yellow color which turned brown within 10 min. After the solution turned brown, 50 ml. of pyridine was added all at once and a brown gelatinous mass was deposited on the bottom of the flask. The mixture was refluxed for 4 hr. at the end of which time, a brown gelatinous mass remained at the bottom of the flask. The solution was distilled at atmospheric pressure to remove 75 ml. of benzene. The remaining solution was then allowed to stand at room temperature for 36 hr. and filtered with suction. The precipitate was washed with ether and then dissolved in hot isopropanol The solution was cooled and the product reprecipitated with anhydrous ether. This pre-

[1] Supplied by U. S. Army Chemical Center, Edgewood, Maryland. Can be prepared by the method of Aaron, H. S., Elkin, S., Owens, O. O., Rosenstock, P. D., Leonard, S., and Miller, J. I., *J. Org. Chem.*, 30, 1331(1965).

cipitate was recrystallized three times from hot isopropanol and ether to yield 12.5 Gm. (73.9%) of product; m.p. 160–164°.

Anal.—Calcd. for $C_{11}H_{15}NO_4$: C, 58.65; H, 6.71; N, 6.22. Found: C, 58.65; H, 6.50; N, 5.95.

Preparation of 3-Quinuclidinyl Hydrogen Glutarate—Into a 3-necked flask equipped with a stirrer, dropping funnel, and condenser were added 8.6 Gm. (0.075 mole) of glutaric anhydride and 100 ml. of dry benzene. This mixture was heated and 25 ml. of pyridine was added. Then 9.6 Gm. (0.075 mole) of 3-quinuclidinol dissolved in 50 ml. of hot dry benzene was added all at once. The mixture was refluxed for 15 hr. whereupon a clear, colorless solution resulted. The solution was distilled at atmospheric pressure to remove 100 ml. of benzene. After allowing the solution to cool to room temperature, anhydrous ether was added until cloudiness developed. The mixture was then permitted to stand at room temperature for 30 hr. at the end of which time a white precipitate separated. The mixture was filtered and the residue washed with ether and dried at 50° for 30 min. The white crystalline powder was then dissolved in hot isopropanol and the solution allowed to come to room temperature. Anhydrous ether was added until a white precipitate formed. This precipitate was recrystallized three times from hot isopropanol and ether to yield 14.6 Gm. (80.7%) of a white crystalline product; m.p. 91–94°.

Anal.—Calcd. for $C_{12}H_{19}NO_4$: C, 59.73; H, 7.94; N, 5.81. Found: C, 59.29; H, 7.95; N, 5.63.

Preparation of 3-Quinuclidinyl Hydrogen 1,2-Cyclohexane Dicarboxylate—Into a 3-necked flask equipped with a stirrer, dropping funnel, and condenser were added 11.6 Gm. (0.075 mole) of 1,2-cyclohexanedicarboxylic anhydride and 125 ml. of dry benzene. The mixture was heated and 20 ml. of pyridine was added. Then 9.6 Gm. (0.075 mole) of 3-quinuclidinol dissolved in 50 ml. of hot dry benzene was added all at once. The mixture was refluxed for 15 hr. whereupon a clear, colorless solution resulted. The solution was distilled at atmospheric pressure to remove 125 ml. of benzene. The remaining solution was then allowed to stand at room temperature for 36 hr. at the end of which time a white precipitate had separated. The mixture was filtered and the gummy white residue was washed with anhydrous ether. The residue was dissolved in hot isopropanol and, after cooling, anhydrous ether was added until a white precipitate formed. This precipitate was recrystallized three times from isopropanol and ether to yield 18.1 Gm. (87.7%) of a white, crystalline product; m.p. 205–206°.

Anal.—Calcd. for $C_{15}H_{23}NO_4$: C, 64.03; H, 8.24; N, 4.98. Found: C, 63.88; H, 8.30; N, 4.87.

Preparation of 3-Quinuclidinyl Hydrogen 2,3-Pyridinedicarboxylate—Into a 3-necked flask equipped with a stirrer, dropping funnel, and condenser were added 11.18 Gm. (0.075 mole) of 2,3-pyridinedicarboxylic anhydride and 150 ml. of dry benzene. The mixture was heated and 10 ml. of pyridine was added. Then, 9.6 Gm. (0.075 mole) of 3-quinuclidinol dissolved in 50 ml. of hot dry benzene was added all at once. The mixture was refluxed for 6 hr. whereupon a white precipitate formed. The mixture was cooled to room temperature and filtered with suction. This precipitate was recrystallized three times from isopropanol and ether to yield 19.6 Gm. (94.7%) of a white crystalline product; m.p. 218°.

Anal.—Calcd for $C_{14}H_{16}N_2O_4$: C, 60.86; H, 5.84; N, 10.14. Found: C, 59.86; H, 6.09; N, 10.10.

Preparation of 3-Quinuclidinyl Hydrogen n-Decylsuccinate—Into a 3-necked flask equipped with a stirrer, dropping funnel, and condenser were added 18.0 Gm. (0.075 mole) of *n*-decylsuccinic anhydride and 100 ml. of dry benzene. The mixture was heated and 25 ml. of pyridine was added. Then, 9.6 Gm. (0.075 mole) of 3-quinuclidinol, dissolved in 50 ml. of hot dry benzene, was added all at once. The mixture immediately developed an amber color. The mixture was refluxed for 18 hr. whereupon a clear, colorless solution resulted. The solution was distilled at atmospheric pressure until only a viscous oil remained. Upon cooling, the oil solidified to a white, waxy material. This was dissolved in a minimum amount of hot isopropanol and after cooling, anhydrous ether was added until a white precipitate formed. This precipitate was recrystallized three times from isopropanol and ether to yield 24.8 Gm. (89.8%) of a white, crystalline product; m.p. 100–103°.

Anal.—Calcd. for $C_{21}H_{37}NO_4$: C, 68.63; H, 10.15; N, 3.81. Found: C, 67.94; H, 10.18; N, 3.77.

Preparation of 3-Quinuclidinyl Hydrogen n-Hexadecylsuccinate—Into a 3-necked flask equipped with a stirrer, dropping funnel, and condenser were added 24.3 Gm. (0.075 mole) of *n*-hexadecylsuccinic anhydride and 125 ml. of dry benzene. The mixture was heated and 25 ml. of pyridine was added. Then 9.6 Gm. (0.075 mole) 3-quinuclidinol, dissolved in 50 ml. of hot dry benzene, was added all at once. The mixture immediately developed an amber color. The mixture was refluxed for 18 hr. whereupon a clear, colorless solution resulted. The solution was distilled at atmospheric pressure leaving a viscous oil. Upon cooling, the oil solidified to a white, waxy material. This was dissolved in the minimum amount of hot isopropanol and, after cooling, anhydrous ether was added until a white precipitate formed. This precipitate was recrystallized three times from isopropanol and ether to yield 30.7 Gm. (89.5%) of a white, crystalline product; m.p. 82–85°.

Anal.—Calcd. for $C_{27}H_{49}NO_4$: C, 71.79; H, 10.94; N, 3.10. Found: C, 71.05; H, 11.20; N, 3.27.

Attempted Preparation of 3-Quinuclidinyl Hydrogen Homophthalate—Into a 3-necked flask equipped with a stirrer, dropping funnel, and condenser were added 12.2 Gm. (0.075 mole) of homophthalic anhydride and 12.5 ml. of dry benzene. The mixture was heated and 15 ml. of pyridine was added. Then 9.6 Gm. (0.075 mole) of 3-quinuclidinol, dissolved in 50 ml. of hot, dry benzene, was added all at once. A dark brown gelatinous mass formed immediately. The mixture was refluxed for 8 hr. at the end of which time a clear amber solution resulted.

All attempts to extract the product from this solution yielded a brown, gelatinous, hygroscopic mass. Repeated trials to produce a crystalline compound (by purification and salt formation) failed.

The IR spectrum of this compound showed the characteristic ester bands and the compound gave a positive hydroxamic acid test.

PHARMACOLOGY

All compounds were tested as aqueous solutions of the ester free base. Although each of the compounds synthesized has not, as yet, been investigated, information is available for a preliminary report. The conclusions drawn from the results should be accepted as tentative and preliminary to more thorough investigation.[2]

Local Anesthetic Activity: Procedure—Four rabbits were placed in rabbit boxes and the hair around the eyes was carefully clipped. The winking reflex was tested by gently touching the cornea with a glass rod. The lower lid of the rabbit's conjuctival sac was held to form a cup, and then four drops of a 1% solution of either procaine or one of the drugs tested were instilled. After instillation of the drug, the solution was allowed to remain in contact with the surface of the eyeball for 2 min. by gently pressing the lids together. Anesthesia was tested for, after 2 min., by touching the glass rod to the cornea. This testing was done at regular intervals in order to note the time required for the winking reflex to return to normal. After recovery from the effects of the drugs, a second trial was made (following the above procedure) in order to compare the duration of anesthesia with that attained in the first trial.

Results—Procaine was utilized for comparative anesthetic effects. Of the seven esters tested, five produced anesthesia in both trials for varying lengths of time. The two esters that gave negative results failed to produce anesthesia in either trial. All results are tabulated in Table I.

Vasomotor and Respiratory Activity—Compounds tested were 3-quinuclidinyl hydrogen glutarate and 3-quinuclidinyl hydrogen 2,3-pyridinedicarboxylate. A male dog was anesthetized with an i.p. injection of sodium pentobarbital. The dose given was 30 mg./Kg. of body weight. The animal was strapped to a bench and the hair was shaved from the neck region. A thin, longitudinal strip of skin in the middle of the neck was cut with a scissors to expose the longitudinal muscles and these were separated along the midline with a blunt forceps. The left carotid artery located in the carotid sheath beside and slightly below the trachea was exposed. A ligature was tied around the artery peripherally and a loose ligature was placed around the artery centrally. A bulldog clamp was placed on the most central portion (beyond the loose ligature) of the artery. During this procedure the entire exposed area was flooded with 10% sodium citrate solution. Then, a fluid-filled system for recording blood pressure was prepared. The system included a Bourdon blood pressure transducer attached to a sodium citrate filled glass cannula. This cannula, which was inserted into the artery, lead to the transducer which detected pressure changes and sent impulses to the recorder. A fluid filled system which included a U-shaped glass tube filled with mercury was used to standardize the blood pressure at intervals to be used as reference points. This was done by squeezing a rubber bulb to change the height of the mercury. After standardization, this manometer-type apparatus was disconnected.

[2] Procedures employed in the pharmacological evaluation were taken from: Mann, D. E., "A Laboratory Manual of Pharmacology," 3rd ed., Temple University, School of Pharmacy, Philadelphia, Pa., 1962–1964.

TABLE I—LOCAL ANESTHETIC ACTIVITY[a]

Compound Tested	Duration of Anesthesia, min.
Trial I	
Procaine	42
1	...
2	20
3	12
4	10
5	...
7	6
8	14
Trial II	
Procaine	28
1	...
2	15
3	10
4	10
5	...
7	12
8	15

[a] The duration of anesthesia does not include the 2 min. when the lids were compressed. All drugs were administered in a dose of 4 drops of 1% aqueous solution.

A V-shaped opening was cut halfway through the artery close to the peripheral ligature to allow for adequate insertion space. The artery was placed over the tip of the cannula and the loose ligature was tied securely around the arterial flap on the tip of the cannula. The bulldog clamp was removed and the area was checked for leakage of blood. The stopcock was opened and the pressure was recorded on the physiograph. Respiration was recorded by means of an impedance pneumograph which was attached to the skin on the chest of the animal.

The thigh area of the dog was shaved and the femoral vein exposed. It was cleared of extraneous matter and two ligatures were slipped around the vein. The vein was cut open and a needle was inserted. Each compound to be tested was injected through the exposed femoral vein. All exposed areas on the dog were kept saturated with the citrate solution.

There was a substantial increase in blood pressure produced upon the administration of 10 mg. of each of the compounds tested. Both compounds produced a marked increase in respiration.

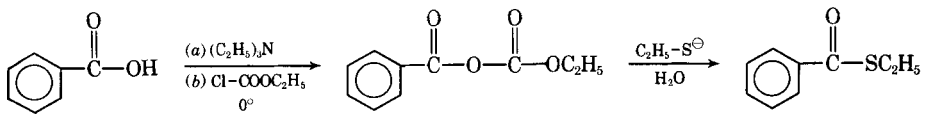
α-Alkyloximino Acid Thiol Esters: New Class of Compounds Showing Antimalarial Activity

By DOMINICK A. COVIELLO and NORMAN L. HINES

New derivatives of α-alkyloximino acids, the thiol esters, were prepared by modification of an application of mixed carboxylic-carbonic anhydrides. In general, the compounds show modest antimalarial activity, though one prolongs the lives of infected mice for more than 3 days longer than controls.

IT IS THE PURPOSE of this communication to report the antimalarial activity of α-alkyloximinocarboxylic acid thiol esters prepared by a modification of a reported method (1). The method utilizes mixed carboxylic-carbonic anhydrides (acyl alkyl carbonates) which are decomposed by a mercaptan in the presence of triethylamine. The authors have found that aqueous solutions of mercaptides are equally efficient in the anhydride decomposition. The modification was inspired by a report that carboxamides are produced by reacting the acyl alkyl carbonates with aqueous ammonia (2) indicating that anhydrous conditions are not essential for success in the anhydride reaction.

In a model reaction, ethyl thiolbenzoate was prepared as follows:



It was found that a better elemental analysis for the product could be obtained in the case of the title compounds through the modified procedure.

The compounds prepared are shown in Table I.

Biological Testing—Groups of five mice were infected with *Plasmodium berghii*. Three days after challenge test compounds were administered subcutaneously The data are reported in Table II.

EXPERIMENTAL

α-Ethyloximinopropionic Acid—This was obtained in 50% yield according to the procedure described by Ferris (3). It melted at 68–69°. Reported: 68–70°.

α-Benzyloximinopropionic Acid—The product was obtained by hypochlorite oxidation of the previously reported α-benzyloximinobutanone (3). The product melting at 84–85° was obtained in 52% yield. Reported melting point 84–85° (3).

α-Methyloximinobutyric Acid—Oxidation of α-methyloximino-2-pentanone in the manner described above gave a 13% yield of acid melting at 75–77°. Its confirmation was by elemental analysis of the thiol ester derivative (see Table I).

α-Ethyloximinobutyric Acid—The acid was prepared according to the procedure of Waters and Hartung (4). The yield was 48% and the melting point 58–59° was in agreement with the reported value.

α-Benzyloximinobutyric Acid—The product was obtained in 55% yield and had a melting point of 89–94° which was in agreement with the reported value (5).

α-Ethyloximinocaproic Acid—This was prepared in 82% yield according to the method of Waters and Hartung (5) and its boiling point of 76–80°/0.05

Received August 8, 1966, from the College of Pharmacy, University of Illinois at the Medical Center, Chicago, IL 60612

Accepted for publication October 13, 1967.

mm. was in agreement with the reported value.

Ethyl Thiolbenzoate—In a 1-L., round-bottom flask was placed 200 ml. of anhydrous ether and 12.2 Gm. (0.1 mole) of benzoic acid. The solution was then cooled to 0° with an ice bath and 10.12 Gm. (0.1 mole) of triethylamine was added followed by 10.85 Gm. (0.1 mole) of ethyl chlorocarbonate, at such a rate as to maintain the temperature at 0–5°. The solution was then stirred for 30 min. in the ice bath. The triethylamine hydrochloride was

filtered off and 50 ml. of a 4 *M* aqueous solution of sodium ethylmercaptide was added. The solution was allowed to stir for 1 hr. at room temperature. The ether layer was separated and the aqueous layer was extracted with two 50-ml. portions of ether. The ethereal layers were combined and dried overnight with anhydrous magnesium sulfate. The magnesium sulfate was removed by filtration and the ether removed by distillation. The residual oil was then distilled under reduced pressure and the fraction distilling between 59–60°/.075 mm. was collected. The product weighed 11.95 Gm. (71.98%) and its refractive index was 1.5690 at 20.5°. The reported boiling point is 83–84° at 2.5 mm. and refractive index is 1.5678 at 25° (5).

α-Alkyloximinocarboxylic Acid Thiol Esters—The title compounds were prepared in the manner described for the preparation of ethyl thiolbenzoate. Pertinent data on the compounds are summarized in Table I.

Molecular Association of the Antibiotic Prasinomycins

By JOEL KIRSCHBAUM

The molecular weight of the antibiotic prasinomycins in ethanol is 1600–2300. In aqueous solvents the prasinomycins associate, forming two aggregates with molecular weights of approximately 31,000 and 61,000. The aggregates may be disrupted by organic solvents, dilution below 0.012 percent, or the addition of salts.

THE prasinomycins are a family of closely related antibiotics isolated from *Streptomyces prasinus* (1). Although the molecular weight of one major component of the mixture, as calculated from phosphate group analysis (1), was 1550 ± 10%, the inability to dialyze these antibiotics through a cellulose membrane indicated the possibility of molecular association. The molecular weight in ethanol, determined by means of an analytical ultracentrifuge,[1] ranged between 1600 and 2300. In aqueous solvents the apparent molecular weights were 31,000 and 61,000. These solvent-induced differences in molecular weight indicate association or aggregation. Some of the properties of these aggregates will be described in this paper.

EXPERIMENTAL

Sedimentation coefficients of prasinomycin solutions of concentrations from 10 mg./ml. to 1.25 mg./ml. were measured in 4°, 12-mm. cells centrifuged in an An-D rotor at 42,040 r.p.m. and 20.7°. The phaseplate angle of the schlieren optical system was 75°. For solutions with concentrations of 1.25 mg./ml. to 0.25 mg./ml., the sedimentation coefficients (s) were determined in a 12-mm. synthetic boundary centerpiece in an interference cell.

Molecular weights were determined using equilibrium and Archibald approach-to-sedimentation equilibrium methods.

For the Archibald (2) method, 5–10 mg./ml. solutions in 12-mm. interference cells were centrifuged in an An-D rotor at 20.7°. Concentration gradients were formed at speeds of 6995, 8766, 12,590, 20,410, 29,500, and 42,040 r.p.m. to test for any dependence of molecular weight on speed, which, in turn, affects concentration of the sedimenting material. The schlieren optical system was used with a phaseplate angle of either 75° or 80°. The concentration gradients at the meniscus and cell bottom were measured from data recorded on Kodak metallographic plates magnified 10-fold on a Nikon magnifier. Engelberg's technique (3) for evaluating the concentration gradient integral was used. Total concentrations were determined in separate experiments using a synthetic boundary centerpiece. An IBM 1620 computer was used for some of the repetitive calculations.

Equilibrium centrifugation (4) aided in obtaining the molecular weights of prasinomycin solutions of 0.15 mg./ml. and lower in concentration. Using a calibrated syringe, 0.03 ml. of prasinomycin solution was injected into one compartment of an interference cell fitted with sapphire windows and layered with fluorochemical FC 43 (Beckman Instruments, Inc.). Solvent was injected into the reference compartment. The final percentage

[1] Model E Analytical Ultracentrifuge, Spinco Division, Beckman Instruments, Inc.

of prasinomycin in the solution compartment was determined by two methods: (*a*) photographically measuring the height of liquid in each compartment of the rotating cell, before and after flow of solvent into the solution compartment and measuring the cell centerpiece cross-section, and (*b*) combining the weight of solvent and solution added to a cell with the densities of liquids.

Diffusion constants (5) were evaluated in the analytical ultracentrifuge at 20.7°, using a synthetic boundary centerpiece and the schlieren optical system. Initial solute concentrations were from 10 to 2 mg./ml. The first image was recorded at two-thirds of the final speed of 29,500 r.p.m. This first picture was considered to be the zero-time image for diffusion constant calculations

The partial specific volume was determined at 20° in a 1-ml. pycnometer. Viscosities were determined with the aid of capillary and Zimm (6) viscometers.

RESULTS AND DISCUSSION

The minimum molecular weights of the prasinomycins, as determined by approach-to-equilibrium sedimentation in either 100% ethanol or in 90% ethanol–10% 0.2 *M* NaCl–0.02 *M* sodium phosphate buffer (pH 6.85), are identical within experimental error and are between 1,600 and 2,300 daltons (Table I). The small quantity of inorganic buffer in the ethanol diminishes charge-charge interactions that may lead to 5 to 20% erroneously lower molecular weight. A minor component, molecular weight approximately 7,200, is evident which may be a tetramer of the prasinomycins. In NaCl–sodium phosphate buffer the molecular weight of the prasinomycins was calculated to be 31,000 daltons, within a 3% experimental error. This is an aggregate since almost all of the solute prasinomycin could be accounted for as the 31,000 dalton component. Occasionally, traces of a component of higher molecular weight were evident; apparent mol. wt. 60,000 daltons. In 0.072 *M* borate buffer, pH 8.6, only the higher molecular weight component, mol. wt. = 61,500, was present. No dependence of molecular weight on speed was found.

The 31,000 dalton aggregate of prasinomycin is stable in various aqueous buffers ranging from pH 4.05 to pH 10.4 (Table I). In pH 12 glycine–NaOH buffer the aggregate is disrupted since the molecular weight is approximately 2,000, with a trace of a 3,600 molecular weight component present.

Verification of the 31,000 dalton molecular weight determined in aqueous solvents and the 1,600–2,300 molecular weight determined in ethanolic solutions was achieved by combining the sedimentation and diffusion constant measurements (7). The aggregate sedimentation constant (*s*) of 4.0 *S* ($S = 10^{-13}$ cm. sec.$^{-1}$) at zero concentration and 20°, together with the diffusion constant, $D^0_{20,w} = 9.0 \times 10^{-7}$ cm.^{2} sec.$^{-1}$ of the aggregate, yields a mol. wt. of 30,000 daltons. The diffusion constant of prasinomycin in ethanol is 2.2×10^{-6} cm.^{2} sec.$^{-1}$ (which itself indicates that prasinomycin in ethanol has a lower molecular weight than prasinomycin in aqueous solvents). Combination with the $D^0_{20,w}$ value of $0.82–1.02 \times 10^{-13}$ cm.^{2} sec.$^{-1}$ gives an approximate mol. wt. of 2,100 daltons for unaggregated prasinomycin, in good agreement with the 1,600–2,300 mol. wt. determined by approach-to-equilibrium sedimentation.

Since the molecular weight of the prasinomycins in ethanolic solutions is 1,600–2,300 and the apparent molecular weight of the prasinomycins in aqueous solvents is 31,000, an obvious question is: what is the apparent molecular weight of the prasinomycins in mixtures of ethanol and aqueous solvents. In Fig. 1 are the curves depicting the changes in molecular weight of the prasinomycins as (*a*) the free acid of prasinomycin dissolved in ethanol is diluted with NaCl–sodium phosphate buffer, and (*b*) sodium salt, of prasinomycin, initially dissolved in NaCl–sodium phosphate buffer is diluted with ethanol. Molecular weights were determined after a 3–18 hr. equilibration. Per-

TABLE I—MOLECULAR WEIGHTS OF THE THREE MAJOR PRASINOMYCINS A, B, AND C DISSOLVED IN VARIOUS SOLVENTS

Form of Prasinomycin	Prasinomycin	Solvent	Mol. Wt. Major Component	Mol. Wt. Minor Component

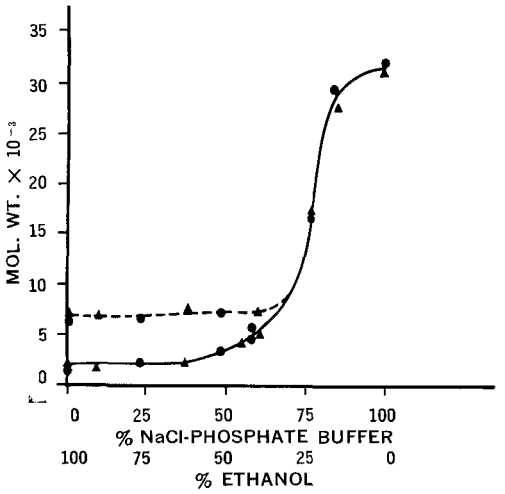

Fig. 1—Changes in mol. wt. of prasinomycin caused by changing the solvent: ●, free acid of prasinomycin initially dissolved in ethanol diluted with NaCl-sodium phosphate buffer; ▲, sodium salt of prasinomycin dissolved in NaCl-sodium phosphate buffer diluted with ethanol. Note existence of tetramer of mol. wt. 7,200–7,600 daltons (broken line) at ethanol concentrations from 30 to 100%.

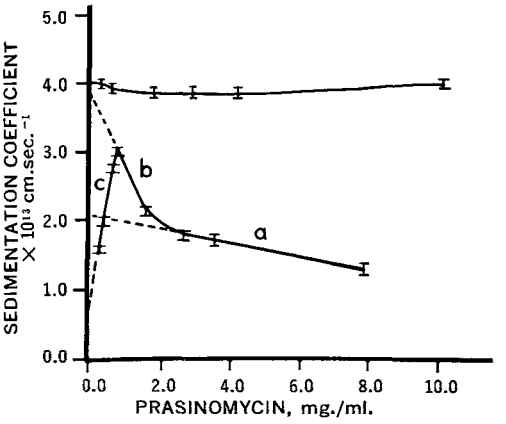

Fig. 2—Dependence of the sedimentation coefficient of prasinomycin on its concentration in 0.2 M NaCl–0.02 M sodium phosphate buffer, pH 6.9, upper curve and in 5.0 M NaCl–0.02 M sodium phosphate buffer, pH = 6.9, lower curve.

sistently found below 65% NaCl–sodium phosphate buffer–35% ethanol is the 7,200 dalton compound identified tentatively as tetramer. The two molecular weight curves, including tetramer branching, are superimposable, as expected, since this procedure of adding the free acid form to buffered solvent is analogous to adding acid to aqueous sodium phosphate.

As seen in Fig. 2, upper curve, variation of concentration from 10 mg./ml. to 0.25 mg./ml. for prasinomycin dissolved in 0.2 *M* NaCl–0.02 *M* sodium phosphate buffer does not appear to result in the dissociation of the aggregate, since $s_{20,w}$ = 4.0 *S* at both the initial and final concentrations. However, the curvature of the line is indicative of some dissociation or rearrangement. When the NaCl concentration of the buffer was increased to 5 *M*, a complex figure was obtained (Fig. 2 lower curve). If the three portions of the curve, labeled a, b, and c are extrapolated to zero concentration (broken lines) and the *s* values measured, a is equal to 2.05 *S*, b is equal to 3.9 *S*, and c is equal to 1.1 *S*; all values corrected for viscosity and density. The sedimentation coefficient of b, *s* = 3.9 *S*, may be considered to be equivalent to a molecular weight of 31,000 daltons. Substituting these values into the formula, molecular weight = $f_s^{2.2}$, *f* is equal to 1,550. The calculated molecular weight of *a* is approximately 7,500 daltons and that of *c* is approximately 1,700 daltons. These molecular weight values approximate closely monomer and tetramer molecular weights.

Since sedimentation coefficient values of prasinomycin solutions below 0.25 mg./ml. cannot be measured by the schlieren optical system, the interference optical system was used, and molecular weights were determined by sedimentation equilibrium methods. At a concentration of 0.012%, two components, with approximate molecular weights of 3,600 and 2,000 were calculated. At 0.005% only a 1,800–2,000 molecular weight component was discernible.

The various molecular weights of prasinomycin found in this study are 1,800–2,300, 3,600, 7,200–6,600, 15,000, 31,000 and, under certain conditions, 60,000–62,000 daltons. It appears that aggregation proceeds by repeated dimerization of the monomer to the 31,000 dalton aggregate.

The aggregate may be stabilized by electrostatic (8) interactions since increasing the ionic strength can dissociate the complex. Conversely, by using water alone as solvent (0 ionic strength but for added prasinomycin), the observed sedimentation coefficient is 5.4 *S*. This *s* value is equivalent to the 61,000 dalton aggregate and is the highest molecular weight aggregate observed.

Cleavage (9) of one prasinomycin species gives a 1,400 dalton and a 350 dalton fragment. The 350 dalton moiety was found to be a hydrocarbon (9). The 1,400 dalton fragment did not aggregate, indicating that the association of the prasinomycins may also require hydrophobic bonding (10).

Hydrogen bonding may not have a role in prasinomycin aggregation because 8 *M* urea did not affect the sedimentation coefficient of the aggregate (*s* = 3.9 *S*), after best correction (11) for density and viscosity.

Gas-Liquid Chromatographic Determination of Lincomycin

By R. L. HOUTMAN, D. G. KAISER, and A. J. TARASZKA

The gas-liquid chromatography of lincomycin and some of its analogs, determined as trimethylsilyl ethers, is reported. The application of this procedure to quantification of lincomycin in bulk material and pharmaceutical preparations is described.

THE APPLICATION of gas-liquid chromatography to polyhydroxy compounds has been greatly enhanced by the advent of methods for the quantitative conversion of these compounds to their trimethylsilyl ethers (1, 2). The silylation procedure consists of dissolving the material in pyridine and adding hexamethyldisilazane and trimethylchlorosilane.

Lincomycin (I) (3), a medium spectrum antibiotic containing an octopyranose moiety, was silanized by this procedure and chromatographed as the intact tetra trimethylsilyl ether. U-21699 (II), an antibiotic produced at about the 3% level in the microbiological synthesis of lincomycin (4) was chromatographed under the same conditions and gave a retention time of 0.85 relative to lincomycin. This separation enabled the quantification of small amounts of U-21699 in lincomycin as well as the determination of lincomycin in bulk material and pharmaceutical formulations.

Since the preparation of the trimethylsilyl ether derivatives of these compounds is rapid, quantitative, and can be applied on a micro scale, GLC analysis of lincomycin and some of its analogs has become a practical laboratory procedure.

EXPERIMENTAL

Reagents and Materials—The lincomycin and analogs used in this study were prepared by the Research Division of The Upjohn Company. Hexamethyldisilizane and trimethylchlorosilane were obtained from the Dow Corning Co., Midland, Mich. A solution of tetraphenylcyclopentadienone[1] in pyridine (5 mg./ml.) was employed as the internal standard. The column packing utilized for gas-liquid chromatography was 3% (w/w) SE-30 on 100–120 mesh Gas Chrom Q.[2] All solvents were reagent grade and used as supplied.

Instrumentation—An F & M model 402 high efficiency gas chromatograph,[3] equipped with a flame ionization detector and U-shaped glass columns (2 m. long × 3 mm. i.d.) was utilized throughout the study. Helium was used as the carrier gas at a flow rate of 60 ml./min. Air and hydrogen flow rates were adjusted to give maximum response. The column oven was operated isothermally at 240°, the flash heater at 270°, and the detector at 290° Peak areas were measured with an Infotronics 11HSB/42 electronic integrator.[4]

Procedures—In general, the silanization technique of Makita and Wells (5) was used. For quantification of lincomycin, 50 mg. of the bulk drug was accurately weighed and dissolved in 10.0 ml. of the internal standard solution. One milliliter of hexamethyldisilizane and 0.5 ml. of trimethylchlorosilane were added. The solutions were allowed

[a] Determined by mass spectrometry.

to stand for 10 min. and then centrifuged prior to chromatography.

Silanizable excipients, such as sucrose and lactose, in formulations required some adjustment in the aforementioned reagent ratios but did not interfere with the quantification of lincomycin. One extreme example was an aqueous solution containing 650 mg. of sucrose and 50 mg. of lincomycin per ml. of formulation. Two milliliters of the solution was lyophilized, dissolved in 10 ml. of internal standard solution, and silanized with 5 ml. of hexamethyldisilazane and 2.5 ml. of trimethylcholorosilane. It was necessary to allow 30 min. for complete reaction. Similarly, centrifuged fermentation beers may be analyzed following lyophilization.

For qualitative examination or determination of analog ratios from fermentation samples, 10 mg. of material was dissolved in 1 ml. pyridine. Hexamethyldisilizane (0.2 ml.) and trimethylchlorosilane (0.1 ml.) were added. Reaction conditions were the same as described for the determination of lincomycin in the bulk drug.

For each series of samples, a reference solution was prepared by accurately weighing an amount of lincomycin reference standard approximately equivalent to that in the sample and treating it identically.

Calculations—The lincomycin concentration in the sample solutions was determined by a direct comparison of peak area ratios.

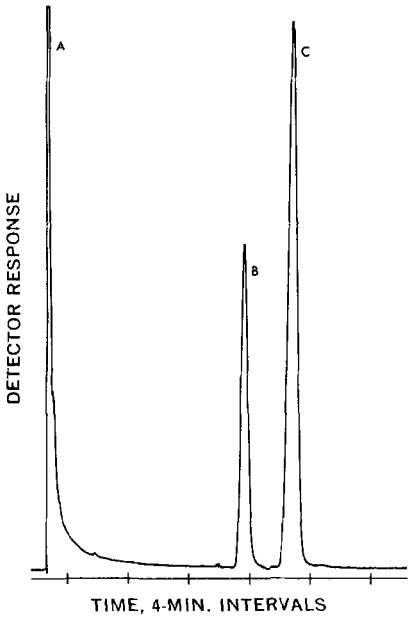

Fig. 1—Chromatogram of U-21699 and lincomycin, A = solvent, B = U-21699, C = lincomycin.

Characterization of Derivatives—Samples of the trimethylsilyl derivatives were collected at the exit port of the chromatograph for characterization. The collected samples were compared either by infrared spectroscopy or mass spectrometry to materials isolated from the reaction solutions. In the case of lincomycin and U-21251F (III) (6) sufficient sample was isolated to enable complete elemental and spectral analysis. These data are summarized in Table I.

RESULTS AND DISCUSSION

Quantification of U-21699 in Lincomycin—In the search for a suitable liquid phase for the separation and quantification of U-21699 in lincomycin, it was observed that any of the nonpolar liquid phases were acceptable. The SE-30 column described in the procedure was selected for its stability and general availability. After establishing conditions

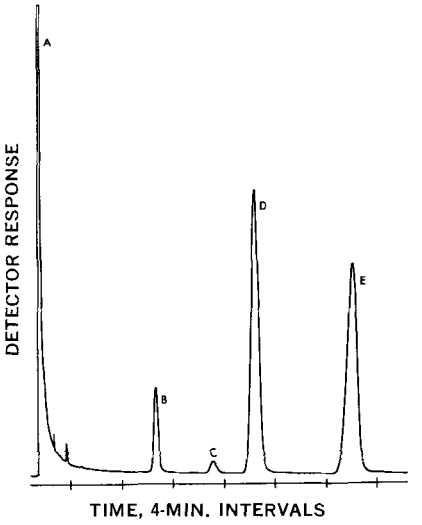

Fig. 2—Chromatogram of an assay preparation from a hard-filled capsule: A = solvent, B = lactose, C = U- 21699 and lactose, D = lincomycin, E = internal standard.

TABLE II—EXCIPIENT RETENTION TIMES

Compound	Relative Retention Time
Sorbitol	0.08
Sucrose	0.56
Lactose	0.81 and 0.54
Lincomycin	1.0
Internal standard (tetraphenylcyclopentadienone)	1.46

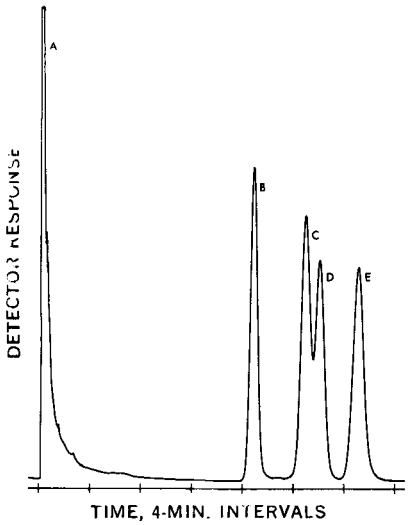

Fig. 3—Chromatogram of lincomycin analogs. A = solvent, B = U-21699, C = lincomycin, D = U-11921, E = U-11973.

for chromatography, the response factors for lincomycin and U-21699 were determined by silylating and chromatographing a 50–50 mixture of the two compounds. The difference in response per mg. for the two materials was less than 1%.

This small difference was insignificant in the determination of small amounts of U-21699 in lincomycin. The comparable response for lincomycin and U-21699 might have been predicted from the similarity of the compounds (I and II). One milligram each of lincomycin and U-21699, when weighed as the monohydrate hydrochloride, yield 0.781 and 0.778 mg. of carbon, respectively, as the trimethylsilylethers. This response relationship was further established by a recovery study. Eight prepared mixtures ranging from 0–10% U-21699 in lincomycin by weight were assayed. Statistical analysis of the data indicated a slope of 0.99.

A chromatogram of a production lot of lincomycin containing 2.7% of U-21699 is presented in Fig. 1. Note the change in attenuation allowing a measurable area for the minor component.

Twenty replicate assays, each on different days, of a sample of lincomycin containing 2.33% U-21699 gave a standard deviation of 0.108% for U-21699. This represents a coefficient of variation of 4.8% for the minor constituent.

Quantification of Lincomycin in Bulk Drug and Formulations—Tetraphenylcyclopentadienone, the internal standard used in the assay, had a retention time relative to lincomycin of 1.46 which minimized the interference of possible decomposition products. The relative retention times of common excipients used in various formulations were established and are shown in Table II.

Table III—Retention Times of Lincomycin Analogs

Compd.	Relative Retention Time	Derivative
II (U-21699)	0.81	Tetra TMS ether
III (U-21251F)	0.86	Tri TMS ether
I (Lincomycin)	1.00	Tetra TMS ether
IV (U-11921A) (7)	1.05	Tetra TMS ether
V (U-11973E) (8)	1.20	Tetra TMS ether
VI (U-24166A) (9)	1.22	Tetra TMS ether
Tetraphenylcyclopentadienone	1.46	...

Precision studies conducted on several formulations indicated that the coefficients of variation were all less than 1%. A chromatogram of an assay preparation from a hard-filled capsule is shown in Fig. 2.

Chromatography of Other Analogs—Figure 3 is a chromatogram of a synthetic mixture of lincomycin and three analogs to illustrate the degree of separation. It should be noted, however, that this is a hypothetical mixture and that only U-21699 is normally produced in the microbiological synthesis of lincomycin. Two other analogs, U-21251F and U-24166A, not shown in Fig. 2, were chromatographed using this technique and a summary of the retention times relative to lincomycin are shown in Table III.

Antitumor Agents from *Bursera microphylla* (*Burseraceae*) I. Isolation and Characterization of Deoxypodophyllotoxin

By E. BIANCHI, M. E. CALDWELL, and J. R. COLE

Deoxypodophyllotoxin has been isolated and characterized as one of several antitumor agents from *Bursera microphylla* (*Burseraceae*). β-Sitosterol has also been shown to be present in this plant.

As a result of a routine screen of Southwestern plants for potential antitumor activity, the chloroform extract of *Bursera microphylla* A. Gray (*Burseraceae*)[1] demonstrated activity toward the human epidermoid carcinoma of the nasopharynx test system (cell culture) of the CCNSC (9KB).

Bursera microphylla is a tree usually less than 30 ft. tall and can be found in Southwestern Arizona, Baja California, Sonora, and southward into Central Mexico. The material used in this research was collected in March and June from rocky dry slopes in the Gila mountains near Ligurta in Yuma County, Arizona. *Bursera microphylla*, as well as other *Bursera* species, have been the subject of previous investigations: various substances such as phellandrene and phellandral (1), α-hydroxylupene and α-amyrin (2), and others (3) have been reported.

The above materials did not show any tumor inhibition activity (4). The plant was then subjected to a systematic fractionation in order to characterize the active principle. The fractionation procedure involved the utilization of solvent extraction followed by adsorption chromatography on alumina, thick-layer chromatography on silica gel, and paper chromatography.

Four substances (I, II, III, and IV) were separated. Substance IV was identified as β-sitosterol on the basis of mixed melting point, superimposable infrared spectra of an authentic specimen, and a comparison of R_f values with a known specimen utilizing thin-layer chromatography. The solvent systems employed were dichloromethane–benzene–ethyl acetate (12:24:3) and ethyl ether–dichloromethane (1:5). Substances I, II, and III showed a strong tumor inhibition against the 9KB system. Substance III was identified as deoxypodophyllotoxin. This is somewhat unique as there are apparently no reports in the literature of this compound being isolated from this plant or any closely related genus and species. In addition, III was treated with a mild alkali and was converted into deoxypicropodophyllin (the "picro" or "B" series). Substance II was subjected to paper and thin-layer chromatography and showed a single spot but all attempts at crystallization failed. The isolation, purification, and characterization of this compound will be reported in a forthcoming publication. Substance I was not present in sufficient quantities to warrant further chemical investigation at this time but will also be investigated at a later date.

