Recrystallization of the first fraction (3.2 Gm.) from dioxane–petroleum ether gave a first crop of 1.9 Gm. (m.p. 170°, $[\alpha]_D^{25}$ −26.8°) and a second crop, by further dilution with petroleum ether, of 701 mg. of impure thalidomide (m.p. 230–250°, $[\alpha]_D^{25}$ −42.6°), which was identified by TLC. Recrystallization of the first crop (1.9 Gm.) from dioxane–petroleum ether gave 1.5 Gm. of L-VIII: m.p. 173–174°; $[\alpha]_D^{25}$ −25.3° (c = 2.00 in dry DMF); TLC (85:15 benzene–methanol), 1 spot.

Anal.—Calcd. for $C_{15}H_{13}N_3O_5$: C, 57.14; H, 4.16; N, 13.33. Found: C, 57.22; H, 4.31; N, 13.25.

DL-Thalidomide from the Cyanomethyl Esters (L-II and L-VIII)—A solution of 368 mg. (1.17 mmoles) of phthaloyl-L-glutamine cyanomethyl ester (L-II) in 5 ml. of dry dimethyl sulfoxide was added dropwise during 10 min. to a stirred mixture of 63 mg. (1.17 mmoles) of sodium methoxide and 10 ml. of dry dimethyl sulfoxide at 20°. The dimethyl sulfoxide had been distilled from calcium hydride, and the reaction mixture was protected from atmospheric moisture by a stream of nitrogen and a calcium sulfate drying tube. After the addition had been completed, 0.1 ml. of glacial acetic acid was added to neutralize the base and the solution was concentrated *in vacuo* at room temperature to a paste. Addition of 20 ml. of water produced a solid that was collected by filtration, washed with water, and dried *in vacuo* at room temperature: yield, 212 mg. (70%); m.p. 269–273° (cap.); $[\alpha]_D^{25}$ 0.0°(c = 2.06 in dioxane).

In another experiment the amount of sodium methoxide was reduced to 13% on a molar basis, and the appearance of thalidomide and the disappearance of the cyanomethyl ester (L-II) were monitored by TLC (9:1 chloroform–methanol). The disappearance of L-II was essentially complete within 3 hr.; and thalidomide, isolated by the procedure described above, was obtained in 80% yield. It also was racemic.

Treatment of phthaloyl-L-isoglutamine cyanomethyl ester (L-VIII) with sodium methoxide in dimethyl sulfoxide likewise caused racemization. DL-Thalidomide was isolated in 78% yield from an experiment, analogous to the first experiment described above, in which L-VIII was added to an equimolar amount of sodium methoxide during 10 min. From an experiment in which L-VIII was treated with 16 mole percent of sodium methoxide for 2.5 hr. by the second procedure described for L-II, DL-thalidomide was also obtained in 78% yield.[9] Isolation of thalidomide from both of these experiments was effected by pouring the reaction solutions into a mixture of crushed ice and water. All samples of DL-thalidomide obtained from L-II and L-VIII were identified by their melting points and infrared spectra (compared with commercial material), by TLC, and by the absence of optical rotation in DMF or dioxane.

[9] The reaction time employed in this experiment was similar to that used for L-II. Since L-VIII cyclizes more readily, a much shorter reaction time might be adequate and might afford optically active thalidomide.

Comparison of L-I and L-VII as Precursors of L-Thalidomide—*Thionyl Chloride–DMF Method*—In identical experiments carried out simultaneously, phthaloyl-L-glutamine (L-I) and phthaloyl-L-isoglutamine (L-VII) were treated with thionyl chloride in DMF. The procedures were identical with that described above for the preparation of L-thalidomide except that the reactions were allowed to proceed for 2 hr. From L-VII, L-thalidomide was obtained in 76% yield; $[\alpha]_D^{25}$ −64.5° (c = 2.00 in DMF). From L-I, only a small quantity of a pink solid was obtained (by exactly the same isolation procedure) $[\alpha]_D^{25}$ −83° (c = 1.0 in DMF). This material contained sulfur (5.9%), and TLC revealed the presence of 2–3 components, one of which was thalidomide. The amount (150 mg. from 1.600 Gm. of L-I) corresponded to a yield of 10%, calculated as thalidomide. A second crop amounted to 12 mg., and finally a third portion of 173 mg. (11.5%) of material shown by its infrared spectrum and by TLC (2 spots) to be impure thalidomide was isolated from the filtrate residue.

Another pair of identical experiments in which the reaction time was 0.5 hr. gave similar results in that L-VII gave L-thalidomide (80% yield, $[\alpha]_D^{25}$ −64.2°, c = 2.00 in DMF), whereas L-I afforded only a small amount (9% calculated as thalidomide) of material that was similar [judged by its infrared spectrum, optical rotation (−88°), and thin-layer chromatogram] to the crude product of the 2-hr. reaction.

N,N′-Carbonyldiimidazole Method—To a solution of 1.265 Gm. of L-VII in 40 ml. of dry DMF (distilled from calcium hydride) was added 0.810 Gm. (91% pure by gas chromatographic determination of liberated carbon dioxide) of *N,N′*-carbonyldiimidazole (40). The reaction solution (protected from moisture by calcium sulfate) was stirred in an atmosphere of nitrogen for 96 hr. at room temperature. Glacial acetic acid (0.34 ml.) was added to the solution, the mixture was concentrated *in vacuo* at room temperature to a viscous oil, and the mixture resulting from the addition of 20 ml. of water was stirred at 0° for 30 min. A white precipitate was removed by filtration, washed with water, and dried *in vacuo* at room temperature: yield, 491 mg. (41%); $[\alpha]_D^{25}$ −57.9° (c = 1.99, DMF). Two reprecipitations from DMF–water (1:4) effected a modest increase in the specific rotation; $[\alpha]_D^{25}$ −59° (c = 2 in DMF).

An identical experiment with phthaloyl-L-glutamine (L-I) afforded DL-thalidomide in 30% yield. The infrared spectrum was identical with that of a commercial specimen. Recrystallization of the DL-thalidomide obtained from L-I from DMF–water (1:4) gave a specimen, m.p. 274–276° (cap.) with an infrared spectrum identical with that of the commercial specimen after it had been recrystallized in the same way; m.p. 275–276° (cap.).

Cyanomethyl Ester Method—As shown above, the cyanomethyl esters of both phthaloyl-L-glutamine and phthaloyl-L-isoglutamine were converted to DL-thalidomide by sodium methoxide in DMSO. In view of the fact that optically active thalidomide was isolated during the preparation of L-VIII, a weaker base was tried. A solution (under a nitrogen atmosphere and protected from moisture with a tube of calcium sulfate) of 315 mg. (1 mmole) of L-VIII, 16.5 ml. of dry DMSO, and 3.5 ml. of a solution containing 0.04 ml. of triethylamine per ml. of DMSO (1 mmole of triethylamine) was stirred at 34–37° for 72 hr. The formation of thalidomide was monitored by TLC (85:15 benzene–methanol). The solution was neutralized with glacial acetic acid and poured into a mixture of 40 Gm. of water and 40 Gm. of crushed ice. After 30 min. of stirring, the product was collected on a filter, washed with water, and dried *in vacuo* at room temperature: yield, 189 mg. (73%, not corrected for the removal of aliquots for TLC); $[\alpha]_D^{25}$ −45.3° (c = 2.02, DMF); TLC showed only thalidomide. The infrared spectrum was identical with that of L-thalidomide except that the doublet at 850 and 830 cm.$^{-1}$ in the L-thalidomide spectrum was replaced by a band at 850 cm.$^{-1}$ with a shoulder at 830 cm.$^{-1}$.

An identical experiment with the glutamine derivative (L-II) caused racemization without appreciable cyclization. Phthaloyl-DL-glutamine cyanomethyl ester was isolated by pouring the reaction solution into 40 ml. of a mixture of water and crushed ice: yield, 263 mg. (84%); m.p. 176–177°; $[\alpha]_D^{25}$ 0.0° (c = 2.02, DMF). This material and the starting material (L-isomer) traveled together on thin-layer plates (9:1 chloroform–methanol) and gave very similar infrared spectra.

Study of Absorption, Translocation, and Residue Properties of 2,3,5-Triiodobenzoic Acid in Field-Grown Soybeans

By L. A. SPITZNAGLE, J. E. CHRISTIAN, A. J. OHLROGGE, and C. E. BRECKINRIDGE, JR.*

The synthesis of carboxyl-^{14}C-2,3,5-triiodobenzoic acid is described. The translocation, biological half-life, and residues remaining in the plant after application to field-grown soybeans are discussed.