The preliminary chloroform extract exhibited activity of less than 1.0×10^{-2} mcg./ml. Deoxypodophyllotoxin showed activity in this system of 2.6×10^{-3} mcg./ml. Activity is defined as $ED_{50} \leqq 10$ mcg./ml. for plant extracts. Results are expressed as the dose that inhibits growth to 50% of control growth 3 days after drug addition (5).

EXPERIMENTAL

Extraction—The stems (12 Kg.) of *Bursera microphylla* were dried in the air, ground, and extracted exhaustively in a Soxhlet with chloroform. After removal of the solvent, the residue (470 Gm.) was treated several times with petroleum ether (b.p. 40–60°). The material obtained from the solution was inactive and, therefore, discarded. The insoluble part separated from the liquid by centrifugation was extracted with ethyl ether. The insoluble portion was inactive and discarded. The organic layer was stirred (not shaken in order to prevent emulsion) three times with a 10% aqueous solution of sodium carbonate. The ethereal extract, after removal of the alkali aqueous solution yielded the active material (Scheme I).

Isolation and Identification of Deoxypodophyllotoxin—The active material was chromatographed through a column of alumina (grade III). The second fraction obtained by elution with benzene yielded material showing improved activity. The fractions obtained by elution with chloroform, ethyl ether, acetone, and methanol were inactive and were discarded. The active fraction was then subjected to thin-layer chromatography. The matrix used was Silica Gel G, Merck. The solvent system employed was dichloromethane–benzene–ethyl acetate (12:24:3). A double run was employed. There appeared to be four predominant materials. In order to obtain each of these in a pure state, the mixture was applied on preparative chromatoplates which were run under the same general conditions. This procedure afforded more precise separation of the four substances designated as I, II, III, and IV. Substance I was neglected because the amount of material obtained was insufficient for further study at this time. Substance IV was identified as β-sitosterol by the procedures indicated above. The yield of β-sitosterol from the dry plant was approximately 0.021%. Since the resolution of II and III was not satisfactory because of the closeness of their R_f values when the above indicated solvent system was used, they were eluted together, applied on preparative chromatoplates (1 mm. thick), and

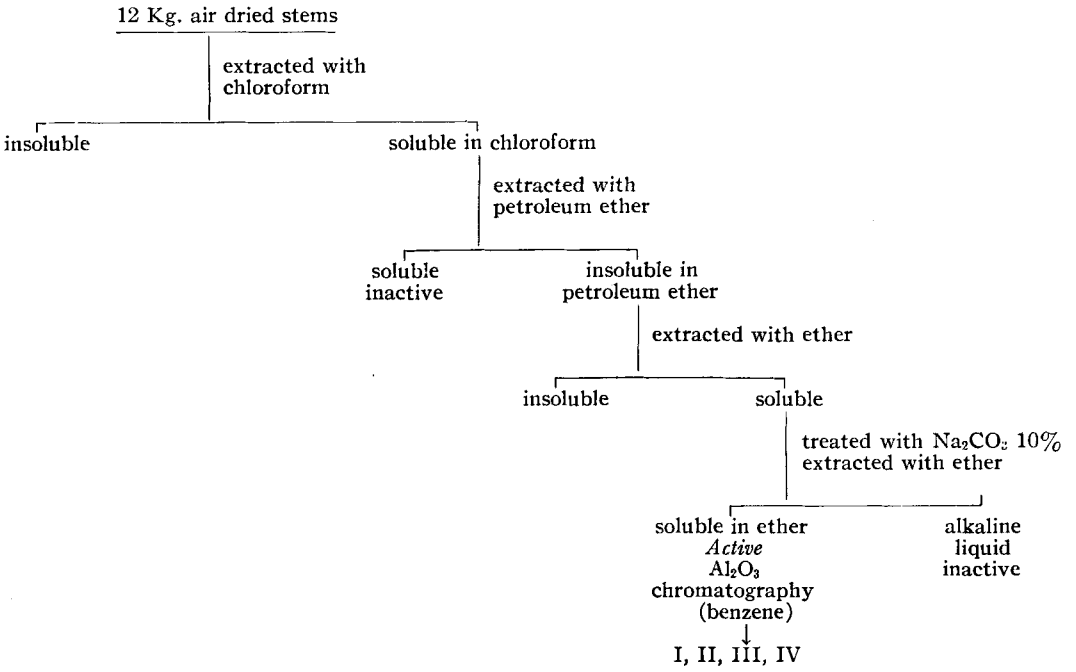
Presented at the IUPAC National Product Symposium, June 1966, Stockholm, Sweden.

[1] Identification confirmed by Robert Barr, College of Pharmacy, and Dr. Charles Mason, Botany Department University of Arizona, Tucson. A reference specimen was also deposited.

Schematic Presentation of Extraction
B. microphylla



Scheme I

run with a dichloromethane–ethyl acetate (5:1) system. This procedure gave good resolution for the separation of III. It was eluted with acetone and recrystallized from methanol, m.p. 162–163°; $[\alpha]_D$ −112° (chloroform). These data are in agreement with that reported by the literature for deoxypodophyllotoxin. Mass spectrometry indicated a parent ion of *m/e* 398 compatible with this compound. In addition, no depression in a mixed melting point and a superimposable infrared spectrum with an authentic sample further proved the identification of III as deoxypodophyllotoxin.[2] The yield of deoxypodophyllotoxin from the dry plant was approximately 0.09%.

Conversion of Deoxypodophyllotoxin into Deoxypicropodophyllin—To a solution of deoxypodophyllotoxin in methanol, a few drops of an aqueous methanolic solution of potassium bicarbonate was added and the mixture was allowed to stand overnight. The mixture was treated as indicated above and yielded deoxypicropodophyllin. The same result was obtained using sodium acetate as the basic catalyst for this conversion (6). The compound showed an inversion of the sign of the optical rotation, $[\alpha]_D$ +30° in chloroform. Its mass spectrum pattern again indicated a parent ion *m/e* 398 indicating that only a geometrical rearrangement took place during the alkali treatment.

CONCLUSIONS

Bursera microphylla has been the subject of a phytochemical investigation in order to determine the chemical agents responsible for the apparent antitumor activity in the 9KB system of the CCNSC. Deoxypodophyllotoxin has been isolated and characterized as being one of these agents. Two other agents have been isolated and will be the subject of future reports. β-Sitosterol has also been shown to be present in this plant.

[2] The authors are indebted to Dr. J. L. Hartwell of the Cancer Chemotherapy National Service Center, National Cancer Institute, Bethesda, Md., who provided a sample of deoxypodophyllotoxin.

Effect of Some Nonionic Surfactants on the Rate of Absorption of Aminophylline from Suppositories in Rabbits

By J. M. PLAXCO, JR., and F. FOREMAN*

The rate of absorption of aminophylline from theobroma oil base suppositories containing 5 percent of various nonionic surfactants was determined. The results were erratic and unpredictable, with no correlation with *in vitro* results reported in a previous communication.

SUPPOSITORIES HAVE received much attention in recent years as a means of administering medication. In the U. S. more attention has been directed toward *in vitro* investigations of drug release. European literature (1–9) contains many reports of *in vivo* work using different drugs and various animals. A previous paper from this laboratory (10) reported the *in vitro* effects of some nonionic surfactants on the rate of release and dialysis of aminophylline and of ephedrine and ephedrine hydrochloride from theobroma oil suppositories.

The purpose of the current investigation was to determine the effects, *in vivo*, of these same surfactant-containing aminophylline suppositories. Because of the reports of Waxler and Schack (11) and Glass and his coworkers (12), it was felt that the concentration of aminophylline (theophylline) in the plasma was a reliable indicator of the rate of absorption of the drug. Waxler and Schack (11) showed that aminophylline (theophylline) is restricted to the plasma, does not penetrate the red cell membrane, and is bound only slightly to the proteins of the blood and to tissue proteins.

EXPERIMENTAL

Materials—The suppositories were those prepared and investigated for *in vitro* release (10). Each suppository contained 5% surfactant and 10 mg. of aminophylline in theobroma oil.

Procedure—Young male white rabbits weighing initially approximately 2 Kg. were used. At the conclusion of the investigation they weighed approximately 3–4 Kg. each. At least 1 week lapsed between tests on each rabbit to allow the rabbits to recuperate and to eliminate completely all traces of drug from the system. As many tests were run on each suppository as time permitted, usually 5 or 6 different rabbits per suppository, though in a few instances only 3 were used. Twenty rabbits were used, mainly in succession, which resulted in different animals testing one suppository. In a few instances in which repeat tests were run, the same animal was used. The variability was less using the same animal than when using different animals but unfortunately insufficient data were available for analysis.

The rabbits were fasted overnight to rid the rectum of fecal matter, and each experiment was started at approximately the same time each morning (9:00 a.m.) for uniformity and to allow ample time to use another rabbit if the suppository was expelled. After weighing the rabbit, a suppository was inserted into the rectum and pushed about 2 cm. with a glass rod lubricated with white petrolatum. No satisfactory method of closing the anus to prevent expulsion of the suppository was found, and occasionally it was expelled, necessitating the use of another rabbit. After insertion of the suppository the animal was returned to its cage for about one-half hr.

The rabbit was then placed in a rabbit holder with its head exposed. At the stated times, approximately 4 ml. of blood was collected from the marginal or medial ear veins in a heparinized tube and 3 ml. of this was pipeted into a separator containing 30 ml. of chloroform-isopropyl alcohol (20:1) mixture. The aminophylline (theophylline) concentration was determined by the method of Schack and Waxler (13) with modifications as noted.

Chloroform NF and isopropyl alcohol NF were freshly distilled weekly and stored in glass-stoppered bottles of 500 ml. capacity. This precaution of fresh solvents had previously been noted by Glass *et al.* (12) and others.

The 3 ml. of blood was extracted for 3 min. with two 30-ml. portions of chloroform–isopropyl alcohol mixture and the portions mixed. Following filtration, 40 ml. of the solution was extracted with 6.0 ml. of 0.1 *N* NaOH and centrifuged. The absorbance at 277 mμ was determined on a Beckman model DB spectrophotometer and compared with a standard curve prepared by adding a known amount of aminophylline to bovine blood and extracting, using the same technique as described. This method gave more uniform and reproducible results than using a standard curve prepared from the absorbance of varying concentrations of aminophylline in 0.1 *N* NaOH and correcting for the absorbance of the blood. Schack and Waxler (13) found "the mean blank value of human blood (300 analyses) to be an optical density of 0.07 ± 0.02 per cc. 0.1 *N* NaOH. Blood and tissues of other species follow this closely." Our experiments confirmed these values for rabbit, swine, and cattle blood. It was also found that following the insertion of blank surfactant-containing suppositories (no aminophylline) the same values were obtained.

A concentration of 10 mg. of aminophylline per suppository was satisfactory for the *in vitro* work but the plasma levels for this concentration were at the lower end of the curve for the *in vivo* work. It is believed that more uniform results would have been obtained with more than 10 mg. of aminophylline per suppository. However, the object of the investigation was to compare *in vitro* and *in vivo* release from the same batches of suppositories.

RESULTS AND DISCUSSION

Table I shows the concentration of aminophylline in the blood plasma. A study of this table reveals no pattern of release. The addition of the surfactants did not result in an increased rate of absorption as compared to theobroma oil. In most instances there was even a decrease in plasma concentration. HLB values, which had a pronounced effect in our and other *in vitro* work, had no discernible effect in the *in vivo* work. No relationship was found between chemical type or structure and effect. There was also no correlation between *in vitro* and *in vivo* results.

Figures 1 and 2 show the scatter pattern of the individual aminophylline plasma concentrations from selected suppositories. Individual differences were great but were more uniform than data obtained using human subjects (11, 12). This was to be expected as conditions were more closely controlled with rabbits than would be possible with humans.

Generally, it has been found that the addition of surfactants to oleaginous bases (suppository or ointment) increased the *in vitro* rate of release (10–15).

Reports of *in vivo* work have been contradictory. Riegelman and Crowell (16) found that the rate of absorption of sodium iodide was accelerated by the presence of surfactants but the rate of absorption of the sodium salt of 2,4,6-triiodophenol was retarded. Kakemi *et al.* (17) showed that the rectal absorption of sulfonamides in the rat was reduced by the presence of nonionic surfactants due to the entrapment of part of the drug within the micelles of the surfactants.

Various attempts have been made to correlate *in vitro* and *in vivo* data regarding drug release from

suppositories. Since *in vitro* conditions cannot take into account the conditions prevailing in the rectum, especially regarding fluid content, the viscosity and chemical composition of the mucus, and the pressure of the walls on the suppository, they have been unsuccessful. Recently Setnikar and Fantelli (18) described an apparatus which more closely reproduces the rectal environment. Using this apparatus, the *in vitro* disintegration time compared favorably with the disintegration time of radiopaque suppositories in man. This was an improvement over other techniques but still omits the effect of many factors.

Kuhne (4) reported results of studies relating *in vitro* to *in vivo* experiments. He prepared suppositories of two pairs of drugs, phenobarbital and its sodium salt, and atropine and atropine sulfate, in several bases. The suppositories were administered to rabbits for the *in vivo* experiments, and dialyzed through a membrane for the *in vitro* experiments. The water-insoluble drugs, phenobarbital and atropine, did not pass from the suppositories through the membrane in the *in vitro* work, but all drugs passed readily through the rectal mucosa into the blood in the *in vivo* experiments. He concluded that *in vitro* results cannot serve as a basis for the prediction of *in vivo* results.

Neuwald and Kunze (5) compared *in vitro* results with blood levels in man of three salicylates: acetylsalicylic acid, calcium acetylsalicylate, and sodium salicylate. The plasma concentrations of all three salicylates were about the same after 2 hr., but there was very wide variation in the amounts of drug diffused *in vitro*. Their *in vivo* results do not agree with animal experiments of others and contradict their own *in vitro* results. They drew the conclusion that the evaluation of suppository medication for man cannot be based on animal experiments, much less on *in vitro* diffusion experiments.

Our data support the unpredictability of absorption of drugs from suppositories. Several explanations may be advanced as to why the addition of the nonionic surfactants retarded the absorption of aminophylline by the rabbits.

It has been shown (19) that, at least for salicylates, drugs are initially absorbed as rapidly as they are released from the suppository—*i.e.*, the rate of release and diffusion to the rectal mucosa is the rate-limiting step. Our *in vitro* study (10) revealed that the addition of nonionic surfactants increased the rate of release and diffusion of aminophylline. Hence, it is evident that the interference with absorption is not due to lessened release.

The cellophene membrane used in the *in vitro* study cannot be compared with the living rectal mucosa. While most drugs are absorbed from the rectum by a simple diffusion process, this diffusion through a lipoidal membrane is different from a cellophene membrane. As reported by Riegelman and Crowell (16) and Kakemi *et al.* (17) it is probable that part of the drug is trapped within the micelles of the surfactant. The nature of the membranes and the size openings were probably such that the surfactants were able to pass through the cellophane membrane much more readily than through the rectal membrane.

Other possible explanations are that the surfactants irritated or in some other manner changed the permeability of the rectal membrane. This is unlikely as Nissim (20) has shown that some nonionic polyoxy surfactants (polyoxyethylene sorbitan esters) exhibited no untoward action on the mucosa.

Another possible explanation is that the surfactants emulsified or in some other manner modified the mucus lining the rectum, causing it to trap or interfere with the absorption of the aminophylline.

SUMMARY AND CONCLUSIONS

(*a*) The rate of absorption of aminophylline from theobroma oil and from theobroma oil containing 5% nonionic surfactants was determined.

(*b*) The addition of the surfactants generally resulted in decreased absorption of the drug.

(*c*) There was little, if any, difference noted in results related to HLB, chemical structure, or chemical type of the surfactant.

(*d*) There was no correlation between *in vitro* and *in vivo* data of aminophylline release and absorption. The evaluation of suppository medication, in rabbits and probably for man, cannot be based on *in vitro* dialysis experiments.

Datura Tissue Cultures: Production of Minor Alkaloids from Chlorophyllous and Nonchlorophyllous Strains

By E. JOHN STABA and ANTONIN JINDRA*

The highest medium concentration of manganese used (14 p.p m.) appeared to stimulate the production of cuscohygrine, choline, and pseudotropine from *Datura stramonium* L., strain 5450, suspension cultures. Amino acid precursors, or chlorophyllous tissue had no significant effect upon the production of these alkaloids. No hyoscyamine or scopolamine was detected. Significant amounts of *Datura* suspension tissues were grown in multiliter fermentors.

RECENTLY, ALKALOIDS have been reported produced by *Catharanthus* (1), *Conium* (2), *Datura* (3), *Ipomoea* (4), *Nicotiana* (5), and *Rauwolfia* (6) tissue cultures. In the past a number of investigators have studied alkaloid production by plant tissue or organ cultures, and their results are comprehensively discussed in review articles (7–9). Plant tissue cultures have been used to biochemically alter alkaloids (10) and cardenolides (11).

The tropane alkaloids are reportedly produced by *Datura* (3, 12, 13) and *Hyoscyamus* (14) callus tissue cultures, and to be potentiated by the addition of certain amino acids to the medium (13). The tropane alkaloids may also be degraded and metabolized by microorganisms (15). Manganese ion supplements stimulated alkaloid production and arginase activity in both sand and field cultures of *Datura stramonium* plants (16).

The principal objective of this study was to determine the nature of the alkaloids present in *Datura* suspension cultures and if they might be increased or modified by altering the manganese ion concentration in the medium, by adding tropane alkaloid precursors to the medium, or by inducing chloroplast formation.

EXPERIMENTAL

Tissue Cultures—The *Datura* tissue culture principally studied was 36 month-old seed callus of *Datura stramonium* L., strain 5450. This culture was established in June 1963 (13) from plants believed to be high in alkaloid content and subcultured to the liquid medium in June 1966. The long-term experiment shown in Table I represents seven continuous subcultures of this strain which were grown as previously described (13, 17).

Forty-one month-old seed callus of *D. stramonium* (13); 36 month-old seed callus of *D. quercifolia* L., strain 52146 and *D. innoxia* Mill. (13); and 4 month-old seed callus of *D. stramonium* (seed origin: Drug Plant Greenhouse, Univ. of Nebraska) were grown as suspension cultures for approximately 3 months, and subsequently the suspension cultures were analyzed for their alkaloid content. A continuous light period was provided (150 ftc. from 40-w. cool-white, fluorescent tubes; Amplex Corp.) to establish and maintain chlorophyllous suspension cultures (*D. stramonium* L., strain 5450).

Three 7.5-L. fermentors (model FS-300, New Brunswick Sci. Co., New Brunswick, N. J.) containing 3.4 L. of medium with 14 p.p.m. of manganese were each inoculated with 12 day-old suspension

cells (approx. 5 Gm. dry wt.). The tissues were grown in the fermentors for 21 days at 28°, and each fermentor received an aeration rate of 1 L. of sterile air per min. and an agitation rate of 80 r.p.m.

Alkaloid Analysis—Approximately 2 Gm. of dry tissue was finely ground and mixed in a porcelain, dish with 1.5 ml. of ammonium hydroxide (28%), 2.0 ml. of ethanol (95%), and 4.0 ml. of ethyl ether. After 12 hr. the dried material was extracted with chloroform in a Soxhlet apparatus for 24 hr. The chloroform extract was evaporated *in vacuo* and the residue redissolved in chloroform. The resultant solution was placed in a glass tube and the solvent removed using infrared heat. The residue was then mixed with 0.50 ml. of 0.1 *N* HCl (in 90% ethanol) and the mixture centrifuged.

Extracts (100–200 μl.) were applied to Whatman paper No. 3 and developed by descending chromatography using the organic phase of the mixture, *n*-butanol–glacial acetic acid–water (50:3:25) (18). The alkaloids were detected by dipping the chromatograms in modified Dragendorff's reagent.[1] The R_f values obtained for the standards were: cuscohygrine[2] 0.08, choline 1.17, pseudotropine[2] 0.29, tropine 0.36, scopolamine 0.50, hyoscyamine 0.69. The alkaloids in the sample were identified by co-chromatography with the standard alkaloids.

Some extracts were applied to Whatman paper No. 3 impregnated with 0.5 *M* KCl and developed in *n*-butanol–concentrated hydrochloric acid (98:2) saturated with water (19). Alkaloid detection was achieved as described above.

Concentrations of alkaloids were estimated either by eluting the Dragendorff-positive zone from the chromatogram with acetic anhydride and photometrically comparing the resultant color with standard hyoscyamine concentrations (20), or by comparing the Dragendorff-positive zone with known concentrations of alkaloids on the chromatogram.

Amino Acid Analysis—The tissue (10 Gm. wet wt.) was ground with washed sand and extracted with 70% ethanol in a conical flask for several hours. This extraction process was repeated five times. The combined extracts (approximately 150 ml.) were filtered and evaporated to dryness *in vacuo*. The residue was dissolved in 5.0 ml. of 70% ethanol.

The amino acid extracts (200 μl.) were analyzed on Whatman paper No. 1 by two-dimensional chromatography[3] (21). The first solvent system was a mixture of phenol–ethanol–chloroform (2:1:1) with 0.1% of oxime. To each liter of this mixture was added 100 ml. of 25% ammonium hydroxide solution. Tropeolin 000 was added to the amino acid mixture to indicate the extent of amino acid resolution. The paper was allowed to develop for approximately 48 hr. After drying at normal room temperature, the chromatograms were developed twice in the organic phase of the second solvent system, *n*-butanol–glacial acetic–water (10:1:3).

The analysis of basic amino acids, especially arginine and ornithine, was achieved by purifying and concentrating a sample through a system of ion exchangers. An Amberlite IR 120 (H^+) column (23.8 Gm. wet wt.) was prepared, and after applying the extract, it was eluted with 25–30 ml. of 1 *N* NH_4OH. The eluate was evaporated to dryness at 50–55°, and the resultant residue dissolved in 5.0 ml. of water. This solution was applied to an Amberlite IRA 400 (CO_3^{-2}) column (11.8 Gm. wet wt.) and the effluent collected and evaporated to dryness at 50–55°. The residue was dissolved in 2.0 ml. of water and either 100 or 200 μl. applied to Whatman paper No. 1 for one-dimensional chromatography using a mixture of amyl alcohol–pyridine–water (35:30:30) (22). The amino acids were detected by dipping the chromatograms in a 0.5% ninhydrin solution (acetone–pyridine; 9:1). After drying at normal room temperature for 10 min. the chromatograms were heated at 60° for 2–3 min. The zones were fixed by dipping in a solution of cupric nitrate.[4] The chromatograms were allowed to dry in the dark for 30 min.

RESULTS AND DISCUSSION

The principal alkaloids detected in the tissue cultures were cuscohygrine (CC), choline (CH), and pseudotropine (PT). Their identification was based upon reported R_f values (23) in two chromatographic procedures previously described (18, 20), and by co-chromatography with reference compounds. At no time was hyoscyamine or scopolamine detected in the tissue cultures. These minor alkaloids are present in *Datura* (24), *Withania* (25, 26), and *Scopolia* (23). No relationship could be established between the minor alkaloid content and callus, suspension, or chlorophyllous tissue cultures. These minor alkaloids were sometimes not found, and also could not be related to tissue age, or tissue morphology (creamy-white suspension cells or vesicular brown tissue). The *D. stramonium*, strain 5450, tissue culture used for this study was previously reported to contain scopolamine and a total alkaloid content of 15 mg.% (13). West and Mika (12) reported *Datura* root callus to contain 47–53 mg. % total alkaloids, and Netien and Combet (3) reported *D. metel* L. stem callus to contain approximately 15.5 mg.% of hyoscyamine and scopolamine.

The results obtained with suspension cultures are shown in Table I. The first two experiments of *Datura* suspension cultures grown in medium with 7 p.p.m. of manganese contained no Dragendorff-positive spots. Tissue grown in Experiment III with amino acid precursors grew very poorly and did not contain Dragendorff-positive spots. However, CC, CH, PT were present in some of the cultures without precursors. The tissue from Experiments IV *a*, *b*, *c* did not contain Dragendorff-positive spots, and was grown in media without precursors and with lower manganese concentrations (1 and 7 p.p.m.). Only 21 day-old tissue grown on medium with 14 p.p.m. of manganese contained the three alkaloids: CC, CH, and PT. Twenty-eight day-old tissue

[1] Modified Dragendorff's reagent: Mix together basic bismuth carbonate 2.6 Gm. and sodium iodide 7.0 Gm. Add 25 ml. glacial acetic acid and boil for 3–4 min., set overnight and filter. The filtrate (20 ml.) was added to ethyl acetate (80 ml.) to make the stock solution. Final detecting solution was formed by mixing and storing the following for at least 24 hr.: 20 ml. of stock solution, 4 ml. of glacial acetic acid, 120 ml. of ethyl acetate, and 10 ml. of water.

[2] Supplied through the courtesy of Dr. W. C. Evans, University of Nottingham, England.

[3] The two-dimensional chromatographic analysis was performed by Dr. V. Jiracek, Department of Biochemistry, Charles University, Praha, Czechoslovakia.

[4] Aqueous saturated solution of cupric nitrate (2 ml.) is mixed with concentrated nitric acid (0.04 ml.), and acetone added to 200 ml.

[a] Average dry weight tissue obtained from 4–10 250-ml. conical flasks containing 75 ml. of medium. Tissue was dried at 90° for 24 hr. [b] Final concentration in medium: 0.02% of L-ornithine HCl and of L-arginine HCl; 0.01% of L-phenylalanine; 0.05% of L-asparagine (anhydrous). The amino acid stock solution used was sterilized by filtration and aseptically added to the medium. [c] Paper chromatographic procedure according to Trabert (18) and detection by modified Dragendorffs reagent. *Rf*: Cuscohygrine, 0.08; Choline, 0.17; Pseudotropine, 0.29. [d] The tissue from Experiment V*a–d* was combined, dried, and assayed as one sample.

grown on similar medium contained a strong PT spot (estimated concentration 0.035%). Pseudotropine was also present (estimated concentration 0.015%) in 28 day-old tissue on similar medium with precursors (Experiment IV). The tissue appearance varied from a creamy-white suspension to a brown vesicular tissue. Supplemental analysis of these two forms indicated that they were similar with regard to their alkaloid content, and the creamy-white suspension tissue was selected for Experiments V and VI, and the multiliter experiment. The three alkaloids, CC, CH, and PT, were present in Experiment V tissues grown in media with high manganese levels (14 p.p.m.), and with or without amino acid precursors. The highest concentration of CC (estimated 0.01%) was in Experiment V*e* tissue, and the highest concentration of PT (estimated 0.017%) in Experiment V *a–d*. A growth curve for Experiment V *a–d* is shown in Fig. 1. At the time of maximum growth (34 days) the growth index value was 8.12; the growth efficiency index (G.E.I.)[5] value 3.18; and the Gm. of tissue (wet wt.) produced per liter per day was 6.2. The moisture content, determined by drying the tissue at 90° for approximately 24 hr. was 95.5%. The tissue grown for Experiment VI in medium with either 7 or 14 p.p.m. of manganese, with and without precursors, contained no Dragendorff-positive spots.

Chlorophyllous cultures grew very rapidly as a green, finely dispersed cellular culture. The cultures analyzed contained CH, but no other Dragendorff-positive spots.

The tissues obtained from the three fermentors contained no Dragendorff-positive spots. As much as 10 Gm. dry wt. of tissue was taken for an analysis, and yet the result was negative for alkaloids. The growth index values for the three fermentors are given in Fig. 1. The fermentor with the maximum growth had a growth index value of 9.34; a G.E.I. value of 0.13; and the Gm. of tissue (wet wt.) produced per liter per day was 14.1. These values were calculated for the growth yield obtained and do not necessarily represent the maximum growth yield possible. There is continued interest in the production of large amounts of plant cells (27, 28). The amount of fresh tissue obtained from the best multiliter fermentation was 14.1 Gm./L./day, and compares favorably with that reported for *Ammi visnaga* (19.0 Gm./L./day) (9).

The amino acids found in the two-dimensional chromatograms of tissue from Experiments III *a, b, c*

[5] G.E.I. = Growth index at maximum growth/medium (L.) × days required for maximum growth.

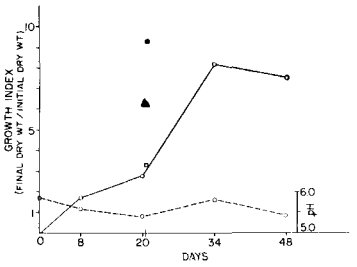

Fig. 1—Datura stramonium *L., strain 5450, growth in flasks (Experiment V), and from multiliter fermentors. Key:* O, *250-ml. conical flasks (75-ml. medium). Growth (average dry wt.) from 4 flasks. Inoculum dry weight: 0.098 Gm.;* □, *fermentor I;* Δ, *fermentor II;* ■, *fermentor III. Fermentors contained 3.4-L. medium and a tissue inoculum of approximately 5 Gm. dry weight. Final medium pH was 5.5.*

and IV *a*, *b*, *c* (Table I) in high concentrations were arginine, glutamic acid, and glutamine; in intermediate concentrations were alanine, γ-aminobutyric acid, and serine; and in low concentrations were aspartic acid, isoleucine, leucine, phenylalanine, proline, threonine, tyrosine, and valine. One-dimensional chromatograms of all samples had a high concentration of arginine and only traces of ornithine. The amino acids ornithine and phenylalanine, which are known to be the principal precursors of the tropane alkaloids (24), did not show any significant stimulating effects on the production of either minor or major alkaloids in the *Datura* tissue cultures studied. An analysis of the amino acids in *Datura* suspension cultures was qualitatively similar, except for the absence of lysine and tryptophan, to that reported for *D. stramonium* plants (16). Large amounts of arginine, and trace amounts of ornithine, are present in *Datura* tissue cultures.

Higher concentrations of manganese, a known activator of arginase (16), appeared to stimulate the production of the minor alkaloids present in *Datura* suspension cultures.

Quantitative Analysis of Flavonoids

By HARUO OGURA, YŌKO SHIKIBA, and YUKIO YAMAZAKI

Some flavonoids, quercitrin, quercetin, and rutin are analyzed quantitatively using zirconium chloride or diphenylboric acid β-aminoethyl ester as a color reagent. These methods are suitable for the quantitative analysis of flavonoids contained in vegetable crude drugs and pharmaceutical preparations.

THE QUANTITATIVE analysis of rutin and its preparations by the determination of the ultraviolet absorption (UV) has been well known (1–4). In the present investigation on the quantitative analysis of rutin (I), quercitrin (II), and quercetin (III), their preparations were investigated. Studies on the quantitative analysis were restricted to colorimetry, and zirconium chloride (*A*) and β-aminoethyl diphenylborate (*B*) (5) were used as the color reagents.

The relative concentration of the colored complex seemed to depend on the pH of the reaction medium. The pH profile for the appearance of the colored complex was determined in acetic acid-sodium acetate buffer (Figs. 1 and 2). The buffer solutions

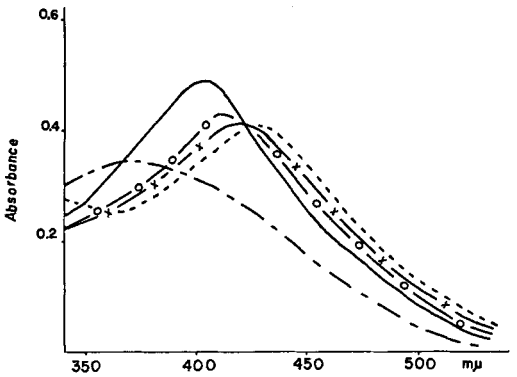

Fig. 1—UV spectra of flavones colored by method A *(rutin) in various buffer solutions. Key:* — — —, *2* M *AcOH;* ———, *2* M *AcOH–2* M *AcONa (3:1);* O, *2* M *AcOH–2* M *AcONa (1:1);* X, *2* M *AcOH–2* M *AcONa (1:3);* – – – –, *2* M *AcONa.*

suitable for method *A* were acetic acid–sodium acetate (3:1) and for method *B*, sodium acetate. The characteristic reactions of these flavones produced a yellow color with method *A* ($\lambda_{max.}$: I, 400 mμ; II, 402 mμ; III, 468 mμ) and method *B* ($\lambda_{max.}$: I, 404 mμ; II, 394 mμ; III, 406 mμ). Calibration curves (Fig. 3) for complexes of I, II, and III by both methods *A* and *B* suggested the possibility of quantitative analysis.

The quantitative analytical data for pharmaceutical preparations are summarized in Table I. Some of the crude drugs analyzed as quercitrin (No. 1) or quercetin (No. 2), and simple preparations of flavones (I, II) and containing ascorbic acid (Nos. 3~6) also gave good quantitative analytical data. The data also revealed that the presence of hesperidin, vitamin K, and carbazochrome showed no interference. On the other hand, preparations containing methylhesperidin, vitamin K_4 diacetate, and/or extracts of coptis, rheum, and scutellaria showed rather a large observational error.

EXPERIMENTAL

Sample solutions were prepared by dissolving 5 mg. each of the materials in 50 ml. of methanol in a

Accepted for publication November 15, 1967.

TABLE I—QUANTITATIVE ANALYSES OF RUTIN IN PHARMACEUTICAL PREPARATIONS

No.	Preparation (Components)	% of Theory—Method *A*	% of Theory—Method *B*
1	Extract *Aesculus* leaf (quercitrin)(6)	42.6[a]	40.6[a]
2	Extract *Aesculus* seed (quercetin) (6)	0[a]	1.3[a]
3	Quercitrin (0.8 mg.) Ascorbic acid (0.25 mg.)/ml.	103.1[a]	99.4[a]
4	Rutin (×10)	100.4	100.4
5	Rutin (50 mg.) Ascorbic acid (25 mg.)/ml.	98.0	100.0
6	Rutin (70 mg.) Ascorbic acid (70 mg.)/tab.	98.9	100.1
7	Rutin (20 mg.) Ascorbic acid (20 mg.) Hesperidin (50 mg.)/tab.	101.8	103.7
8	Carbazochrome 3-sodium sulfonate (25 mg.) Hesperidin (50 mg.) Rutin (40 mg.) Ascorbic acid (100 mg.) Vitamin K (5 mg.) Dibasic calcium phosphate (300 mg.)/Gm.	100.3	103.7
9	Methylhesperidin (40 mg.) Rutin (40 mg.) Ascorbic acid (100 mg.) Adrenochrome monosemicarbazone (2 mg.) Vitamin K_4 diacetate (2 mg.)/Gm.	124.9	116.0
10	Rutin (100 mg.) Scutellaria root (50 mg.) Coptis (25 mg.) Rheum (25 mg.) Extract rheum, coptis, scutellaria root (85 mg.)/Gm.	120.3	120.3
11	Rutin (20 mg.) Scutellaria root (10 mg.) Coptis (5 mg.) Rheum (5 mg.) Extract rheum, coptis, scutellaria root (17 mg.)/tab.	114.4	118.1

[a] Each value represents a % of quercitrin (Nos. 1 and 3) and quercetin (No. 2) in the preparations.

volumetric flask and diluting with water to make 100 ml.

(A) Zirconium Chloride—To 5 ml. of the sample solution in a 25-ml. volumetric flask, 1 ml. of a buffer solution [*a*, 2 *M* acetic acid; *b*, 2 *M* acetic acid–2 *M* sodium acetate (3:1); *c*, 2 *M* acetic acid-2 *M* sodium acetate (1:1); *d*, 2 *M* acetic acid–2 *M* sodium acetate (1:3); *e*, 2 *M* sodium acetate] and 1 ml. of 3% zirconium chloride were added, and diluted with water to the mark.

(B) β-Aminoethyl Diphenylborate—To 5 ml. of the sample solution in a 25-ml. volumetric flask, 1 ml. of a buffer solution (same as above) and 1 ml. of methanolic 1% β-aminoethyl diphenylborate were added, and diluted with methanol to the mark.

CONCLUSION

As shown in Fig. 1, 2 *M* acetic acid–2 *M* sodium acetate (3:1) solution (*b*) was suitable for method *A*. On the other hand, 2 *M* sodium acetate solution (*e*) was suitable for method *B* as shown in Fig. 2. Calibration curves for I are shown in Fig. 3.

It is considered that further investigation should be carried out to introduce a new quantitative analytical method for rutin preparations and/or vegetable crude drugs. In addition to the two methods mentioned above, there is another method for the quantitative analysis of flavonoids under investigation in our laboratories.

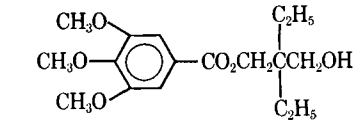
Preparation of 2,2-Diethyl-3-(3,4,5-trimethoxybenzoyloxy)propyl Carbamate

By JOSEPH SAM*

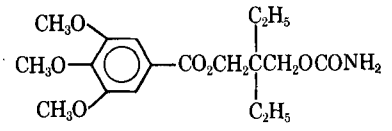
The preparation of the 3,4,5-trimethoxybenzoate of 2,2-diethyl-1,3-propanediol, and the conversion of the ester to the carbamate are described.

THE USEFUL depressant properties of propanediols (1) and the presence of the 3,4,5-trimethoxybenzoyl group in the rauwolfia alkaloids (2) prompted the preparation of a hybrid involving the two groups.

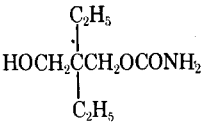
The esterification of an excess of 2,2-diethyl-1,3-propanediol with 3,4,5-trimethoxybenzoyl chloride provided the mono ester, I. The treatment of I



I



II



III

with phosgene, followed by ammonolysis yielded the mixed ester-carbamate, II. Compound II also was prepared by the esterification of 2,2-diethyl-3-hydroxypropyl carbamate (III).

Preliminary pharmacological studies in mice demonstrated that compounds I and II exhibit mild central nervous system depressant properties.

EXPERIMENTAL[1]

2,2-Diethyl-3-hydroxypropyl-3,4,5-trimethoxybenzoate—A mixture of 46 Gm. (0.2 mole) of 3,4,5-trimethoxybenzoyl chloride, 53 Gm. (0.4 mole) of 2,2-diethyl-1,3-propanediol, and 300 ml. of toluene was refluxed for 7 hr. The mixture was cooled and washed with a 5% sodium carbonate solution. The toluene solution was dried over anhydrous sodium sulfate and then distilled to yield 25 Gm. (39%) of product, b.p. 193–196° (0.2 mm.).

Anal.—Calcd. for $C_{17}H_{26}O_6$: C, 62.6; H, 8.03. Found: C, 62.0; H, 7.88.

2,2-Diethyl-3-(3,4,5-trimethoxybenzoyloxy)propyl Carbamate—*Method A*—A solution of 17.5 Gm. (0.1 mole) of 2,2-diethyl-3-hydroxypropyl carbamate (3, 4) and 23 Gm. (0.1 mole) of 3,4,5-trimethoxybenzoyl chloride in 300 ml. of benzene was refluxed for 3 hr. and then cooled. The benzene solution was washed with water and 5% sodium bicarbonate, respectively, and then dried over anhydrous sodium sulfate. Distillation of the solvent and crystallization of the residual material from a mixture of benzene and *n*-hexane gave 15 Gm. (41%) of light brown solid, m.p. 110–118°. Recrystallization from benzene gave product, m.p. 124.5–126°.

Anal.—Calcd. for $C_{18}H_{27}NO_7$: C, 58.5; H, 7.37. Found: C, 58.3; H, 7.41.

Method B—The procedure (5) described for the preparation of carbamates of aryl glycerol ethers was followed using the same molar ratios of reactants. From 3.3 Gm. (0.01 mole) of 2,2-diethyl-3-hydroxypropyl-3,4,5-trimethoxybenzoate there was obtained 0.4 Gm. (10%) of product which was washed with petroleum ether (b.p. 60°) and recrystallized from benzene; m.p. 124.5–126°. A mixed melting point with the product obtained by method *A* showed no depression.

Correlation of Pharmacologic Activity and Dissolution Rates of Reserpine-Desoxycholic Acid Dispersions

Sir:

The usefulness of solid-state dispersions for enhancing the dissolution rate of drugs has been demonstrated in a number of recent reports (1–5). The principal reason for the observed effects appears to be particle size reduction. An interesting example of the enhanced pharmacologic activity of such dispersions has been provided by Malone *et al.* (6). These workers found a significant increase in the blepharoptotic activity of reserpine in mice after oral administration of the drug as a solid dispersion in desoxycholic acid (DCA). A correlation between the composition of the reserpine-DCA dispersion and apparent biologic activity was also noted in that an increase in the DCA:reserpine ratio resulted in an increase in activity (see Table I). Results of studies to be reported in this communication suggest that particle size reduction of reserpine in the dispersion, leading to increased dissolution and absorption rate, and possibly increased availability of reserpine, is likely to be a major factor in the enhancement of pharmacologic activity.

Reserpine[1] and DCA[2] dispersions were prepared according to the methods of Malone *et al.* (6) which involve co-precipitation of the materials from chloroform–absolute alcohol solutions upon evaporation of the solvent system. Attempts to determine the dissolution rate of reserpine in aqueous systems were unsuccessful because of assay difficulties and adsorption problems introduced by the extremely low aqueous solubility of the drug. Hence, dissolution rates of reserpine from 12 to 20-mesh particles of the various preparations were determined in the following manner. Each sample, containing an equivalent of 150 mg. reserpine, was added to a round-bottom flask containing 300 ml. of ethyl acetate (certified A.C.S. grade) at 37° ± 0.1°. Stirring was provided by means of an overhead motor, connected to a Teflon blade, operating at 50 r.p.m. Samples were withdrawn at periodic intervals, filtered, diluted 1:10 with methanol, and assayed for reserpine using a Beckman DB-G spectrophotometer at 268 mμ. Desoxycholic acid appeared to be essentially "insoluble" in ethyl acetate. Solutions of DCS equilibrated in ethyl acetate at room temperature and 37°, upon 1:10 dilution, showed no spectral activity from 350 mμ to 220 mμ. In addition, the spectrum of reserpine at various concentrations was found to be identical in ethyl acetate and ethyl acetate saturated with DCA.

The dissolution data plotted in Fig. 1 indicate an increased dissolution rate of reserpine from the DCA dispersions. The greater the percentage of DCA in the dispersion, the faster the dissolution of reserpine. The raw dissolution data were replotted assuming that dissolution followed an apparent first-order process under nonsink conditions, as previously discussed by Gibaldi and Feldman (7). These plots are shown in Fig. 2.

TABLE I—CORRELATION OF DISSOLUTION DATA AND BIOLOGIC ACTIVITY OF VARIOUS RESERPINE-DCA DISPERSIONS

Molar Composition of Dispersions (Reserpine: DCA)	$k \times 10^4$ (mg.$^{-1}$min.$^{-1}$)	Ratio of Rate Constants	Oral Potency[a]
1:0	2.55	—	—
1:4	3.68	1.4	2.6
1:8	5.38	2.1	2.8
1:16	8.10	3.2	3.8
1:32	16.3	6.4	1.9

[a] Peak blepharoptotic activity after oral administration, as compared to the peak activity of reserpine base after oral administration (from *Reference 6*).

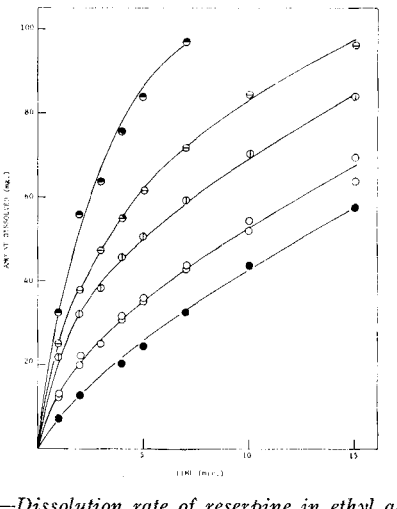

Fig. 1—Dissolution rate of reserpine in ethyl acetate from various preparations. Key: ●, reserpine-DCA, 1:0; ○, 1:4; ◑, 1:8; ⊖, 1:16; ◓, 1:32.

[1] Generously supplied by Ciba Pharmaceutical Company.
[2] Special enzyme grade, Mann Research Laboratories, Inc.

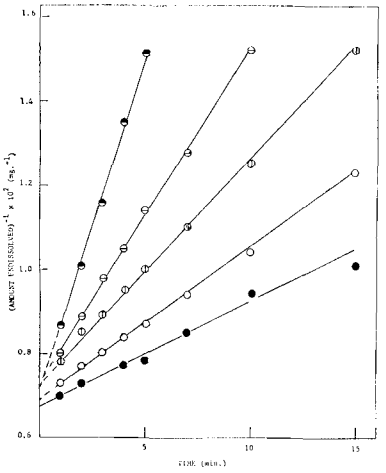

Fig. 2—Second-order plot of reserpine dissolution data assuming dissolution was apparent first order under nonsink conditions. Key: ●, reserpine–DCA, 1:0; ○, 1:4; ◑ 1:8; ⊖, 1:16; ◓, 1:32.

The apparent second-order rate constants were calculated and these are reported in Table I together with the corresponding ratios. A rank correlation is noted between the apparent second-order dissolution rate constants and the biologic activities of the various reserpine preparations. The sole exception is the 1:32 reserpine–DCA dispersion which is significantly less biologically active than would be predicted by the dissolution data.

The use of organic solvents in correlation studies between *in vitro* and *in vivo* data is rarely desirable or logical. However, as noted by Levy (8) dissolution in organic solvents does reflect adequately the particle size of the drug. Furthermore, dissolution in an organic solvent may reflect changes in crystal structure. To explore the latter possibility, diffraction spectra were obtained for reserpine and DCA, separately precipitated from the solvent system, and for various dispersions, using a General Electric XRD-6 diffractometer.[3] All samples appeared to be noncrystalline. In view of the absence of solution interaction between DCA and reserpine in ethyl acetate, and the lack of change in crystal form, it is concluded that the physical state of reserpine (*i.e.*, an extremely fine particle size attained by co-precipitation with DCA) is responsible for the increased dissolution rates observed with the reserpine-DCA dispersions.

Antidepressive Effect of N-3,4,5-Trimethoxybenzoyl Heptamethylenimine

Sir:

It was Luts *et al.* (1) who reported on the synthesis and preliminary pharmacological investigation of *N*-3,4,5-trimethoxybenzoyl heptamethylenimine. As stated by these authors, unlike other amines containing trimethoxybenzoyl group the compound is void of depressant and analgesic action; moreover, it exerts a mild stimulating effect.

In a series of studies concerned with a large number of derivatives of heptamethylenimine substituted by benzoic acid the above-mentioned compound has also been synthesized and subjected to close pharmacological investigation.

Synthesis was carried out principally by the method reported by Luts *et al.* (1).

Antidepressive Effect of N-3,4,5-Trimethoxybenzoyl Heptamethylenimine

Sir:

It was Luts *et al.* (1) who reported on the synthesis and preliminary pharmacological investigation of *N*-3,4,5-trimethoxybenzoyl heptamethylenimine. As stated by these authors, unlike other amines containing trimethoxybenzoyl group the compound is void of depressant and analgesic action; moreover, it exerts a mild stimulating effect.

In a series of studies concerned with a large number of derivatives of heptamethylenimine substituted by benzoic acid the above-mentioned compound has also been synthesized and subjected to close pharmacological investigation.

Synthesis was carried out principally by the method reported by Luts *et al.* (1).

In mice the LD_{50} was 170 ± 5.15 i.p. 200 ± 21.52 s.c.

Investigated after Zetler's (2) cataleptic method, in i.p. doses of 20 mg./Kg., the compound was found to be a strong antagonist of catalepsy caused by reserpine or chlorpromazine. It has furthermore strongly antagonized the toxicity of reserpine under acute and subacute conditions. Alone it gave rise to slight hyperthermia. In doses of 40 mg./Kg. it has reversed hyperthermia due to reserpine. In rotarod test (3) the compound alone failed to exert any effect in doses of 10–80 mg./Kg. i.p., but doses from 10 mg./Kg. have antagonized incoordination caused by 2.5 mg./Kg. reserpine. In doses of 10 mg./Kg. the compound has intensified the hypertensive effect of epinephrine in cats. After preliminary treatment for 5 days, the effect of epinephrine and norepinephrine on blood pressure has been greatly enhanced. As shown by Knoll's motimeter (4), the compound induced minimal hypermotility when administered in i.p. doses of 20 mg./Kg.

Hypermotility caused by amphetamine has been inhibited in the first 60 min., but in the period from 60–210 min. it has been increased in an extraordinary measure. When administered simultaneously with hexobarbital, the compound has slightly prolonged the narcosis time. However, after premedication over 24 hr., anaesthesia was considerably shortened. The compound has exerted practically no influence on pentylenetetrazol,[1] strychnine, and electroconvulsions.

No analgesic effect could be demonstrated. Monoamino oxidase has not been inhibited either *in vitro* or *in vivo* after premedication for 1 week The compound has shown no noteworthy harmful effect in subacute toxicity tests.

Upon due consideration of the obtained findings, the compound would seem to display an extraordinary likeness in pharmacological properties to tricyclic antidepressants, and as such it may be denoted as a potential antidepressive drug of new chemical type.

A report on detailed pharmacological results is to be published later.

Validity of the Doty Reaction as a Stability-Indicating Assay for Isoproterenol in an Aerosol Preparation

Sir:

The sensitivity, accuracy, precision, and manipulative simplicity of the ferro-citrate color reaction described by Doty (1) have led to its wide use for assay of preparations containing isoproterenol, epinephrine, and other catecholamine drugs. The reaction is selective for the catechol function, and it will therefore be stability indicating where the degradation reaction involves the catechol group. Higuchi, Sokoloski, and Schroeter (2) assayed known mixtures of epinephrine and its oxidative degradation products by four procedures; they reported close correspondence between the result obtained by the Doty reaction and the true value, indicating that the reaction is stability indicating where degradation occurs by oxidation. Schroeter, Higuchi, and Schuler (3) described a nonoxidative degradation reaction of epinephrine with bisulfite, used as an antioxidant, where a physiologically inactive substituted benzylsulfonic acid is formed. A similar reaction occurs between bisulfite and isoproterenol (4). The epinephrine-bisulfite reaction product was prepared by the literature method (5). As expected, this product was found to give a color with the Doty reagent, vitiating this assay method for catecholamines in solutions preserved by bisulfite. The Doty method would have obvious limitations in following the stability of those catecholamines subject to racemization in solution (6); however this limitation does not exist with the racemic isoproterenol salts official in the compendia.

In mice the LD_{50} was 170 ± 5.15 i.p. 200 ± 21.52 s.c.

Validity of the Doty Reaction as a Stability-Indicating Assay for Isoproterenol in an Aerosol Preparation

Sir:

The sensitivity, accuracy, precision, and manipulative simplicity of the ferro-citrate color reaction described by Doty (1) have led to its wide use for assay of preparations containing isoproterenol, epinephrine, and other catecholamine drugs. The reaction is selective for the catechol function, and it will therefore be stability indicating where the degradation reaction involves the catechol group. Higuchi, Sokoloski, and Schroeter (2) assayed known mixtures of epinephrine and its oxidative degradation products by four procedures; they reported close correspondence between the result obtained by the Doty reaction and the true value, indicating that the reaction is stability indicating where degradation occurs by oxidation. Schroeter, Higuchi, and Schuler (3) described a nonoxidative degradation reaction of epinephrine with bisulfite, used as an antioxidant, where a physiologically inactive substituted benzylsulfonic acid is formed. A similar reaction occurs between bisulfite and isoproterenol (4). The epinephrine-bisulfite reaction product was prepared by the literature method (5). As expected, this product was found to give a color with the Doty reagent, vitiating this assay method for catecholamines in solutions preserved by bisulfite. The Doty method would have obvious limitations in following the stability of those catecholamines subject to racemization in solution (6); however this limitation does not exist with the racemic isoproterenol salts official in the compendia.

Our concern related to the validity of the ferrocitrate assay as a stability method for isoproterenol in a nonaqueous aerosol preparation[1] with thonzonium bromide, ascorbic acid, alcohol, and propellants. In order to ascertain whether or not degradation of isoproterenol in this preparation furnished a product with an intact catechol function, we subjected aged samples to thin-layer chromatography and sprayed the developed chromatograms with Doty reagent prepared according to the NF (7). (The use of this reagent as a selective spray for detection of catechol derivatives on chromatograms has not been described previously. A fuller description of its application will be published elsewhere.)

The aerosol containers were chilled by immersion in a freezing bath of solid carbon dioxide–acetone, opened with pliers, then allowed to warm to room temperature to evolve propellants. The remaining solution was diluted with an equal volume of absolute methanol, and 25-μl. volumes of it and a 600 mcg./ml. solution of reference isoproterenol HCl were spotted 3 cm. from the bottom edge of a commercial precoated 20 × 20 cm. thin-layer plate consisting of a 0.25-mm. thickness of microcrystalline cellulose without binder or phosphor on glass.[2] Before use, the plates were developed in the solvent to about 15 cm. from the starting line and air dried to remove contaminants from the plate. Pretreatment of the plate in this manner eliminated an apparent second front across the chromatogram which resulted in artifactual spots such as those described by Choulis (8). The chromatogram was developed to about 15 cm. from the starting line with a mixture of 2-propanol and 0.1 *N* hydrochloric acid (5:1). After air drying and spraying with the Doty reagent, only one purple spot was obtained at R_f 0.4, corresponding to intact isoproterenol. The detection limit for isoproterenol HCl or epinephrine HCl is below 0.3 mcg. (2% of the amount spotted from the formulation). A volume of 0.5 μl. of 0.6 mg./ml. epinephrine HCl (0.3 mcg.) was added to a sample preparation spot. It was readily detected at R_f 0.2 after chromatographic separation and treatment with Doty reagent. Thus, the method was shown to be capable of separating isoproterenol from a closely related catecholamine and detecting at least 2% of the amount spotted.

The procedure was applied to isoproterenol and thonzonium bromide aerosol samples stored at room temperature for more than 5 years. Examination of stability data obtained for five lots of the formulation during this time revealed no consistent pattern of degradation. Instead, it appears that each sample reacts to the extent of the oxygen present and remains substantially unchanged thereafter. Although some degradation was evident in all of the stability samples, isoproterenol content remained satisfactory throughout the testing period.

Absolute Stereochemistry and Analgesic Potency of Prodine Enantiomers

Sir:

Stereochemical factors are known to be of importance in analgesic action (1). Among the structures in this well-known class of biologically active compounds, α and β-prodine (Ia and Ib, respectively) (2) distinguish themselves by being highly potent synthetic analgesics possessing two asymmetric centers. While the relative stereochemistries of Ia and Ib are known (3), the absolute configurations and potencies of the optically pure enantiomers have not been reported and are of great interest because they possess an asymmetric center in common with isomethadone (4). In this communication evidence is presented which permits assignment of the complete absolute stereochemistry of these enantiomers.

Treatment of racemic IIa (2) with an equivalent of (+)-tartaric acid in methanol–acetone

Our concern related to the validity of the ferrocitrate assay as a stability method for isoproterenol in a nonaqueous aerosol preparation[1] with thonzonium bromide, ascorbic acid, alcohol, and propellants. In order to ascertain whether or not degradation of isoproterenol in this preparation furnished a product with an intact catechol function, we subjected aged samples to thin-layer chromatography and sprayed the developed chromatograms with Doty reagent prepared according to the NF (7). Absolute Stereochemistry and Analgesic Potency of Prodine Enantiomers

Sir:

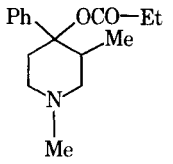
Stereochemical factors are known to be of importance in analgesic action (1). Among the structures in this well-known class of biologically active compounds, α and β-prodine (Ia and Ib, respectively) (2) distinguish themselves by being highly potent synthetic analgesics possessing two asymmetric centers. While the relative stereochemistries of Ia and Ib are known (3), the absolute configurations and potencies of the optically pure enantiomers have not been reported and are of great interest because they possess an asymmetric center in common with isomethadone (4). In this communication evidence is presented which permits assignment of the complete absolute stereochemistry of these enantiomers.

Treatment of racemic IIa (2) with an equivalent of (+)-tartaric acid in methanol–acetone

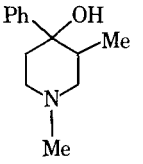
afforded the acid tartrate salt, m.p. 161–162°, $[\alpha]_D^{22}$ + 13.5° (c 1, H_2O), from which the amine, m.p. 89–90°, $[\alpha]^{22}$ + 10.2° (c 1, acetone), was regenerated. This was transformed to the methiodide, m.p. 169–170°, $[\alpha]_D^{22}$ + 1.6° (c 1, EtOH), which was converted to the quaternary hydroxide and then heated at 170° for 1 hr. The structure of the elimination product, III, $[\alpha]_D^{26}$ + 59.8° (c 2, Et_2O), (75% yield) was confirmed by the NMR spectrum which showed a doublet methyl resonance at 0.82 p.p.m. (J = 6.5 c.p.s.) and three olefinic proton resonances; H_a = 5.13 p.p.m., H_b = 5.44 p.p.m. (J_{ab} = 2 c.p.s.), H_c = 6.40 p.p.m. (J_{bc} = 17 c.p.s., J_{ac} = 10 c.p.s.). Hydroxylation of III with osmium tetroxide followed by *in situ* cleavage of the triol with sodium metaperiodate afforded (−)-IV which was isolated as the maleate salt, m.p. 127–129°, $[\alpha]_D^{20}$ − 52.6° (c 1, EtOH). The physical properties were found to be in accord with those of the maleate salt, m.p. 127–128°, $[\alpha]_D^{20}$ − 53.2° (c 1, EtOH), derived from authentic IV (5) which has been determined to be in the (*R*)-series. Esterification of (+)-IIa with propionyl chloride afforded (+)-α-prodine hydrochloride, m.p. 191–193°, $[\alpha]_D^{21}$ + 26.5° (c 1, EtOH). Employing the same procedure, (−)-α-prodine hydrochloride, m.p. 192–193°, $[\alpha]_D^{21}$ − 27.9° (c 1, EtOH), was prepared from (−)-IIa, m.p. 88–89°, $[\alpha]_D^{21}$ − 10.7° (c 1, acetone), obtained by using (−)-tartaric acid in the resolution of the racemic alcohol. The IR spectra of both antipodes were superimposable and virtually identical to that of the racemate.

The above chemical correlation establishes (+)-Ia·HCl as having the (3*R*) configuration. Since it is known (3) that the phenyl and methyl groups in Ia have a *trans* relationship, it follows therefore that the complete stereochemistry of (+)-α-prodine hydrochloride is (3*R*:4*S*) and is depicted by structure VIa. Due to its enantiomeric relationship with (+)-Ia·HCl, the stereochemistry of (−)-α-prodine hydrochloride is designated as (3*S*:4*R*).

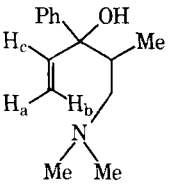
Treatment of (±)-IIb (2) with one equivalent of (−)-dibenzoyltartaric acid in H_2O–MeOH afforded the acid dibenzoyltartrate salt, m.p. 163–164°, $[\alpha]_D^{22}$ − 42.6° (c 1, MeOH), from which (+)-IIb, m.p. 136–137°, $[\alpha]_D^{20}$ + 74.5° (c 1, acetone) was obtained. Employing (+)-dibenzoyltartaric acid in an identical procedure gave (−)-IIb, m.p. 136–137°, $[\alpha]_D^{20}$ − 75.0° (c 1, acetone). Dehydration of (+)-IIb with aqueous HCl yielded (−)-V, $[\alpha]_D^{22}$ − 115° (c 1, Et_2O), whose IR and NMR spectra were identical to that of the racemic olefin (6). Pyrolysis of (+)-Ia according to the procedure of Diamond (7)



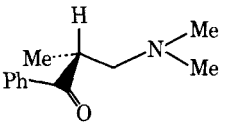
Ia *trans*-Ph:Me
Ib *cis*-Ph:Me



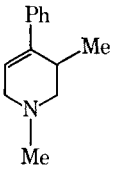
IIa *trans*-Ph:Me
IIb *cis*-Ph:Me



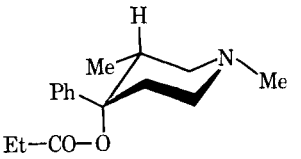
III



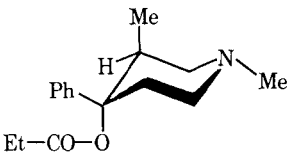
IV



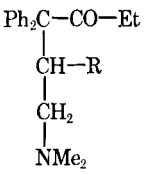
V



VIa



VIb



VII, R = Me
VIII, R = H

afforded (+)-V, $[\alpha]_D^{22}$ + 93.2° (c 1, Et_2O), which possessed IR and NMR spectra identical to that of enantiomeric and racemic material. Esterification of (+)-IIb with propionyl chloride gave (+)-Ib·HCl, m.p. 186–188°, $[\alpha]_D^{20}$ + 74.5° (c 1, EtOH). Employing (−)-IIb in an identical procedure afforded (−)-Ib·HCl, m.p. 186–188°, $[\alpha]_D^{20}$ − 73.7° (c 1, EtOH). The IR spectra of both enantiomers were virtually identical to that of the racemate.

The preceding stereochemical correlation and the known *cis* relationship (3) between phenyl and methyl groups in β-prodine permits the configurational assignment of (+)- and (−)-Ib·HCl as (3*S*:4*S*) (VIb) and (3*R*:4*R*), respectively.

It was found that most of the analgesic activity of both α- and β-prodine resides in the (+)-antipodes (Table I). The analgesic potency of the diastereomeric tartrate salts of Ib has been reported (8). However, in view of the reported low enantiomeric potency ratio and our inability to effect complete optical resolution by this

TABLE I—ANALGESIC POTENCY OF PRODINE ENANTIOMERS

dl-β-Prodine HCl	0.35
(+)-β-Prodine HCl	0.25
(−)-β-Prodine HCl	2.6
3-Desmethylprodine HCl	1.3
Meperidine HCl	12.0

[a] Analgesic activity was determined by a modified hot plate method (13).

method, it is very probable that Ib was only partially resolved.

It is significant that the C-3 asymmetric centers in the more potent isomers have opposite configurations. This, coupled with the observation that desmethylprodine (9) possesses greater potency than either of the less active prodine isomers (Table I) suggests that the 3-methyl group does not contribute to the drug-receptor interaction in a totally positive fashion. The difference in potency between (+)-Ia and (+)-Ib most probably is related to different brain levels[1] and it is conceivable that the lower potency of desmethylprodine, when compared to the more active antipodes, may largely be due to lower brain levels rather than to the absence of involvement of the 3-methyl group at the receptor level.

It is noteworthy that the more active enantiomers of isomethadone (VII) (10) and Ia are configurationally related (11). Since the desmethyl analog (VIII) (12) possesses potency which is comparable to VII, there exists the possibility that in this case the methyl group of (*S*)-isomethadone is also playing primarily a passive role in the interaction with analgesic receptors.

[1] Preliminary experiments indicate that the brain levels of β-prodine in rats are greater than those of the α-isomer and that this is the primary factor determining the potency difference between these diastereomers.

4,4′-Dihydroxybibenzyl, a Reduction Metabolite of *trans*-Stilbene

Sir:

Our investigations of the metabolism of certain stilbenes has revealed a unique conversion of *trans*-stilbene in rabbits (2.1%)[1] to 4,4′-dihydroxybibenzyl.

The above metabolite (originally designated X) was found in a phenolic fraction obtained from an ether extract of urine of rabbits, which had been administered *trans*-stilbene (25 mg./Kg., i.m.). Paper, thin-layer, and vapor phase chromatography (VPC) (1) of this phenolic fraction disclosed the presence of the *trans*-stilbenes, 4-hydroxy-, 4,4′-dihydroxy-, 3-hydroxy-4-methoxy-, and 4-hydroxy-3-methoxystilbene, and X, which was not comparable to these or other simple phenolic stilbenes. A 2-mg. sample of the trimethylsilyl (TMS) either of X, obtained by preparative VPC, was subjected to IR, UV, and mass spectral analysis.

The IR spectrum of the TMS derivative of X,

[1] Determined by VPC (TMS ether). Chromatographic analysis of urine obtained from guinea pigs administered *trans*-stilbene has indicated an even greater (10.6%) conversion to 4,4′-dihydroxybibenzyl.

4,4′-Dihydroxybibenzyl, a Reduction Metabolite of *trans*-Stilbene

Sir:

Our investigations of the metabolism of certain stilbenes has revealed a unique conversion of *trans*-stilbene in rabbits (2.1%)[1] to 4,4′-dihydroxybibenzyl.

The above metabolite (originally designated X) was found in a phenolic fraction obtained from an ether extract of urine of rabbits, which had been administered *trans*-stilbene (25 mg./Kg., i.m.). Paper, thin-layer, and vapor phase chromatography (VPC) (1) of this phenolic fraction disclosed the presence of the *trans*-stilbenes, 4-hydroxy-, 4,4′-dihydroxy-, 3-hydroxy-4-methoxy-, and 4-hydroxy-3-methoxystilbene, and X, which was not comparable to these or other simple phenolic stilbenes. A 2-mg. sample of the trimethylsilyl (TMS) either of X, obtained by preparative VPC, was subjected to IR, UV, and mass spectral analysis.

The IR spectrum of the TMS derivative of X,

[1] Determined by VPC (TMS ether). Chromatographic analysis of urine obtained from guinea pigs administered *trans*-stilbene has indicated an even greater (10.6%) conversion to 4,4′-dihydroxybibenzyl.

except for differences in the fingerprint region, was similar to that of reference 4-trimethylsiloxy- and 4,4′-di(trimethylsiloxy)stilbene. The UV spectrum, however, with a single $\lambda_{max.}$ at 280 mμ, was atypical for the *trans*-stilbene chromophore (2). Mass spectral analysis[2] of the isolated derivative showed a weak parent peak at m/e = 358, a base peak at m/e = 179, and other prominent peaks at m/e = 286 and m/e = 107.

With these data, structure I was proposed for the TMS derivative of X and its mass spectral breakdown was rationalized as in Scheme I.

Based upon this determined molecular weight of 358, a molar absorptivity of 3460 (at 280 mμ) was calculated for the TMS derivative of X and this provided additional evidence for the proposed structure (3).

The TMS derivative of X was found to co-chromatograph (VPC) with the di-TMS ether of authentic 4,4′-dihydroxybibenzyl. Hydrolysis of the isolated TMS derivative of X and comparison of the product (X) with 4,4′-dihydroxybibenzyl showed complete agreement in mobility and reaction to diazotized sulfanilic acid in three thin-layer systems and further substantiated the identity of X as 4,4′-dihydroxybibenzyl.

The formation of a bibenzyl derivative, a reduction product from *trans*-stilbene, involves a novel metabolic transformation for this class of compounds. In contrast, metabolic schemes incorporating reductions are well established for nitro- and azo-compounds, including the reduction of the stilbene isostere, azobenzene to hydrazobenzene (4), a postulated intermediate in the reductive cleavage of azobenzene (5). Reports of metabolic reductions of carbon-carbon double bonds are primarily limited to Δ^4-3-keto-steroids (6, 7) and certain cinnamic acid derivatives (8). These reductions are analogous to the well-known hydrogenations of α,β-unsaturated carbonyl compounds which occur in intermediary metabolism. Reductions resembling the one found in the present investigation, however, are rare and in combination with the implied reductive step in the formation of 1,2-dihydronaphthols (9), advance the significance of hydrogenation in the metabolism of similar conjugated ethylenic compounds.

[2] The authors are indebted to Luther H. Smithson, Jr., and Rick Faubert of Varian Associates, Palo Alto, Calif., for the mass spectral data.

The Mannich Reaction

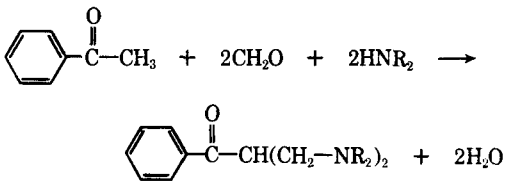
Mechanistic and Technological Considerations

By B. BLACKBURN THOMPSON

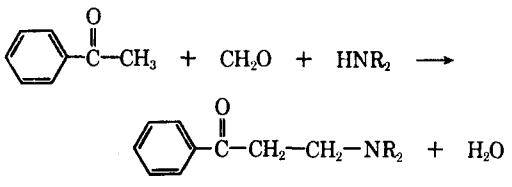
THE EARLIEST EXAMPLES of the Mannich reaction were published in succession by Tollens and co-workers (1, 2), Petrenko-Kritschenko and co-workers (3–6), and by Mannich and Krösche (7). Mannich was the first to recognize the reaction as a general one, and a detailed investigation was begun in 1917. The Mannich reaction was reviewed by Blicke (8), Karbe (9), Nobles (10, 11), Reichert (12), and others (13, 14) and it was the subject of recent books by Reichert (15) and by Hellmann and Optiz (16).

The Mannich reaction consists of the condensation of ammonia or a primary or secondary amine usually as the hydrochloride salt, an aldehyde, and a compound capable of supplying one or more active hydrogen atoms. As a result of the reaction an aminomethyl group generally replaces the active hydrogen atom. Products of the condensation are known as "Mannich bases." A typical condensation, with acetophenone as the active hydrogen compound, may be illustrated as in *Scheme I.*

As cited in the excellent review by Blicke (8), multiple product formation is possible. For example, multiple aminomethylations may occur at the α-position of compounds such as acetophenone of the previous example, *viz.*, *Scheme II.* Similarly, mono- and disubslituted products including position isomers, result from multiple aminomethylation of phenols.[1] In this case the replaceable hydrogens are not all equivalent as indicated in *Scheme III.* These examples illustrate the complications which may result from the presence of multiple replaceable hydrogen atoms in the molecule.



Scheme I



Scheme II

The amine used also promotes formation of mixed products. With secondary amines, only a single product is possible, however, with primary amines and ammonia, reacting ratios of active hydrogen compounds, formaldehyde, and amine may be 2:2:1 and 3:3:1, respectively. In the reaction of antipyrine salicylate, formalde-

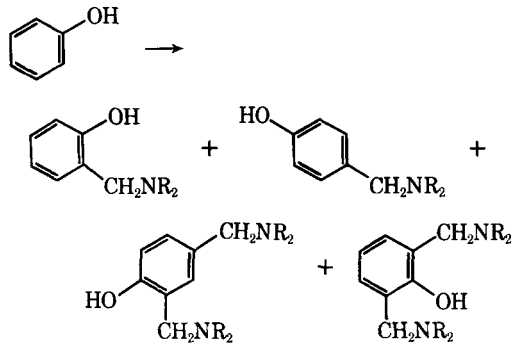
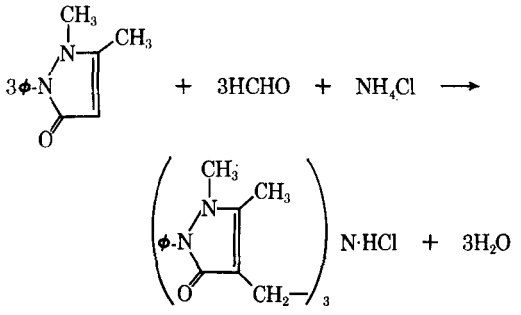
[1] The observation that *ortho*-mono-substitution predominates has been the subject of the mechanistic studies (17, 36).



Scheme III

hyde, and ammonium chloride (7), the reaction which reportedly stimulated Mannich's pioneering interest in the condensation which bears his name, the reaction ratio is 3:3:1, respectively, and may be illustrated as in Scheme IV.



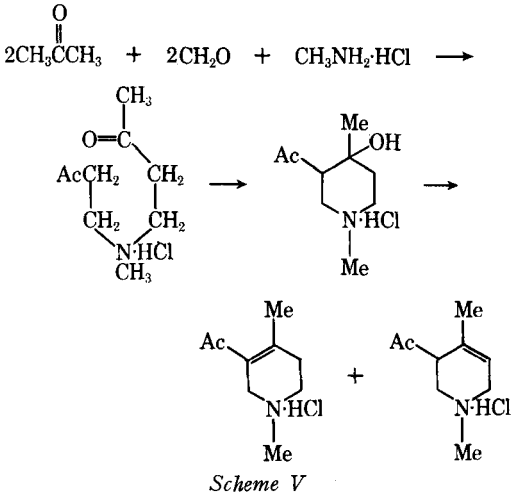
Scheme IV

Gautier *et al.* (18) have reported on the problem of isomer formation associated with utilization of compounds with mixed functionality such as ethynylalkyl aryl ketones as the active hydrogen compound. In this case both the hydrogen of the acetylenic substituent and the ketone's α-hydrogens are reactive under Mannich conditions.

A somewhat different isomer problem is presented in the case of methyl isopropyl ketone in which seemingly sound evidence for aminomethylation of the methyl group (19, 20) and of the isopropyl group (21) have been reported.

In many cases, by-products may be formed by side-reactions. In not a few cases, such processes may occur to the exclusion of normal Mannich reaction or, if sequential to the Mannich reaction, completely destroy the normal products. Such processes include (*a*) formation of α, β-unsaturated ketones (8, 22), a process which could result from deamination (elimination of amine) of the Mannich base, or alternatively, through hydroxymethylation followed by dehydration of the active hydrogen compound; (*b*) formation of methylene-bis derivatives of the active hydrogen compound; and (*c*) formation of methylene-bis-amines or similar compounds. These processes will be discussed within the framework of the Mannich reaction mechanism.

Mannich and Ball (23) and Mannich and Ritsert (24) reported formation of an unstable Mannich base derived from acetone, formaldehyde, and methylamine (2:2:1 reacting ratio). This Mannich base readily cyclizes as Scheme V shows:

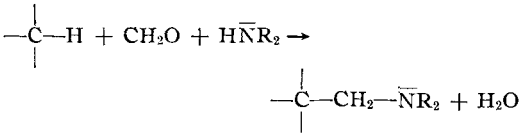


Scheme V

The stability of the products of the Mannich reaction will be covered more thoroughly in the succeeding sections.

MECHANISM OF THE CONDENSATION

The classical examples of the Mannich reaction involved reaction of an active hydrogen compound (reactive $\diagup$C—H $\diagdown$ linkage present) with formaldehyde and ammonia or a primary or secondary amine, *i.e.*, Scheme VI.



Scheme VI

The product, known as a "Mannich base," is an unsymmetrical derivative of methylene. Modern theoretical considerations permit inclusion of acidic $\diagup$NH, —OH, or —SH $\diagdown$ containing compounds as qualified "active hydrogen" compounds susceptible to the Mannich aminomethylation process.

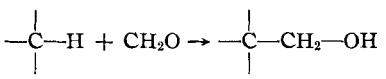
A great deal of work has been done relevant to the progress of the Mannich reaction (17–18, 22, 25–47), and several workers have proposed mechanisms (17, 22, 25, 34, 35, 40–47). A his-

torical development of the mechanism studies will be presented in the following paragraphs.

An evaluation of Scheme VI reveals that formaldehyde, an electrophilic agent, reacts with two nucleophilic components, the amine and a carbanic center derivable from the replaceable hydrogen compound. The product of the Mannich reaction is the result of an unsymmetrical condensation, and any satisfactory mechanism must take this factor into consideration.

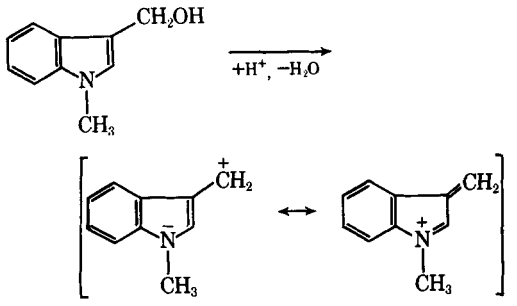
According to Hellmann and Opitz (25), the course of the condensation might be expected to follow one of the following sequences: (*a*) reaction of the labile hydrogen compound with formaldehyde to yield the hydroxymethyl derivative which then condenses with the amine to produce a Mannich base; or (*b*) addition of the amine to formaldehyde to form an *N*-hydroxymethyl or related derivative which then reacts with the labile hydrogen compound to produce a Mannich base.

In consideration of proposition *a*, if the nucleophilicity of the carbanion derived from the labile hydrogen compound be greater than that of the amine, formation of a hydroxymethyl derivative of the labile hydrogen compound would be favored (proposition *a*) over formation of an aminomethylol (proposition *b*). Thus the initial reaction, Scheme VII, would be expected to occur.



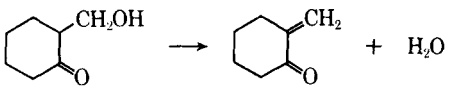
Scheme VII

This hydroxymethyl derivative will now react further if it can form either a resonance-stabilized carbonium ion, *e.g.*, Scheme VIII,



Scheme VIII

or if the loss of water can occur according to Scheme IX.



Scheme IX

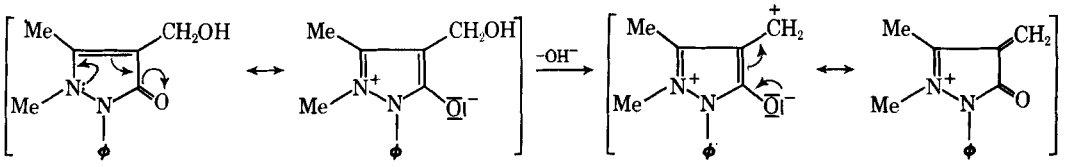
Either of these intermediates, *i.e.*, the resonance-stabilized carbonium ion in Scheme VIII or the unsaturated dehydration product shown in Scheme IX, would then be expected to condense with another molecule of the compound or ion with the highest nucleophilic potential, in this case, the carbanion derived from the labile hydrogen compound. Such a pathway could only lead to a symmetrical methylene derivative of the labile hydrogen compound and not to a Mannich base. If such reasoning is supported by experimental evidence, proposition *a* would seem untenable. Such evidence is available and will be presented below.

4-Hydroxymethylantipyrine, which forms a resonance-stabilized carbonium ion according to Scheme X, was studied by Bodendorf and Koralewski (31) as a possible intermediate in the Mannich reaction. 4-Hydroxymethylantipyrine, according to these workers, does not react with either free amine or with amine hydrochloride. Furthermore, free amine and variable amounts of acid likewise fail to yield the Mannich base of antipyrine. These observations were offered as proof against a hydroxymethyl derivative of the labile hydrogen compound as the intermediate in the Mannich reaction.

In their investigation of the Mannich reaction, Bodendorf and Koralewski (31) reported that the formation of methylene-bis(antipyrine) took place when 4-hydroxymethylantipyrine was warmed with dimethylamine hydrochloride but not with the free base. Hellmann and Opitz (25, 26) reinvestigated, based on the assumption that 4-hydroxymethylantipyrine is not the true intermediate in the Mannich, but that it is an intermediate in the synthesis of methylene-bis(antipyrine). If these be reasonable assumptions, then as the acidity of the media increases the yields of Mannich base and of methylene-bis(antipyrine) should not be coordinated closely. In fact, these workers (26) obtained 11.51% of Mannich base with piperidine, formaldehyde, and antipyrine with no methylene-bis(antipyrine), while piperidine hydrochloride under the same conditions gave 61.54% of Mannich base. When the quantity of acid present reached a 10% excess over the molar requirements, the yield of Mannich base fell to 16.8% and a yield of 9.7% of methylene-bis(antipyrine) also resulted.

While the above results disprove the participation of 4-hydroxymethylantipyrine as a resonance-stabilized derivative (formed *via* Scheme VIII) in the Mannich reaction is it equally unlikely that 2-methenylketones[2] (formed *via*

[2] These α-methenylketones may be viewed as vinylogs of formaldehyde. Free amines, but not their salts, will add to such compounds.