INCREASED KNOWLEDGE of plant metabolism has led to a search for chemicals which stimulate or inhibit the growth of plants. One such chemical is 2,3,5-triiodobenzoic acid, commonly referred to as TIBA. TIBA has been shown by Galston (1) to decrease apical dominance and to affect the flowering of soybean plants, causing an increased number of flowers. Anderson (2) reported that the result of several combined effects is an increased yield of soybeans per acre, making TIBA a useful agricultural chemical. However, since soybean products are used in animal feeds and for human consumption, the residue and metabolism properties of TIBA must be determined prior to general usage.

Wheeler and Johns (3) reported the first synthesis of TIBA by reacting anthranilic acid with iodine monochloride. The product was diazotized, and allowed to react with potassium iodide yielding TIBA. Olivier and Combe (4) were able to obtain 95% of the theoretical yield of TIBA by making minor changes in the method of Wheeler and Johns (3). Munakata and Nakai (5), and Ice, Breckinridge, and Christian (6) described the synthesis of 2(^{131}I),3,5-triiodobenzoic acid. They followed closely the procedure of Olivier and Combe (4) substituting sodium iodide-131 for potassium iodide. Jarboe (7) synthesized 2,3(^{131}I),5(^{131}I)-triiodobenzoic acid by substituting iodine-131 monochloride for iodine monochloride.

EXPERIMENTAL

Synthesis—To facilitate tracing the TIBA molecule through the entire growth period of the soybean plant from the flowering to the bean stage, radioactive TIBA was synthesized containing carbon-14 in the carboxyl position. One hundred millicuries (2.584 Gm.) of anthranilic acid[1] ($C_6H_4{}^{14}CO_2H$-2-NH_2), was suspended in 60 ml. of

0.7 *N* hydrochloric acid and cooled to 0°. Eleven grams (3.5 ml.) of iodine monochloride[2] and 30 ml. of 0.7 *N* hydrochloric acid were added to the cold suspension with stirring. To allow for completion of the reaction, stirring was continued for 48 hr. at room temperature after which excess iodine was reacted with sodium bisulfite. The solution was cooled to 0°, the precipitated reaction product (3,5-diiodoanthranilic* acid)[3] was collected by filtration. The reaction product was partially purified by acid-base reaction, ammonium hydroxide solution was added to give a pH of 9.5. The alkaline solution was filtered through a sintered-glass funnel. Glacial acetic acid was added to give a pH of 3. The solution was cooled to 0° and the resulting crystals of 3,5-diiodoanthranilic* acid collected on a sintered-glass funnel.

The 3,5-diiodoanthranilic* acid was diazotized by dissolving it in 40 ml. of concentrated sulfuric acid and cooling to 0°, followed by slowly adding 4 Gm. of sodium nitrite with stirring. After 2 hr. of cooling and stirring, the diazotized product was poured on ice. Nitrogen dioxide was removed from the solution by bubbling air through the solution for 30 min.

To the cold solution, 12 Gm. of potassium iodide in 12 ml. of water were added slowly with stirring. Nitrogen was removed from the solution by heating, and excess iodine was reacted with a sodium bisulfite solution.

After the solution was cooled to 0°, crude TIBA* was collected on a sintered glass-funnel. Fifteen milliliters of ether and enough hot ethanol to effect solution was added to the crude TIBA* and the solution was filtered. Ten milliliters of water was added, and the solution cooled to 0°. The crystals of TIBA* which formed were dried and weighed, the compound melted at 223–225.5°. The reported melting point for TIBA is 223–226° (3, 8). Approximately 55% of the theoretical yield (5.15 Gm.) of TIBA* (specific activity 16.240 dpm/mcg.[4]) was obtained.

The radiochemical purity of the compound was studied using thin-layer chromatography and autoradiography. Adsorbosil-1 (Applied Science Laboratories, Inc.), 250-μ thick, and a solvent system of petroleum ether (30–60° fraction)–propionic acid (10:1) were used. Nonradioactive compounds were chromatographed simultaneously and located by spraying with a 0.1% methanol solution of bromocresol green. Radioactive spots on the thin-layer plate were scraped from the plate and analyzed by internal liquid scintillation counting techniques to obtain a quantitative evaluation of the components.

The following compounds in addition to the TIBA* were separated: 3,5-diiodobenzoic* acid (1.36% of the radioactivity spotted), 2,5-diiodobenzoic* acid (1.16% of the radioactivity spotted), and an unidentified compound remaining at the origin (3.88% of the radioactivity spotted). Repeated recrystallization failed to improve the radiochemical purity of the compound. Work by another investigator (9) indicates that photochemical degradation occurs during chemical manipulation, resulting in the presence of impurities.

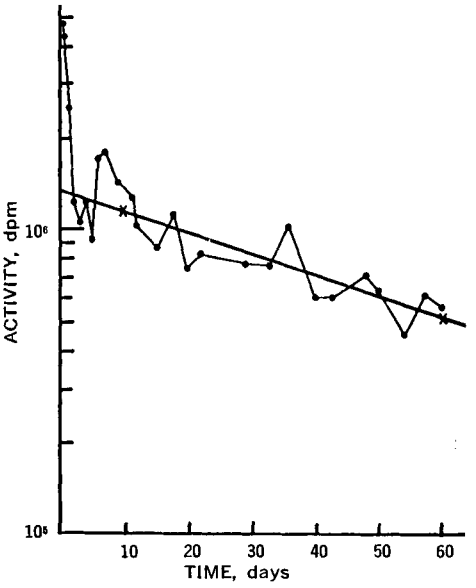

Fig. 1—Carbon-14 activity in soybean plant.

Plant Studies—A soybean plot, which at the beginning of the flowering stage contained approximately 600 plants averaging in the ninth trifoliate stage and about 35.5 cm. (14 in.) in height, was sprayed with a solution of TIBA* in water (650 mg. of TIBA* dissolved in ethanol 95% and brought up to a volume of 3 L. with distilled water). The spray was applied to the soybean plants with a hand sprayer to provide even application at the level of about 1 mg. of TIBA* per plant.

Three plants were taken from the plot at various time intervals (see Fig. 1) up to 60 days after application of the TIBA*, and the remaining plants were harvested at 110 days. Each sample was separated into the following parts: roots, stems, old leaves and old petioles, new leaves and new petioles (those which formed after the ninth trifoliate stage), pods, and seeds. After weighing, the samples were frozen in liquid nitrogen and ground in a blender to reduce the particle size and to provide a uniform mixture.

Five- to ten-gram samples of the plant parts were quantitatively converted to carbon dioxide using a modification of the Van Slyke-Folch wet oxidation procedure described by Jeffay and Alvarez (10). Each sample plus 7 Gm. of potassium iodate and 25 Gm. of chromium trioxide was placed in a suction flask connected to the fritted-glass dispersion tube of a gas-washing tower. Two hundred fifty milliliters of acid mixture[5] was added slowly to the suction flask from a separator. The mixture was boiled for 10 min. and the emitted carbon dioxide collected in 200 ml. of a mixture of ethanolamine and 2-ethoxyethanol (1:2). Heating was then discontinued and the system flushed with dry, carbon dioxide-free air. Controls were run using a known

amount of TIBA* and 10 Gm. of plant material.

The liquid scintillation solution consisted of toluene and 2-ethoxyethanol (1:1), PPO[6] (4 Gm./L.) and dimethyl-POPOP[7] (100 mg./L.). All samples (3 ml. of the ethanolamine solution) were counted in a Tricarb liquid scintillation counter[8] and the results corrected for background and quenching following the method suggested by Schrodt, Gibbs, and Cavanaugh (11).

Results and Discussion—The radioactivity data for the whole soybean plant and the old leaves, Table I, indicated a rapid initial loss of radioactivity. Figures 1 and 2 are semi-log plots of the radioactivity against time for the soybean plant and the old leaves, respectively. At application the total

activity of a plant was 4,767,000 dpm; by 2 days after application the activity found on a plant was 1,200,000 dpm. Since absorption was being studied, the first 2 days were not included in the calculations of the linear regression for the soybean plant and the old leaves. From the linear regression lines shown on the graphs, the biological half-lives were calculated to be 42.5 and 24 days from the soybean plant and the old leaves, respectively. The difference between the half-lives indicated a translocation to other parts of the plant.

To better indicate this translocation, the percent of the carbon-14 in the various plant parts at the various sampling times was determined (Table II) and plotted against time. Figures 3–6 show the

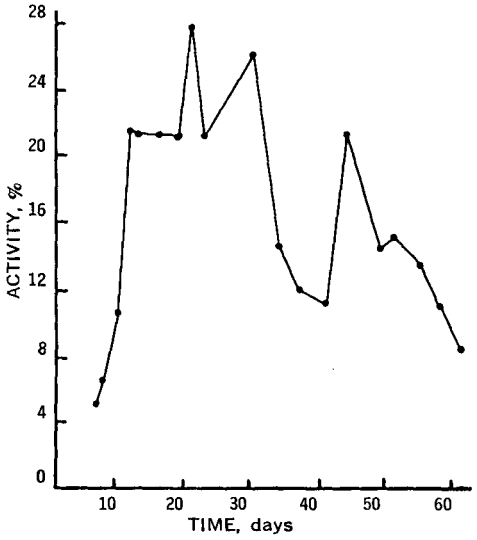

Fig. 3—Percent carbon-14 activity of the soybean plant in new leaves.

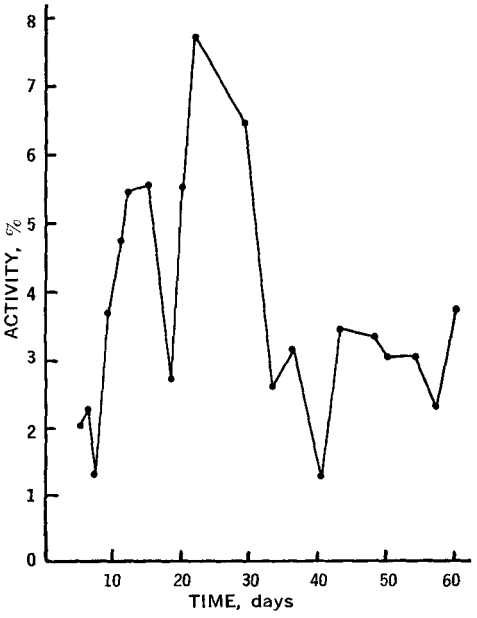

Fig. 4—Percent carbon-14 activity of the soybean plant in new petioles.

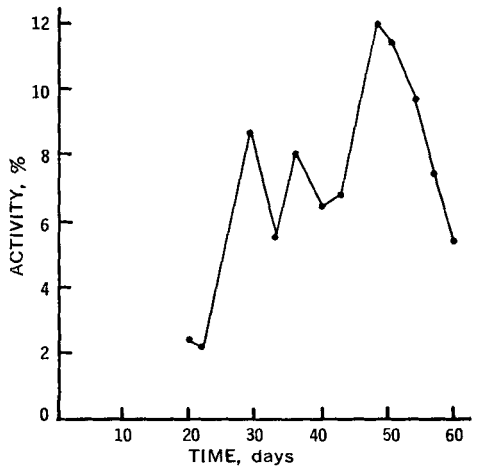

Fig. 5—Percent carbon-14 activity of the soybean plant in pods.

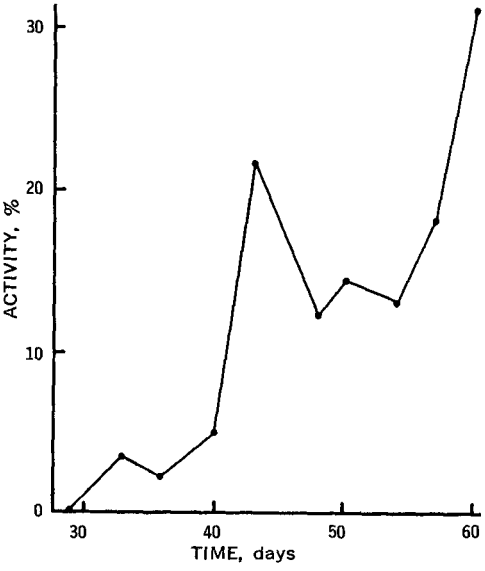

Fig. 6—Percent carbon-14 activity of the soybean plant in seeds.

percent of the carbon-14 activity in the soybean plant found in the new leaves, new petiole, pods, and immature seeds, respectively. From these figures it can be seen that carbon-14 was translocated to sites of new growth within the plant, and that as these parts aged, there was a translocation to newer parts of the plant. Although the seeds accounted for an increasing percentage of the radioactivity in the plant, the actual dpm/Gm. of soybeans did not increase after day 50.

Eleven samples of harvested soybeans were analyzed and the 95 percentile confidence level for the average radioactivity per Gm. of seeds was calculated. The 95 percentile confidence limits equaled 2709 dpm ± 950 dpm/Gm. of seeds, equivalent to 167 ± 59 ng. of TIBA* and/or metabolites per Gm. of seeds.[9]

[9] The 95% confidence interval = mean ± (1.96) (standard error of the mean).

SUMMARY

The plant growth regulator 2,3,5-triiodobenzoic acid containing carbon-14 in the carboxyl position was synthesized and applied to field-grown soybeans. A biological half-life of 42.5 days was found for the radioactivity in the soybean plant. Radioactivity was translocated to sites of new growth within the plant. At harvest the seeds contained a residue equivalent to 167 ng. of TIBA* and/or its metabolites per Gm. Before an assessment of the health hazard associated with the use of this chemical on soybeans can be made, there must be further study as to the nature of the residue.

Mechanism of Action of Phenolic Disinfectants VIII

Association of Phenolic Disinfectants With Proteins

By JON E. STARR and JOSEPH JUDIS

Association of phenol-^{14}C (P-C-14), *p-tert*-amylphenol-^{14}C (PTAP-C-14), and 2, 4-dichlorophenol-^{14}C (DCP-C-14) with human serum and bacterial (*Micrococcus lysodeikticus*) proteins was investigated by means of density gradient ultracentrifugation and Sephadex gel filtration. Definite association between the phenols, PTAP-C-14 and DCP-C-14, and human serum proteins could be demonstrated by sucrose density gradient ultracentrifugation and with Sephadex gel filtration. The major protein in human serum involved in this association appeared to be albumin. Sucrose density gradient ultracentrifugation provided data indicating association of bacterial proteins with the three phenolic compounds, but most clear-cut in the case of PTAP-C-14. Protein binding could explain interference of serum with germicidal effects of phenolic disinfectants and enzyme inhibition and structural damage may account for bactericidal action.

TWO MAJOR CONSIDERATIONS motivated the investigation of the possible association of proteins and phenolic disinfectants. The interference of organic matter with the action of many disinfectants including phenol derivatives is a well recognized, troublesome phenomenon (1) and the authors desired to gain direct evidence for the basis of this interference, namely, whether binding of disinfectant by protein occurs. Secondly, an understanding of the mechanism by which phenolic disinfectants are lethal to bacteria would be much more complete if it could be shown that certain microbial cell components are specifically attacked by these disinfectants. One could presume that if a chemical component of the microbial cell bound phenolic disinfectants, this component could be, hypothetically, the one damaged by these germicides. Proteins, of course, play a major structural and functional role in all living cells and the general toxicity of phenolic disinfectants could be best explained on the basis of affinity for a generally distributed cell component, such as proteins.

The proteins selected for the preliminary studies were human serum, human serum albumin,

and an extract of *Micrococcus lysodeikticus* cells. The methods chosen for demonstrating possible binding of phenolic disinfectants by these proteins or more specifically, a protein-disinfectant complex, were density gradient centrifugation and Sephadex gel filtration. In previous work (2) three carbon-14 labeled phenol derivatives were used, phenol, 2, 4-dichlorophenol, and *p-tert*-amylphenol. The same compounds were utilized in the studies described here.

MATERIALS AND METHODS

Materials—The radioactive phenol derivatives used in the experiments were synthesized by New England Nuclear Corporation, Boston, Mass., and had the following specific activities: phenol-^{14}C (P-C-14), 50 μc. per 3.04 mg.; 2, 4-dichlorophenol-^{14}C (DCP-C-14), 50 μc. per 12.0 mg.; and *p-tert*-amylphenol-^{14}C (PTAP-C-14), 50 μc. per 30.4 mg. The label in all three compounds was uniformly distributed in the ring. Phenol-C-14 was used in aqueous stock solution while the other derivatives were dissolved in 0.1% sodium hydroxide and all stock solutions contained 5 μc./ml.

Human serum (tissue culture grade) was obtained from Difco Laboratories, Inc., Detroit, Mich. Albumin, human crystalline 4x, and crystalline D-sucrose, C.P., were obtained from Nutritional Biochemicals Corporation, Cleveland, Ohio. The albumin was reconstituted in distilled water to a concentration of 42 mg./ml. Sephadex G-200 and G-25 obtained from AB Pharmacia, Uppsala, Sweden, were used in the gel filtration experiments. All other materials used were reagent grade.