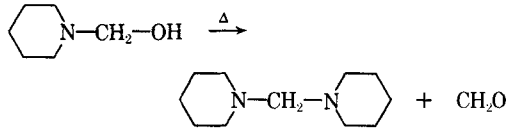
Scheme X

Scheme IX) could represent true intermediates? In answer to this question, such intermediates were discounted since dehydration of hydroxymethyl derivatives of the active hydrogen component often requires temperatures far in excess of those required by the Mannich reaction (25). Furthermore the observation that piperidine, formaldehyde, and cyclohexanone gave a 37% yield of Mannich base (31) while use of piperidine hydrochloride provided a 62% yield (48) appears to rule out addition to an α,β-unsaturated derivative as a possible course.

These data seem conclusive in proving that hydroxymethylation of the active hydrogen component does not represent a true course for the Mannich reaction. The conclusion that may, therefore, be drawn is that proposition *b* above probably is valid. This second postulate, that formaldehyde interacts with the amine as the initial step in the condensation, will now be discussed.

In order to present an effective discussion of the mechanistic aspects of *N*-hydroxymethylamine and related derivatives of aldehyde and amine, a brief discussion of the chemistry of these intermediates based on articles by Henry (49), Stewart and Bradley (50), Hellmann and Opitz (25–30), and by Wagner (51) will be covered below. For a more detailed discussion the reader should consult the original articles.

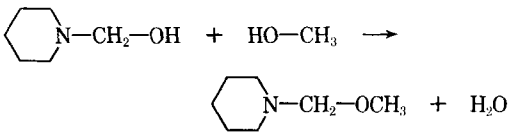
The *N*-hydroxymethylamines, as reported by Henry (49) in 1895, may be obtained from aqueous formaldehyde and the amine with cooling. These oily, nondistillable *N*-hydroxymethylamines are difficult to purify, and exist only in the cold. Warming causes decomposition to formaldehyde and free amine along with some recondensation to form methylenediamine, *e.g.*, Scheme XI.



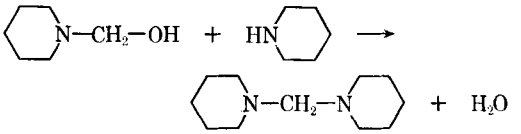
Scheme XI

Methylenediamines are formed exclusively when formaldehyde and amine are allowed to react without cooling.

In contrast to oxygen hemi-acetals, nitrogen hemi-acetals are converted to *O,N*-acetals with alcohols or to *N,N*-acetals (methylenediamine) with amines without added catalysts. For example, Schemes XII and XIII.



Scheme XII



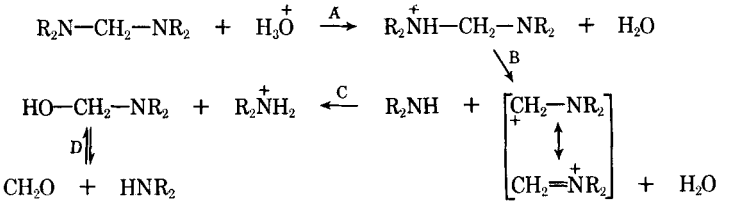
Scheme XIII

The members of both compound classes are very acid-sensitive and follow a well-defined reaction course in acid hydrolysis (50) from the symmetrical methylenediamine as illustrated in Scheme XIV.

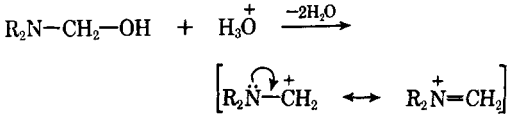
The ammonium salt of methylenediamine which formed in step A decomposes immediately in water to form an aminomethyl carbonium ion (reaction B). The acid in this system may react further to neutralize the free amine formed in equilibrium (D), or it may act directly on the intermediate, *N*-hydroxymethylamine. The latter action was discussed by Stewart and Bradley (50), who reported that addition of an *N*-hydroxymethylamine to a solution of aqueous acid followed the course illustrated in Scheme XV. The reverse order of mixing appeared to favor formation of the salt of the free amine.

The above cleavage at first glance appears to be unlikely since nitrogen, the most basic center of the molecule, ought to bind the proton. Experimentally, however, it has been demonstrated that the ammonium salt is unstable in aqueous solution and can be formed only under anhydrous conditions (31, 52).

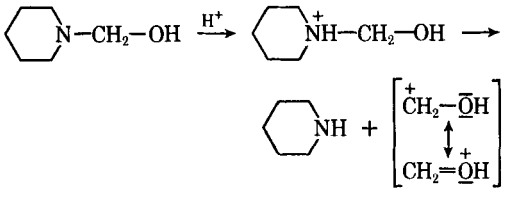
If the stability of the ionic species formed in the cleavage is considered, the formation of the aminomethyl carbonium ion according to Scheme XIV is understandable. The two possible courses for the cleavage are shown in Schemes XVI and XVII. The hydroxymethyl carbonium ion of Scheme XVI is considerably less stable than the aminomethyl carbonium ion of Scheme XVII, hence the greater resonance stabilization of the



Scheme XIV

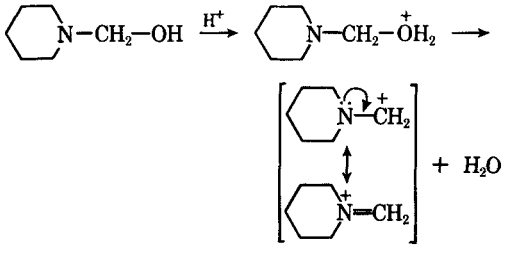


Scheme XV



Scheme XVI

or,



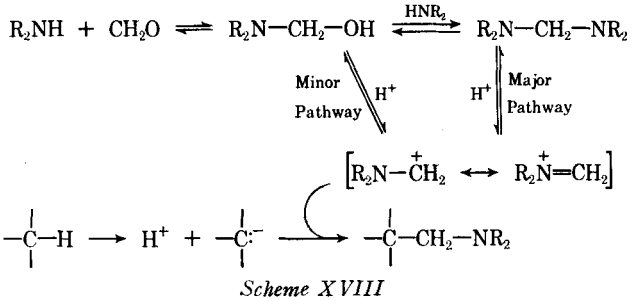
Scheme XVII

latter ion makes Scheme XVII the favored pathway.

In studying the possible role of *N*-hydroxymethylamines in the Mannich condensation, Bodendorf and Koralewski (31) condensed antipyrine with formaldehyde and piperidine hydrochloride to obtain the Mannich base, 4-piperidinomethylantipyrine, in 62% yield. With free piperidine and formaldehyde a 37% yield of the Mannich base was obtained. With preformed *N*-hydroxymethylpiperidine, the compound suggested by Mannich as the reaction intermediate, a yield of only 20% was obtained. These workers concluded that *N*-hydroxymethylamine is not the intermediate in the Mannich reaction.

Hellmann and Opitz later proved that the Mannich base in the latter two combinations is formed during the isolation procedure when acid conditions prevail (26). If the active aminomethylating agent is the electrophilic aminomethyl carbonium ion, which arises only under acidic conditions, then the conclusion of Bodendorf and Koralewski (31) against *N*-hydroxymethylamine as the intermediate was based on inaccurate information. Certainly knowledge of the formation of this ion, contributed by Stewart and Bradley (50), supports the work of Hellmann and Opitz (25–30).

The next significant studies of the mechanism of the Mannich reaction were published in 1949 by Liebermann and Wagner (32) and by Alexander and Underhill (33). Liebermann and Wagner concluded that each combination of reactants requires a different pH for the best results and that an initially high acidity is required. These workers concluded that the aminomethyl carbonium ion previously mentioned is the final electrophilic intermediate and that it reacts with a carbanion which arises from the acidic or labile hydrogen compound. According to the mechanism proposed by these authors, methylenediamine is the intermediate formed in the Mannich reaction prior to formation of the aminomethyl carbonium ion. However, the possibility that *N*-hydroxymethylamine might be required in a few reactions demands its retention in the overall



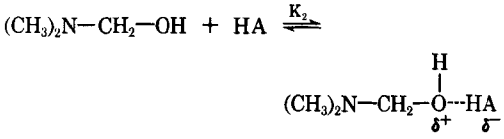
Scheme XVIII

mechanism. The complete sequence is shown in Scheme XVIII.

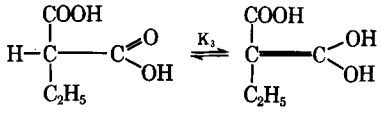
Alexander and Underhill (33) offered a mechanism which involved *N*-hydroxymethylamine as the intermediate and in which the acidic hydrogen compound was suggested to react in the enol form rather than to ionize as Liebermann and Wagner proposed. The reason for suggesting an enolic intermediate rather than an ionic intermediate was based on ionic strength effect experiments which failed to alter the rate of the reaction. Had an ionic intermediate been involved prior to the rate-controlling step, the reaction rate should have changed in proportion to the change in the ionic strength of the media. The reaction is observed to proceed immediately if preformed *N*-hydroxymethyl-*N*,*N*-dimethylamine is employed, but an induction period is required if formaldehyde and free amine are used instead. This observation indicates that a slow reaction between formaldehyde and dimethylamine is required before typical third-order kinetics are observed. It also indicates that the rate of this condensation between formaldehyde and dimethylamine, although faster than the rate-controlled step, is of the same general magnitude.

The mechanism proposed for the condensation of ethylmalonic acid with formaldehyde and dimethylamine shown in Schemes XIX–XXIII.

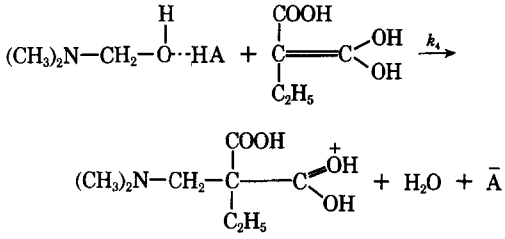
Scheme XIX



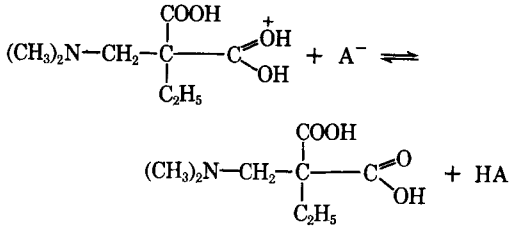
Scheme XX



Scheme XXI



Scheme XXII



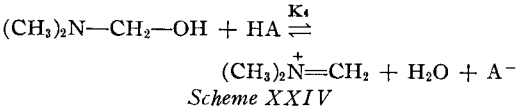
Scheme XXIII

This sequence calls for general acid catalysis by HA with Scheme XXII as the rate-controlling step. The rate expression reduces to:

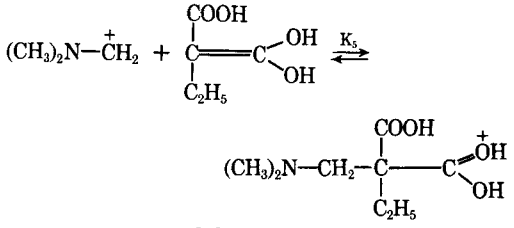
$$\frac{dx}{dt} = k[CH_2O][(CH_3)_2NH][C_2H_5 \cdot CH(COOH)_2]$$

where k includes the concentration of HA which remains constant.

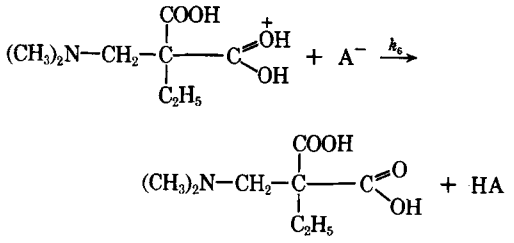
The possibility was considered that Schemes XX, XXII, and XXIII might be replaced by the sequence in Schemes XXIV–XXVII.



Scheme XXIV



Scheme XXV



Scheme XXVI

This was ruled out since Scheme XXVI is very unlikely to be the rate-determining step. Consideration of Scheme XXV as rate determining requires that the reaction velocity be dependent upon the oxonium ion concentration. Alexander and Underhill decided against this course because of the somewhat complex pH dependency of the reaction. As Hellmann and Opitz later indicated (25), the complicated nature of the pH dependency may be solved when one considers that acid retards formation of *N*-hydroxymethyldimethyl amine to such an extent that Scheme XIX, which

appears to be only slightly faster than the rate-controlling step, may finally become rate determining. Since dimethylaminomethyl carbonium ion is used up faster than it can be formed, the reaction may decrease with decreasing pH. This problem was also dismissed by Cummings and Shelton (34), who pointed out that the reaction in Scheme XXVII properly belongs in the kinetic

$$R_2\overset{+}{N}H_2 + \bar{A} \rightleftharpoons R_2NH + HA$$

Scheme XXVII

equation since, in acid solution, the amine exists largely in the salt form. This fact accounts for the conclusion (above) by Hellmann and Opitz (25) and simultaneously rids the kinetic expression of its "specific oxonium requirement." Therefore, Schemes XXIV, XXV, and XXVI cannot be eliminated as possibilities.

When, as in the example by Alexander and Underhill (33), an acid is employed as the active hydrogen compound and reacts in the acid form, a term to account for the acid to anion dissociation reaction must be included. It is probably in part for this reason that these workers observed the complex interaction between pH and the rate constant. Contrary to the opinion of Alexander and Underhill (33) that specific oxonium ion catalysis cannot explain this complex variation of rate constant with pH, it seems likely that the above-discussed factors could easily account for this complexity (34).

Hellmann and Opitz (25–30), in a series of comprehensive studies, proved that *N*-hydroxymethylamine, *N*-methoxymethylamine, and methylenediamine could all be formed in the course of the Mannich reaction, depending upon the conditions employed. Since highest yields were obtained when one of these materials was added to a mixture of excess aqueous acid and the acidic or labile hydrogen compound, a method which gives the highest concentration of the aminomethyl carbonium ion (50), it was concluded that this ion was the active aminoalkylating agent. The reverse order of addition, *i.e.*, adding acid to a mixture of the reactants, does not offer favorable pH conditions until the addition is essentially complete. It was also found that a pH as low as 1.0 is successful in some cases if the proper order of addition is used.

Based on the extensive experimentation carried out, Hellmann and Opitz (25) concluded that rather strong inductive effects must be operating in order to activate the labile hydrogen compound sufficiently to react as a carbanion, or there must be enol formation in the absence of strong inductive effects (28). The proposed mechanism offered is quite similar to the mechanism in acid media offered by Cummings and Shelton (34) and represents an S_E2 mechanism. The S_N2 mechanism under basic conditions was covered under the title of transmethylation owing to the opinion by Hellmann and Opitz that the Mannich reaction is that aminomethylation occurring under acidic conditions (25, 30).

Hellmann and Opitz (25, 26) reinvestigated the condensation between antipyrine, formaldehyde, and piperidine in the belief that the data of Bodendorf and Koralewski (31) simply did not seem to fit available postulates. Among other things they determined that the purification procedure of Bodendorf and Koralewski failed to remove methylene-bis(4-antipyrine), a major contaminant of the Mannich base. Following the published procedure (31), in which a 37% yield had been reported but purifying by *in vacuo* distillation, Hellmann and Opitz (26) were able to remove methylene-bis(4-antipyrine) (b.p. 238° at 760 mm.; 100° at 2 mm.) and thus effect an improved purification of the Mannich base. The yield of Mannich base amounted to only 11.51% (26). The use of *N*-hydroxymethylpiperidine and antipyrine gave 13.89% (26) instead of 20% as reported by Bodendorf and Koralewski (31). Using antipyrine, formaldehyde, piperidine, and an equimolar portion of hydrogen chloride provided 62% yields according to both groups (26, 31). These data point to an acid-catalyzed reaction for production of the Mannich base of antipyrine. Of itself, antipyrine is too weakly acidic to catalyze the reaction.

The negligible yields with basic conditions in the antipyrine example suggested that perhaps the Mannich reaction on antipyrine does not occur at all under these conditions. A careful study of the procedures of Bodendorf and Koralewski (31) led Hellmann and Opitz (26) to the conclusion that the small quantity of Mannich base formed in the procedure arises during product isolation, when acidic conditions prevail. By redesigning the workup procedure as little as 3–5% of product was obtained, an observation which certainly supports the "no-reaction" hypothesis.

According to Stewart and Bradley (50) the maximum concentration of the aminomethyl carbonium ion occurs on addition of *N*-hydroxymethylamine *N*-alkoxymethylamine or methylene-bis(amine) to aqueous acid. Reversing the order of addition leads to little or at best very slow production of the necessary ion. It may be inferred from these data that proper order of addi-

tion is important for the successful testing of these intermediates.

In order to evaluate the relative effectiveness of these intermediates, Hellmann and Opitz (25, 26) compared yields using the two different orders of addition with each of the three possible intermediates. *N*-Hydroxymethylpiperidine, when added to a solution of antipyrine and excess acid (10% excess, pH 2.5), gave a 71% yield of Mannich base, while the same ingredients gave only 56% of Mannich base along with some methylene-bis(4-antipyrine) when the acid was added to the antipyrine and *N*-hydroxymethylpiperidine mixture. Use of *N*-methoxymethylpiperidine gave, on addition to a mixture of antipyrine and excess acid (6% excess, pH 3.0), gave an 87% yield of Mannich base. When the acid was present to the extent of a 40% excess (pH 1.0), the reaction still gave a 77% yield of Mannich base. They found that with similar conditions but reversing the order of addition completely inhibited the Mannich reaction. Finally, Hellmann and Opitz report an 81% yield of Mannich base when methylene-bis(*N*-piperidine) is added to antipyrine and excess acid (12% excess, pH 2.0).

The above data certainly support the concept that *N*-hydroxmethylpiperidine, and methylene-bis(*N*-piperidine) can serve as a source of the aminomethyl carbonium ion. The apparent success of this procedure supports the contention that the Mannich reaction does require one of these substances as an intermediate. The possibility certainly exists that no one of these intermediates can serve for all examples of the Mannich reaction (17, 25–47). Additional results which should be cited for this study include the observation that addition of aldehyde decreases the pH of the solution (25), *i.e.*, Scheme XXVIII.

$$R_2\overset{+}{N}H_2 + \bar{A} + CH_2O \rightleftharpoons R_2N{-}CH_2{-}OH + HA$$

Scheme XXVIII

Hellmann and Opitz (25) also expressed doubt regarding the possible formation of methylene-bis(*N*-amines) under acidic conditions, particularly if water is present. These derivatives of formaldehyde and amine simply are not stable under these conditions (50).

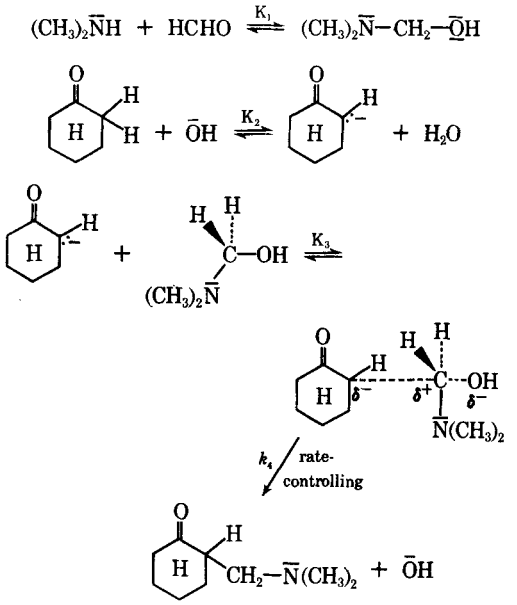
In the two major contributions to the mechanism of the Mannich reaction which had appeared in 1949, a divergence of views was obvious. Liebermann and Wagner (32) had proposed a process in which two ions, a carbanion derived from the active hydrogen compound and the aminomethyl carbonium ion, derived from an aminomethylol or a methylene-bis-amine, neutralized each other. Alexander and Underhill (33) found that no significant change in the rate occurred with changes in ionic strength of the media. If a carbanion-carbonium ion neutralization is present in the transition state of the rate-controlling process, a large change in rate with change in ionic strength ought to have been observed (53). Secondly, based on mechanistic pathways visualized by Alexander and Underhill, the outright liberation of a free aminomethyl carbonium ion for reaction with a carbanion would require kinetic independence of the reaction from pH influence. Alexander and Underhill had, however, observed a pH maxima at 3.8. They reasoned that below this pH, the rate began to be severely limited by extensive conversion of amine into its salt form.

Hellmann and Opitz (25–30) pointed out that the conversion of amine and formaldehyde into aminomethylol was reported by Alexander and Underhill to be only slightly faster than the rate-controlling step. They pointed out that the complex pH effects could be explained when one recalls that the effect of mounting acidity is to decrease the concentration of free amine. This deficiency of free amine can make the already slow conversion to aminomethylol finally become rate controlling. The mounting acidity, which does not favor carbanion formation, coupled with the absence of ionic strength effects, convinced Hellmann and Opitz that the reaction proceeded without involving the carbanion of the active hydrogen compound. The aminomethyl carbonium ion, derived from an *N*-hydroxymethylamine, was concluded to be the aminomethylating agent.

A recent kinetic study by Cummings and Shelton (34) reached conclusions quite similar to those of Hellmann and Opitz (25–30) concerning the mechanism of the Mannich reaction. The mechanisms proposed by these workers are given for basic media in Scheme XXIX and for acidic media in Scheme XXX. Several comments by Cummings and Shelton (34) were made relevant to the previous kinetic and qualitative studies. They pointed out, as did Hellmann and Opitz (25–30), that the amine is largely present as the salt under acidic conditions. Incorporating this factor into the reaction sequence they obtained a rate equation in which the rate was independent of the pH. At sufficiently low pH, this is precisely what was observed with cyclohexanone as the active hydrogen compound (34). The example chosen by Alexander and Underhill (33) involved an acid as the active hydrogen compound. If the reactive form is the acid, as shown in their mechanism, then another term to account for the acid form and ionic form equilibria should be present

in the equation. This would make the rate equation dependent upon the hydronium ion concentration.

It is of interest to note that the mechanistic pathway and rate equations of Cummings and Shelton (34) in acid media involve production of a dimethylaminomethyl carbonium ion from *N*-hydroxymethyldimethylamine and that this ion then reacts with an α-carbanic center developed



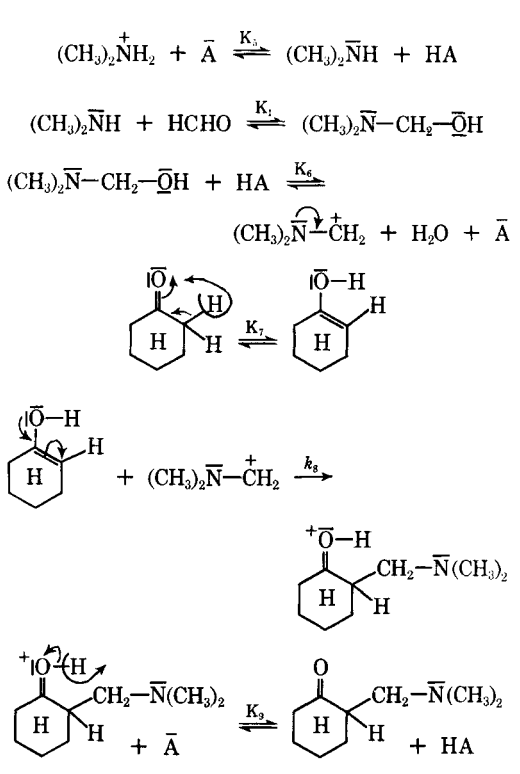
$$\frac{dx}{dt} = k[(CH_3)_2\bar{N}H]\cdot[CH_2O]\cdot[C_6H_{10}O]\cdot[\bar{O}H]$$

Scheme XXIX

on the enol form of cylcohexanone. The rate expression does not contain an HA or an H_3O^+ term. The view is, therefore, a composite of previous suggestions (33, 25–30).

The mechanism for basic media does not suggest formation of the dimethylaminomethyl carbonium ion, which indeed should only be present in acidic media. Instead dimethylaminomethanol is the intermediate on which an S_N2 displacement of OH^- by the cyclohexanone carbanion takes place. The appropriate carbanion presumably arises by base attack on the reactive α-protons of cyclohexanone.

The above-mentioned kinetic study does much to clarify the general views on the course of the Mannich reaction but have been unable to resolve problem of deciding among methylene-bis-amines, *N*-alkoxymethylamines, or *N*-hydroxymethylamines as the true intermediate in the Mannich reaction. Several recent kinetic studies provide further information on the mechanism and technology of the Mannich reaction (17, 35, 36, 43–47, 54–58).



$$\frac{dx}{dt} = k[(CH_3)_2\overset{+}{N}H_2]\cdot[CH_2O]\cdot[C_6H_{10}O]$$

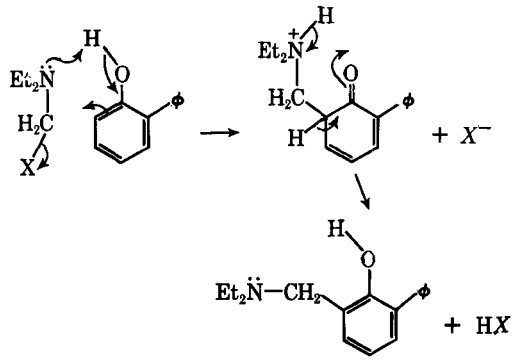
Scheme XXX

Burckhalter and co-workers (17, 36) have studied the mechanism of the Mannich reaction on phenols with emphasis on the observed preponderance of *ortho* substitution. For example, Burckhalter (59) obtained a preponderance of the *ortho*-substituted product (42%) of 2-phenylphenol and less than a third (13%) of the *para*-substituted isomer. Several additional references are cited by Burckhalter and Leib (36) in reviewing the subject.

In the mechanistic and kinetic studies carried out in basic media by Burckhalter and co-workers (17, 36), the rate of condensation of formaldehyde and morpholine with 2,4-dimethylphenol is controlled by formaldehyde if the concentration of formaldehyde is *less* than half the morpholine concentration. Conversely, morpholine concentration is critical if it is *less* than *twice* the formaldehyde concentration. These data suggest the participation of methylene-bis(*N*-morpholine) as an intermediate. A pure sample of this compound gave data kinetically indistinguishable from those of the formaldehyde and morpholine mixture. Calorimetric data by Fernandez and Butler (44) also supported a methylene-bis-(amine) intermediate.

Burckhalter and co-workers (17, 36) suggested that *ortho*-substitution predominates in amino-

methylation of phenols because of hydrogen bond participation. The process was visualized as in Scheme XXXI.



$X = -OH, -OR, -NR_2$.

Scheme XXXI

In view of preceding comments the most likely intermediate would be the methylene-bis(amine) ($X = -NR_2$). Since phenols are acidic and capable of existing as free phenol or phenolate ion and, since the reactive intermediate amine conceivably might react as a neutral molecule or as a positively charged molecule, a maximum rate ought to be observed at some definite pH if two neutral (phenol plus amine) or two charged ions (phenolate ion plus positively charged amine derivative[3]) interact. Conversely the reaction rate should increase with (*a*) decreasing pH if free phenol and protonated amine interact, and (*b*) with increasing pH if phenolate and free amine interact. The observed rate *versus* pH profile provided a maximum between pH 9.6 and 10.2 (maxima at approximately pH 10.0) indicating that the reaction occurs between either a pair of neutral reactants (phenol plus amine) or between a pair of ions (phenolate plus amine salt). Several factors weaken the case for the latter possibility. First, the pH at which the maximum occurs is basic. The methylenebis-(morpholine) salt should not be stable under strongly acidic conditions (25, 51) unless present in an anhydrous medium (52), and is not likely to form in the basic pH studied. Secondly, the preponderance of *ortho*-substitution isomers previously observed (36, 59) ought to involve a concerted mechanism (36) which is most favorably accommodated by a hydrogen bonded complex between the neutral phenolic molecule and the methylene-bis(amine) structure (Scheme XXXI).

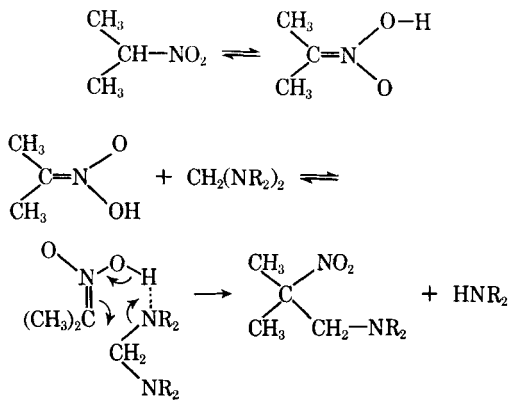
Fernandez and associates (44–47, 55–58) have contributed calorimetric, cryoscopic, and kinetic studies recently. Based on the colorimetric data obtained in the conversion of formaldehyde and amine to *N*-hydroxymethylamine and then, with a second mole of amine, to methylene-bis(amine), Fernandez and Butler (44) concluded that the reaction proceeds in most cases to methylene-bis-(amine). There seems to be little *N*-hydroxymethylamine at equilibria in most of the examples studied. This is not surprising in view of the technique used, *viz.*, amine (two parts), was treated slowly with aqueous formaldehyde (one part). It has been reported that the intermediate, *N*-hydroxymethylamine, is unstable in the presence of excess amine, reacting to yield the bis(amine) (49, 51). The previous study by Burckhalter *et al.* (17, 36) certainly supports the concept of a methylene bis(amine) as the most likely intermediate under basic conditions as did this calorimetric study (44).

Fernandez and Fowler (45) in 1964 reported the kinetics associated with the reaction of 2-nitropropane and methylene-bis(piperidine) or methylene-bis(morpholine). Choice of the methylene bis(amines) simplified the process and circumvented the necessity of speculation concerning identity of the intermediate form of the formaldehyde and amine. To further ensure the integrity of this intermediate, water was excluded by use of anhydrous solvents. The choice of methylene bis(piperidine) and methylene-bis(morpholine) provided widely different basicities (pKb 2.78 and 5.64 for the starting amines, respectively). Solvents included dioxane, DMF, nitrobenzene, and triethylamine.

Briefly, results of the experiments confirmed that the more basic methylene-bis(piperidine) exhibited much faster rates than did the morpholine derivative. Excessive basicity, as with excess methylene-bis(piperidine) or triethylamine as solvent, caused a slowing of the condensation. Fernandez and Fowler (45) reasoned that under these conditions the nitropropane reacts in the anionic form and produces an extremely reactive amide ion (R_2N^-) as the conjugate base. The latter is not a favored state and thus slows the overall rate. The rate also increased with an increase in dielectric constant. In media of low dielectric constant the mechanism is suggested to occur *via* a hydrogen-bonded complex of the *aci*-form of 2-nitropropane interacting with methylene-bis(amine). (See Scheme XXXII.)

At higher dielectric constant the activation parameters suggested to Fernandez and Fowler (45) that the mechanism changes to one involving a higher enthalpy of activation and lower entropy of activation. The mechanism visualized involves incorporation of a molecule of methylene-

[3] The charged amine was referred to as a protonated methylene-bis(amine) (17). The aminomethyl carbonium ion might also be a possibility.



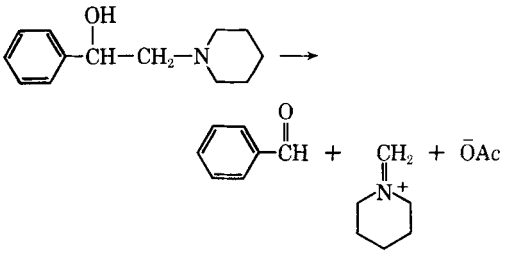
Scheme XXXII

bis(amine) into the solvent shell of 2-nitropropane. The transition state visualized thus involves coordination of the hydroxyl proton of *aci*-2-nitropropane with solvent, thus differing from the above cyclic or quasi-6-membered transition in which this hydroxyl proton is coordinated with the amino group which will be eliminated. The transition state for high dielectric media is, therefore, less rigid and restrained but yields the reactive amide ion, R_2N^-, on conversion to product. The value for ΔS^* is thus less and ΔE^* greater than for the low dielectric media transition state.

Methylene-bis(piperidine) gave accelerated rates when compared to the morpholine derivative. This was attributed to the enhancement of electron density at the α-methylene by the more basic piperidine moieties (45).

The mechanism studies on 2-nitropropane (45) were extended by Fernandez, Fowler, and Glaros (46) to nitromethane and nitroethane. Methylene-bis(piperidine) and methylene-bis(morpholine) again were used as the aminoalkylating agents. Previously all attempts to prepare mono-aminomethylated nitromethane resulted in multiple substitution (40, 60–63). In the study by Fernandez *et al.* (46) mono-substitution of nitromethane resulted when it was treated with methylene-bis(amines) under anhydrous conditions. When a small amount of water is present, or if *N*-ethoxymethylpiperidine is used, disubstitution results. These data suggest that the second alkylation step probably requires *N*-hydroxymethylamine or *N*-alkoxymethylamine in order to be successful. By inference, the initial aminoalkyl substitution probably may occur with any one of the three possible aminoalkylating agents. The evidence presented by Fernandez *et al.* (45, 46, 55) and by Burckhalter and coworkers (17, 36) certainly supports the hypothesis that basic conditions favor *formation* of methylene-bis(amines) (49, 51) and that these intermediates may function as aminoalkylating agents (25, 26). This does not lead to the conclusion that such an intermediate is necessarily the *best* agent for aminoalkylation based on rate or position of equilibria.

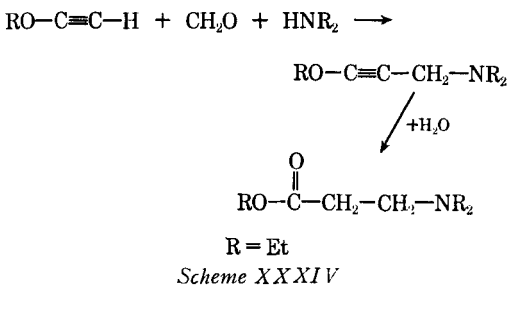
Roth, in 1961, suggested that the lead tetraacetate cleavage of 1, 2-amino-alcohols in which the amine is tertiary leads to formation of aminomethyl carbonium ions according to Scheme XXXIII (64).



Scheme XXXIII

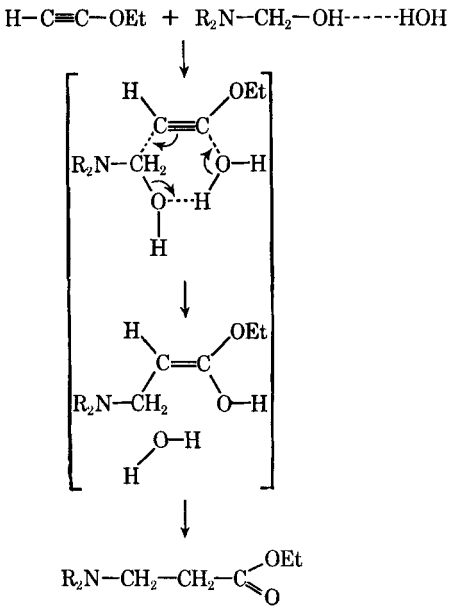
In a later study Roth was able to demonstrate that the aminomethyl carbonium intermediate did indeed occur in this cleavage (35). By adding typical Mannich reaction components (acidic C—H and N—H containing compounds) during the above type cleavage reaction, Roth was able to isolate the corresponding Mannich bases in high yields. Although this did not afford absolute proof that the aminomethyl carbonium ion is the true aminomethylating agent, it provided additional support for this hypothesis. In the absence of a suitable trapping agent, the aminomethyl carbonium ion formed in the study cited above (64) was hydrolyzed yielding formaldehyde and secondary amine hydrochloride or acetate. Among the compounds selected by Roth as suitable acidic hydrogen-containing compounds (either CH or NH) are phthalimide, theophylline, succinimide, carbazol, benzoxazolone, benzamide, isatin, saccharin, barbital, acetophenone, antipyrine, cyclohexanone, and indole (35).

Studies involving use of acetylenic compounds in the Mannich reaction have afforded successful condensations in the case of phenylacetylene and its substituted analogs (65). When ethoxyacetylene was employed in the Mannich reaction, Arens and co-workers (66) obtained what appeared to be the hydrolysis product of the corresponding Mannich base, *i.e.*, Scheme XXXIV. Under anhydrous conditions (dioxane as solvent) no trace of Mannich base was isolable. The mechanism proposed suggests that a hydrated *N*-hydroxymethylamine interacted as shown in Scheme XXXV. The alkoxy group in such acetylene derivatives tends to create electron-rich



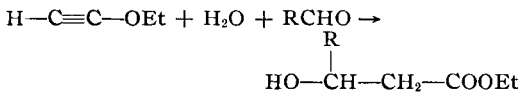
R = Et

Scheme XXXIV



Scheme XXXV

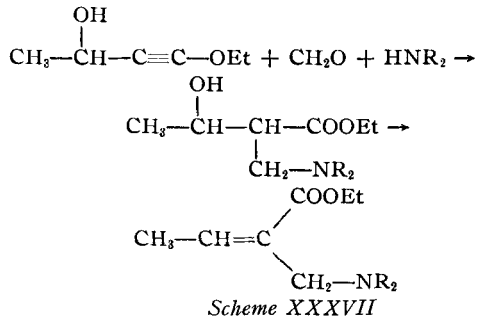
character about the carbon bearing the "replaceable" hydrogen. The above process obviously is not a Mannich reaction and the "replaceable" hydrogen never leaves the acetylenic group. Further proof was offered when, in 1957, Vieregge and Arens (67) demonstrated that ethoxyacetylene, water and aldehyde would react as in Scheme XXXVI.



Scheme XXXVI

The obviously similar product was formed in the absence of added amine. In the same paper, these workers cited experiments by van der Werf and Arens (unpublished data) in which the aminomethylation and hydrolysis had occurred in a molecule that did not contain a replaceable hydrogen (Scheme XXXVII).

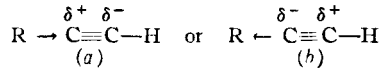
Fernandez *et al.* (55) reported that propargyl alcohol was aminomethylated at the hydroxyl group in preference to the acetylenic group in the absence of added catalyst. Salvador and Simon



Scheme XXXVII

(43) undertook a more detailed study of the behavior of propargyl alcohol under Mannich reaction conditions. Under conditions chosen for the study, Salvador and Simon were not able to isolate the aminomethyl propargyl ethers said to be the preferred product under previously used conditions (55). Instead methylene-bis(amines) were the sole isolable products (43).

According to Salvador and Simon (43) the electronic nature of acetylenes can be represented as follows:



The presence of an α-hydroxyl group as in propargyl alcohol precludes formation of form *b* and, since this is thought to be the type of electron distribution required for a successful Mannich condensation with acetylenic substances, propargyl alcohol should not undergo the Mannich condensation. By conversion of propargyl alcohol to a copper salt,

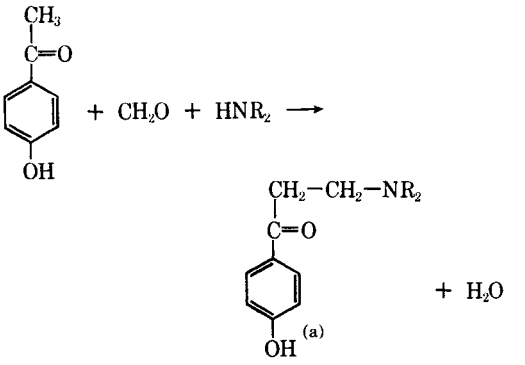
the problem of providing a suitable carbanic species for reaction with a suitable derivative of formaldehyde and amine was easily solved. In practice, the addition of a quantity of cupric sulfate to the buffered, aqueous solution was sufficient to catalyze the reaction (43).

Since the reaction was carried out in aqueous media, insoluble reaction products separated and were accessible for identification. During condensation of propargyl alcohol, piperidine, and formaldehyde, an oily layer separated (43). On distillation the oil produced a strong evolution of formaldehyde and gave methylene-bis(piperidine) as the distillate. Since formaldehyde and piperidine originally were introduced in 1:1 ratio infrared spectral data were obtained on the original oil prior to distillation. The original oil was thus identified as *N*-hydroxymethylpiperidine by comparison with an authentic sample (49). Salvador and Simon (43) then combined propargyl alcohol and *N*-hydroxymethylpiperidine in aqueous cupric sulfate and obtained poorer yields than was

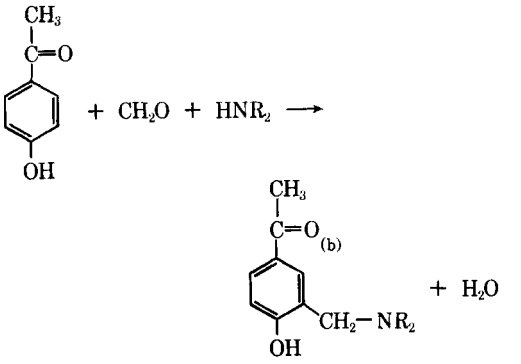
obtained with simple starting materials. Substitution of methylene-bis(piperidine) for the *N*-hydroxymethylpiperidine gave yields similar to those of the regular ingredients. These data indicate that methylene-bis(piperidine) is the true reaction intermediate. It should be recalled that the above-mentioned intermediates were isolated and identified from the reaction itself.

Based on isolation of *N*-hydroxymethylpiperidine from the reaction mixture, its ready conversion to methylene-bis(piperidine) on heating, and the significantly more favorable results on using the latter as a starting material, Salvador and Simon proposed the reaction pathway shown in Scheme XXXVIII. In this pathway the formation and existence of *N*-hydroxymethylpiperidine in mildly acidic conditions is not a very favorable pathway hence its further conversion to the aminomethyl carbonium ion is slow. This effect plus the decreasing availability of the acetylide ion in more acidic media results in slow condensation under mildly acidic conditions (about 80% yield in 5.5 hr. at pH 6.0) and no condensation below pH 3.0. In basic media the cupric acetylide formed more readily as did methylene-bis(piperidine). Thus an 80% yield was obtained in only 1.0 hr. at pH 8.4. The formation of a protonated methylene-bis(piperidine) in mildly basic media, and its subsequent decomposition to an aminomethyl carbonium ion is not very plausible. In this respect the proposed pathway of Salvador and Simon (43) probably is in error since much evidence to support methylene-bis(piperidine) *per se* as the intermediate under basic conditions has been presented (17, 36, 45, 46, 55).

Examples are available in which the Mannich reaction may occur at two different sites within a molecule, each of which represents a different class of active hydrogen. For example, with *p*-hydroxyacetophenone the following reaction courses are conceivable (68): Schemes XXXIX and XL.

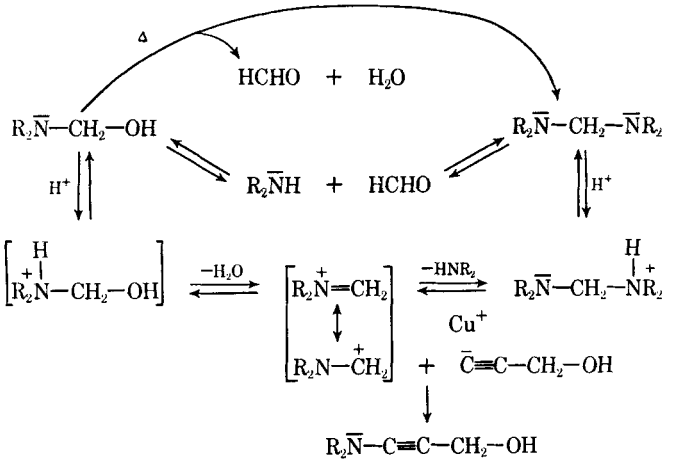


Scheme XXXIX



Scheme XL

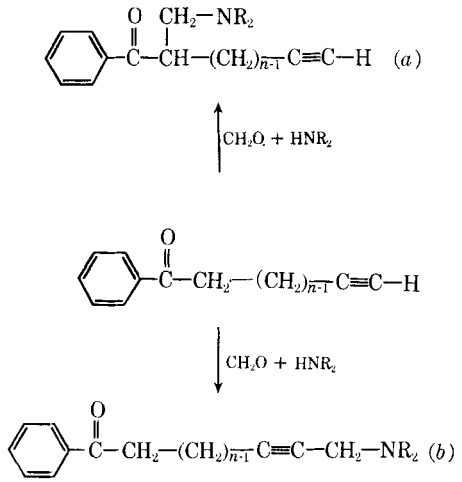
However, only examples of the first class of reaction were available (69–74) prior to 1964. Recently, the selective occurrence of reactions, illustrated as Scheme XL, has been recorded by Gautier *et al.* (68). Products were obtained in 50–60% yields. In general these workers found



Scheme XXXVIII

that acidic conditions favored condensation at the ketonic site, the suggested mechanism being similar to the Cummings and Shelton (34) proposal (Scheme XXX). Under basic conditions interaction with the neutral form of the aminomethylating agent [*N*-hydroxymethylamine or methylene-bis(amine)] occurs preferentially at the ring positions situated *ortho* to the phenolic group. Unfortunately, no examples were given for testing these "selective" conditions in which the phenolic group and ketonic carbonyl groups were not conjugated. This ought to affect the relative reactivities of the two sites to a noteworthy extent.

Gautier *et al.* (18) also have reported success in selective aminomethylation of ketonic and acetylenic moieties within the same molecule. The possible pathways, Scheme XLI, *a* and *b*, proved



Scheme XLI

to be accessible under acidic and basic conditions, respectively. Yields of type *a* compounds were in the 10–55% range while type *b* products were obtained in 48–63% yields. Gautier *et al.* (18) postulated an acetylide carbanion attack (SN2 mechanism) on *N*-hydroxymethylamine as the course of the reaction. In view of earlier discussions the methylene-bis(amine) is more likely to be present as the reactive intermediate. In acidic media, the reaction was considered to occur by means of an aminomethyl carbonium ion attack on the enol form of the ketone (18).

Faberov and Mironov (54) recently conducted a kinetic study of the Mannich reaction applied to ketones and aldehydes with subsequent amine elimination. Much of the data presented parallel data offered by Alexander and Underhill (33), Cummings and Shelton (34), and Fernandez *et al.* (45, 46). Both the product identity in one case (75) and the high yield reported (54) have been challenged (76). Such confusion concerning product identity in the case of unsymmetrical aliphatic ketones has been the subject of many publications (19–21, 75–82). Faberov and Mironov also calculated activation energies for some of the active hydrogen compounds used in the study.

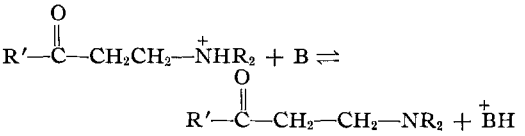
DECOMPOSITION REACTIONS OF MANNICH BASES

Mannich bases frequently are unstable. One type of instability, *i.e.*, propensity for amine elimination, has long been recognized (8, 11, 83–87). This type of decomposition can occur only if a proton is situated vicinal to the amine group and appears to be more prevalent when β-aminoketone salts or the free base form of β-aminocarboxylic acids are heated with water, *e.g.*, as in steam distillation. Faberov and Mironov (54) have reported obtainment of very high yields of α,β-unsaturated ketones and aldehydes by conducting the Mannich condensation in acidic solution and steam distilling without prior isolation of the intermediate Mannich base. Success of the method was reported to be dependent upon successful formation of Mannich base salts in high yields. These workers studied the relationship of pH to the rate of the Mannich reaction in order to assure rapid attainment of maximum yields (54).

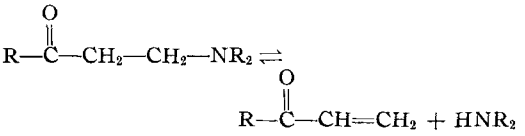
Angeloni and Tramontini (89) studied the rate of decomposition of β-aminoketone hydrochlorides in boiling water. They observed pseudo first-order kinetics for the decomposition. Their data are summarized as follows. The stronger the base (amine) present in the structure, the greater the stability of the Mannich base hydrochloride; addition of sulfuric acid slows the deamination reaction thus suggesting that the free Mannich base and not its salt is the reacting species. The unsaturated ketone product can add free amine but not amine salts. Because of this fact, elimination should be more complete with an equivalent of acid present even though the rate is greater in basic solution.

Horák and co-workers (88), using a polarographic method, were able to follow the deamination of 2-piperidinomethylcyclohexanone and of ω-piperidinopropiophenone and its methiodide. As they expected, different mechanisms for Mannich base salts and their quaternized derivatives were suggested by the data. As the pH increased, the value for the measured rate increased steadily for the methiodide but followed a typical "dissociation" curve in the case of the Mannich

bases. These data indicate that decomposition of the methiodide salt is a base-catalyzed reaction although other data suggest it to be more complex than an E2 mechanism. The data, including that relating occurrence of a dissociation reaction as given above, suggest that the Mannich base salts first undergo a dissociation followed by a unimolecular deamination of the free Mannich base. The process may be illustrated as given in Schemes XLII and XLIII.



Scheme XLII



Scheme XLIII

It is of interest to note that type and concentration of the buffer had no effect on the rate constant for the above process while the methiodide salt decomposition was very decidedly dependent upon these factors.

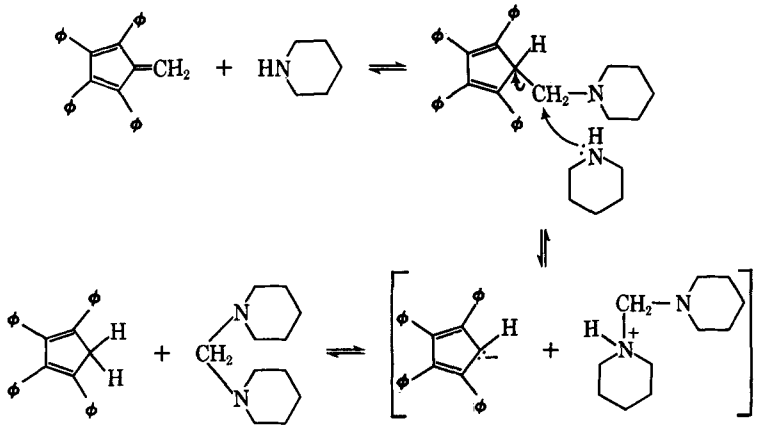
Rivière (22), in a study on the reversibility of the Mannich reaction, also discussed amine elimination to a limited extent. Principal among the stated conclusions is that elimination is especially important as a pathway if further, irreversible changes involving the unsaturated ketone can take place. Dimerization is a frequently seen irreversible process which forces the elimination reaction toward completion. Michael-type addition reactions also can force an elimination reaction toward completion (90–92). The presence of acid which can tie up the eliminated amine preventing reversal or the removal of the unsaturated ketone by steam distillation are adequate procedures.

Several studies on the application of the Mannich reaction to sulfones have been conducted (28, 92–98). With simple aryl alkyl sulfones the reaction failed (28, 92) but gave amine elimination products when arylsulfonylalkanoic acids and esters were used (92–98). Some Mannich base could be isolated in addition to the α,β-unsaturated sulfones when primary amines or ammonia were used along with aromatic aldehydes (92, 94–98). Either use of a secondary amine or of formaldehyde sufficed in order to result in complete elimination. The most likely mode of formation of the unsaturated sulfone is amine elimination (97, 98) rather than the concerted decarboxylation-amine elimination process previously suggested (93).

REVERSIBILITY OF THE MANNICH REACTION

Spoerri and co-workers (37, 38), in studying the addition of bases to 2,3,4,5-tetraphenylfulvene, obtained 1,2,3,4-tetraphenyl-1,3-cyclopentadiene when the starting material was heated with excess cold piperidine. They suggested that the phenomenon represents a reverse Mannich reaction and proposed the course shown in Scheme XLIV for the reaction. With brief contact time at 0° it was possible to isolate the intermediate Mannich base. Heating resulted in amine elimination while refluxing with excess piperidine yielded a reverse Mannich reaction. In literature references cited by Spoerri *et al.* (37) the most successful reversals took place in the presence of excess amine.

Larramona and Tchoubar (99) presented an informative review of the reversibility of the Mannich reaction. It is significant that they



Scheme XLIV

reported reversal with β-aminoalkyl aryl ketones but not with those Mannich bases containing only *alkyl* groups. Both water and amine were effective in catalyzing this reverse reaction.

Riviére (22) contributed much to an understanding of factors which can influence the reversibility of the Mannich reaction. His research further proves the reversibility of the Mannich condensation. In this report the reaction of free amines and amine hydrochlorides on β-aminoketones was studied and found to produce three competitive reactions: (*a*) desaminomethylation (reverse Mannich), (*b*) deamination (elimination), and (*c*) amine exchange between the β-aminoketone and reactant amine. The reversal of the Mannich reaction was found to be dependent on three factors. These are: (*a*) the carbon structure of the β-aminoketone must contain a C_6H_5—C=O— group although this, by itself, was not sufficient for desaminomethylation; (*b*) the presence of anilino as the amino group was unfavorable for reversal of the Mannich reaction; (*c*) aminoketones which were unable to undergo desaminomethylation could, after undergoing amine exchange with amines contained in the media, then undergo a reverse Mannich reaction.

Riviére concluded that the Mannich reaction is reversible in basic media and that its success therefore depends on the position of the equilibria. The position of the equilibria can be altered by irreversible side reactions or by amine exchange. The solvent also has a profound effect: in toluene the equilibria position could be approached from either side; in ethanol, the solvent seems to interfere with simple equilibria and provides different positions depending upon direction of approach.

FACTORS AFFECTING SELECTION OF CONDITIONS

Formaldehyde for use in the Mannich condensation may be provided by aqueous formalin, trioxymethylene (trioxane), or paraformaldehyde (100, 101). Unfortunately selection of one of these forms is not as simple as it may appear.

Aqueous *formalin* (37–40% usually) is a generally satisfactory source of formaldehyde for Mannich reactions which form stable products and have very favorable equilibria positions (8, 22). It must be remembered that the water present can both serve as a solvent and/or lead to reversal of the Mannich reaction in basic media (22). Aqueous formaldehyde may also be used for acidic media condensations, again providing some reversibility difficulties in certain cases.

Trioxymethylene (trioxane) is a cyclic trimer of formaldehyde (100, 101) and is prepared by allowing formaldehyde, obtained by distillation of 60% aqueous formaldehyde solution containing 2% of sulfuric acid, to polymerize and extracting the trioxane and linear polymer mixture with methylene dichloride. Trioxymethylene is a true acetal and can yield formaldehyde only in the presence of acid even in nonaqueous solvent systems. Studies have shown that trioxymethylene can provide formaldehyde in aqueous acid solution at a uniform rate (pseudo first order) (101). Unfortunately, the weakly acidic conditions of the Mannich reaction frequently result in such a slow depolymerization that trioxymethylene is impractical as a source of formaldehyde. A 75% depolymerization requires 2.3 hr. at 70° with 4 N H_2SO_4 and 2.3 days at 70° with 0.5 N H_2SO_4.

The third form of formaldehyde is a linear polymer called *paraformaldehyde* (100), more properly called polyoxymethylene, and may exist in three different forms. The first is *α-polyoxymethylene*, a linear polymer of moderate size (n of 30) and belonging to the "hemiacetal" class. The internal bonds are of the acetal type, hence depolymerization in base can occur, albeit from the terminal ends of the molecules. Cleavage may occur in aqueous or nonaqueous acid solutions all along the polymer chain and at both ends. The second type of polymer is *β-polyoxymethylene* which is similar chemically to the α form. The polymer size is significantly larger, hence this is a less soluble form. This β form of paraformaldehyde is formed by adding sulfuric acid during dehydration of formaldehyde. The third *polyoxymethylene* is the γ isomer which is formed from formaldehyde in methanol by sulfuric acid dehydration. This isomer is stable to bases since it is a true acetal formed from α- and β-polyoxymethylene and methanol. The rate of depolymerization probably is slow as it is with trioxymethylene.

Some chemical supply houses have persisted in using the name "trioxymethylene" as a substitute for "paraformaldehyde." This, of course, creates confusion regarding identity of the material. Furthermore, use of the name "polyoxymethylene" by other suppliers without specifying α-, β-, or γ-isomers may be an occasional source of difficulty.

In many cases it will be advantageous to use derivatives of the amine component and formaldehyde in order to overcome disadvantageous acidity, basicity, or stability of the acidic hydrogen compound or of the product (25).

In the acid-catalyzed Mannich reaction the aminomethylating agent seems to be an amino-

methyl carbonium ion (25, 34) which may be formed most easily and in highest yields by adding *N*-hydroxymethylamine, *N*-alkoxymethylamine, or methylene bis(amine) to a solution of the replaceable hydrogen compound in excess acid. The disadvantages of this procedure include the retarding influence of excess acid on formation of a carbanic center on the replaceable hydrogen compound. Addition of aliquot or aliquant quantities of the total acid followed by addition of a similar quantity of the aldehyde and amine derivative being used often overcomes this difficulty. The acid must always be in excess but, for most reactants, this excess should never be very great. Methylene-bis(amines) will require double the stoichiometric quantity of acid in order to neutralize the mole of amine given off. When amine hydrochloride and active hydrogen compound are dissolved in absolute ethanol and paraformaldehyde is added portionwise (8, 102), excellent results are likewise obtained. The addition of amine hydrochloride assures only moderate acidity and, as formaldehyde is gradually released and reacts with the amine salt, the observed release of free acid will likewise be gradual. The Mannich base, as it forms, will take up the acid and the acidity never builds up in this procedure. A similar procedure for free amine is used when the amine salt is not available (102).

In basic media the same three aminomethylating agents may be utilized with good results (25, 26, 45, 46). Although the actual aminomethylating agent under basic conditions probably is the methylene bis(amine) the experimental evidence offered by Fernandez presents a strong case for *N*-hydroxymethylamine as being a more forceful reagent (45, 46). In basic media in particular, methylene bis(amine) yields an equivalent of free amine which can, as previously shown, accelerate Mannich reaction reversal. Since the amine occurs as part of the equilibria, the position of equilibria will also be affected. When such unfavorable equilibrium positions occur with methylene bis(amine) the use of *N*-alkoxymethylamine or *N*-hydroxymethylamine will give differently constituted equilibria involving alcohols or water, respectively, and hence a totally different equilibrium constant. It is entirely possible that the new equilibria will now provide the desired product in high yield. It is sometimes possible to force the condensation if a solvent such as toluene is used in conjunction with a Dean-Stark trap to remove water from the equilibria. For small quantities of water a Soxhlet thimble containing a nonreacting drying agent is even more effective than the Dean-Stark trap.

With regard to the active hydrogen component of the condensation, two major methods of developing a carbanic center are applicable (25). These are ionization and electronic localization in enols and heterorings. For strongly acidic materials ionization may even take place in moderately acidic media, although it is rare that very low pH values will be conducive to formation of the necessary carbanion or to formation of the required aminomethyl carbonium ion if amine hydrochloride and formaldehyde are used *per se*. Excessive acidity also binds the free electron pairs in enols and heterocyclic systems sufficiently to prevent condensation with the aminomethyl carbonium ion.

The use of basic conditions with strongly acidic components often yields carbanions with greater nucleophilicity than that of the amine. Under such conditions a symmetrical methylene derivative of the active hydrogen compound results (25, 31, 32, 97, 98, 103–105). Basic conditions are favored over acidic conditions in the case of nitroalkanes, acetylenes, phenols, and related materials. The acetylenes in particular undergo the Mannich reaction more readily in the presence of cupric sulfate (43) or under more strongly basic conditions than most active hydrogen sources (18, 43, 68).

Choice of solvent frequently is of great importance (22). The common solvents for the Mannich reaction include water, acetic acid, ethanol, isoamyl alcohol, and toluene (8). The first four are possessed of varying degrees of polarity and thus foster the formation of ionic species to different degrees. Water, acetic acid, and isoamyl alcohol have more elevated boiling points than does ethanol, and their use can therefore speed up an otherwise slow approach to equilibria. The higher temperature also can hasten the elimination of amine from the Mannich base product (37, 38) and thus complicate the process. In base this elimination is reversible while in acid it is slower but tends to go to completion if heated long enough. Acetic acid as a medium can suppress ionization of the acidic compound and thus alter its reactivity. This phenomenon may sometimes be used to advantage. Toluene on the other hand tends to act uniformly to suppress all ion formation. For condensations which seem to involve nonionic reactants, *e.g.*, simple enols or heterosystems reacting with *N*-hydroxy- or *N*-alkoxymethylamines or methylene bis(amines), such media may afford excellent results.

The preceding comments have been quite general in order to afford a broad view of Mannich reaction technology. Other comments of value are to be found in Blicke's review (8) and in the discussions of Hellmann and Opitz (25), and others (11, 22, 99). When difficulties are encountered one must decide if these be in the nature of poor equilibrium position, formation of elimination products, incorrect solvent, or inappropriate conditions or ingredients for proper formation of the intermediates in the reaction. Often steps, such as those discussed above, may be taken which will circumvent these problems.

The value of varying the pH, changing solvents, and, in general, attempting to ascertain why difficulties seem to be occurring in an attempted Mannich condensation cannot be valued too highly. Such knowledge may lead to easily successful variations in the procedure. The observed simplicity of the Mannich condensation procedure in the successful cases should not lead anyone to believe that the process is not indeed complicated and one frequently beset with pitfalls. The author sincerely hopes that this review will serve a useful purpose and that it will aquaint those in the field with more of the work which has been published in other languages.

Electrolyte Alterations in Vascular Smooth Muscle and Hypotensive Activity of a New Chalcone Derivative

By GERALD P. SHERMAN, ELIAS W. PACKMAN, and G. VICTOR ROSSI

Chalcone R-2803 [2-(2-dimethylaminoethoxy)-3′,4′,5′-trimethoxy chalcone hydrochloride] is an effective and long-acting depressor agent when administered intravenously and orally to dogs and rats. In the intact animal, R-2803 is essentially devoid of adrenolytic or ganglioplegic activity. Cross-circulation studies indicate that R-2803 does not possess central hypotensive activity. A direct action at the vascular level is demonstrated by inhibition of norepinephrine- and angiotensin-induced contractions of isolated aortic muscle. Single intravenous doses increase the sodium and potassium content of rabbit aorta, but decrease serum sodium and potassium values, reflecting an apparent shift in the equilibrium of electrolytes between blood and vascular tissue. Although a decrease in hypotensive activity is not observed after administration of R-2803 for 3 days, the electrolyte changes are less than those observed after single intravenous doses. An equidepressor dose of hesperidin methyl chalcone produces similar elevations of aortic sodium and potassium levels. The electrolyte alterations are not a consequence of blood pressure reduction as evidenced by failure of other hypotensive agents to alter aortic electrolyte balance. Sodium and potassium changes in vascular muscle may play a role in the initial phase of the hypotensive effect of the chalcones.

PHARMACOLOGIC EVALUATION by Rossi and Packman (1) of 14 chalcone derivatives synthesized by Packman and Rubin (2) indicated 2-(2-dimethylaminoethoxy) chalcone to be the most active hypotensive compound in the series. Further modification of this molecule by Packman (3) resulted in a derivative, 2-(2-dimethylaminoethoxy)-3′,4′,5′-trimethoxy chalcone hydrochloride (compound R-2803), characterized by greater depressor potency and extended duration of action.

Based primarily on studies on isolated intestinal smooth muscle, Riedesel and Combs (4) postulated that hesperidin methyl chalcone, which

Electrolyte Alterations in Vascular Smooth Muscle and Hypotensive Activity of a New Chalcone Derivative

By GERALD P. SHERMAN, ELIAS W. PACKMAN, and G. VICTOR ROSSI

Chalcone R-2803 [2-(2-dimethylaminoethoxy)-3′,4′,5′-trimethoxy chalcone hydrochloride] is an effective and long-acting depressor agent when administered intravenously and orally to dogs and rats. In the intact animal, R-2803 is essentially devoid of adrenolytic or ganglioplegic activity. Cross-circulation studies indicate that R-2803 does not possess central hypotensive activity. A direct action at the vascular level is demonstrated by inhibition of norepinephrine- and angiotensin-induced contractions of isolated aortic muscle. Single intravenous doses increase the sodium and potassium content of rabbit aorta, but decrease serum sodium and potassium values, reflecting an apparent shift in the equilibrium of electrolytes between blood and vascular tissue. Although a decrease in hypotensive activity is not observed after administration of R-2803 for 3 days, the electrolyte changes are less than those observed after single intravenous doses. An equidepressor dose of hesperidin methyl chalcone produces similar elevations of aortic sodium and potassium levels. The electrolyte alterations are not a consequence of blood pressure reduction as evidenced by failure of other hypotensive agents to alter aortic electrolyte balance. Sodium and potassium changes in vascular muscle may play a role in the initial phase of the hypotensive effect of the chalcones.

PHARMACOLOGIC EVALUATION by Rossi and Packman (1) of 14 chalcone derivatives synthesized by Packman and Rubin (2) indicated 2-(2-dimethylaminoethoxy) chalcone to be the most active hypotensive compound in the series. Further modification of this molecule by Packman (3) resulted in a derivative, 2-(2-dimethylaminoethoxy)-3′,4′,5′-trimethoxy chalcone hydrochloride (compound R-2803), characterized by greater depressor potency and extended duration of action.

Based primarily on studies on isolated intestinal smooth muscle, Riedesel and Combs (4) postulated that hesperidin methyl chalcone, which

possesses blood pressure reducing activity, inhibits potassium efflux thus preventing effective depolarization of the muscle membrane. Preliminary investigations conducted with chalcone R-2803, including spasmolytic activity *in vitro* and effect on regional perfusion rate *in situ*, suggested an action directly at the level of vascular smooth muscle. This report characterizes the depressor activity of chalcone R-2803 in experimental animals and examines the possible relationship between the blood pressure reducing effect of chalcones and alterations in the electrolyte composition of vascular tissue.

EXPERIMENTAL

Hypotensive Activity in Anesthetized Dogs—Blood pressure was monitored in 20 male and 17 female mongrel dogs (9–18 Kg.), anesthetized with allobarbital[1]–urethan (0.6 ml./Kg., intravenously), by coupling a femoral arterial cannula *via* a photoelectric transducer to a physiograph (E & M Instrument Co., Houston, Texas). In this series of experiments all drugs were administered intravenously. The intensity and duration of the hypotensive response to 5, 10, and 20 mg./Kg. of chalcone R-2803 were determined, and the effect of prior administration of 10 mg./Kg. of R-2803 was evaluated on the pressor or depressor response to: bilateral occlusion (30 sec.) of the common carotid arteries, electrical stimulation (30 v., 120 p.p.s. for 15 sec.) of the central and peripheral stumps of the severed vagus nerve, epinephrine (25–50 mcg.), norepinephrine (5–10 mcg.), acetylcholine (5–10 mcg.), dimethylphenylpiperazinium (12.5 mcg.), 5-hydroxytryptamine (250 mcg.), and angiotensin amide (10 mcg.).

Three dog cross-circulation pairs were prepared according to the procedure detailed by Bickerton and Buckley (5). Compound R-2803 was administered into the arterial inflow to the recipient's head, and subsequently into the recipient's femoral vein in doses of 1 and 5 mg./Kg.

Hypotensive Activity in Unanesthetized Dogs—The hypotensive effect of 10 and 20 mg./Kg. of R-2803, administered orally in gelatin capsules, was evaluated in 2 male and 2 female unanesthetized mongrel dogs (7–11 Kg.). Femoral arterial systolic and diastolic pressures were monitored externally by means of an automatic cuff inflation pump functioning in conjunction with an electrosphygmograph which provides a system for continuous recording of occluding cuff pressure and superimposed Korotkoff sounds.

Hypotensive Activity in Unanesthetized Rats—The depressor response to oral administration of 20 mg./Kg. of R-2803 was determined in unanesthetized normotensive and experimental hypertensive male Sprague-Dawley rats (150–190 Gm.). Sustained elevated blood pressure (*i.e.*, systolic pressure in excess of 170 mm. Hg) was induced by extirpation of the left kidney and replacement of drinking water by 2% saline solution. Caudal arterial pressure was estimated indirectly by means of an electrosphygmographic system.

Effect on Contraction of Rabbit Aortic Spirals In Vitro—Spiral strips prepared, according to the procedure described by Furchgott (6), from the descending thoracic aorta of male New Zealand white rabbits (1–2 Kg.) were suspended in Krebs-bicarbonate solution at 37.5°, aerated with 95% O_2 + 5% CO_2, and arranged for kymographic recording of contractions. The concentration of *l*-norepinephrine bitartrate required to elicit a submaximal response was determined individually for each muscle preparation, after which the extent of inhibition of norepinephrine-induced contraction was evaluated with concentrations of R-2803 ranging from 1.67 to 20 mcg./ml. This assay procedure was repeated with other aortic strips using angiotensin amide as the spasmogenic stimulus.

Sodium and Potassium Levels in Rabbit Aorta—Analyses of the sodium and potassium content were performed with aortic tissue samples obtained from male New Zealand white rabbits (1–2 Kg.) 2 hr. after intravenous administration of: R-2803 (10 mg./Kg.), hesperidin methyl chalcone (40 mg./Kg.), mecamylamine (5 mg./Kg.), guanethidine (15 mg./Kg.), chlorothiazide (100 mg./Kg.), and normal saline (volumes equal to injected solution of the experimental drugs). The descending thoracic and abdominal aorta was excised from animals sacrificed by air embolism; the tissue was rinsed in deionized water, trimmed of fat and connective tissue, weighed and ashed (600°, 12–14 hr.). Sodium and potassium concentrations were determined by means of a Perkin-Elmer 303 atomic absorption spectrophotometer, and results expressed in terms of meq./Kg. wet weight of tissue.

RESULTS

Hypotensive Activity in Anesthetized Dogs—Reduction of systolic and diastolic pressure was apparent within 60 sec. after intravenous injection of 5 mg./Kg. of chalcone R-2803 in anesthetized dogs. Blood pressure decreased progressively and attained a hypotensive plateau within 60–90 min. (Fig. 1). A dose-response relationship was evident with the 5, 10, and 20 mg./Kg. dosage range examined.

The chalcone had a more pronounced effect on diastolic than on systolic blood pressure. There was

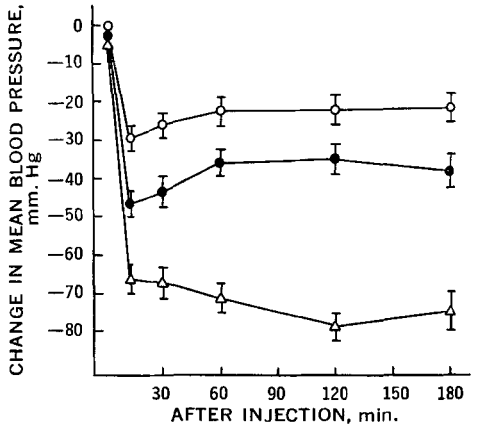

Fig. 1—Reduction of mean blood pressure in anesthetized dogs after intravenous injection of chalcone R-2803. Key: ○, 5 mg./Kg. (N = 3); ●, 10 mg./Kg. (N = 4); △, 20 mg./Kg. (N = 3). Vertical bars indicate standard errors of the mean.

[1] Dial, Ciba Pharmaceutical Co., Morris Plains, N. J.

little change in heart rate and no apparent alteration in the electrocardiogram. A short period of hyperpnea occurred following intravenous administration of the chalcone.

In no case was there a substantial return to pretreatment pressure levels after 3 hr. (arbitrary termination of most assays in this series), and the blood pressure remained depressed 6 hr. after drug administration in those experiments ($N = 5$) conducted for an extended time period. There were no detectable differences in the depressor response to intravenous administration of 10 mg./Kg. of R-2803 in nonpretreated dogs ($N = 4$) and in dogs ($N = 3$) pretreated with 3 daily intraperitoneal injections of 10 mg./Kg. of the chalcone.

A moderate additional reduction in blood pressure (Δ 20 mm. Hg) occurred when the position of anesthetized dogs administered 10 mg./Kg. of R-2803 intravenously, and secured to a tilt table, was abruptly changed from the horizontal plane to an angle of 60°. In contrast, this postural change elicited a further marked reduction in pressure (Δ 50 mm. Hg) in dogs injected intravenously with 15 mg./Kg. of phenoxybenzamine.

Intravenous injection of 10 mg./Kg. of R-2803 partially blocked the carotid occlusion pressor reflex and the responses to electrical stimulation of the central and peripheral ends of the severed vagus nerve, but did not significantly alter the characteristic pressor or depressor effects of epinephrine, norepinephrine, acetylcholine, dimethylphenylpiperazinium, 5-hydroxytryptamine, and angiotensin.

Administration of the antihistaminic compound chlorpheniramine (6 mg./Kg., intravenously) 30 min. prior to intravenous injection of 5, 10, and 20 mg./Kg. of R-2803 in anesthetized dogs ($N = 3$, 4, 3, respectively) decreased by 26–42% the extent, but did not significantly affect the duration of the hypotensive activity of the chalcone. Pretreatment, intravenously, of anesthetized dogs with 150 mcg. of the histamine-releasing agent 48/80 ($N = 3$), or 150 mg. of the antiserotonin agent cyproheptadine ($N = 3$) did not alter the intensity or duration of the depressor response to intravenous injection of 10 mg./Kg. of R-2803.

Administration of R-2803 [1 mg./Kg. ($N = 1$) and 5 mg./Kg. ($N = 2$)] into the arterial inflow to the recipient's head in cross-circulation preparations reduced blood pressure in the donor dog but did not elicit a hypotensive response in the recipient animal. However, administration of the chalcone into the arterial inflow resulted in a marked reduction in perfusion pressure to the recipient's head, indicative of cerebral vascular dilation.

Hypotensive Activity in Unanesthetized Dogs—Blood pressure reduction was detectable within 30 min. after oral administration of 10 and 20 mg./Kg. of R-2803 to unanesthetized dogs; the maximal response was evident within 2 hr. (Fig. 2). The extent of blood pressure reduction following oral administration of 20 mg./Kg. was approximately equivalent to that produced by intravenous injection of 10 mg./Kg. of the chalcone. In those animals monitored for an 8-hr. period after oral administration, the blood pressure had not returned to the predrug level at the termination of the assay.

That the anesthetic employed in a previous phase of this study had no appreciable effect on the depressor response was evidenced by the lack of a significant difference between the hypotensive activity of the chalcone (10 and 20 mg./Kg., orally) in unanesthetized dogs and in dogs anesthetized (allobarbital–urethan) immediately following administration of R-2803.

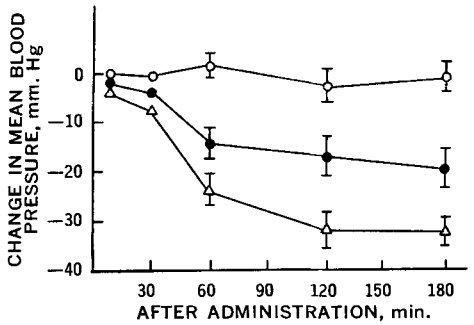

Fig. 2—Reduction of mean blood pressure in unanesthetized dogs after oral administration of chalcone R-2803. Key: ○, placebo capsule (N = 4); ●, 10 mg./Kg. (N = 5); △, 20 mg./Kg. (N = 5). Vertical bars indicate standard errors of the mean.

Hypotensive Activity in Unanesthetized Rats—Oral administration of 20 mg./Kg. of R-2803 produced essentially the same degree and duration of blood pressure reduction in normotensive rats and in renal hypertensive rats (Fig. 3). Although the extent of depressor activity following oral administration of R-2803 in unanesthetized rats was comparable to that observed in unanesthetized dogs, the duration of blood pressure reduction was considerably shorter in the rat (approximately 2.5 hr.) than in the dog (exceeding 6 hr.).

Inhibition of Contraction of Rabbit Aortic Spiral In Vitro—With reference to blocking the contractile response of isolated spiral strips of rabbit aorta to norepinephrine, the ED_{50} concentration of R-2803 was found to be 3.2 mcg./ml. ($N = 22$). A concentration of 20 mcg./ml. of R-2803 reduced angiotensin-induced contractions of aortic smooth muscle by approximately 30% ($N = 8$). It was not possible, however, to determine an ED_{50} value for angiotensin-antagonism inasmuch as concentrations of chalcone in excess of 20 mcg./ml. elicited contracture in aortic strips previously exposed to angiotensin.

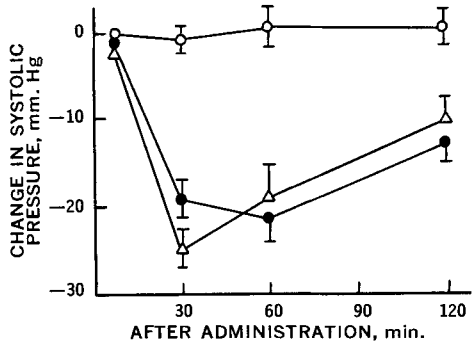

Fig. 3—Reduction of systolic blood pressure in unanesthetized rats after oral administration of chalcone R-2803. Key: ○, saline administration in normotensive rats (N = 2); ●, 20 mg./Kg. in normotensive rats (N = 12); △, 20 mg./Kg. in hypertensive rats (N = 11). Vertical bars indicate standard errors of the mean.

TABLE I—MEAN SODIUM AND POTASSIUM LEVELS IN RABBIT AORTA AND SERUM 2 HR. AFTER INTRAVENOUS ADMINISTRATION OF VARIOUS HYPOTENSIVE AGENTS

Chalcone R-2803	10	14	2.078 ± 0.580	<0.05	0.705 ± 0.036	<0.05

[a] Mean logarithmic values ± standard error. [b] Pretreatment with R-2803, 10 mg./Kg., intraperitoneally in single doses for 3 days and sacrified 2 hr. after administration of R-2803, 10 mg./Kg., intravenously.

Sodium and Potassium Levels in Rabbit Aorta—Chalcone R-2803 (10 mg./Kg., intravenously) increased aortic sodium and potassium levels, and decreased the serum concentration of these electrolytes (Table I). The aortic potassium elevation following intravenous administration of R-2803 was less in rabbits pretreated with the chalcone (10 mg./Kg./day, intraperitoneally, for 3 days) than in those animals which received only the single intravenous injection.

An approximate equidepressor dose (40 mg./Kg., intravenously) of hesperidin methyl chalcone produced alterations in aortic sodium and potassium values similar to those obtained with R-2803.

With the exception of a decreased potassium level following treatment with mecamylamine, the intravenous administration of mecamylamine (5 mg./Kg.), guanethidine (15 mg./Kg.), and chlorothiazide (100 mg./Kg.) did not elicit significant changes in the sodium or potassium content of aortic tissue.

DISCUSSION

Chalcone R-2803 [2-(2-dimethylaminoethoxy)-3′,4′,5′-trimethoxy chalcone HCl] was found to be an effective and long-acting depressor agent when administered intravenously to anesthetized normotensive dogs, and orally to unanesthetized normotensive dogs, normotensive and hypertensive rats. Prolonged moderate reductions in arterial pressure were consistently obtained following intravenous injection of 5–10 mg./Kg., and oral administration of 10–20 mg./Kg. of the chalcone in dogs.

In the intact animal, R-2803 does not possess significant ganglionic blocking or alpha-adrenergic blocking activity. Cross-circulation studies with R-2803 did not reveal any basis for a central mechanism of hypotensive action. A direct action at the vascular level was indicated by an increase in the regional perfusion rate *in situ*, and inhibition of the contractile effect of norepinephrine and angiotensin on isolated aortic smooth muscle.

The possibility of histamine release as a component of the hypotensive action was explored by comparing the blood pressure patterns following intravenous administration of R-2803 in anesthetized saline-pretreated (control) dogs, in dogs pretreated with an effective histamine-blocking dose of chlorpheniramine, and in dogs administered repeated doses of compound 48/80 until the onset of refractoriness. Chlorpheniramine appreciably diminished the degree of blood pressure reduction at all dosage levels of R-2803 examined, but did not consistently affect the duration of the depressor response. No comparable inhibition of the hypotensive action of R-2803 was observed in dogs pretreated with compound 48/80. These latter results may be considered inconclusive inasmuch as there is no definitive method for determining the completeness of histamine depletion in the intact animal, although Slomka and Goth (7) have proposed that refractoriness to subsequent doses of 48/80 is indicative of depletion of available histamine stores. It has frequently been noted that the histamine release which occurs with the peak blood levels resulting from the intravenous injection of certain drugs may not occur or may be less apparent following the relatively slow absorption of the same drugs from the gastrointestinal tract. However, the hypotensive response to intraduodenal administration of R-2803 was also diminished in dogs pretreated with chlorpheniramine. Partial reduction rather than complete abolition by chlorpheniramine of the hypotensive response suggests that histamine release may contribute to, but cannot completely account for, the blood pressure reducing effect of R-2803.