For the preparation of the bacterial extracts, *M. lysodeikticus* ATCC 4698 was grown on the medium previously used (2) and prepared in the following manner. Cells were washed twice with distilled water, and resuspended in distilled water to give a 1:3 w/v ratio. Glass beads measuring 25 μ in diameter were added in a 1:3 v/v ratio and the suspension subjected to sonic disintegration for 25 min. at 5° using a Branson sonifier, Branson Instruments Inc., Danbury, Conn., at the maximum power output. The material was then centrifuged at 12,000 × g for 10 min., and the supernatant, recentrifuged once. The supernatant contained 12.5 mg. of protein per ml., using the Lowry-Folin method (3) with crystalline human serum albumin as a standard.

Methods—Radio-assay was carried on in a Nuclear-Chicago Liquid Scintillation System and an aliquot of a sample was diluted when necessary with enough distilled water to produce a total volume of 2.0 ml., which was added to 13 ml. of a phosphor solution (2). Enough counts were accumulated in all experiments to give a nine-tenths error of less than 5%.

Density gradient separations were carried out as follows. In all experiments, 0.3 ml. of protein solution was added to 0.2 ml. of diluted radioactive phenol derivative. The stock solutions of the latter were diluted 8:50 (0.8 ml. of phenol derivative plus 4.2 ml. of 0.1% sodium hydroxide). In the experiments in which bacterial extract was used the ratio of the latter to the phenol derivative solutions was 9:1, using the stock solution of the phenol derivative undiluted. All mixtures were incubated for 10 min. at 25°. Gradients of 2–20% sucrose in 0.067 *M* tris(hydroxymethyl)aminomethane hydrochloride (TRIS-HCl), with a pH of 7.4, were used in the density gradient analysis involving human serum, serum albumin, and the radioactive phenols. Gradients of 1–20% sucrose in 0.067 *M* TRIS-HCl pH 7.4, were used in the studies with the bacterial extract. The gradients were produced in 5 ml. lusteroid centrifuge tubes using a gradient former constructed after the design of Britten and Roberts (4). In all of the analyses except those involving the bacterial extracts, 0.1 ml. of the sample was layered on the top of the sucrose gradient. In the experiments in which bacterial extract was used, 0.15 ml. of sample was taken for density gradient analysis. The tubes were centrifuged for 2–10 hr. at 165,000 × g at 3.5° in a Spinco model L-2 preparative ultracentrifuge using a SW50-L swinging bucket rotor. The contents of the tube were fractionated by piercing the bottom of the tube with a needle and eight drops were collected per fraction. Each fraction was diluted with 2.0 ml. of distilled water in all cases except those experiments involving the bacterial extract, in which case the fractions were diluted with 1.5 ml. of distilled water. One milliliter of each fraction was analyzed for protein using the Lowry-Folin method (3) and another aliquot of each diluted fraction was taken for measurement of radioactivity.

The procedure for gel filtration studies involving PTAP-C-14 was as follows. Sephadex G-200 was allowed to come to equilibrium in 1.0 *M* sodium chloride solution and a bed 30 cm. in height was prepared in a 2.5 × 45 cm. column obtained from AB Pharmacia, Uppsala, Sweden. The column was washed with 1.0 *M* sodium chloride for 3 days to stabilize the bed and a nylon gauze was placed on the surface of the bed to minimize its disruption when layering the samples (5). Reaction mixtures containing 2.0 ml. of human serum and 0.5 ml. of PTAP-C-14 (0.2 ml. of stock solution and 9.8 ml. of 0.1% sodium hydroxide), were incubated for 10 min. at 25°. Two milliliters of the mixture was layered on the bed and eluted with 1.0 *M* sodium chloride. Three-milliliter fractions of the eluant were collected on a fraction collector and 1 ml. of each fraction was diluted with 2.0 ml. of distilled water and the protein content determined by measuring light absorption at 279 mμ in a Bausch and Lomb Spectronic 600 spectrophotometer. The remaining 2.0 ml. of each fraction was used for measurement of radioactivity. In the experiments in which DCP-C-14 was used, Sephadex G-25 replaced G-200; 0.3 *M* sodium chloride was used as the eluant; and the reaction mixture consisted of 1.0 ml. of human serum, 1.0 ml. of 0.067 *M* phosphate buffer at pH 7.4, and 0.5 ml. DCP-C-14 (0.3 ml. stock solution and 2.7 ml. of 0.1% sodium hydroxide). Sephadex G-25 was used in place of Sephadex G-200 in the experiments with DCP-C-14 because Sephadex G-25 interacts less than G-200 with phenolic compounds (5) thus offering less competition to the proteins in the formation of complexes of the latter.

RESULTS AND DISCUSSION

Figures 1 through 3 represent the results of the density gradient studies of mixtures of human

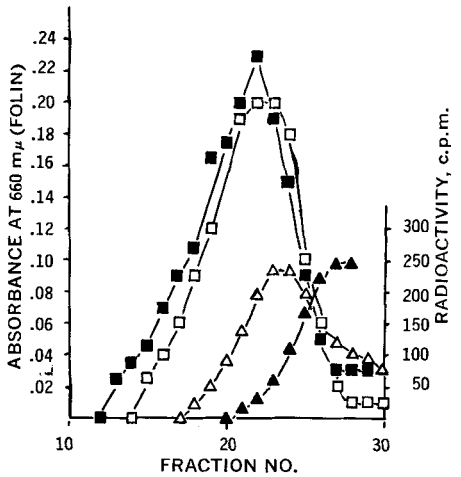

Fig. 1—Density gradient ultracentrifugation of human serum, PTAP-C-14, and a mixture of human serum and PTAP-C-14. The mixture was incubated for 10 min. at 25°. One-tenth ml. of the mixture was layered on a 2–20% sucrose gradient, centrifuged at 165,000 × g at 3.5° for 300 min., fractionated, and analyzed for protein and radioactivity. The initial mixture contained 0.3 ml. serum and 0.2 ml. of isotope (see Materials and Methods). *Key:* ■, *human serum alone;* □, *human serum mixed with PTAP-C-14;* ▲, *PTAP-C-14 alone;* △, *PTAP-C-14 mixed with human serum. In all figures,* □ ■ *refers to data obtained by analysis for protein and* △ ▲ *refers to radioactivity.*

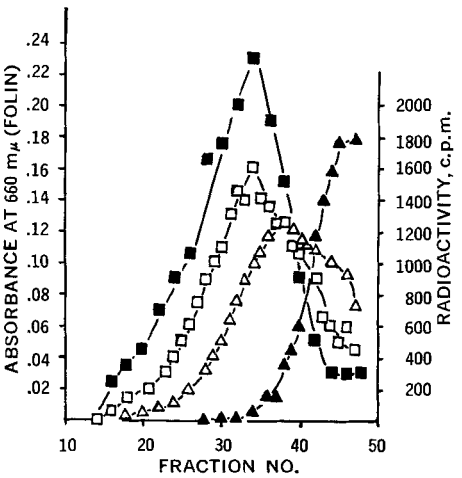

Fig. 2—Density gradient ultracentrifugation of human serum, DCP-C-14, and a mixture of human serum and DCP-C-14. Experimental conditions were the same as in Fig. 1 except the samples were centrifuged for 600 min. Key: ■, *human serum alone;* □, *human serum mixed with DCP-C-14;* ▲, *DCP-C-14 alone;* △, *DCP-C-14 mixed with human serum.*

serum and the radioactive derivatives of phenol. As one would expect, the phenol derivatives moved very little in the centrifugal field employed while the human serum proteins moved a considerable distance. The radioactive peaks obtained upon analysis of the mixtures of phenol derivatives with human serum are taken to represent bound phenol derivative. In most cases, the radioactive peak

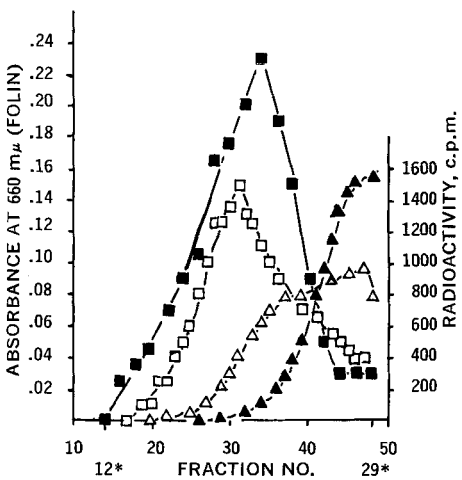

Fig. 3—Density gradient ultracentrifugation of human serum, P-C-14, and a mixture of human serum and P-C-14. Experimental conditions were the same as in Fig. 1. Key: ■, *human serum alone;* □, *human serum mixed with P-C-14;* ▲, *P-C-14 alone;* △, *P-C-14 mixed with human serum.*

from the mixtures did not correspond exactly with that of free protein and this slight difference in mobility may be due to the change of properties of the proteins when they are in combination with phenol derivatives. Chen (6) points out that serum albumin may have different physical properties when combined with fatty acids. The data in Fig. 3 would suggest that phenol does not form as tight a complex with serum proteins since the radioactive peak obtained from the phenol-human serum mixture is not as distinct nor was it located as close to the protein peak as it was in the cases of the other two phenol derivatives.