Correlations among the ionic and bioelectric properties of smooth muscle provide a foundation for the proposed roles of altered electrolyte composition of the vascular tree in the increased peripheral resistance characteristic of essential hypertension, and in the mechanism of action of certain blood pressure reducing agents. Su and Bevan (8) have suggested that intracellular antagonism of potassium may be involved in the reduction of arteriolar tone produced by the alpha-adrenergic blocking agents, phenoxybenzamine and SY-14 [*N*-(2-chloroethyl)-*N*-ethyl-1-naphthalenethylamine HCl]. It has been theorized that the gradient of sodium and/or potassium ions existing between the intracellular and extracellular spaces is related to inherent vascular responsiveness and that the thiazides may elicit their hypotensive effect by altering these electrolyte gradients (9).

This basic hypothesis remains plausible although the thiazides have not been found to alter the concentration of sodium in the plasma of hypertensive patients (10), or the sodium content of the arterial walls of experimental animals (11).

The studies with intestinal smooth muscle conducted by Riedesel and Combs (4) on the basis of which they postulated that hesperidin methyl chalcone inhibits potassium efflux, and our observations that chalcone R-2803 increased regional perfusion rate and decreased the reactivity of isolated aortic smooth muscle to norepinephrine and angiotensin, prompted an investigation of the effect of R-2803 on the electrolyte composition of vascular tissue. Single intravenous hypotensive doses of R-2803 increased the sodium and potassium content of rabbit aorta and decreased the serum sodium and potassium levels. These data may reflect a shift in the equilibrium of electrolytes between blood and vascular muscle, *i.e.*, alterations in the intracellular/extracellular gradients of sodium and potassium ions. An approximate equidepressor dose of hesperidin methyl chalcone, which was about one-fourth as potent as R-2803 on a milligram basis, produced similar changes in aortic sodium and potassium levels.

The electrolyte alterations in vascular muscle following administration of R-2803 and hesperidin methyl chalcone are apparently not a consequence of the blood pressure reduction as evidenced by the failure of other potent hypotensive agents (*i.e.*, mecamylamine, guanethidine, and chlorothiazide) to similarly alter the aortic electrolyte concentrations.

Sodium and potassium imbalances in vascular smooth muscle may play a role in the initial phases of the hypotensive action of the chalcones, with the inhibition of potassium efflux preventing effective depolarization of the muscle membrane. However, due possibly to compensatory mechanisms, the electrolyte concentrations in vascular tissue revert toward normal levels within a time period during which refractoriness to the blood pressure reducing effect does not develop.

Cyclic α,β-Unsaturated Ketones Related to Ethacrynic Acid

By JOHN G. TOPLISS and LEROY M. KONZELMAN

2-Carboxymethoxy-8,9-dihydro-6-methyl-5*H*-benzocyclohepten-5-one and 5-carboxymethoxy-2-methylindone, which are structurally related to ethacrynic acid, have been synthesized and the acute renal excretory response to intravenous injections of the compounds in the anesthetized dog has been evaluated. Only marginal activity, compared to ethacrynic acid, was observed.

THE DISCOVERY of a new class of diuretic agents, α,β-unsaturated ketone derivatives of aryloxyacetic acids of the general structure I, was reported by Schultz *et al.* in 1962 (1). Subsequently, pharmacological and clinical reports (2) have appeared on a compound in this series, ethacrynic acid (II).

The authors were interested in determining the effect on diuretic activity of the incorporation of the α,β-unsaturated ketonic function in a ring system in compounds of this general structural type. Consequently, it was decided to synthe-

Received October 19, 1967, from the Medicinal Chemical Research Department, Schering Corporation, Bloomfield, NJ 07003

Cyclic α,β-Unsaturated Ketones Related to Ethacrynic Acid

By JOHN G. TOPLISS and LEROY M. KONZELMAN

2-Carboxymethoxy-8,9-dihydro-6-methyl-5*H*-benzocyclohepten-5-one and 5-carboxymethoxy-2-methylindone, which are structurally related to ethacrynic acid, have been synthesized and the acute renal excretory response to intravenous injections of the compounds in the anesthetized dog has been evaluated. Only marginal activity, compared to ethacrynic acid, was observed.

THE DISCOVERY of a new class of diuretic agents, α,β-unsaturated ketone derivatives of aryloxyacetic acids of the general structure I, was reported by Schultz *et al.* in 1962 (1). Subsequently, pharmacological and clinical reports (2) have appeared on a compound in this series, ethacrynic acid (II).

The authors were interested in determining the effect on diuretic activity of the incorporation of the α,β-unsaturated ketonic function in a ring system in compounds of this general structural type. Consequently, it was decided to synthe-

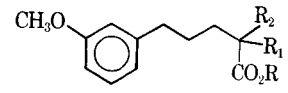
DISCUSSION

The route for the synthesis of the benzocycloheptenone (III) started from *m*-methoxycinnamylidenemalonic acid (Va) which was esterified with methanol in the presence of hydrogen chloride and the resulting dimethyl ester (Vb) was reduced in methanol solution with a palladium catalyst to give dimethyl 3-(*m*-methoxyphenyl)-propylmalonate (VIa). Methylation with methyl iodide and sodium hydride in dimethylformamide gave the malonic ester (VIb) which was then hydrolyzed with alkali and the resulting malonic acid (VIc) was decarboxylated by heating to give 5-(*m*-methoxyphenyl)-2-methylvaleric acid (VId). Cyclization of VId was effected using polyphosphoric acid in high dilution at 70° furnishing 2-methoxy-6-methylbenzocycloheptan-5-one (VIIa). The four-step sequence VIa through VIIa could be performed without purification of the individual intermediates in an overall yield of 80%. Demethylation of VIIa with hydrogen iodide in acetic acid afforded 2-hydroxy-6-methylbenzocycloheptan-5-one (VIIb) which was then transformed into its acetic acid derivative, VIIc, with chloroacetic acid in aqueous alkali. Bromination of VIIc using bromine in methylene chloride yielded the α-bromoketone VIId and this compound on dehydrobromination with refluxing 2,4-lutidine afforded the desired 2-carboxymethoxy-8,9-dihydro-6-methyl-5*H*-benzocyclohepten-5-one (III).

Va, R = H
Vb, R = CH_3



VIa, R = CH_3; R_1 = CO_2CH_3; R_2 = H
VIb, R = CH_3; R_1 = CO_2CH_3; R_2 = CH_3
VIc, R = H; R_1 = CO_2H; R_2 = CH_3
VId, R = H; R_1 = H; R_2 = CH_3

IX was effected with a boron trifluoride catalyst in chloroform solution to give 5-hydroxy-2-methyl-1-indanone (Xa)[1] which was converted into its acetic acid derivative Xb. The α-bromoketone, Xc, was obtained by bromination of Xb with bromine in methylene chloride solution and Xc was converted into the desired 5-(carboxymethoxy)-2-methylindone (IV) by treatment with refluxing 2,4-lutidine.

Renal Pharmacology[2]—The acute renal excretory response to intravenous injections of the compounds was examined in dogs anesthetized with 50 mg./Kg. of vinbarbital. Physiological saline was infused intravenously at a rate of 1.0 to 3.0 ml./min. continuously except for the experiment on IV. In this instance the infusion fluid (3.0 ml./min.) contained 5% mannitol and 0.25% sodium chloride. Ureters were cannulated with polyethylene tubing to facilitate urine collections. Compounds were dissolved in alkali and, after adjustment of pH, injected into the infusion tube. A standard diuretic, ethacrynic acid, dissolved in 5% sodium bicarbonate was given at a dose of 5 mg./Kg. after at

[1] Cyclization of *m*-hydroxy-α-methylcinnamic acid (VIII) under various conditions to give 5-hydroxy-2-methylindone was unsuccessful.

[2] Determined by the late Dr. R. M. Taylor, Biological Research Division, Schering Corporation.

least 1 hr. had elapsed from the time of injecting the test compound. Sodium and chloride ions were determined in 10-min. urine collections by flame photometery and electrometric titration with silver ion, respectively.

The activity of each compound, included in Table I, represents the percent increase in sodium

TABLE I—NATRIURETIC ACTIVITY OF SOME CYCLIC KETONES RELATED TO ETHACRYNIC ACID

Compd.	Dose, mg./Kg.	Natriuretic Activity[a]

Xb	10	26
III	10	16
VIIc	10	11
Ethacrynic acid	5	411

[a] Percent increase in sodium excretion based on mean values of three 10-min. control and treated periods. Changes in chloride and urine flow were roughly similar to sodium excretion in magnitude and duration.

excretion over control values using averages for three 10-min. periods before (control) and after (treated) injection. The activity of ethacrynic acid given in Table I is an average value for these experiments.

Biological Results—The compounds showed only marginal diuretic activity compared to ethacrynic acid. The latter appears to exert its diuretic effect through interaction of the α,β-unsaturated acyl group with functionally important sulfhydryl groups (3). Structure-activity studies in the series indicated that for maximum biological activity one position in the aromatic nucleus *ortho* to the unsaturated ketone function must be substituted (1) and that monosubstitution of the methylene of the unsaturated acyl group causes some loss of activity (4). Saturation of the double bond results in almost complete loss of activity (1, 4). With regard to the compounds synthesized in the present study the very low order of activity exhibited by the cyclic saturated ketones VIIc and Xb, was in accord with expectations. In the case of the cyclic unsaturated ketones III and IV, although the known structural requirements for activity appear to be satisfied, the observed diuretic activity was of a marginal character. It seems unlikely that the double bond in these compounds would be chemically unreactive to sulfhydryl groups. However, the relative orientations in space of the double bond, carbonyl group, and phenyl ring are fixed which may interfere with the ability of the compounds to achieve an adequate fit at the receptor site.

EXPERIMENTAL[3]

Dimethyl m - Methoxycinnamylidenemalonate (Vb)—A solution of Va (5) (150 Gm.) in methanol (1,000 ml.) and concentrated HCl (25 ml.) was refluxed for 16 hr. The solution was evaporated *in vacuo* leaving a brown viscous oil which was used in the next step without further purification. Crystallization of the oil from $CHCl_3$-hexane gave the analytical sample, m.p. 61–63°.

[3] Melting points (uncorrected) were determined on a Thomas-Hoover capillary melting-point apparatus and ultraviolet absorption spectra were determined in methanol solution.

Anal.—Calcd. for $C_{15}H_{16}O_5$: C, 65.21; H, 5.84. Found: C, 65.06; H, 5.89.

Dimethyl 3 - (m - Methoxyphenyl)propylmalonate (VIa)—A solution of crude Vb (161 Gm.) in methanol (600 ml.) was hydrogenated for 16 hr. at 3.4 Kg./cm.^{2} pressure and room temperature in the presence of 5% Pd/C catalyst (6 Gm.). Removal of the catalyst by filtration followed by evaporation of the methanol *in vacuo* gave the product (148 Gm.) as a brown oil which was used without further purification in the next step.

Dimethyl 3 - (m - Methoxyphenyl)propylmethylmalonate (VIb)—Sodium hydride (3.54 Gm., 0.079 mole, of a 53.5% suspension in mineral oil) was added in small portions to a stirred solution of VIa (20.0 Gm., 0.071 mole) in dry DMF (100 ml.) at room temperature. The solution was heated at 90° for 0.5 hr., cooled to room temperature, and methyl iodide (30.4 Gm., 0.214 mole) was then added dropwise. After heating the stirred reaction mixture at 90° for 5 hr., the solvent was removed *in vacuo* to give the crude product which was used without further purification in the next step.

3-(m-Methoxyphenyl)propylmethylmalonic Acid (VIc)—NaOH (20 Gm.) in water (110 ml.) was added to the crude VIb obtained in the previous step and the reaction mixture stirred under reflux for 5 hr. The resulting solution was acidified with concentrated HCl, extracted with $CHCl_3$, and the $CHCl_3$ extract washed with water, dried (Na_2SO_4), and the solvent evaporated. A small portion of the residue solidified on trituration with hexane. This was recrystallized twice from ether-hexane to give the analytical sample, m.p. 93–95°.

Anal.—Calcd. for $C_{14}H_{18}O_5$: C, 63.14; H, 6.81. Found: C, 63.20; H, 6.78.

5-(m - Methoxyphenyl) - 2 - methylvaleric Acid (VId)—The crude malonic acid (VIc) was decarboxylated by heating at 160–170° for 1 hr. to give crude VId (17.2 Gm.) characterized as the *S*-benzylisothiuronium salt, m.p. 125–126°.

Anal.—Calcd. for $C_{21}H_{18}N_2O_3S$: C, 64.92; H, 7.26; N, 7.21; S, 8.25. Found: C, 64.89; H, 7.51; N, 7.26; S, 7.83.

2- Methoxy - 6 - methylbenzocycloheptan - 5 - one (VIIa)—Crude VId (16.7 Gm.) was added to polyphosphoric acid at 70° with rapid stirring. The reaction mixture was stirred at 70° for 1.5 hr. and then poured onto ice and extracted with $CHCl_3$. The $CHCl_3$ extracts were washed with 10% NaOH followed by water, dried (Na_2SO_4), and the solvent was evaporated. The residual crude ketone was chromatographed on an alumina column and elution with 1:1 benzene-hexane gave VIIa (10.5 Gm.), $\lambda_{max.}$ 222 mμ (ϵ 11,700); 270 mμ (ϵ 12,400). The semicarbazone crystallized from methanol–water, m.p. 191–192°.

Anal.—Calcd. for $C_{14}H_{19}N_3O_2$: C, 64.34; H, 7.33; N, 16.08. Found: C, 64.01; H, 7.46; N, 16.14.

2- Hydroxy - 6 - methylbenzocycloheptan - 5 - one (VIIb)—A solution of VIIa (6.8 Gm.) in glacial acetic acid (35 ml.) and 47% hydriodic acid (35 ml.) was refluxed for 1 hr. under nitrogen. The reaction mixture was diluted with water (100 ml.) and extracted with ether. The ether extracts were washed with saturated $NaHCO_3$ and then extracted with 10% NaOH. Evaporation of the ether gave recovered VIIa (2.7 Gm.). Acidification of the NaOH extracts gave crude VIIb (3.2 Gm.), m.p. 120–125°.

Recrystallization from ether–hexane gave 2.8 Gm., m.p. 135–137°. The analytical sample had m.p. 136–137°.

Anal.—Calcd. for $C_{12}H_{14}O_2$: C, 75.76; H, 7.42. Found: C, 75.90; H, 7.36.

2-Carboxymethoxy-6-methylbenzocycloheptan-5-one (VIIc)—Chloroacetic acid (2.2 Gm., 0.023 mole) was added to a solution of VIIb (2.9 Gm., 0.015 mole) in NaOH (from 1.7 Gm. NaOH and 25 ml. water) and the resulting solution was refluxed for 5 hr., cooled and acidified with concentrated HCl. The precipitated solid was collected and stirred with saturated $NaHCO_3$ solution (80 ml.) for 1 hr. Filtration gave starting material (0.65 Gm.) and acidification of the filtrate afforded the crude product (2.6 Gm.), m.p. 148–150°. The analytical sample was obtained on recrystallization from ether, m.p. 152–153°.

Anal.—Calcd. for $C_{14}H_{16}O_4$: C, 67.72; H, 6.50. Found: 67.59; H, 6.74.

6-Bromo-2-carboxymethoxy-6-methylbenzocycloheptan-5-one (VIId)—A solution of bromine (1.7 Gm., 0.011 mole) in CH_2Cl_2 (20 ml.) was added dropwise to a stirred refluxing suspension of VIIc (3.0 Gm.) in CH_2Cl_2 (100 ml.). Stirring was continued for 20 min. at room temperature on completion of the bromine addition, and the solvent was then evaporated in an air current giving crude α-bromoketone m.p. 206–209°. Recrystallization from $CHCl_3$ gave 3.1 Gm., m.p. 212–214°. The analytical sample, obtained by recrystallizing once more from the same solvent, had a m.p. 213–214°.

Anal.—Calcd. for $C_{14}H_{15}BrO_4$: C, 51.39; H, 4.62. Found: C, 51.32; H, 4.76.

2-Carboxymethoxy-8,9-dihydro-6-methyl-5H-benzocyclohepten-5-one (III)—A solution of VIId (3.1 Gm.) in 2,4-lutidine (12 ml.) was heated at 160° (oil bath) for 1.5 hr., cooled, diluted with water (40 ml.), acidified with concentrated HCl, and filtered. The crude product, 1.8 Gm., m.p. 158–160°, was recrystallized from $CHCl_3$-hexane to give 1.7 Gm., m.p. 161–162°, unchanged on further recrystallization, $\lambda_{max.}$ 237 mμ (ϵ 10,700); 291 mμ (ϵ 7,060).

Anal.—Calcd. for $C_{14}H_{14}O_4$: C, 68.28; H, 5.73. Found: C, 68.28; H, 5.63.

m-Hydroxy-α-methylhydrocinnamic acid (IX)—A solution of VIII (6) (90.0 Gm.) in 10% NaOH (300 ml.) was hydrogenated in a Parr shaker over 5% Pd/C (2.0 Gm.) at 3.4 Kg./cm.^{2} pressure and room temperature. After filtration to remove the catalyst, the solution was acidified with concentrated HCl, extracted with ether, and the extracts washed with water and dried (Na_2SO_4). Evaporation of the ether gave the product as a viscous brown oil (89.5 Gm.) which was characterized as the piperidine salt, m.p. 142–144° after crystallization from acetone.

Anal.—Calcd. for $C_{15}H_{22}NO_3$: C, 67.89; H, 8.75. Found: C, 67.70; H, 9.00.

5-Hydroxy-2-methyl-1-indanone (Xa)—Boron trifluoride was bubbled into a cold stirred solution of IX (20.0 Gm.) in $CHCl_3$ (500 ml.) for 4 hr. The reaction mixture was stirred at room temperature for 16 hr. and then 10% Na_2CO_3 (400 ml.) was slowly added, after which stirring was continued at room temperature for 1 hr. more. The chloroform layer was separated, washed with water, dried (Na_2SO_4), and the solvent was evaporated to give the crude indanone (16.0 Gm.) m.p. 136–142°. Recrystallization from ether-hexane gave 11.6 Gm., m.p. 153–155° [reported (7) m.p. 155.5–156.5°, prepared by different method].

5-Carboxymethoxy-2-methyl-1-indanone (Xb)—The procedure for the preparation of VIIc was employed using Xa (7.0 Gm., 0.043 mole), chloroacetic acid (6.2 Gm., 0.065 mole), and NaOH (4.6 Gm.) in water (200 ml.) yielding crude Xb (6.1 Gm.), m.p. 125–135° and recovered Xa (2.7 Gm.). The product was recrystallized from chloroform-hexane giving 4.9 Gm., m.p. 147–149°. The analytical sample had m.p. 148–150°.

Anal.—Calcd. for $C_{12}H_{12}O_4$: C, 65.64; H, 5.49. Found: C, 65.19; H, 5.39.

2-Bromo-5-carboxymethoxy-2-methyl-1-indanone (Xc)—The technique employed for the preparation of VIId was used. Bromination of Xb (31.9 Gm.) gave crude bromoketone (42.0 Gm.) m.p. 110–115°. Recrystallization from ether–hexane gave 37.0 Gm., m.p. 138–140°. The analytical sample had m.p. 138–139°.

Anal.—Calcd. for $C_{12}H_{13}BrO_4$: C, 48.14; H, 3.71; Br, 26.72. Found: C, 48.17; H, 3.90; Br, 27.04.

5-Carboxymethoxy-2-methylindone (IV)—A solution of Xc (18.29 Gm.) in 2,4-lutidine (73 ml.) was heated at 160° for 1.5 hr., poured into dilute HCl and filtered giving crude IV (10.1 Gm.), m.p. 165–170°. Recrystallization from chloroform–hexane furnished 6.1 Gm. of yellow crystals, m.p. 183–185°. The analytical sample had m.p. 187–188°. $\lambda_{max.}$ 218 mμ (ϵ 20,300); 257 mμ (ϵ 52,500); 330 mμ (ϵ 6,900).

Anal.—Calcd. for $C_{12}H_{10}O_4$: C, 66.05; H, 4.62. Found: C, 66.39; H, 4.33.

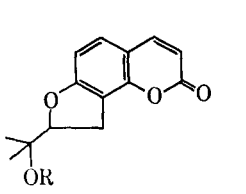
Coumarins V

Mass Spectra of Columbianetin and Its Esters

By M. SHIPCHANDLER and T. O. SOINE

The mass spectra of columbianetin and its acetate, angelate, tiglate, and 3-bromoangelate have been determined. Columbianetin shows M →188 → 187 (base peak 187) as the principal fragmentation pathway whereas the esters show M→ 228 → 213 (base peak 213) as the major fragmentation route. Probable mechanisms for fragmentation are suggested.

In connection with our interest in physiologically active naturally occurring coumarins (1) a number of new representatives of this class have been isolated and structurally characterized. Among these were two dihydrofurocoumarins, columbianin and columbianadin, which were reported by Willette and Soine (2) as the D-glucoside (I) and angelate (II), respectively, of the parent alcohol, columbianetin (III). Since then, the structure of columbianin has been revised (3) to that of a β-D-gentiobioside of columbianetin (IV). During the research leading to the revised structure, employment of mass spectrometry for a molecular weight determination also led to an examination of the mass spectral characteristics of III and certain of its esters. The present report concerns itself with the spectra of III, its acetate (V), angelate (II), tiglate (VI), and 3-bromoangelate (VII).



R

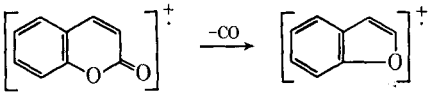
VIII—H
IX—OH

Mass spectrometry has been employed by others on similar coumarins both for structural elucidation and for determination of fragmentation patterns. Abdel-Hay *et al.* (4), for example, carried out mass spectral studies on linear dihydrofurocoumarins including marmesin (VIII) which is the linear isomer of III and, similarly, Schneider *et al.* (5) examined rutaretin (IX). The mass spectra of VIII, IX, and III have common features except that, in IX, the peaks are displaced to 16 higher *m/e* units because it possesses an extra phenolic group. Virtually all of the important peaks found in the case of III are to be found in the spectra of VIII and IX. It may be pointed out that, in the case of IX, the fragmentation mechanisms have been supported by accurate mass measurements. Seshadri *et al.* (6) reported the mass spectral characteristics of selinidin, the angelate of lomatin (7), which is a closely related coumarin of the dihydroseselin type. Here, again, the spectrum bore similarities to the isomeric II.

Barnes and Occolowitz (8) studied the mass spectra of a number of oxygen-containing heterocyclic compounds occurring in nature and Budzikiewicz *et al.* (9) reviewed the work done on this aspect up to 1964. According to the latter authors, and agreeing with the present study, CO is a highly stable neutral particle and, therefore, fragments arising due to its loss are characteristic features of all coumarins. For example, coumarin itself shows a stepwise loss of two molecules of CO and umbelliferone (7-hydroxycoumarin) loses 3 molecules of CO in a similar manner. Barnes and Occolowitz (8) suggest that the molecular ion of coumarin (X) loses the first molecule of CO by way of the lactone carbonyl and that the resulting ion has the structure of the molecular ion of benzofuran (XI) as indicated by a close similarity



m/e 146 X — *m/e* 118 XI

of the spectra of these two compounds. The validity of the benzofuran structure, however, has been challenged by Pirkle (10). Nevertheless, structures written for certain ions are often simply a convenient means of representing fragmentation pathways and are not intended to imply an actual ion structure. In this sense, the present paper employs the benzofuran system as resulting from loss of CO from the coumarinic

Scheme I

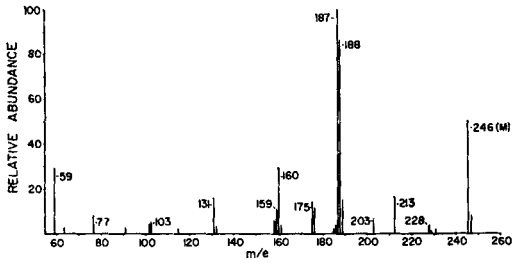

Fig. 1—Mass spectrum of III. Peaks of abundance ratio less than 3% have been omitted in all spectra unless a reference has been made to them in the text. Numbers in all figures correspond to those cited in the text.

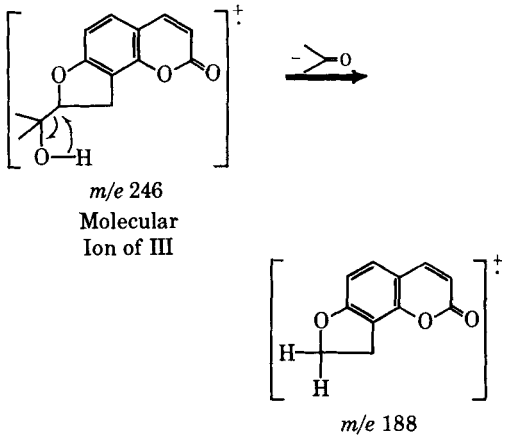
lactone carbonyl. In many cases, the proposed fragmentation pathways are supported by the appearance of metastable ions, these being indicated in the several schemes by heavily lined arrows.

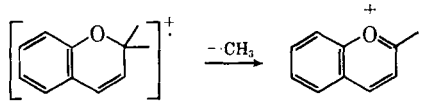
The mass spectrum of III (see Fig. 1) shows a molecular ion which fragments by different routes as shown in Scheme I. The principal pathway of fragmentation involves loss of acetone from the side chain of the molecular ion giving rise to a rearranged ion of *m/e* 188 which has the probable structure shown in Scheme I. This ion then loses an H atom to give rise to a highly stabilized ion of *m/e* 187 which forms the base peak in the spectrum. The *m/e* 188 and 187 ions each lose two molecules of CO in a stepwise manner to generate the ions of *m/e* 160 and 132 in the first case and ions of *m/e* 159 and 131 in the latter case. The ion of *m/e* 159 can also arise from the ion of *m/e* 160 by loss of H atom as indicated by the corresponding metastable ion peak. In a similar fashion the ion of *m/e* 131 can also arise from the ion of *m/e* 132. The ion of *m/e* 131 could be a highly stabilized allylic carbonium ion or could be a rearranged furotropylium ion as proposed in the case of osthol and dihydroosthol (8). This ion then shows loss of another molecule of CO to generate an ion of *m/e* 103 which fragments by losing a molecule of C_2H_2 to give an ion of *m/e* 77. Aromatic systems are known to lose C_2H_2 as a neutral fragment (11). The mechanism of fragmentation M → 188 can be rationalized as shown in Scheme II.

The peak at *m/e* 228 is due to an ion arising through loss of H_2O from the molecular ion. A mechanism similar to that suggested in the case of VIII (4) can be proposed for its formation. This ion then loses a methyl radical, giving rise to an ion of *m/e* 213 which probably has a stabilized benzopyrilium structure. The appearance of this type of ion is the most prominent feature in the mass spectra of the esters of III, selinidin (6),



Scheme II

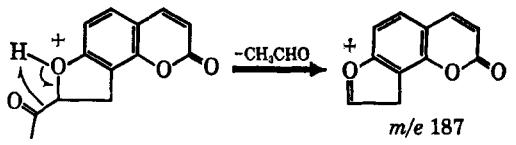
seselin (8), braylin (8), 2,2-dimethylchromene (8), and substituted 2,2-dimethylchromenes (8). The molecular ion of 2,2-dimethylchromene (XII), for example, shows a loss of methyl radical with the resulting ion (XIII) being assigned the structure of a stabilized benzopyrilium ion (8). This ion forms the base peak and there are no other peaks of comparable intensity in its entire spectrum. The ion of *m/e* 213 shows a loss of CO giving rise to an ion of *m/e* 185. The pathway M → 228 → 213 → 185 is very prominent in



the spectra of the esters of III. The alternate pathway for the formation of the ion of *m/e* 185 is probably 228 → 200 → 185 as shown in Scheme I.

The M-15 peak at *m/e* 231 is apparently due to the loss of methyl radical from the molecular ion. This ion, in turn, can lose a molecule of CO to generate an ion of *m/e* 203 which can further lose another molecule of CO to give rise to an ion of *m/e* 175. The ion of *m/e* 231 can also lose CH_3CHO by rearrangement and thus give rise to the ion of *m/e* 187 which represents an alternate pathway for the formation of the latter ion. Similarly, the ion of *m/e* 203 can give rise to an ion of *m/e* 159. Both of these pathways are substantiated by the appearance of metastable ions in the present study as well as in the case of IX (5). However, the metastable peak at *m/e* 151.1 can represent either the transformation 231 → 187 or 203 → 175 or both. A possible rearrangement mechanism leading to formation

of the ion of *m/e* 187 from the ion of *m/e* 231 is shown in Scheme III.



Scheme III

A peak at *m/e* 59 is due to the protonated form of acetone arising from the side chain of III. The appearance of this ion is a characteristic feature of coumarins containing the 2-hydroxyisopropyl grouping [*e.g.*, marmin (12)]. This ion forms the base peak in the spectrum of *tert*-butyl alcohol (13).

The probable fragmentation pathway for V (see Fig. 2) is shown in Scheme IV. The molecular ion loses acetic acid giving rise to a peak at *m/e* 228 which further loses a methyl radical providing an ion of *m/e* 213 which forms the base peak. This fragmentation is quite similar to that of the parent compound and, as mentioned before, is the principal pathway. The ion of *m/e* 213 loses a molecule of CO giving an ion of *m/e* 185. An alternate pathway, 228 → 200 → 185, could also operate in this case as shown in Scheme I. The molecular ion also shows loss of ketene which generates the molecular ion of III by rearrangement. Hence, it is expected that all the ions found in the spectrum of III should also be found in this case. An additional pathway is available for formation of the ion of *m/e* 187, *i.e.*, M → 229 → 187 as shown in Scheme IV. The transformation 229 → 187 is substantiated by a metastable peak at *m/e* 152.8 in the case of the D-glucoside of III (14). The ion of *m/e* 229 is produced from the molecular ion by loss of an acetate radical. This ion can lose an H atom to give the ion of *m/e* 228. Finally, the peak at *m/e* 231 is quite intense in the case of V as compared to III. The reasons for this difference are not entirely clear.

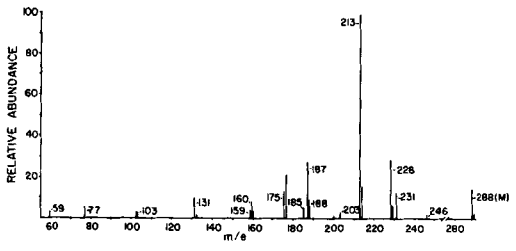


Fig. 2—Mass spectrum of V.

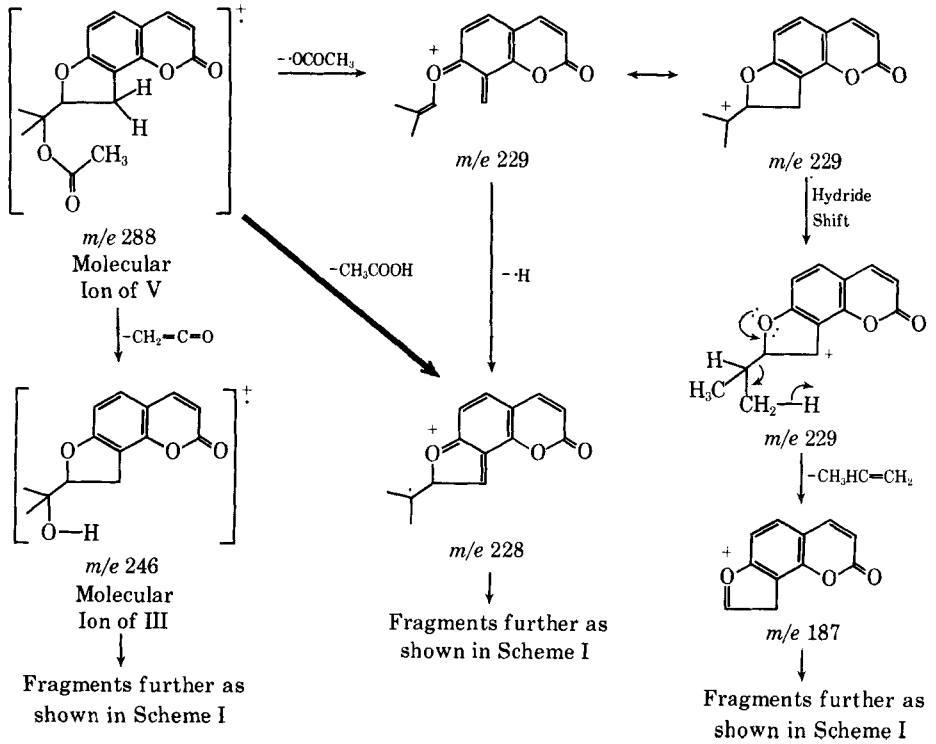
The major fragmentation pathways for II (see Fig. 3) are represented in Scheme V and are similar to those of selinidin (5), the dihydroseselin-type coumarin isomeric with II. As in the case of the acetate ester, the principal pathway for fragmen-



VI Scheme

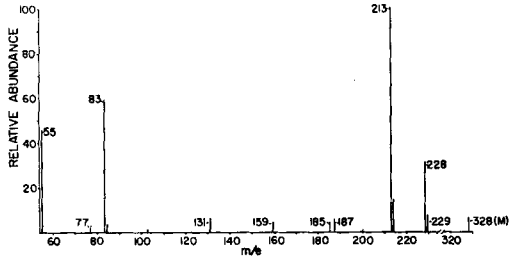


Fig. 3—Mass spectrum of II.

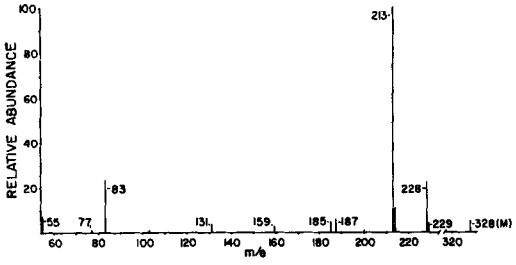

Fig. 4—Mass spectrum of VI.

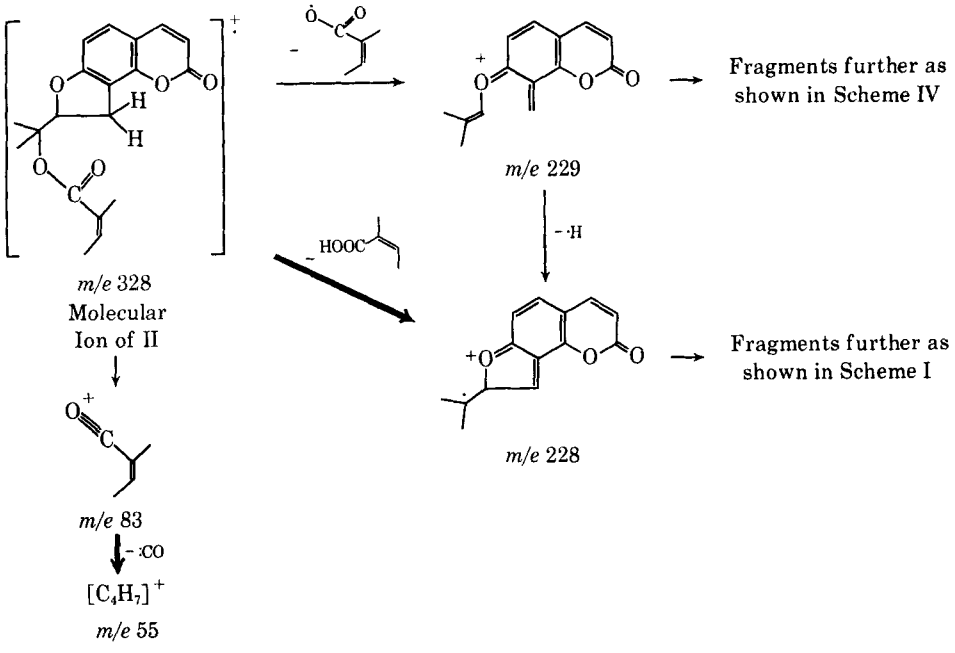

Scheme V

tation is M → 228 → 213 → 185. Another important pathway is the generation of an ion of *m/e* 83 arising by α-cleavage from the acid part of the ester which further loses a molecule of CO to give an ion of *m/e* 55. This latter transformation is substantiated by the corresponding metastable ion peak. The peak at *m/e* 188 is quite inconspicuous and, therefore, the ion of *m/e* 187 can only arise from the ion of *m/e* 229.[1] Furthermore, a rational rearrangement mechanism cannot be written for the generation of the molecular ion of III which then fragments further to generate the ion of *m/e* 188 as in the case of V. Peaks at *m/e* 160 and 132, due to the ions arising from the ion of *m/e* 188, are also inconspicuous.

The spectrum of VI (see Fig. 4), the geometric isomer of II, shows all the peaks present in the spectrum of II. However, there are substantial differences in the abundance ratios in certain cases, namely the peaks that can be ascribed to the acid portion of the ester. Presumably, the fragmentation pathways as represented for II in Scheme V are valid for VI.

The principal fragmentation pathways for VII are shown in Scheme VI (see Fig. 5). They are quite similar to those for II and show twin peaks of molecular ions at *m/e* 406 and 408. These ions fragment in the same manner as does the corresponding ion for II. The ions which do not involve the acid part of the ester appear at the

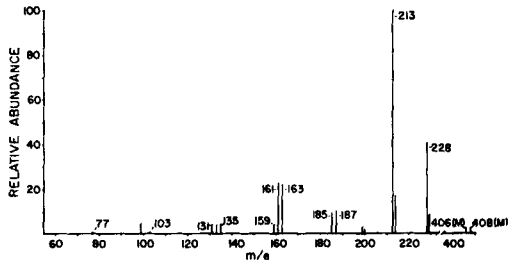

Fig. 5—Mass spectrum of VII.

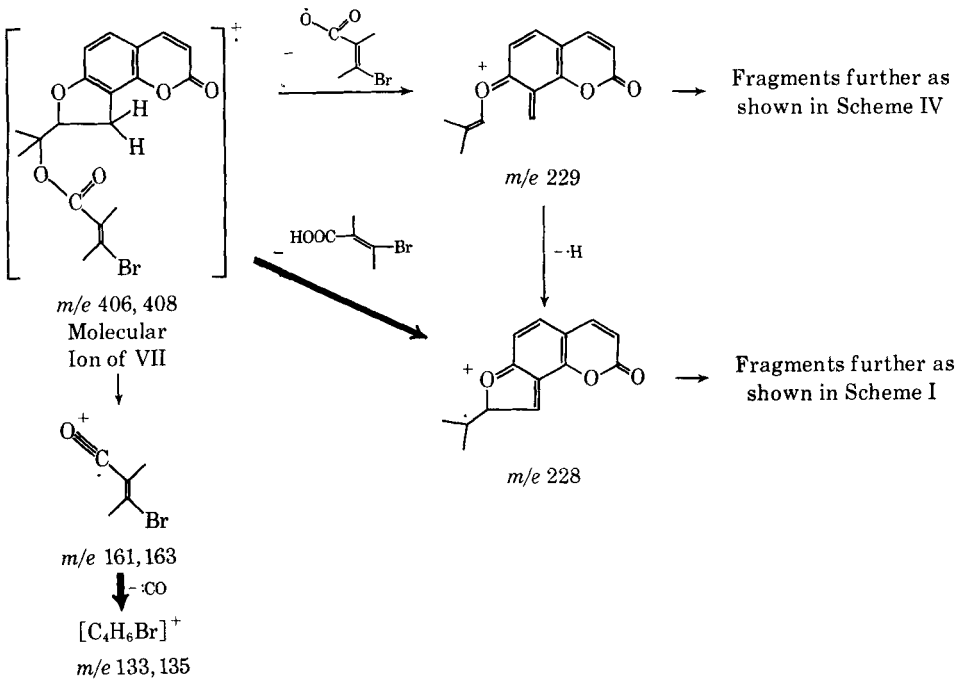
[1] The peak at *m/e* 229 is extremely small in the case of III. However, this peak (corrected for the *P* + 1 satellite peak of 228) is observable in the case of the esters of III. This is probably due to the expulsion of ·OOC—R radical as against ·OH radical, the former being much more stable.