The data obtained from the experiments in which human serum albumin was substituted for human serum are given in Figs. 4 through 6. The results are similar to those obtained with human serum including the suggestion of relatively poor binding of phenol. While the radioactive peak obtained on analysis of phenol-albumin mixtures was in a significantly different position from that of free phenol (Fig. 6), the former certainly did not correspond well to the curve representing albumin.

Previous work from this laboratory (2) indicated that bacterial extracts did bind phenol derivatives in that the extracts interfered with binding of the phenol derivatives to whole cells. Density gradient analysis of mixtures of bacterial extract and radioactive phenols did show evidence for protein-phenol derivative complexes but most conclusively in the case of PTAP-C-14 (Fig. 7). The radioactive peak obtained in mixtures of DCP-C-14 and P-C-14 (Figs. 8 and 9) were significantly different in location from free phenol derivatives but not as distinctly as in the case of PTAP-C-14.

Evidence for protein-phenol derivative complexes was more unequivocal in the experiments utilizing gel filtration as the analytical method (Figs. 10 through 13). For example, PTAP-C-14 had a distinctly different rate of elution from the human serum proteins (Fig. 10) when subjected to gel filtration individually, but in a mixture, a radioactive peak appeared at a position (5) identical

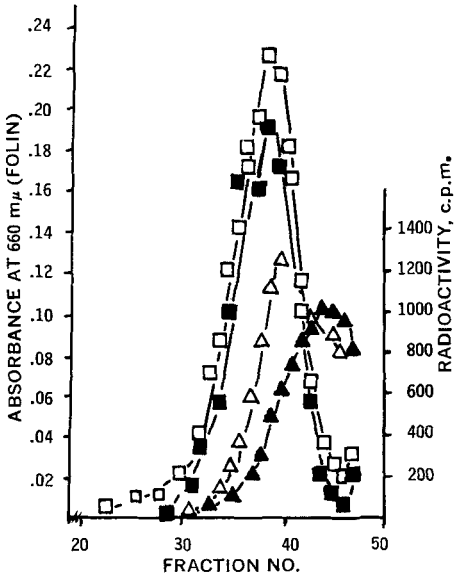

Fig. 4—Density gradient ultracentrifugation of human serum albumin, PTAP-C-14, and a mixture of serum albumin and PTAP-C-14. Experimental conditions were the same as in Fig. 1. Key: ■, albumin alone; □, albumin mixed with PTAP-C-14; ▲, PTAP-C-14 alone; △, PTAP-C-14 mixed with albumin.

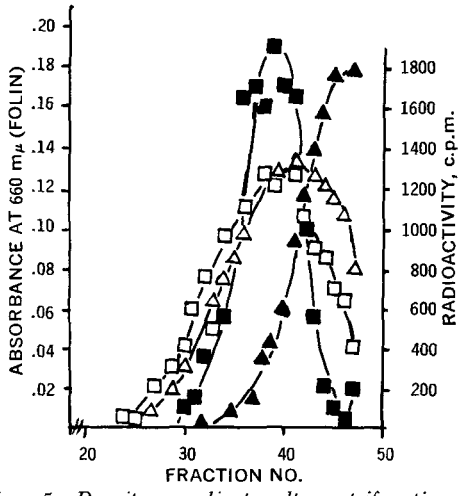

Fig. 5—Density gradient ultracentrifugation of human serum albumin, DCP-C-14, and a mixture of serum albumin and DCP-C-14. Experimental conditions as for Fig. 1. Key: ■, albumin alone; □, albumin mixed with DCP-C-14; ▲, DCP-C-14 alone; △, DCP-C-14 mixed with albumin.

with that of the human serum albumin peak (Fig. 11). Similar results were obtained with human serum and DCP-C-14 (Figs. 12 and 13) although in these experiments, the human serum proteins did not separate since Sephadex G-25 was used instead of G-200. Phenol-C-14 was not included in this series because preliminary experiments demonstrating definite association of the other two phenol derivatives with serum proteins indicated no binding of phenol-C-14.

In the opinion of the authors, the experimental

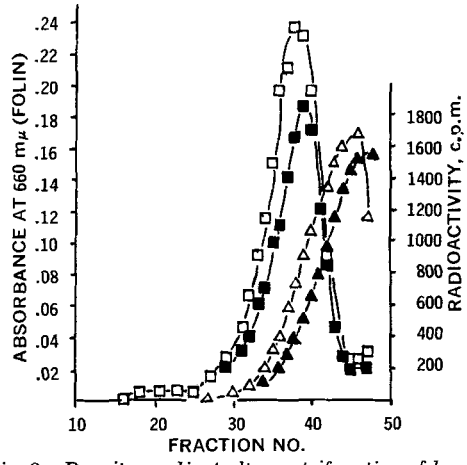

Fig. 6—Density gradient ultracentrifugation of human serum albumin, P-C-14, and a mixture of serum albumin and P-C-14. Experimental conditions as in Fig. 1. Key: ■, albumin alone; □, albumin mixed with P-C-14; ▲, P-C-14 alone; △, P-C-14 mixed with albumin.

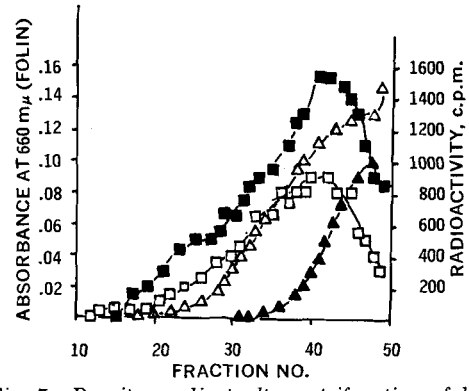

Fig. 7—Density gradient ultracentrifugation of bacterial extract, PTAP-C-14, and a mixture of bacterial extract and PTAP-C-14. Changes in experimental conditions from those in Fig. 1 were that 0.15 ml. of sample was layered on a 1–20% sucrose gradient, and centrifuged for 180 min. The initial mixture contained 0.9 ml. of bacterial extract and 0.1 ml. of phenol derivative (see Methods and Materials*). Key: ■, bacterial sonicate alone; □, bacterial sonicate mixed with PTAP-C-14; ▲, PTAP-C-14 alone; △, PTAP-C-14 mixed with bacterial sonicate.*

results present evidence for a protein-phenol disinfectant complex and would thus indicate that phenol derivatives are bound to serum proteins and presumably bacterial proteins, since the latter should constitute the major component of the bacterial extracts and the analytical method used would detect no other high molecular weight compounds other than proteins. These results are in accord with work previously reported from this laboratory (2) and that of Weinbach and Garbus (7–9) who reported the binding of several halophenols including DCP, to albumin. In all of the methods used in the studies reported here, the evidence for a protein-PTAP or DCP complex was much more clear-cut than for a protein-P complex in that the former were characterized by radioactive and protein curves corresponding rather

closely but in the case of the latter, correspondence was relatively poor. It is conceivable that the phenol derivatives did not associate with albumin as such but perhaps some other protein in the albumin fraction. Another explanation for the noncorrespondence of protein and phenol derivative curves could be that the phenol-protein complex had different mobility or rate of elution from those of the protein only. The same data might be considered in terms of relative affinities of the three phenol derivatives for proteins and one might expect that phenol is a poorer disinfectant because it is capable of less or looser binding to proteins. Although the specific activities of the three phenol derivatives were not identical, tightness of binding to proteins was considered to be related to identity of location of radioactivity and protein.

It was hoped that the experiments concerning bacterial extracts would result in clear-cut evidence for the existence of a protein-phenol derivative complex since previous work (2) described experiments indicating binding of phenol derivatives by whole cells. In mixtures of bacterial extracts and disinfectants PTAP-C-14 seemed to be located in a

centrifugal field similarly to protein in the bacterial extract (see Fig. 7), but the same was not true of DCP-C-14 or P-C-14 (Figs. 8 and 9). It is possible that in the process of preparing the bacterial extracts, major components responsible for binding of the phenol derivatives to whole cells were not obtained or were lost in the process of centrifugation of the sonic disintegrates. It is equally conceivable that the major component responsible for binding of phenol derivatives is present in such low concentrations in the extracts that it would not be detected by the method for protein analysis used. In any case, further work is presently in progress to obtain more conclusive evidence for binding of phenol derivatives by a component of these bacterial cells and characterization of this component. In addition, additional studies are being carried on to characterize the nature of binding of serum albumin to phenol derivatives, especially the number and nature of the binding sites involved. In conclusion, it is felt that the data herein presented suggest that phenols do bind to proteins including bacterial proteins and that this phenomenon could well

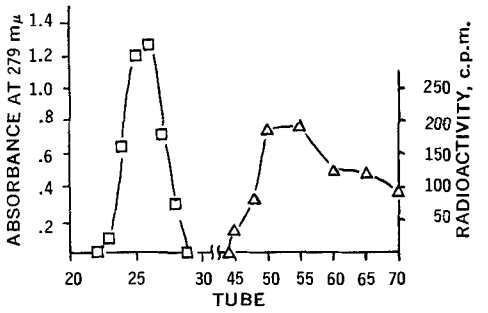

Fig. 12—Gel filtration of human serum and DCP-C-14 separately. Experimental conditions were the same as those used in the experiment represented by Fig. 10 except Sephadex G-25 was used and elution was done with 0.3 M sodium chloride. Key: □, human serum; △, DCP-C-14.

account for the antibacterial action of phenols. If binding is to the proteins in bacterial membranes, this association could well lead to disruption of the integrity of bacterial membranes, a phenomenon which has been demonstrated (10). Inactivation of enzymes by phenol is well documented (7, 11–15) and the latter could be a result of this binding process. It is interesting to note that there appears to be a correlation between the phenol coefficient of a given derivative and the extent of binding to whole bacterial cells. It is hoped that it may be possible to demonstrate a similar correlation in regard to binding to proteins in general.

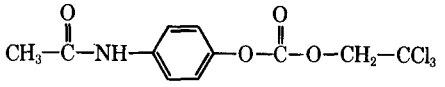
Acetaminophen Prodrugs I

Synthesis, Physicochemical Properties, and Analgesic Activity

By L. W. DITTERT*, H. C. CALDWELL, H. J. ADAMS†, G. M. IRWIN, and J. V. SWINTOSKY*

Carbonate and carboxylic acid ester prodrugs of acetaminophen were prepared. As expected, they had lower water solubilities and higher oil/water partition coefficients than acetaminophen itself. At pH 7.4 the prodrugs were slowly hydrolyzed in phosphate buffer, but human plasma enzymes markedly accelerated the hydrolyses. The LD_{50}'s of some of the compounds in mice suggest that, following oral administration, their solubility properties play a greater part in controlling the availability of acetaminophen than do their hydrolysis rates. Several of the compounds were found to have weak analgesic activity orally in rats supporting the theory that their analgesic activities and toxicities are due to release of acetaminophen. The results show how the carbonate linkage may be employed to create prodrugs and how it is possible to obtain a series of pharmacologically similar compounds possessing vastly different physicochemical properties.

THE SYNTHESIS, physical properties, and *in vitro* hydrolysis behavior of 4-acetamidophenyl 2,2,2-trichloroethyl carbonate (ATC)



ATC

have been reported previously (1). This compound was found to have the same spectrum of pharmacologic activity as a physical mixture of trichloroethanol and acetaminophen, but its analgesic and sedative properties were less intense and persisted for a longer period of time than those of the physical mixture (2). These results suggested that the pharmaceutical properties and dose-time-action profiles of trichloroethanol and acetaminophen can be modified, without modifying their qualitative pharmacologic activity, by combining them in a readily cleavable prodrug carbonate ester. The prodrug ester has physicochemical properties different from those of the parent compounds and may be absorbed at a different rate following oral administration.

It was the purpose of the present study to pursue further the principles of chemical synthesis and physicochemical and biologic evaluation of carbonate prodrugs. The authors wished to determine: (*a*) whether carbonate esters of acetaminophen, other than the trichloroethanol carbonate, would behave as prodrugs; (*b*) whether carboxylic acid esters of acetaminophen would behave as prodrugs; (*c*) which physicochemical properties are important in determining the *in vivo* activities of these compounds; (*d*) to what extent the physical properties of the prodrugs vary with structure; and (*e*) to what degree their *in vitro* cleavage rates vary with structure.

Received July 19, 1967, from Smith Kline & French Laboratories, Philadelphia, PA 19101

Accepted for publication January 22, 1968.

The authors wish to acknowledge the assistance of the following: Philip Goldman and Andrew Sivak for assistance in the syntheses; Dr. R. Walter Thompson and Margaret Carrol for analytical support; William Mann for assistance in the animal work, and Elisabeth Rattie for assistance in the solubility and hydrolysis studies.

EXPERIMENTAL

Chemical Synthesis

Melting points were determined in capillary tubes on a Thomas-Hoover apparatus and are uncorrected. Most of the reactions were run only once. Reported yields are of pure compound.

***p*-Acetamidophenyl Butyrate–Procedure A**—A mixture of 30.2 Gm. (0.2 mole) of 4′-hydroxyacetanilide, 32.4 ml. (0.2 mole) of butyric anhydride, 1 ml. of pyridine, and 50 ml. of tetrahydrofuran was heated on a steam bath for 2.5 hr. The solvent was removed *in vacuo*, and the residue was recrystallized from benzene and washed with ether to give the pure compound in 87% yield.

***p*-Acetamidophenyl Chloroacetate–Procedure B**—To a solution containing 30.2 Gm. (0.2 mole) of 4′-hydroxyacetanilide and 16.2 ml. (0.2 mole) of pyridine in 100 ml. of tetrahydrofuran was added with stirring 15.2 ml. (0.2 mole) of chloroacetyl chloride in 30 min. The mixture was stirred at ambient temperature for 2 hr. The solid was collected and recrystallized twice from ethanol to yield 21% of pure compound.

***p*-Acetamidophenyl 4-Morpholinoacetate Hydrochloride–Procedure C**—A mixture of *p*-acetamidophenyl chloroacetate, morpholine, and triethylamine (0.05 mole of each) in 800 ml. of benzene was heated at reflux for 1 hr. to give an oily precipitate. This precipitate was decolorized with activated carbon in acetone. The hydrochloride salt was then prepared and recrystallized from dilute alcohol.

Bis (*p*-Acetamidophenyl) Succinate–Procedure D—To a chilled solution containing 7.8 Gm. (0.05 mole) of succinoyl chloride and 50 ml. of toluene was added slowly with stirring, a mixture of 4 Gm.

(0.1 mole) of sodium hydroxide and 15.1 Gm. (0.1 mole) of 4′-hydroxyacetanilide in 100 ml. of water. The addition required 15 min., and the reaction was stirred for an additional 1.5 hr. at room temperature. The product was filtered off and washed with water. Two recrystallizations from ethanol gave 33% of a white solid.

p-Acetamidophenyl Hydrogen Succinate–Procedure E—To a mixture of 20 Gm. (0.2 mole) of succinic anhydride in 75 ml. of toluene was added with stirring and cooling under nitrogen a solution of 30.2 Gm. (0.2 mole) of 4′-hydroxyacetanilide and 8 Gm. (0.2 mole) of sodium hydroxide in 100 ml. of water. The addition required 15 min. and the solution was stirred for 1.5 hr. with cooling. The mixture was filtered and the aqueous layer was acidified to give the desired product. The product was dissolved in sodium bicarbonate solution and precipitated with HCl. Finally it was dissolved in tetrahydrofuran, dried over anhydrous magnesium sulfate, diluted with 3 volumes of warm benzene, and cooled to give 28% of pure compound.

Bis (p-Acetamidophenyl) Carbonate–Procedure F—Phosgene was added with stirring under nitrogen to a solution containing 1 mole of 4′-hydroxyacetanilide and 1 mole of sodium hydroxide in 2 L. of water until the reaction mixture was neutral. The product was collected and recrystallized from dilute alcohol containing activated carbon and sodium sulfite to give 50% of the hydrate, m.p. 207–208°.

Anal.—Calcd. for $C_{17}H_{16}N_2O_5 \cdot H_2O$: C, 58.96; H, 5.24; N, 8.09. Found: C, 59.37; H, 5.25; N, 8.16.

An additional recrystallization from absolute alcohol gave the desired product.

p-Acetamidophenyl Hexylcarbonate–Procedure G—To 4′-hydroxyacetanilide (0.2 mole) and pyridine (0.22 mole) in 150 ml. of methylene chloride was added with cooling and stirring hexyl chloroformate (0.2 mole) in 75 ml. of methylene chloride. The resulting mixture was stirred for 2 hr., washed with water, and dried over anhydrous magnesium sulfate. The solvent was removed and the product was recrystallized from dilute alcohol.

Solubilities

The saturation solubilities of the compounds at 37° were determined in water and spectral grade cyclohexane (Fisher) in rotating bottles utilizing an assembly that has been described previously (3). To minimize hydrolysis, the aqueous samples were rotated for only 6 hr. The cyclohexane samples were rotated for 16 hr. (overnight). Samples of the clear supernatant saturated solutions were withdrawn into hypodermic syringes through Millipore filters held in Swinney filter adapters (Millipore Filter Corporation). The samples were analyzed spectrophotometrically.