Scheme VI

same *m/e* units as in the case of II. Once again, the ion of *m/e* 213 forms the base peak. However, the peak at *m/e* 83 in the case of II which arises from the acid part is displaced to *m/e* 161 and 163. Similarly, the peak at *m/e* 55 is displaced to *m/e* 133 and 135.

EXPERIMENTAL

Materials—Columbianetin (III) and its acetate (V), angelate (II), tiglate (VI), and 3-bromoangelate (VII) were available in these laboratories as products isolated or synthesized during the studies of Willette and Soine (2) on *Lomatium columbianum* Mathias and Const.

Mass Spectra—These were carried out by Mr. A. R. Swanson and Mr. R. D. Berg, School of Chemistry, University of Minnesota, employing a Hitachi Perkin-Elmer RMU-6D mass spectrometer. The instrument was operated with a source temperature of 250° and an ionizing voltage of 50 ev. The sample inlet temperature was 70° in the case of columbianetin, 90° for the acetate, 120° in the case of the angelate, and 125° for the tiglate and 3-bromoangelate. Assistance in the interpretation of the spectra was given by Dr. Thomas Watson, Pharmacy Department, University of Sydney, Sydney, Australia.

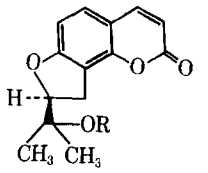
A Revised Structure of Columbianin and Pertinent Mass Spectral Studies

By M. SHIPCHANDLER and T. O. SOINE

The previous erroneous assignment of the structure of columbianin as a D-glucoside of columbianetin has been revised to indicate that it is a β-D-gentiobioside. The mass spectral characteristics of columbianin, its acetate, the true β-D-glucopyranoside of columbianetin, and its acetate have been examined and probable fragmentation pathways proposed.

THE ISOLATION of a new coumarin from the umbelliferous plant, *Lomatium columbianum* Mathias and Const., was reported in 1964 (1). The name assigned to this coumarin, a glycoside, was *columbianin* and it subsequently has been shown to be present in *L. dissectum* var. *multifidum* (Nutt.) Mathias and Const. (2) as well as in *L. nuttallii* (A. Gray) Macbr. (3). Upon acid hydrolysis, columbianin yielded D-glucose and a tertiary alcohol, columbianetin (I). Various chemical and spectral studies (1) indicated the validity of the structure assigned to I which has since been confirmed by Nielsen and Lemmich (4) who extended their studies (5) to show that an 8(S) configuration could be assigned as well. The erroneous assignment of a D-glucoside structure (II) for columbianin was based on the fact that only D-glucose and I were obtained from acid hydrolysis and that the elemental analyses obtained for both the glycoside and its acetate could reasonably have been interpreted as dihydrates, the originally proposed formulase. More recently, an examination of the nuclear magnetic



R

I —H
II —D-Glucosyl
III —β-D-Gentiobiosyl
IV —β-D-Glucopyranosyl

resonance (NMR) spectrum of the acetate of columbianin showed that it was inconsistent with the proposed structure and, therefore, rendered untenable the structure of the parent glycoside.[1] Specifically, the spectrum of the glycosidic acetate showed the *O*-acetyl methyls appearing as four peaks at 7.92, 8.00, 8.04, and 8.07 τ and the *gem*-dimethyls of the columbianetin moiety at 8.69 τ. The denouement, however, was the surprising peak ratio of 3.52:1 between the *O*-acetyl methyls and the *gem*-dimethyls since a ratio of 2:1 was expected. Additional analytical and degradative studies were indicated by this finding.

An ebullioscopic determination on the acetate, while not necessarily definitive, suggested the molecular weight to be about 800 rather than the lower value required by the original structure. Supporting this value was the observance of a rather weak molecular ion peak at *m/e* 864 (±4) in the mass spectrum. More definitive was an *O*-acetyl value that was about 7% higher than the expected value for the dihydrate of a tetraacetate. Finally, elemental analysis of a carefully purified sample of the acetate showed close correspondence to the required $C_{40}H_{48}O_{21}$ from the mass spectral study.

These data, of course, suggested that a disaccharide moiety was present in columbianin since the acetate was obviously a heptaacetate rather than the earlier suggested tetraacetate. To identify this disaccharide moiety, columbianin was subjected to a partial hydrolysis under mild conditions using a cation-exchange resin in the acid cycle (6). The hydrolysate was examined by paper chromatography using the silver nitrate technique for carbohydrate spot detection (7). Two spots appeared, one of which was identical in mobility with D-glucose and the other having a mobility consistent with a 1 → 6 linked disaccharide. The two possibilities, isomaltose (1 → 6,α) and gentiobiose (1 → 6,β) have nearly the same R_f values. Preparative paper chromatography made possible the isolation of this disaccharide ($[\alpha]_D^{20}$ −6° [c 2.0, H_2O]). The specific rotations (8) of the two possibilities are rather far apart—*isomaltose* $[\alpha]_D^{24}$ +120° (H_2O); *gentiobiose* $[\alpha]_D^{20}$ +8.7° (H_2O)—and, therefore, it ap-

Accepted for publication December 15, 1967.

This investigation was supported in whole by Grant HE-07101 from the National Institutes of Health, U. S. Public Health Service, Bethesda, Md.

The authors acknowledge with gratitude the assistance of Dr. B. A. Lewis, Biochemistry Department, St. Paul Campus, University of Minnesota, St. Paul, in providing valuable guidance and authentic samples for comparison. The authors are also indebted to Dr. Thomas Watson, Department of Pharmacy, University of Sydney, Sydney, Australia, for assistance in the interpretation of the mass spectra contained herein.

[1] A preliminary communication covering the revised structure appeared in *J. Pharm. Sci.*, **56**, 661(1967).

pears that gentiobiose must be the disaccharide under consideration with the small differences being attributed to impurities extracted from the paper during the workup. All doubt on this score was eliminated by showing that acetylation of the disaccharide provided β-D-gentiobiose octaacetate which was identical in all respects to an authentic sample. These data prove that columbianin is a gentiobioside of I but do not clarify the configurational α- or β-linkage of the disaccharide to the aglycone.

Gentiobiose is known to occur in nature in the glycosidic form (8). A well-known example is the cyanogenetic glycoside, amygdalin, which was studied by Fischer (9). He showed that amygdalin liberates a molecule of glucose and a new glucoside when treated with an enzyme isolated from yeast extract. Very recently, the hydrolysis of amygdalin, catalyzed by β-glucosidase from almonds, has been studied by Haisman and Knight (10). The enzyme has been shown to cleave β-linked glucose units in a stepwise manner from the nonreducing end of the sugar chain (10, 11). Amygdalin is hydrolyzed in three steps, the last being the hydrolysis of the cyanohydrin to benzaldehyde and HCN. In a similar manner, if columbianin is a β-gentiobioside, it should be hydrolyzed in two steps and no gentiobiose should be observed in the hydrolysate as opposed to acid hydrolysis where the cleavage is random and gentiobiose is observed (10). In considering whether the disaccharide unit is bonded to I by an α- or β-linkage it would be expected that enzymatic hydrolysis with β-glucosidase would stop after the first step if columbianin is an α-gentiobioside. On the other hand, if columbianin is a β-gentiobioside, it would proceed to I, albeit slowly, since tertiary alkyl β-glucosides are known to hydrolyze slowly (12). Experiment showed that columbianin liberated the aglycone in good yield when

$$\text{columbianin} \xrightarrow{\text{fast}} \text{glucose} + \text{monosaccharidic coumarin} \xrightarrow{\text{slow}} \text{glucose} + \text{aglycone (I)}$$

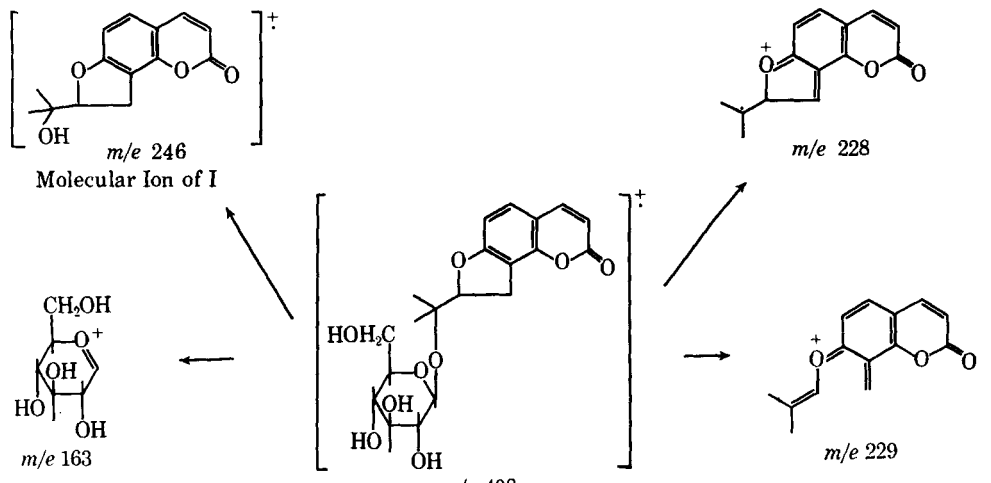
hydrolyzed with β-glucosidase in a prolonged experiment, paper chromatograms showing no gentiobiose but an abundance of glucose. However, paper and thin-layer silica gel chromatograms showed a fluorescent spot having a lesser polarity than the original glycoside but having a greater polarity than I. This material has been isolated in fairly good yield by the use of silica gel and preparative paper and thin-layer chromatography on an enzymatic hydrolysate that had been allowed to run for only a limited amount of time. The isolated compound did not exhibit a definite melting point but did give a small molecular ion peak in the mass spectrum corresponding to *m/e* 408 (*i.e.*, $C_{20}H_{24}O_9$). It provided a tetraacetate, m.p. 163.5–164.5°, in which the ratio of *O*-acetyl methyl peaks and *gem*-dimethyl peaks in the NMR spectrum was 2:1 as expected. The acetyl value as well as the elemental analysis was consistent with the $C_{28}H_{32}O_{13}$ formula of a tetraacetate. The acetate showed a fairly strong molecular ion peak at *m/e* 570 which was in accord with the assigned formula. The enzymatic study of columbianin proves conclusively that columbianin is the β-D-gentiobioside (III) of I. The name, columbianetin β-D-glucopyranoside, is assigned to the monosaccharidic coumarin since all of the analytical and spectral data are consistent with the structure (IV) assigned to it.

Mass Spectral Considerations—The mass spectrum of IV retains almost all of the features characterizing the fragmentation of I (13). The principal fragmentations of the molecular ion have been described in Scheme I[2] whereas the abundance ratios of the ions have been shown in Fig. 1. A peak at *m/e* 246 is probably the molecular ion of I arising from rearrangement of the molecular ion of IV, the probable mechanism being shown in Scheme II. Hence, it is expected that all of the peaks found in the mass spectrum of I will also be found in the present case, assuming that the ion arising by direct electron impact on I is similar to the one arising by the fragmentation shown in Scheme II. The fragments shown in Scheme I would follow the same fragmentation pathways as described previously (13). Many of these pathways have been supported in our earlier paper (13) by the appearance of the corresponding metastable ion peaks.

The peak at *m/e* 229 is very conspicuous as compared to the corresponding peak in the mass spectrum of I. This is probably due to the increased stability of the glucosyl radical as against the hydroxyl radical. Furthermore, the peak at *m/e* 229 is quite conspicuous in the spectra of the esters of I (13) and may, probably, be ascribed to being due to a similar reason.

The ion of *m/e* 188 could either be generated from the ion of *m/e* 246 (*i.e.*, the molecular ion of I) or could arise directly from the molecular ion of IV or both. This ion could then fragment by two routes as in the case of I, *i.e.*, 188 → 187 → 159 → 131 → 103 → 77 and 188 → 160 → 132 with the latter route being of relatively minor consequence.

[2] The ion structures given are not necessarily accurate representations, being used primarily as a convenient means for showing the fragmentation pathways. Further fragmentation pathways for the coumarinic ions have been discussed in the previous paper.



Scheme I

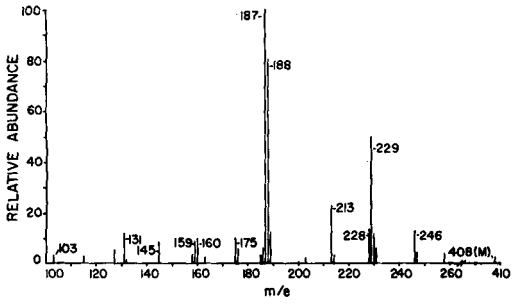


Fig. 1—Mass spectrum of IV. Peaks of abundance ratio less than 3% have been omitted in all spectra unless a reference has been made to them in text. Numbers in all figures correspond to those cited in the text.

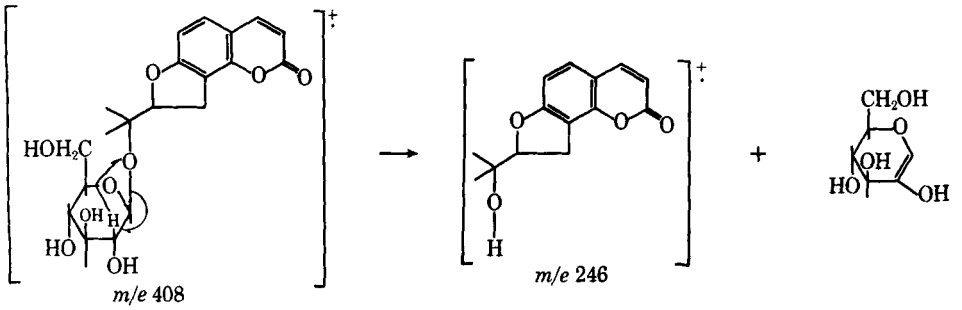
The ion of *m/e* 187 forms the base peak which, in addition, could arise by two more routes, *i.e.*, M → 246 → 231 → 187 and M → 229 → 187. The transformation 229 → 187 is supported by the appearance of a metastable peak at *m/e* 152.8. A pathway of minor consequence is 231 → 203 → 175.

The ion of *m/e* 228 arises from the molecular ion by loss of a molecule of glucose. A mechanism similar to that proposed in the case of I for its formation (13) can be proposed in this case also. The ion fragments by the route 228 → 213 → 185.

In addition to the features that can be ascribed to the coumarinic part, there are peaks which arise from the carbohydrate portion although these are of lesser consequence. Reed *et al.* (14) have studied the mass spectrum of methyl β-D-glucopyranoside and suggest that the peak at *m/e* 163 can be ascribed to an ion arising from the cleavage of the bond between the anomeric carbon and its substituent. This ion, in turn, loses H_2O to generate an ion of *m/e* 145. The latter ion has been shown to fragment into ions of *m/e* 85, 74, 71, and 60 (14).

The tetraacetate of IV shows quite a predictable mode of fragmentation (see Fig. 2) characteristic of the parent compound and also of the polyacetate derivatives of glucose. The peaks which can be said to have originated from the sugar part of the molecule are quite prominent with the peak at *m/e* 169 forming the base peak. Pearl and Darling (15) have recently studied a number of natural glucoside acetates and have found that all of these, in general, possessed a similar pattern as far as the sugar portion is con-



Scheme II

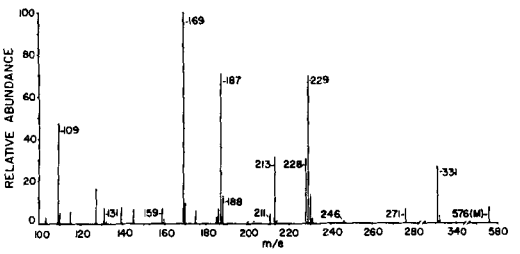


Fig. 2—Mass spectrum of the acetate of IV.

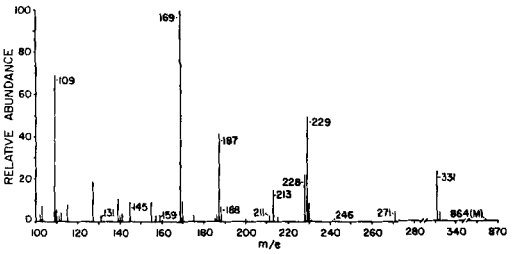

Fig. 4—Mass spectrum of the acetate of III.

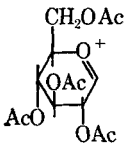
cerned. Biemann *et al.* (16) have shown that the peak at *m/e* 331 in the spectra of glucose pentaacetate and the tetraacetates of methyl and phenyl glucosides is due to V, *i.e.*, the ion arising from cleavage between the anomeric carbon and its substituent. Pearl and Darling (15), likewise, found this type of ion in a number of glucoside acetates. This ion fragments by two routes, *i.e.*, 331 → 271 → 229 → 169 → 109 and 331 → 211 → 169 (16,17). Triacetyl and diacetyl oxonium ions at *m/e* 145 and 103 are also observed. One would expect to find almost all of the ion peaks in



m/e 331

V

the spectrum of the tetraacetate as are found in the spectrum of IV as far as fragments arising from the coumarinic portion of the molecule are concerned.

Columbianin shows almost all the principal features of IV in the mass spectrum (see Fig. 3), the difference being in the peak ratios. The base peak appears at *m/e* 187 just as in the mass spectrum of IV. We failed, however, to observe a molecular ion peak.

The mass spectrum of the heptaacetate of III (see Fig. 4) resembles that of the tetraacetate of IV, once again the differences being mainly in the abundance ratios. The ion of *m/e* 169 forms the base peak. The molecular ion peak, however, is rather weak.

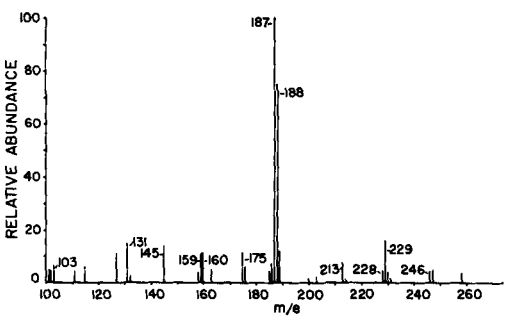


Fig. 3—Mass spectrum of III.

EXPERIMENTAL

Melting points were determined in capillary tubes in a Thomas-Hoover melting point apparatus and are uncorrected.

Infrared spectra were determined on a Perkin-Elmer 237B grating infrared spectrophotometer.

Values of $[\alpha]$ were determined on a Perkin-Elmer 141 polarimeter.

Nuclear magnetic resonance (NMR) spectra were determined on a Varian Associates A-60 instrument in $CDCl_3$ using tetramethylsilane (TMS) as the internal standard.

Mass spectra were obtained by Mr. A. R. Swanson and Mr. R. D. Berg, School of Chemistry, University of Minnesota, employing a Hitachi Perkin-Elmer RMU-6D mass spectrometer. The instrument was operated with a source temperature of 250° and an ionizing voltage of 50 ev. The sample inlet temperature was 300° in the case of IV, 250° for the tetraacetate of IV, 350° in the case of III, and 380° for the heptaacetate of III.

Silica gel for column chromatography refers to Baker Analyst No. 3405 and silica gel for thin-layer chromatography refers to "Chromagram" sheets supplied by Distillation Products Industries, Rochester, N. Y.

Columbianin—The product isolated during the studies of Willette and Soine (1) in these laboratories was employed.

Columbian Acetate—The acetate of columbianin was prepared in the manner previously described (1) and was crystallized from chloroform–cyclohexane, m.p. 218–219°, undepressed on admixture with the authentic acetate.

Anal.[3]—Calcd. for $C_{40}H_{48}O_{21}$: C, 55.55; H, 5.59; mol. wt., 864; *O*-acetyl, 34.84. Found: C, 55.63; H, 5.53; mol. wt. (ebullioscopic), 800; *O*-acetyl, 34.92.

Partial Hydrolysis of Columbianin—Columbianin (20 mg.) was dissolved in 0.5 ml. of water in a small test tube and to this was added 40 mg. of cation-exchange resin in the acid cycle[4] and the mixture placed into a boiling water bath for 1 hr. The

[3] Microanalyses were determined by the Microanalytical Laboratory, School of Chemistry, University of Minnesota, Minneapolis, or by the Schwarzkopf Microanalytical Laboratory, Woodside, N. Y.

[4] Marketed as Amberlite IR-120 by Rohm and Haas Co., Philadelphia, Pa., and converted to the acid cycle with 10% sulfuric acid.

hydrolysate was spotted on standard size Whatman paper No. 1 together with authentic samples of glucose, isomaltose, maltose, and gentiobiose. The paper was developed by the descending chromatographic technique using a pyridine–ethyl acetate–water (2:5:7, upper layer) mobile phase for about 16 hr. The paper was dried and then developed with silver nitrate in acetone in the usual manner (7). Two spots appeared, one of which had moved the same distance as glucose and another which had moved the same distance as isomaltose and gentiobiose, the latter two having traveled almost identically.

Isolation of Gentiobiose—Columbianin (400 mg.) was dissolved in 10 ml. of water and 800 mg. cation-exchange resin in the acid cycle was then added and the reaction mixture heated in a boiling water bath for 5.5 hr. The water lost by evaporation was replaced from time to time. After the end of the heating period the hydrolysate was filtered and the filtrate streaked on standard length Whatman paper No. 3 and developed in the manner described above. After drying, narrow strips were cut from each side of the paper and developed with silver nitrate to locate the zone containing the disaccharide. This zone was cut out, divided into small pieces, and eluted with water. Removal of the water under vacuum followed by drying gave several mg. of the crude disaccharide $\{[\alpha]_D^{20} -6°$ (c 2.0, $H_2O)\}$. The crude product was acetylated with acetic anhydride and sodium acetate in the usual manner to give 30 mg. of β-D-gentiobiose octaacetate, m.p. 191–192°; $[\alpha]_D^{20} -1.86°$ (c 0.64, $CHCl_3$) {lit., m.p. 193°; $[\alpha]_D^{19.5} -5°$ (c 1.8, $CHCl_3$) (8)}. The melting point was not depressed on admixture with an authentic sample of β-D-gentiobiose octaacetate and the infrared spectra were identical.

Isolation of the Aglycone from the Enzymatic Hydrolysis—Columbianin (200 mg.) was dissolved in 20 ml. of water and the aid of heat and to the cooled solution was added 100 mg. of β-glucosidase.[5] The mixture was slowly stirred at room temperature for 56 hr. at which time it was boiled for a few minutes and, after cooling, treated with another 100 mg. of enzyme followed by an additional 36 hr. of stirring. Silica gel thin-layer chromatographic examination in the beginning showed blue fluorescent coumarinic spots when developed with chloroform–ethanol–ethyl acetate (2:3:10) and examined under ultraviolet light. The R_f values of the three principal spots were: 0.07, 0.37, and 0.66 with the first (R_f = 0.07) corresponding to columbianin and the last to columbianetin. Presumably, the spot of intermediate R_f value was an intermediate product of hydrolysis. Paper-chromatographic examination using the pyridine–ethyl acetate–water system previously employed also showed three blue fluorescent spots under ultraviolet light. However, development of the paper chromatogram of the hydrolysate using the silver nitrate technique failed to show the presence of gentiobiose although a spot corresponding to glucose was observed. As the hydrolysis proceeded, the spot corresponding to columbianin slowly lost its fluorescence, whereas the spot corresponding to columbianetin gained in brilliance. When the hydrolysis was terminated the hydrolysate showed only a spot corresponding to columbianetin (R_f = 0.66) and the spot of intermediate polarity (R_f = 0.37). The hydrolysate was extracted with ether until a portion of the ether failed to fluoresce under ultraviolet light when spotted on filter paper. The ether extract was dried with anhydrous sodium sulfate, stripped of solvent, and crystallized to provide 35 mg. (40% of theory) of columbianetin, m.p. 160–161°, which failed to depress the melting point of an authentic sample with which it showed an identical infrared spectrum.

Isolation of Columbianetin β-D-Glucopyranoside—Columbianin (500 mg.) was dissolved in 25 ml. of water with the aid of heat and, after cooling, 100 mg. of β-glucosidase was added. The mixture was stirred for 12 hr. at room temperature at which time thin-layer chromatographic examination showed only traces of unhydrolyzed columbianin, only a small amount of columbianetin, and the major part of the fluorescence in the spot of intermediate polarity. The hydrolysis was then stopped by heating the reaction mixture on a steam bath for several minutes. The isolation, in several runs, was carried out by three different chromatographic techniques. Preparative paper or thin-layer chromatographic procedures employing the previously described solvent systems were employed effectively followed by final elution of the product with methanol. Column chromatography employing silica gel activated at 110° and impregnated with 5% of water appeared to be quite satisfactory also. Elution with ethyl acetate–chloroform (1:1) yields the aglycone and, subsequently, elution with ethyl acetate provides the compound of intermediate polarity (R_f = 0.37) which can be crystallized with difficulty from ethyl acetate–cyclohexane. This compound does not have a definite melting point, softening at *ca* 117–120°, honeycombing at about 130°, and finally becoming transparent at about 180°; $[\alpha]_D^{18.5}$ +206 (c 1.0, CH_3OH). Because of the indefinite melting point and difficulty in crystallization, this compound was analyzed as the acetate derivative.

Columbianetin β-D-Glucopyranoside Acetate—Preparation of the acetate in the usual manner employing acetic anhydride and sodium acetate yielded white crystals from a mixture of ethyl acetate and cyclohexane. Since solvation of the product with cyclohexane was evident from the NMR it was dried at 85° for several hours in vacuum to give a product with m.p. 163.5–164.5°; $[\alpha]_D^{19.5}$ +146° (c 1.0, $CHCl_3$).

Anal.—Calcd. for $C_{28}H_{32}O_{13}$: C, 58.33; H, 5.59; *O*-acetyl, 29.86. Found: C, 58.33; H, 5.73; *O*-acetyl, 29.60.

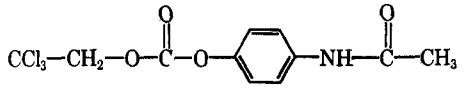
4-Acetamidophenyl 2,2,2-Trichloroethyl Carbonate Synthesis, Physical Properties, and *In Vitro* Hydrolysis

By J. V. SWINTOSKY*, H. C. CALDWELL, C. W. CHONG, G. M. IRWIN, and L. W. DITTERT*

A trichloroethyl carbonate prodrug ester of acetaminophen has been made by reacting acetaminophen with trichloroethyl chloroformate. It is a virtually tasteless crystalline compound retaining the pharmacologic effects of acetaminophen and trichloroethanol. It is lipophilic; its solubility in water is less than 0.05%. It undergoes base-catalyzed hydrolysis, and at pH 7.4 has a half-life in water solution of about 7 hr. Its stability in the solid state makes this compound amenable to use in dosage forms such as tablets and capsules. Hydrolysis of this compound is not catalyzed by human gastric fluid, but it is catalyzed by human intestinal fluid, rat intestinal mucosa, rat plasma, rat liver, and human plasma. It was surmised, therefore, that following oral administration to animals, a portion of the prodrug may be absorbed intact, but some cleavage may occur before and during absorption from the intestines. Furthermore, since enzymes that hydrolyze it are prevalent in plasma and liver, the prodrug on entering the blood will be hydrolyzed very rapidly.

THIS PAPER deals primarily with the preparation and *in vitro* hydrolysis characteristics of a new prodrug (1, 2) form of acetaminophen and trichloroethanol possessing the following structure:



4-Acetamidophenyl 2,2,2-Trichloroethyl Carbonate (ATC)

Albert (3) has used the term "prodrug" to describe compounds which undergo biotransformation prior to exhibiting their pharmacologic effects. Harper (4) has used the term "drug latentiation" to describe chemical modification of a biologically active compound to form a new compound which upon *in vitro* enzymatic attack will liberate the parent compound.

During the past few decades there have been numerous *in vitro* studies describing hydrolysis of esters using serum and other body tissues as enzyme sources. Glick (5) measured the enzymatic hydrolysis of a variety of esters including those of choline. Related studies were undertaken by Adams and Whittaker (6) and Alles and Hawes (7). Levine and Clark (8) studied the relationship between structure and *in vitro* hydrolysis of various esters and amides in human serum. Frazer (9) performed hydrolysis studies on succinylcholine esters using cholinesterases. Other studies of these types have been reported

in the literature as, for example, those of Kalow (10) and Casida and Augustinsson (11).

The carbonate ester, ATC, was designed to exhibit analgesic and sedative properties only after biotransformation following ingestion. Combining the sedative and analgesic activities of the parent drugs, acetaminophen and trichloroethanol, into a single molecule seemed logical since their pharmacologic activities are complementary, and their molar doses are somewhat equivalent. But the primary objectives were to impart new physical-chemical properties to the prodrug so that its absorption rate might be slowed, its dose-time-action profile modified in a useful way, and its profile of physical-chemical properties would be more desirable.

Both acetaminophen and trichloroethanol have an unpleasant taste, and trichloroethanol, a liquid, is especially unsuited for convenient pharmaceutical formulation. It was surmised that blocking the hydroxy groups through a carbonate bridge and linking the molecules together would suppress hydrophilic properties, improve taste, and yield a chemically neutral solid with more lipophilic quality than its parent drugs. Implicitly in the work underlying the preparation of ATC was the assumption that the compound would undergo cleavage in the body releasing the parent drugs at a rate that would result in a useful therapeutic action.

When administered to mice, ATC was shown to possess low acute oral toxicity, to be analgesic, and to reduce spontaneous motor activity, suggesting that it acted in a manner that would be expected of a prodrug of acetaminophen and trichloroethanol (1). Since the pharmaceutic and pharmacologic profiles of this compound seemed to have possible practical value in therapeutics, the authors set out to determine: (*a*) its hydrolysis rate in buffered water, (*b*) its cleavage rates in gastric and intestinal fluids, and (*c*) its cleavage rates in blood and tissue homogenates. It was hoped that these data would yield information about the hydrolytic stability of ATC in dosage forms, the importance and distribution of enzymes in the body that would cause it to be cleaved hydrolytically, the influence of enzymes on the cleavage rates of this apparent prodrug, and the cleavage, if any, of the compound in the gastrointestinal tract before absorption into the blood stream.

EXPERIMENTAL

Hydrolysis Studies

Chromatographic Procedure—The hydrolyses were carried out in a beaker with stirring at 37° as follows: 110 ml. of the biologic material (human gastric fluid or rat liver homogenate, *etc.*) was placed in the beaker and stirred until its temperature reached 37°. A 10-ml. blank sample of the biologic material was withdrawn. Three milligrams of ATC dissolved in 1 ml. of 95% ethanol was added to the biologic material and samples were withdrawn for analysis at appropriate time intervals.

Analyses were carried out as follows: samples (usually 10 ml.) removed from the reaction mixture were placed immediately in glass mortars containing three drops of concentrated hydrochloric acid (sufficient to bring the pH below 1). One gram of diatomaceous earth[1] for each ml. of reaction mixture plus 1 Gm. excess was added to each mortar, and this was triturated. This material was then packed on chromatography columns containing 5 Gm. of diatomaceous earth wet with 4 ml. of water. The mortars were "rinsed" with 2 Gm. of diatomaceous earth wet with 1 ml. of water, and this material was packed onto the columns. The columns were capped with a pledget of glass wool, and 50 ml. of reagent chloroform was poured in. The first 25 ml. of eluate was evaporated to dryness in a jet of air on a steam bath, and the residue was dissolved in 95% ethanol with gentle heating. The ethanol solution was transferred to a volumetric flask, brought to 25 ml. with ethanol, and analyzed spectrophotometrically using the absorption maximum of ATC at 240 mμ. The blank sample of the enzyme preparation was treated in exactly the same way, and the resulting alcohol solution was used in the reference cell of the spectrophotometer.

Initial experiments with mixtures of ATC and acetaminophen showed that the chromatographic procedure separated these two compounds completely.

Spectrophotometric Procedure—Hydrolysis reactions utilizing biologic materials as enzyme sources which were sufficiently dilute to allow direct UV analysis were carried out in the thermostated cell compartment of a Cary model 15 spectrophotometer. The biologic material (50 ml.) was warmed to 37° in a 125-ml. conical flask and a portion placed in the spectrophotometer reference cell. One-half milliliter of 95% ethanol containing 1.5 mg. of ATC was injected by means of a hypodermic syringe, and the flask was swirled gently until mixing was complete. A portion of this mixture was transferred to the sample cell of the spectrophotometer and the absorbances at 240 mμ (for ATC) or 300 mμ (for acetaminophen) were followed with time. The reaction was allowed to proceed until no further change in absorbance was observable, and the data were plotted in terms of Δ absorbance *versus* time (12).

At pH 7.4 the spectra of ATC and acetaminophen are similar; but there are sufficient differences in their molar absorptivities at 240 and 300 mμ to readily follow the hydrolysis reactions at either of these wavelengths. Since the hydrolysis reactions all followed first-order kinetics, plots of absorbance *versus* time, as the absorbance of the reaction mixture approached an equilibrium value, yielded the first-order rate constant. The values of many of the rate constants were verified by following the reactions at both wavelengths and, in several cases, by following the reactions using the chromatographic procedure. The same half-lives were obtained by all three techniques.

Syntheses

2,2,2-Trichloroethyl Chloroformate (13)—Conversion of trichloroethanol to the chloroformate was done in a hood. Vapors of phosgene and the chloroformate[2] were trapped in a sodium hydroxide solution.

A mixture of 150 ml. of toluene and 41 ml. (0.5 mole) of pyridine was cooled wih a dry ice–isopropanol bath. Phosgene (0.75 mole) was added with stirring to this cold mixture. Freshly distilled trichloroethanol (0.5 mole) was then dripped into the mixture, and the dry ice–isopropanol bath was removed after 10 min. The mixture was then stirred for 1 hr. with ice water cooling and for 4 hr. at room temperature. The excess phosgene was removed *in vacuo* at room temperature and the pyridine hydrochloride was removed by filtration.

4-Acetamidophenyl 2,2,2-Trichloroethyl Carbonate—The reaction between acetaminophen and 2,2,2-trichloroethyl chloroformate was carried out in a hood.

Seventy-five and one-half grams (0.5 mole) of 4-hydroxyacetanilide was dissolved in a solution of 20 Gm. (0.5 mole) of sodium hydroxide in 300 ml. of water. This solution was dripped into a chilled toluene solution of the above chloroformate with stirring over a period of 15 min., and stirring was continued for 90 min. The precipitate was recrystallized from dilute alcohol (charcoal) to give 107 Gm. (66%) of product, a white crystalline solid, m.p. 151–153.5°.

Anal.—Calcd. for $C_{11}H_{10}Cl_3NO_4$: C, 40.46; H, 3.09; Cl, 32.57. Found: C, 40.67; H, 3.14; Cl, 32.47.

ATC has a solubility in water of about 35 mcg./ml., and in cyclohexane of 56 mcg./ml., at 37°. It is much more soluble (> 1%) in alcohol and chloroform. As a fine powder, ATC is poorly wetted by water and tends to float.

Materials

Phosphate Buffer—A 0.02 *M* phosphate buffer solution was used to study hydrolysis rates of ATC in water at various pH's. A 0.1 *M*, pH 7.4 phosphate buffer was used in hydrolysis studies involving biological materials, with the exception of human gastric fluid. All hydrolysis studies were done at about body temperature, 37°.

Human Gastric and Intestinal Fluids—These materials were obtained from patients at the Presbyterian University of Pennsylvania Medical Center, Philadelphia. The gastric fluid had a pH of 1.1 and was used undiluted in the hydrolysis studies. The intestinal fluid was used for hydrolysis studies in dilutions of 1, 2, 3, and 4% in phosphate buffer, pH 7.4. The hydrolysis studies in gastric fluid were carried out using the chromatographic procedure, whereas the studies in intestinal fluid employed the spectrophotometric procedure.

Human Plasma—Samples of human plasma were obtained from the Philadelphia Serum Exchange, Children's Hospital. Studies utilizing fresh plasma, 1 part in 50 of phosphate buffer, were carried out using the spectrophotometric procedure to follow hydrolysis rates.

Rat Plasma—The plasma was separated from fresh blood collected in a heparinized beaker by centrifuging the blood at about 20,000 r.p.m. for 5 min.; then the plasma was frozen immediately and stored frozen until used. Hydrolysis studies were carried out utilizing rat plasma at a concentration of 1% in phosphate buffer. The spectrophotometric method was used to follow concentrations of ATC or acetaminophen.

Rat Liver—A Dierolf rat (about 200 Gm.) was killed, and its liver was removed, weighed, and homogenized in a small volume of ice cold normal saline solution using a Waring blender. The homogenate was strained through cotton gauze and brought to 100 ml. with cold normal saline solution. This suspension was then diluted with sufficient phosphate buffer to make a final concentration of 0.1% liver tissue based on the wet weight of the original liver. Hydrolysis studies in this suspension were carried out using the chromatographic procedure.

Rat Intestinal Mucosa—A Dierolf rat (about 200 Gm.) was killed, and its entire small intestine [about 61 cm. (24 in.)] was removed. The intestine was opened, and the solid contents were removed by gentle rinsing with cold water. Mucosal scrapings from the entire segment were obtained by means of a microspatula with a curved blade. The scrapings were mixed with cold normal saline solution (10 ml.) in a tissue grinder, and the resulting suspension was filtered through filter paper. The filtrate was diluted 1:20 (volumetrically) with phosphate buffer, and hydrolysis rate studies were carried out in this solution using the spectrophotometric procedure.

RESULTS AND DISCUSSION

Nonenzymatic Cleavage of ATC—The influence of pH on the hydrolysis rates of this compound was studied: (*a*) to determine to what extent this might influence shelf life of dosage forms prepared from it, and (*b*) to estimate if these rates alone would be sufficiently fast to produce drug from prodrug at a rate which would elicit a pharmacologic response.

In Fig. 1 there are plotted the half-lives ($t_{1/2}$) of ATC as a function of pH in the pH range 2 to 10.5. Hydrolysis reactions all followed first-order kinetics. Studies on the effect of phosphate ion, though not reported here, were done to determine how this might influence the hydrolysis rate. Some catalysis due to phosphate was observed at pH's above 8. However, 0.02 *M* phosphate buffer exerted almost no effect on the hydrolysis rate in this pH range. Below pH 8, phosphate buffer exerted virtually no catalytic effect on hydrolysis.

Between pH 7.6 and 10.5 the plot of log $t_{1/2}$ *versus* pH (Fig. 1) is a straight line with a slope of approximately −1, indicating that the hydrolytic process is first-order with respect to hydroxyl ion in this pH range. Below pH 7, the hydrolytic rate approaches a constant value perhaps due to simple water hydrolysis. At 7.4, the pH of blood and other tissue fluids, the $t_{1/2}$ is about 7 hr. At pH's of 1 to 3, corresponding to stomach pH, the $t_{1/2}$ is about 15 hr. Therefore, at pH's normally encountered in the body, *i.e.*, about 1 to 7.4, it is apparent that the $t_{1/2}$ in the absence of enzymes is always more than about 7 hr. From these data we surmise that at the pH's of body fluids the cleavage of this compound would

[2] Vapors of the chloroformate are very irritating, and they are reported to be as toxic as chlorine (14).

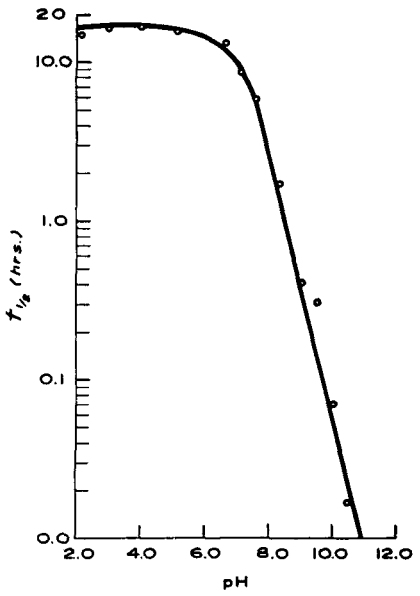

Fig. 1—Plot showing half-lives at various pH's for hydrolysis of 4-acetamidophenyl 2,2,2-trichloroethyl carbonate (ATC) in 0.02 M phosphate buffer at 37°.

not occur at a sufficient rate in the body to elicit a useful response from the acetaminophen and trichloroethanol that were formed unless the hydrolysis reaction was catalyzed by enzymes.