Partition Coefficients

The partition coefficients of the compounds between cyclohexane and water at 25° were determined using a method and apparatus previously described (4).

In Vitro Hydrolysis Rates

*M*Half-lives for hydrolysis of the compounds in 0.1 pH 7.4 phosphate buffer with and without 2% human plasma at 37° were determined by a spectrophotometric method previously described (1). Frozen human blood plasma (Type O^+) was obtained in approximately 100-ml. quantities from single donors through the Philadelphia Serum Exchange.

Particle Size Reduction

Before *in vivo* testing, all compounds were micronized by one or more passes through a fluid energy mill (Trost Jet Mill, Helme Products, Inc., Helmetta, N. J.). This procedure produced particles in the 2–20 μ size range.

Oral Toxicity in Mice

Male Carworth Farms mice, weighing between 12–18 Gm. were randomly divided into groups of 10 and dosed orally with drug suspended in 0.5% tragacanth. Concentrations were calculated so that each animal received a dose volume of 20 ml./Kg. Control animals received 20 ml./Kg. of 0.5% tragacanth. After dosing, the animals were housed 10 per cage and observed daily for 5 days; if no deaths occurred during the subsequent 48 hr. (a total of 7 days), the study was terminated. If any deaths occurred during this 48-hr. period, the study was continued until no further deaths occurred for 2 consecutive days.

Analgesic Activity in Rats

The method of Randall and Selitto was employed (5). Male Dierolf rats (100–148 Gm.) were used after fasting 16–18 hr. Inflammation was produced by the injection of 0.1 ml. of a 20% suspension of brewer's yeast into the plantar surface of the rat's left hind foot. Pressure was applied to the foot at a constant rate of 20 mm. Hg/sec. by a glass cone attached to the plunger of a 10-ml. syringe connected to an air pressure line and pressure gauge. The pain threshold was determined as the amount of pressure in mm. Hg required to induce struggle. Control threshold measurements (referred to as the Yeast Control) were obtained for both the inflamed foot and normal foot 2 hr. after injection of the yeast suspension, immediately before administration of the drug. All changes in pain threshold within each control and each treated group are reported as: mm. Hg pressure at time "t" after treatment minus; mm. Hg pressure at time "t_0" immediately preceding administration of the drug (Yeast Control). Subsequent threshold determinations were made 30, 60, 120, 180, and 240 min. after administration of the test compounds.

On the basis of preliminary trials, a dose of 400 mg./Kg. of acetaminophen was selected, and the prodrugs were administered in molar equivalent doses. Because of its low oral toxicity, the 4-acetaminophenyl ester was administered in twice the molar equivalent dose, *i.e.*, equivalent to 800 mg./Kg. of acetaminophen. The drugs were administered orally as suspensions in 0.5% tragacanth, and concentrations were adjusted so that each animal received 20 ml./Kg. The control animals received 20 ml./Kg. of 0.5% tragacanth. There were 5 animals per treated group and 5 per control group for the acetaminophen carbonates; there were 11 treated animals and 11 controls for acetaminophen. All testing was done on a "blind" basis.

tions of matter, did not present unusual problems. The molecular weights, yields, melting points, recrystallization solvents, and elemental analyses of the compounds are shown in Tables I and II.

The solubilities of acetaminophen and the various esters in water and cyclohexane at 37° and the cyclohexane/water partition coefficients for the compounds at 25° are shown in Table III. As expected, the prodrug esters of acetaminophen, in most cases, were much less soluble in water and much more soluble in cyclohexane than acetaminophen. The aqueous solubilities of the carbonate esters decreased rapidly as the chain length of the alcohol moiety increased.

Branching in the alcohol chain tended to increase both aqueous and cyclohexane solubilities as illustrated by the solubilities of the butylcarbonate compared with those of the isobutylcarbonate. This effect could be attributed to loss of symmetry in the molecules which reduces crystal lattice energy. As the alcohol chain length increased, the cyclohexane solubilities and cyclohexane/water partition coefficients of the carbonate esters also increased. Although chain branching tended to increase the cyclohexane solubility, it did not increase the partition coefficient because of the concomitant increase in aqueous solubility. It would seem, however, that branching would tend to increase the oral availability of these compounds, since both the aqueous and lipid solubilities were increased. Chlorine substitution in the alcohol moiety decreased aqueous solubility and increased cyclohexane solubility. Thus, the chloroethylcarbonate had the highest partition coefficient of all the carbonate esters. The acetaminophencarbonate esters of phenol and of 4-acetaminophenol (bisacetaminophenyl carbonate) were relatively high melting compounds and, consequently, were not very soluble in either water or cyclohexane. The discrepancies between the measured partition coefficients shown in Table III, and the partition coefficients that could be calculated for these two compounds from the solubility data, are due to ex-

[a] *f.d.* = fractional distribution of the compound in a cyclohexane/water system calculated by dividing the cyclohexane solubility by the sum of the cyclohexane solubility and the water solubility. [b] Availability factor = *f.d.* × molar aqueous solubility × 10^4.

perimental analytical error resulting from the low concentrations measured in the solubility studies. Nonetheless, it would seem that addition of the polar acetamido group significantly reduces lipid solubility and consequently the cyclohexane/water partition coefficient is reduced.

The solubility behavior of the carboxylate esters was essentially the same as that of the carbonate esters. Increasing chain length in the acid moiety decreased aqueous solubility and increased lipid solubility, although the cyclohexane solubilities of the carboxylate esters were not as high as their analogous carbonate esters. Apparently, carboxylates are inherently more polar than carbonates. Branching in the acid moiety seemed to have less effect on the solubilities of the carboxylates than it did on the solubilities of the carbonates (compare butyryl with pivalyl and butylcarbonate with isobutylcarbonate) and unsaturation in the acid moiety also seemed to have little effect on the solubility (compare butyryl with crotonyl). The high melting fumaryl ester was extremely insoluble in both water and cyclohexane so that no measurement of its solubilities could be made by our methods. The succinyl ester, also a high melting compound, was also very insoluble in both water and cyclohexane. The acid succinyl ester was quite soluble in water due to its free carboxyl group, but its lipid solubility was very low. As with the carbonate esters, aromatic groups in the carboxylate esters tended to decrease both aqueous and lipid solubilities, and chlorine tended to decrease aqueous, but increase lipid, solubilities. Because it is a salt, the morpholinoacetyl·HCl derivative was very soluble in water and very insoluble in cyclohexane.

Availability Factors—In evaluating the availability of a relatively insoluble compound for oral absorption, one must take into consideration both the aqueous solubility, which is directly related to the rate at which the compound dissolves in the gut lumen, and the lipid solubility, which is directly related to the rate at which the compound partitions into the lipid gut barrier. In order to compare compounds, it would be convenient to express both these factors in one number. The "availability factors" listed in Table III are an attempt to do this. They are products of the molar aqueous solubilities and a factor related to the lipid/water distribution characteristics of the compounds. Because partition coefficients can be extremely low or extremely high and thus offset significant changes in aqueous solubilities, the lipid/water distribution characteristics of the compounds were expressed in terms of "fractional distributions" (*f.d.*). These values were calculated using the following empirical equation:

$$f.d. = \frac{\text{cyclohexane solubility}}{\text{cyclohexane solubility} + \text{aqueous solubility}}$$

Whereas partition coefficients may vary from 0 to infinity, fractional distributions, as defined above, vary from 0 to 1.

The availability factors for nearly all the acetaminophen carbonate esters are of the same order of magnitude and are larger than that for acetaminophen itself. The isobutylcarbonate derivative is more soluble in both water and cyclohexane than the other carbonates; and, consequently, its availability factor is somewhat higher than that of the other aliphatic carbonates. How-

ever, the chloroethylcarbonate has an even higher factor which is primarily due to its high cyclohexane solubility. The factor for the octylcarbonate is low due to its low aqueous solubility, while the factors for the phenyl- and 4-acetaminophenylcarbonates are low because both their aqueous and cyclohexane solubilities are low.

The factors for the carboxylate esters show a similar degree of variability and are generally lower than those of the carbonates. Factors for some of the carboxylates could not be calculated because their solubilities in water and cyclohexane are too low. The factor for the acid succinyl derivative is notably low because of its low cyclohexane solubility and in spite of its relatively high aqueous solubility. This is also true of the morpholinoacetyl·HCl derivative, although this compound would probably have a higher factor in its free base form than in its salt form. The benzoyl and cinnamoyl derivatives have low factors due to low aqueous and cyclohexane solubilities.