Hydrolysis of ATC Catalyzed by Enzymes from Human and Animal Materials—Since preliminary pharmacologic and biochemical studies, to be reported in another paper, indicated that ATC was an active compound with the predicted pharmacologic properties, knowledge pertaining to sites in the body where the presence of enzymes might induce cleavage of the compound took on added significance.

Thus, it became of interest to assess the hydrolytic effects of various body fluids and tissues, for example, gastrointestinal fluids, blood, and liver. These studies were concerned primarily with the enzymic cleavage rate of the compound relative to its cleavage rate in buffer. No attempts were made to elucidate the mechanism of the enzyme-induced cleavage of ATC, nor to identify the specific enzymes responsible for this cleavage.

All the reactions studied followed, or were assumed to follow, first-order kinetics; and all the data were plotted as log Δ absorbance *versus* time from which the half-lives were determined. Occasionally, it was either impossible or impractical to allow a reaction to go to completion in order to determine the terminal absorbance of the reaction mixture, and, occasionally, apparent terminal absorbance values observed experimentally produced curved semilog plots. In these cases, the terminal absorbances were adjusted to straighten the semilog plots. This approach was found to be as reliable and somewhat more convenient than the Guggenheim method of plotting first-order data (12).

Although enzyme reactions often are not simple first-order reactions, the half-lives determined in these experiments are indicative that the enzyme systems we studied have a definite catalytic effect on the hydrolysis of ATC and that enzyme systems obtained from human and animal sources vary widely in their ability to accelerate the hydrolysis reaction.

In cases of enzyme catalyzed reactions, it is often observed that the rate of decrease of substrate concentration, $-dS/dt$ varies with the substrate concentration [S] according to the Michaelis-Menten equation,

$$\frac{-dS}{dt} = \frac{V[S]}{K_S + [S]}$$

where V is the maximum velocity reached at infinite concentrations of substrate, and K_S is the dissociation constant of the enzyme-substrate complex. When $[S] \ll K_S$, the velocity of the reaction is proportional to the substrate concentration, *i.e.*, the reaction follows first-order kinetics. Thus, in enzyme-catalyzed hydrolysis reactions, pseudo first-order kinetics are often observed through a significant portion of the reaction.

In our studies of ATC hydrolysis using body fluids and tissues as enzyme sources, first-order kinetics were observed usually beyond 50% hydrolysis of the substrate. Thus, in these screening studies it was convenient to determine approximate first-order hydrolysis rate constants. Enzyme-catalyzed hydrolyses, therefore, are expressed as half-lives or in terms of the quotient

$$\frac{t_{1/2}\text{ (water)}}{t_{1/2}\text{ (biologic material)}}$$

at pH 7.4 and 37°.

Hydrolysis of ATC in Human Gastric Fluid—Half-life values in human gastric fluid were in excess of 5 hr. indicating that if there were enzymes here that could catalyze the hydrolysis reaction their effects were insignificant.

Hydrolysis of ATC in Human Intestinal Fluid (HIF)—Typical rates of hydrolysis of ATC in human intestinal fluid, diluted with 0.1 *M* phosphate buffer, pH 7.4, are summarized in Table I.

These results support the view that the fluids of the lumen of the intestine possess substances which have rather pronounced catalytic effects on the hydrolysis of ATC. For example, measured in 4% human intestinal fluid, the hydrolysis rate proceeds 18 times faster than in buffer alone. Though ATC might dissolve and be absorbed intact to some extent from the stomach, it appears that some hydrolysis must occur in the fluids of the intestinal lumen prior to absorption. Therefore, both ATC and its cleavage products could be absorbed from the small intestine.

Effect of Mucosal Scrapings from Rat Small Intestine on ATC Cleavage—Mucosal scrapings appear to be high in esterases that cleave ATC. When ATC

TABLE I—EFFECT OF HUMAN INTESTINAL FLUID ON CLEAVAGE RATES OF ATC AT 37°

Concentration of Human Intestinal Fluid (HIF) in 0.1 *M* Phosphate Buffer, pH 7.4, %	$t_{1/2}$, Min.	$t_{1/2}$ (buffer)/ $t_{1/2}$ (HIF in buffer)
0	420	1
1	98	4
2	46	9
3	33	13
4	23	18

was dissolved to a concentration of 30 mcg./ml. in 200 ml. of phosphate buffer containing the mucosal scrapings of the entire small intestine of a rat, it underwent hydrolysis with a half-life of 5.5 min. This is about 65 times the hydrolysis rate observed in buffer alone. These data support the hypothesis that a drug such as ATC might undergo considerable hydrolytic cleavage in the process of passing through the mucosal lining as it is being absorbed in the intestine.

Hydrolysis by Rat Liver—When ATC was dissolved to a concentration of 30 mcg./ml. in a 0.1% suspension of rat liver in phosphate buffer, it hydrolyzed with a half-life of 5 min. This is about 70 times as fast as the hydrolysis in buffer alone.

Hydrolysis in Plasma—A dilution of 1:50 human plasma in phosphate buffer caused a 30 mcg./ml. solution of ATC to cleave with a half-life of 20 min. This is about 18 times faster than the hydrolysis rate in buffer; on the other hand, it is a much slower rate than was observed in rat plasma of the same dilution. Figure 2, depicting hydrolysis in diluted human plasma, represents typical data observed in the catalyzed hydrolysis of ATC in the presence of body fluids and tissues.

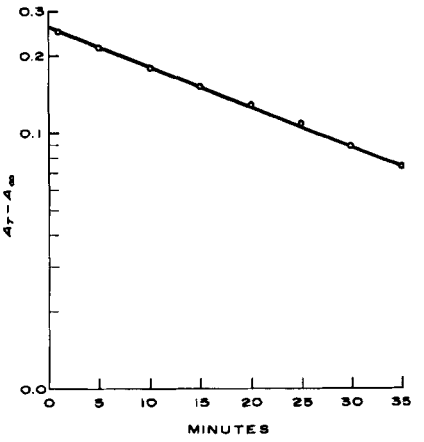

Fig. 2—First-order plot of the hydrolysis of 4-acetamidophenyl 2,2,2-trichloroethyl carbonate (ATC) in pH 7.4 phosphate buffer (0.1 M) containing 2% (v/v) human plasma at 37°. Absorbances were determined at 240 mμ. A_t, absorbance at time t; A_∞, absorbance when reaction is apparently complete; half-life, about 20 min.

CONCLUSIONS

These studies have shown the utility of the carbonate linkage in creating a prodrug from two well-known drugs. They show how the physical-chemical properties of both acetaminophen and trichloroethanol were modified substantially to produce a new compound with good lipid solubility but with low water solubility and a relatively slow dissolution rate. The compound is virtually tasteless apparently as a result of "locking" the hydrophilic hydroxy groups of the parent drugs and markedly decreasing the aqueous solubility of the parent drugs. The profile of new physical properties makes it possible to use ATC in certain dosage forms, such as tablets, which would have been impossible with a simple physical combination of the parent drugs.

A hydrolysis rate corresponding to a half-life of 15 hr. in water at pH 4–7 suggests that suspensions of ATC in water would not be stable for prolonged periods despite its very low aqueous solubility. On the other hand, the low water solubility, coupled with a dose that would be relatively large, suggest that suspensions might be prepared that would retain appreciable potency, at least for several weeks.

A hydrolysis rate at pH 2 corresponding to a $t_{1/2}$ of 15 hr. coupled with an intrinsic low water solubility and slow cleavage rate in human gastric fluids suggest that this compound, when administered orally, is absorbed from the stomach primarily in the form of ATC. The presence in human intestinal fluid and rat intestinal mucosa of enzymes which catalyze the cleavage of ATC suggest that absorption from the intestine of both ATC and its cleavage products could occur simultaneously. The fact that esterases are abundant in the plasma and liver would suggest that in animals and humans the ATC that was absorbed intact would be very short lived and might not even be detectable in the blood but rather, would be quickly converted to acetaminophen and trichloroethanol.

4-Acetamidophenyl 2,2,2-trichloroethyl carbonate (ATC)—synthesis
Prodrug—acetaminophen, trichloroethyl carbonate ester
Hydrolysis, ATC—pH, enzyme effect
Column chromatography—separation
UV spectrophotometry—analysis

Synthesis of D- and L-Thalidomide and Related Studies

By Y. FULMER SHEALY, CLYDE E. OPLIGER*, and JOHN A. MONTGOMERY

The optical isomers of thalidomide were synthesized by a route based on D- and L-isoglutamine. The thalidomide isomers were obtained in high yields by treating the optical isomers of N^2-phthaloylisoglutamine at 0° with thionyl chloride in dimethylformamide. L-Thalidomide was also obtained by using N,N'-carbonyldiimidazole to close the glutarimide ring. Application of these two methods, together with the active (cyanomethyl) ester method, to both N^2-phthaloyl-L-isoglutamine and N^2-phthaloyl-L-glutamine showed that L-thalidomide is formed more readily and with less risk of racemization from the isoglutamine derivative. DL-Thalidomide was also prepared under much milder conditions than those previously used.

THE DESIRABLE SEDATIVE, the undesirable neurotoxic, and the tragic teratogenic properties of thalidomide (IX) are well known. Summaries of these properties have been published (*e.g.*, 1–3), and numerous other publications of biological and biochemical studies have appeared. The synthesis of thalidomide consists, in essence, of the formation of two imide rings. In most of the recorded methods of synthesis, the final step was the formation of the glutarimide ring at temperatures of 150–250° (4–15). The glutarimide ring has also been formed before the introduction of the phthalimido group (16, 17). Prior to the development of *N*-ethoxycarbonylphthalimide for the phthaloylation of amino acids (18), the preparation of phthaloylglutamic acid derivatives was usually accompanied by some racemization (19, 20), although procedures have been devised to obviate or minimize racemization (*e.g.*, 19, 21). However, even when optically active glutamic acid or glutamine was employed for thalidomide synthesis, racemization apparently occurred, either during the phthaloylation with phthalic anhydride, or at the high temperatures used for glutarimide-ring formation. Syntheses of L-thalidomide (22) and of both D- and L-thalidomide (23) have been reported in preliminary communications. Several biological studies (24–29) that have included D- and L-thalidomide have been published without revealing the method of preparation of the optical isomers. In this report a full account of the studies resulting in a synthesis of D- and L-thalidomide is presented (23).

These investigations began with attempts to form the glutarimide ring from N^2-phthaloyl-L-glutamine (L-I) by using peptide-forming reagents. The preliminary investigations produced evidence of the formation of some thalidomide under relatively mild conditions and, also, of partial conversion of the amide group to a nitrile group by dehydrating agents. Dehydration of glutamine and asparagine derivatives to nitriles by certain peptide-forming reagents has been reported (30–35). The active-ester method was investigated by utilizing the cyanomethyl ester of L-I, since it is conveniently prepared. In the strongly basic medium of one equivalent of sodium methoxide in dimethyl sulfoxide (DMSO), the L-I cyanomethyl ester (L-II, $[\alpha]_D^{25}$ −46.6° in dimethylformamide [DMF]) was rapidly cyclized at room temperature to thalidomide in a yield of 70%. Cyclization in good yield also occurred, at a slower rate, with less than one equivalent of methoxide. The conditions employed were much milder than those previously reported; even so, DL-thalidomide (DL-IX) was the product of both experiments.

The preliminary evidence of difficulties in basing a synthesis of L-thalidomide on L-I was suggestive, rather than conclusive, because the application of peptide-forming reactions was not thoroughly investigated. During the course of these studies, Liberek presented evidence that phthaloyl derivatives (36) and cyanomethyl esters (37) of amino acids are especially susceptible to base-catalyzed racemization. Since our evidence and evidence from the literature suggested that dehydrating-type reagents might produce considerable nitrile from glutamine derivatives (30–35) and that base-catalyzed cyclizations might cause racemization, these studies were subsequently based on isoglutamine for the following reasons. Activation of the carboxyl group of glutamine derivatives increases the acidity of the C—H bond of the adjacent asymmetric carbon atom and, thereby, enhances the tendency to racemize. In isoglutamine

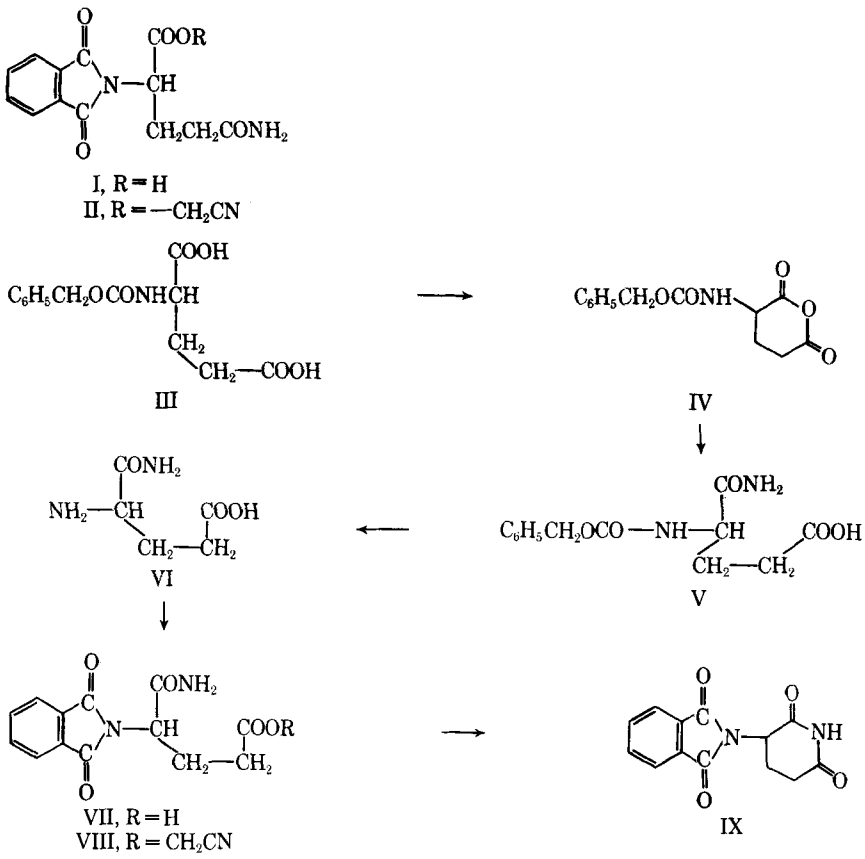

Scheme I

(VI) derivatives, however, the carboxyl group to be activated for ring-closure is separated from the asymmetric carbon atom by two methylene groups. In addition, there is evidence from peptide chemistry (*e.g.*, 38–40) of rather facile imide formation from α-glutamyl peptides.[1]

The synthetic route to D-and L-thalidomide is outlined in Scheme I, and details, including some refinements of procedures reported in the literature for intermediates (III–VI), are described in *Experimental.* The method of Nefkens *et al.* (18), which introduces the phthaloyl group without racemization, was used to prepare the phthaloyl derivatives (I, VII) of L-glutamine (already mentioned), L-isoglutamine, and D-isoglutamine. After work on the synthesis of these compounds had been completed, Schröder and Klieger (41) reported the synthesis of L-I and L-VII by this method, although the optical rotation of L-VII was not recorded. The formation of the glutarimide ring was effected readily by thionyl chloride in DMF at 0° or, over a longer period of time, by *N,N'*-carbonyldiimidazole (42). The thionyl chloride-DMF method afforded L- and D-thalidomide (L-IX and D-IX), with optical rotations comparable to those of subsequently purified specimens, in yields of 75–85%. The optical rotations[2] of L- and D-thalidomide recrystallized from DMF–water were −64.6° and +64°, respectively, in dry DMF at 25°. The optical isomers and commercial DL-thalidomide moved identically on thin-layer chromatograms and gave identical nuclear magnetic resonance spectra in DMSO-d_6. The infrared spectra, determined by the potassium bromide disk method, of D- and L-thalidomide were identical, as expected, and were also identical with a published spectrum (43) of DL-thalidomide, except for minor differences ascribable to the fact that the spectra were determined in the solid state.

Tipson (20) had found that the phthalimide ring of phthaloylglutamic acid is readily opened by dilute aqueous base, and Williams (45) reported that DL-thalidomide undergoes hydrolysis in the neutral pH range to at least 12 compounds.[3] These findings led us to design our

[1] Battersby and Reynolds (40) reported the failure of a γ-glutamyl (glutamine-type) peptide to cyclize under conditions that gave a low yield of a glutarimide from an α-glutamyl (isoglutamine-type) peptide.

[2] Values reported in the literature for L-thalidomide are $[\alpha]_D^{20}$ −62° in dioxane (22) and $[\alpha]_D^{20}$ −45.7° in DMF (26) and for D-thalidomide, $[\alpha]_D^{20}$ +53.2° in DMF (26). A very recent publication (44) on some biological properties of L- and D-thalidomide gave $[\alpha]_D^{20}$ −58° and +60°, respectively, in DMF.

[3] A complete description of the studies of Williams and coworkers on hydrolysis has subsequently been published (26). Other reports of facile hydrolysis have also been published (*e.g.*, 46, 47).

preparative and isolation procedures with the aim of preventing, or minimizing insofar as possible, hydrolysis of the imide rings, as well as racemization. In addition, after the thalidomide isomers had been obtained, we attempted to determine the stability of L-thalidomide and its immediate precursor (L-VII) in DMF and aqueous DMF. Both compounds were in DMF solution (containing trace amounts of water) during the preparation of L-thalidomide and during the determination of their optical rotations, and L-thalidomide was exposed to aqueous DMF during isolation and recrystallization. Optical rotation data indicated that L-thalidomide suffered little or no change in dry DMF or in 80% DMF during observation periods of 18 and 43 hr., respectively, and that L-VII was stable in both of these solutions for at least 24 hr. However, a specimen of L-thalidomide that had not been recrystallized (after isolation from a thionyl chloride–DMF reaction) exhibited a decrease in specific rotation in both dry DMF and in 80% DMF; the decrease was more rapid in the latter solution. Subsequently, at least one recrystallization from DMF–water was performed on the day of the preparation of L- or D-IX. As a further precaution, the preparation of L-VII at a pH lower than that of the customary Nefkens phthaloylation was performed, but there appeared to be no advantage in this modification.

In the course of our studies, comparison of L-glutamine and L-isoglutamine derivatives as precursors of thalidomide was made. L-I and L-VII were treated with thionyl chloride in DMF in experiments identical in procedure and isolation methods. One pair of reactions was allowed to proceed for 0.5 hr.; another pair, for 2 hr. L-VII gave L-thalidomide in yields of 75–80%; L-I gave a low yield (9–10% calculated as thalidomide) of crude material that contained sulfur, had an optical rotation greater in magnitude than that of L-thalidomide, and produced 2–3 spots (one of which was thalidomide) on thin-layer chromatograms. From the filtrate of the 2-hr. reaction of L-I, a yield of 11% of crude thalidomide was obtained. Although L-I gave a small amount of thalidomide of unknown optical purity, L-VII obviously gave vastly superior results in this procedure.

In another pair of identical experiments, reactions of L-I and of L-VII with *N,N'*-carbonyldiimidazole gave a 41% yield of L-thalidomide ($[\alpha]_D^{25}$ −58°) from L-VII and a 30% yield of DL-thalidomide from L-I.

Cyclization of the cyanomethyl ester (L-VIII) of phthaloyl-L-isoglutamine with sodium methoxide in DMSO in experiments identical with those employed for the L-glutamine derivative (L-II) likewise gave DL-thalidomide. However, during the preparation of L-VIII in the presence of triethylamine, optically active thalidomide, as well as L-VIII, was obtained. This observation alone did not necessarily demonstrate a greater propensity of L-VIII to cyclize, since the reaction time required to prepare L-VIII was greater than that used to prepare L-II. However, it did show that L-VIII would cyclize under less basic conditions than those of the sodium methoxide–DMSO reagent. The product isolated after treating L-VIII with triethylamine in DMSO was partially racemized L-thalidomide ($[\alpha]_D^{25}$ −45°), whereas L-II in an identical experiment was racemized but failed to cyclize. Thus, isoglutamine derivatives were cyclized much more readily by the three methods investigated and were much less susceptible to racemization than the corresponding glutamine derivatives.

EXPERIMENTAL[4]

Infrared spectra were recorded with a Perkin-Elmer model 521 spectrophotometer using samples in potassium bromide disks. Melting points were determined on a Kofler Heizbank melting point apparatus unless otherwise noted. TLC was performed by the ascending method on layers of Silica Gel H[5] of standard 0.25 mm. thickness supported on glass plates. Crude and purified specimens of the thalidomides were applied to the adsorbent in DMF, although D- and L-thalidomide could also be applied in ethyl acetate. Generally, 20- and 80-mcg. portions of each sample were spotted, and commercial DL-thalidomide and the starting material were used as reference compounds. At 80 mcg. the thalidomide spots were usually convex. Spots were detected with an ultraviolet lamp, which emits principally at 254 mμ, after the developed chromatograms had been sprayed with Ultraphor WT.[6] A spray of basic potassium permanganate was sometimes also used to detect nonabsorbing impurities. Unless otherwise indicated, either 95:5 (v/v) chloroform–methanol or 85:15 (v/v) benzene–methanol was used to develop the chromatograms. In these solvent systems L- and D-VII remain at the origin, but they migrate in 1:1 chloroform–methanol.

N^2-Benzyloxycarbonyl-L-isoglutamine (L-V)—*N*-Benzyloxycarbonyl-L-glutamic acid anhydride (L-IV) was prepared by the method of Bergmann and Zervas (48) and recrystallized from chloroform–ether (49): yields, 80–83%; m.p. 94–95°; $[\alpha]_D^{25}$ −43 to −45.0° (c = 10.0 in glacial acetic acid).

[4] The authors are indebted to Drs. W. J. Barrett, W. C Coburn, Jr., and P. D. Sternglanz of the Analytical and Physical Chemistry Division of this Institute for spectral determinations and elemental analyses; to Mrs. Frances Dean for optical rotations; and to Misses Kathleen Hewson and Imogene Baswell for thin-layer chromatographic determinations.

Lit. values $[\alpha]_D$, m.p.: −44.1°, 94° (48); −43°, 91–92° (49); −45.1° (50). Although the melting point and optical rotation of a batch of commercial *N*-benzyloxycarbonyl-L-glutamic acid (L-III) were in agreement with values reported in the literature, partially racemized anhydride was obtained unless the commercial material was purified as follows. A solution of 98 Gm. of commercial *N*-benzyloxycarbonyl-L-glutamic acid in 600 ml. of ethyl acetate was washed twice with 100-ml. portions and 4 times with 50-ml. portions of water, dried with magnesium sulfate, and diluted with 2.5 L. of petroleum ether. The white precipitate was washed twice on a filter with 500-ml. portions of petroleum ether: yield, 83.5 Gm.; m.p. 120–122°; $[\alpha]_D^{25}$ −7.8° (c = 3.00 in glacial acetic acid).

The procedure of Bergmann and Zervas (48) for the preparation of L-V was modified. Anhydrous ammonia was introduced during approximately 30 min. into a stirred solution (protected from atmospheric moisture with a tube of calcium sulfate) of 84 Gm. of the anhydride (L-IV) in 1 L. of freshly distilled chloroform, 500 ml. of anhydrous ether, and 150 ml. of dry, purified dioxane at 0°. The mixture was stirred at 0° for an additional 75 min., the solvents were removed *in vacuo* at 30–40°, the residue was dissolved in 700 ml. of water, and the aqueous solution was acidified to pH 3.4 at 0°. The precipitated product was washed four times with 300-ml. portions of water and recrystallized from 1.8 L. of water: yield, 54.6 Gm. (61%); m.p. 174–175°; $[\alpha]_D^{25}$ −7.1° (c = 2.00 in methanol). Lit. m.p. 175° (48), 174.5–175° (51); $[\alpha]_D^{19}$ −6.0° (methanol) (51).

N^2-Benzyloxycarbonyl-D-isoglutamine (D-V)—*N*-Benzyloxycarbonyl-D-glutamic acid (D-III: m.p. 122°; $[\alpha]_D^{25}$ +7.7°, c = 10.0 in glacial acetic acid) was prepared by the method of Klieger and Gibian (52) and purified by the procedure used for the L-isomer. It was converted *via* *N*-benzyloxycarbonyl-D-glutamic anhydride (52) (D-IV: 84% yield; m.p. 92–93°; $[\alpha]_D^{25}$ +42.6°, c = 10.0 in glacial acetic acid) to D-V (56% yield; m.p. 174°; $[\alpha]_D^{25}$ +6.1°, c = 1.96 in methanol) by the procedures used in the preparation of the L-isomer. Klieger and Gibian report specific rotations of +7.6° and +43.1° for D-III and D-IV, respectively.

D-Isoglutamine (D-VI)—A solution of 8.0 Gm. of D-V, 680 ml. of 50% aqueous methanol, and 2 ml. of acetic acid was prepared and was treated with hydrogen in the presence of 5% palladium-charcoal catalyst (2 Gm.) at atmospheric pressure with stirring for 2 hr. (Slight warming may be required to prepare the 50% methanol solution of D-V, and rewarming to 35–40° during the early part of the hydrogenation may be necessary if some precipitation occurs.) The system was flushed with fresh hydrogen after 15- and 75-min. intervals. The filtrate from the catalyst was evaporated to dryness *in vacuo* at 25–30°, and the residue was dissolved in 25 ml. of water and reprecipitated with 250 ml. of acetone. The white precipitate was collected by filtration from the chilled mixture, washed with acetone, and dried *in vacuo* over phosphorus pentoxide at room temperature: yield, 3.78 Gm. (90%); m.p. 188°; $[\alpha]_D^{22}$ −20.6° (c = 5.39 in water). Recrystallization of 2.1 Gm. of crude product from water (20 ml.) and acetone (120 ml.) gave 1.95 Gm. (93% recovery); m.p. 188°; $[\alpha]_D^{22}$ −21.3° (c = 5.41 in water).

Anal.—Calcd. for $C_5H_{10}N_2O_3$: C, 41.09; H, 6.90; N, 19.17. Found: C, 41.17; H, 6.94; N, 19.03.

L-Isoglutamine (L-VI) was prepared from L-V by the procedure used for D-VI: yield, 89%; m.p. 187° (Heizbank), 178–179° (capillary); $[\alpha]_D^{22}$ +20.6°(c = 5.4 in water). Lit. m.p. 186–186.5° (51); $[\alpha]_D^{22}$ + 21.1° (48), + 21.2° (51).

N^2-Phthaloyl-L-isoglutamine (L-VII)—To a cold (0–5°) solution consisting of 6.9 Gm. (47 mmoles) of L-isoglutamine (L-VI), 7.0 Gm. (56.5 mmoles) of sodium carbonate monohydrate, and 100 ml. of water was added 14.6 Gm. (66.6 mmoles) of *N*-ethoxycarbonylphthalimide (18), and the resulting suspension was stirred vigorously for 10 min. at 0–5°. The initial pH was approximately 9. The ice bath was removed, and the mixture was stirred for 50 min. as it warmed to room temperature. The unreacted *N*-ethoxycarbonylphthalimide was removed by filtration, the filtrate was acidified at 0° to pH 4 with concentrated hydrochloric acid, and the solution was allowed to stand (for about 10 min.) until a white precipitate began to form. The mixture was then acidified further to pH 2, stirred at 0–5° for 1 hr., and filtered. The precipitate was washed with three 20-ml. portions of water at 0–5° and dried *in vacuo* over phosphorus pentoxide at room temperature. A solution of the product (m.p. 150–151°) in 125 ml. of hot ethanol was diluted with 100 ml. of petroleum ether (b.p. 30–60°), cooled slowly, and stored at 0–5° for 2 hr. The recrystallized product was collected by filtration, washed with petroleum ether, and dried as before: yield, 8.3 Gm. (63%); m.p. 151–152° and 158–160°; $[\alpha]_D^{25}$ −27±0.5°(c = 2 in DMF).

Anal.—Calcd. for $C_{13}H_{12}N_2O_5$: C, 56.52; H, 4.38; N, 10.14. Found: C, 56.46; H, 4.42; N, 10.11.

In view of the facile formation of thalidomide from L-VII by methods described below, the product of this reaction was examined by TLC (95:5 chloroform–methanol). At the high spotting level of 500 mcg. a trace amount of thalidomide was detected in the crude product, but not in the recrystallized sample. Schröder and Klieger (41) reported a melting point of 122–124° and did not give $[\alpha]_D$. We have sometimes observed melting of apparently pure samples in this temperature range or lower. For example, one specimen melted at 110–120°, resolidified, and remelted at 150°; the analytical data (C, 56.41; H, 4.40; N, 10.24) and rotation (−27.2°) were satisfactory. Most specimens would melt at 150–152° (Heizbank or capillary) and, when induced to resolidify, would remelt at 158–161°.

The procedure described above was similar to that used by Nefkens, Tesser, and Nivard (18) to prepare phthaloyl-L-glutamic acid. The studies of Williams (45) on the stability of DL-thalidomide and those of Tipson (20) on phthaloyl-L-glutamic acid suggested that reopening of the phthalimide ring might occur in some degree in the basic solution. Therefore, a similar experiment was performed in a less basic solution in which the initial, millimolar proportions of L-isoglutamine, *N*-ethoxycarbonylphthalimide, and sodium carbonate monohydrate were 10:13.8:1.58 in 25 ml. of water. The pH of the mixture at the beginning was 7.4, and solid sodium carbonate monohydrate (6.22 mmoles) was added in portions

so as to maintain the pH at 7.3–7.7. The reaction time after the removal of the mixture from the ice bath was 70 min. This modified procedure did not give improved results; the product, isolated as before, was obtained in 56% yield; m.p 150°; $[\alpha]_D^{25}$ −27.2°(c = 2 in DMF).

N^2-Phthaloyl-D-isoglutamine (D-VII) was prepared by the first procedure described above: yield, 64%; m.p. 151°; $[\alpha]_D^{25}$ + 26.5 ± 0.5° (c = 2.0 in DMF). Found: C, 56.79; H, 4.09; N, 10.06. The infrared spectrum was identical with that of the L-isomer.

L-Thalidomide (L-N-(2,6-Dioxo-3-piperidyl)phthalimide) (L-IX)—A solution of 2.00 Gm. (7.25 mmoles) of phthaloyl-L-isoglutamine (L-VII) in 50 ml. of dry DMF was cooled to −5 to 0° in an ice-salt bath. To the cold solution, which was under a current of nitrogen and was protected from moisture with a tube of calcium sulfate, 0.65 ml. (9 mmoles) of thionyl chloride was added dropwise with vigorous stirring during 4 min.[7] The solution was then stirred at −5 to 0° for 1 hr. and poured slowly (4 min.) into a mechanically stirred mixture of 1.78 Gm. (18.1 mmoles) of potassium acetate, 150 ml. of ice-cold water, and 75 Gm. of crushed ice. The white precipitate was collected after 30 min. of stirring, washed with three 10-ml. portions of cold water, and dried *in vacuo* over phosphorus pentoxide at room temperature: yield, 1.63 Gm. (87%); $[\alpha]_D^{25}$ −65.5°(c = 2.00 in dry DMF). Values of $[\alpha]_D^{25}$ (c = 2 in dry DMF) of the products of several experiments in which the reaction times were 0.5–2 hr. were 64 ± 1.5°; melting temperatures were similar to those of purified specimens.

Specimens of L-thalidomide were purified by reprecipitation from 1:4 (v/v) DMF–water[8] as follows. A solution of a specimen of L-thalidomide (55–65 mg./ml.) in dry DMF was filtered and chilled to −5 to 0°. Cold water (4 volumes) was introduced dropwise with vigorous mechanical stirring at a rate (20–40 min.) that kept the temperature at 0 ± 4°. The mixture was stirred at 0° for an additional 0.5 hr.; and the precipitate was collected on a filter, washed with cold water, and dried *in vacuo* over phosphorus pentoxide at room temperature. The recovery after each reprecipitation was 90–94%. The product obtained from the reaction described above was recrystallized three times from DMF–water, the first recrystallization being performed on the same day that the reaction was performed. The optical rotation was essentially unchanged after the first reprecipitation; $[\alpha]_D^{25}$ −64.6 ± 0.5° (c = 2.00 in DMF).

Anal.—Calcd. for $C_{13}H_{10}N_2O_4$: C, 60.46; H, 3.91; N, 10.85. Found: C, 60.63; H, 3.73; N, 10.94.

D-, L-, and DL-Thalidomide (applied in DMF) moved identically and near the front on thin-layer plates of silica gel developed in 95:5 chloroform–methanol or in 85:15 benzene–methanol. DMSO-d_6 solutions (prepared without heating) of D-, L-, and DL-thalidomide gave identical NMR spectra. The melting point observed for L-thalidomide depended on the techniques used in the determination, the variability being due evidently to thermal racemization. Pure specimens melted at 244–245° when sprinkled along the gradiently heated bar of a Kofler Heizbank apparatus. Specimens that melted in this range would resolidify and remelt at a higher temperature, usually near the melting point of DL-thalidomide. Melting in the region of 240–250° could be observed in a capillary tube, provided that the specimen was inserted near its melting point.

Reference infrared spectra recorded for specimens obtained by recrystallizing commercial DL-thalidomide from dioxane, from 1:4 DMF–water by the procedure described for the optical isomers, or from glacial acetic acid displayed minor differences. The spectra of an untreated commercial sample, the specimen from dioxane, and several specimens prepared by the cyanomethyl ester method (below) were all identical with a subsequently published spectrum (43). The spectra of L- and D-thalidomide were identical with the published spectrum of DL-thalidomide except that a broad, weak band near 860–850 cm.$^{-1}$ in the spectrum of DL-IX was replaced by a weak, poorly resolved doublet near 850 and 830 cm.$^{-1}$ in the spectra of the optical isomers. The spectra of specimens of DL-IX (either commercial or prepared from L-II or L-VIII) that had been recrystallized from DMF–water (by the procedure described for the optical isomers) differed somewhat more from the spectra of the optical isomers, although the spectra were very similar. The principal differences have already been listed (23); the difference in the 860–800 cm.$^{-1}$ region was more pronounced since the band near 850 cm.$^{-1}$ was considerably weaker in the spectrum of DL-IX recrystallized in this way. Differences between the spectra of D- or L-IX and DL-IX are undoubtedly due to the fact that all spectra were determined in the solid state.

D-Thalidomide (D-IX) was prepared by the thionyl chloride–DMF procedure described for the L-isomer: yield of crude product, 85%; m.p. (Kofler Heizbank), 243°; $[\alpha]_D^{25}$ + 63.2° (c = 2.00 in DMF). The D-isomer was reprecipitated from DMF–water by the procedure described for the L-isomer: m.p. 244–245° (variable as for the L-isomer); $[\alpha]_D^{25}$ + 64 ± 0.5° (c = 2.00 in dry DMF). The infrared spectrum was identical with that of L-IX.

Anal.—Found: C, 60.52; H, 3.68; N, 10.76.

Optical Rotatory Stability of L-Thalidomide and L-VII—Since it was considered possible that trace amounts of water in DMF solutions of thalidomide and L-VII might effect some hydrolysis, observations of the specific rotation over a period of time were first made with solutions prepared from DMF containing small amounts of water. The amount of water was determined by vapor-phase chromatography. A solution of a recrystallized specimen of L-thalidomide in DMF, containing less than 0.1% water, was allowed to stand for 18 hr. The initial (−63.4°, determined within 20 min. of the addition of DMF) and the final (−63.2°) rotations (c = 2.0) were in agreement within experimental error. Addition of sufficient water to form an 80% (v/v) DMF solution caused the rotation to drop to −61.4°. This change was presumably due to the change of solvents (DMF to 80% DMF) since values of $[\alpha]_D^{25}$ were in the range of 60.9 ± 0.5° during the next 43 hr., at which time the experiment was dis-

[7] Another experiment was identical except that the thionyl chloride was first dissolved in a small portion of DMF, and this solution was then added similarly. Both the yield (20%) and the optical rotation (−60°) were lower.

[8] A decrease in optical rotation was observed after a crude specimen of L-thalidomide had been recrystallized from acetic acid. Dioxane gave a low recovery when used to recrystallize DL-thalidomide.

continued. These data indicate little, if any, degradation. In contrast, a specimen of L-thalidomide obtained directly from a thionyl chloride–DMF procedure showed a decrease in $[\alpha]_D^{25}$ (c = 2) in dry DMF (less than 0.01% water, distilled from calcium hydride and dried further over molecular sieves) from an initial value of −63.5° (determined 5–10 min. after the addition of DMF) to the following values (hr. after initial determination in parentheses): −60.1°(7), −52.8°(24), −47.6°(96), −46.7°(103), −46.4°(119). Values of $[\alpha]_D^{25}$ (c = 1.6) for a solution of the same specimen of L-thalidomide in 80% DMF decreased from an initial value of −61.7° as follows (hr. in parentheses): −58.8°(1), −56.8°(2), −54.7°(3), −52.6(4), −51.3°(6), −43.3°(24), −42.4°(29.5), −39.5°(94), −39.4(118). The infrared spectra of the residues recovered (by evaporation of the solvents *in vacuo*) from the last two solutions after approximately 5 days were intermediate between that of L-thalidomide and that of DL-thalidomide recrystallized from DMF–water.

The specific rotations of a specimen of N^2-phthaloyl-L-isoglutamine (L-VII) in dry DMF (less than 0.01% water) and in 80% (v/v) DMF were within the range of −26.5 ± 0.2° (c = 2.0) and 26.8 ± 0.2° (c = 1.6), respectively, during a 24-hr. observation period.

N^2-Phthaloyl-L-glutamine Cyanomethyl Ester (L-II)—Chloroacetonitrile (1.63 ml.) was added to a mixture (protected from atmospheric moisture with a tube of calcium sulfate) consisting of 3.0 Gm. of phthaloyl-L-glutamine (L-I) (18, 39), 1.6 ml. of anhydrous triethylamine, and 10 ml. of purified, anhydrous dioxane. The reaction mixture was kept at 60°, with stirring, for 1 hr. The solid phase dissolved, and a new solid later precipitated. The reaction mixture was chilled in an ice bath; and the precipitate was separated by filtration, washed with several portions of water, and dried *in vacuo* over phosphorus pentoxide at room temperature: yield, 1.5 Gm. (44%); m.p. 189–190°; $[\alpha]_D^{25}$ −46.4° (c = 2.01 in DMF). A specimen was recrystallized twice from dioxane: m.p. 189–190°; $[\alpha]_D^{25}$ −46.6° (c = 1.98 in DMF).

Anal.—Calcd. for $C_{15}H_{13}N_3O_5$: C, 57.14; H, 4.16; N, 13.33. Found: C, 57.38; H, 4.00; N, 13.12.

N^2-Phthaloyl-L-isoglutamine Cyanomethyl Ester (L-VIII) and Thalidomide from Phthaloyl-L-isoglutamine (L-VII)—A solution of 4.0 Gm. of L-VII 3.2 ml. of triethylamine, 3.2 ml. of chloroacetonitrile, and 20 ml. of purified, anhydrous dioxane was stirred at 60–65° for 4 hr. Examination of aliquots from an earlier experiment by TLC had shown that a considerable quantity of L-VII remained after 1.25 hr. The mixture, containing a precipitate, was poured into 150 ml. of ether; the new mixture was stirred at 0° for 30 min.; the ether was decanted; the gummy residue was treated again with ether (50 ml.), which was also decanted; and the flocculent residue was stirred at 0° with 150 ml. of water. After the solid had been separated by filtration, washed with water, and dried *in vacuo* at room temperature over phosphorus pentoxide, it weighed 3.2 Gm.; m.p. 163° to a cloudy liquid; $[\alpha]_D^{25}$ −35° (c = 2.0 in DMF). TLC (85:15 benzene–methanol) indicated that this fraction was a mixture of L-VIII and thalidomide; the latter presumably was formed from L-VIII.

Evaporating the solvent from the ether decantates and stirring the residue with cold water gave 0.4 Gm. of solid (m.p. 238–244°, $[\alpha]_D^{25}$ −56° in DMF) that was shown by TLC (1 spot) and infrared spectroscopy to be thalidomide.