It should be mentioned that conjecture based on availability factors, such as those shown in Table III, must be restricted to compounds of closely similar structure. Cyclohexane and most other organic solvents probably have solvent properties which are markedly different from those of the G.I. barrier lipids. However, cyclohexane was chosen for these solubility and partitioning studies because it is one of the most nonpolar pure solvents available commercially. Moderate solubilities in cyclohexane should reflect a high degree of lipophilic character in the drugs. However, the G.I. barrier is not pure hydrocarbon, and drugs which have a relatively low solubility in cyclohexane may have a much greater solubility in G.I. barrier lipids due to polar interactions. As long as one is dealing with drugs of similar enough structure that the polar interactions are relatively equal and the structural differences result in changes in the nonpolar portions of the molecule, it is relatively safe to make comparative predictions of oral absorbability. However, when the structures differ as much as the difference between a carbonate ester and a carboxylate ester of equal chain length, or even as little as the difference between an aliphatic carbonate and a chlorine-substituted aliphatic carbonate ester, such predictions must be made with great caution. Therefore, it is dangerous to say that acetaminophen itself is less "available" than the prodrugs; but it is reltively safe to say that the aliphatic carbonates are all about equally available, with the isobutyl derivative being perhaps slightly more rapidly available for absorption than the rest.

In Vitro Hydrolysis Behavior—It was expected that the prodrug carbonate and carboxylate esters of acetaminophen would be hydrolyzed *in vivo* before, during, or after absorption to release free acetaminophen which would then exert its characteristic pharmacologic actions. It was, therefore, desirable to determine the relative susceptibility of these compounds to both nonenzymatic and enzymatic hydrolysis *in vitro*. It was of particular interest to look for relationships between the hydrolysis rates and the pharmacologic activities of the compounds.

Table IV shows half-lives for the hydrolyses of the prodrugs at 37° in pH 7.4 phosphate buffer with and without 2% human plasma. In general, all the compounds hydrolyzed slowly in pH 7.4 buffer; and most exhibited half-lives in excess of 24 hr. (1440 min.). The carbonate and carboxylate esters behaved very similarly in this regard, but the cinnamoyl and chloroacetyl (carboxylate ester) derivatives were unusually labile to hydrolysis exhibiting half-lives of 1.2 min. and 12 min., respectively, in buffer.

In pH 7.4 buffer containing 28% human plasma, the hydrolysis rates were much more rapid. The degree of acceleration is illustrated in the column headed "$t_{1/2}$ buffer/$t_{1/2}$ plasma." This column shows that some of the compounds hydrolyzed as much as 2,000 times faster in the presence of 2% human plasma than in plain pH 7.4 buffer. This accelerated hydrolysis rate is attributed to the esterases present in the plasma. In other experiments, it was observed that as plasma concentrations increased, hydrolysis rates likewise increased.

Toxicity and Analgesic Activity—On the basis of the hydrolysis data, it might be concluded that all of the carbonate and carboxylate compounds should behave as prodrugs of acetaminophen, hydrolyzing to release free acetaminophen in the tissues of humans and animals. On the basis of the availability factors shown in Table III for the carbonate esters, for example, it might be concluded that these compounds should not differ appreciably in their rates of dissolution and absorption from the gastrointestinal tract. To test the validity of these conclusions *in vivo*, the oral LD_{50}'s were determined of some of the compounds in mice and the analgesic

TABLE V—HALF-LIVES FOR HYDROLYSIS IN HUMAN PLASMA, AVAILABILITY FACTORS, AND ORAL LD_{50}'s IN MICE FOR PRODRUG CARBONATE ESTERS OF ACETAMINOPHEN

Derivative	Availability Factor[a]	LD_{50} (Limits) moles/Kg.	LD_{50} (Limits)[b] mg./Kg.

Isobutyl	3.8	8.6 (6.7–10.9)	2150 (1693–2731)
Phenyl	0.56	12.5 (8.9–17.7)	3400 (2411–4794)

[a] See Table III for definition. [b] LD_{50}'s and 95% confidence limits were calculated by the method of Litchfield and Wilcoxon (12).

activities of some of the compounds in rats using the Randall-Selitto technique.

Table V shows half-lives for enzymatic hydrolysis, availability factors, and oral LD_{50}'s in mice for some of the carbonate esters. The LD_{50}'s are given in moles/Kg. since 1 mole of each prodrug would release 1 mole of acetaminophen regardless of the molecular weight of the prodrug. Thus, comparison of toxicities on a molar basis gives a more precise evaluation of *in vivo* availability than comparison on a mg./Kg. basis. The molar LD_{50}'s of the carbonate prodrugs are virtually identical, and their confidence limits overlap each other and those of acetaminophen in almost all cases. In those cases in which the confidence limits do not overlap, the lack of agreement does not appear to be the result of either availability or slow enzyme hydrolysis. For example, the isobutyl derivative has the highest availability factor; but its toxicity overlaps that of the phenyl compound which has the lowest factor. The methyl compound is the slowest hydrolyzing compound, but it is equitoxic to the isobutyl compound, which is relatively rapidly hydrolyzed. It would seem that normal biological variation or some physical factor, such as poor wetability, may have caused the variations in the toxicities of these compounds. All of the compounds were micronized to reduce the particles to the 2–20 μ size range before biological testing.

The oral LD_{50}'s of the acetyl, butyryl, hexanoyl, and stearoyl carboxylate esters in mice were found to be in excess of 12 moles/Kg. The stearoyl derivative was so insoluble that no deaths could be produced at any dose. Thus, it would appear that the generally lower availability factors given for these compounds in Tabe III indicate that they are less available than the carbonates. However, the LD_{50}'s were so high that meaningful comparisons could not be made.

It is well known that it is difficult to quantitate the activity of mild nonnarcotic analgesics in laboratory animals (10); therefore, the authors attempted only to establish whether or not the acetaminophen carbonates possess analgesic activity in the range of acetaminophen. The method of Randall and Selitto was employed, and a control group of animals was included to show that the yeast-injected rat paw retains its increased sensitivity to pain for the duration of the study (4 hr.). The results of a statistical analysis of the postdrug pain threshold data are shown in Table VI. The isopropyl and phenyl carbonates had significant analgesic activity at doses equimolar to a 400 mg./Kg. dose of acetaminophen. These compounds have availability factors of 2.1 and 0.56, respectively (Table V); but the difference between these values is apparently not great enough to cause a significant difference in analgesic activity by this test. If prodrug derivatives had been prepared of a drug with a more potent and more easily quantitated pharmacologic activity, perhaps a difference in availability factor such as that found for these prodrugs would have made a significant difference in the pharmacologic responses. However, with drug activity as weak and difficult to measure as mild analgesia, it is impossible to tell whether or not the carbonate prodrugs are absorbed at any different rates or with greater or lesser efficiencies than acetaminophen itself.

TABLE VI—ANALGESIC ACTIVITY (RANDALL-SELITTO) OF ACETAMINOPHEN AND CARBONATE PRODRUGS OF ACETAMINOPHEN ORALLY IN RATS

Compd.	Time Postdrug (Min.)[a] 30	60	120	180	240
Acetaminophen	+	+	+	+	+
Carbonate Esters					
Isopropyl	+	0	+	+	0
Phenyl	0	0	+	+	+

[a] + = Significant ($p \leq 0.05$) analgesic activity; 0 = no significant analgesic activity. Significance was determined by means of Student's t test (13).

Because this study was concerned primarily with establishment of principles rather than a determination of the pharmacologic activity profiles of every compound made, a number of the acetaminophen esters were not studied *in vivo* for their activity profiles. Nevertheless, since each of the compounds that were thus studied exhibited the gross pharmacologic activities of acetaminophen, and each underwent relatively rapid hydrolysis in the presence of plasma, it seems fair to assume that most of the compounds reported here would behave as acetaminophen prodrugs.

CONCLUSIONS

Carbonate and carboxylate esters prepared as potential prodrugs of acetaminophen were shown to have a variety of physicochemical properties, particularly lipid and water solubilities. *In vitro* enzyme-catalyzed hydrolysis studies suggested that most of the compounds would be hydrolyzed to release acetaminophen following oral administration to animals and humans. Toxicity and analgesic

activity studies in mice and rats suggested that the lipid and water solubilities of the compounds, rather than their enzyme-catalyzed hydrolysis rates, probably control the availability of acetaminophen following oral administration. These experiments provide additional evidence that the carbonate linkage may be an importantly useful one for the creation of variant physical and chemical properties in an entity with a singular pharmacologic action (11). This might then offer the opportunity to the formulator to choose among a variety of compounds with a singular pharmacologic action for the one which is: (*a*) amenable to physical formulation in a given dosage form; (*b*) stable in a given dosage form where all forms of the drug may not be equally stable; (*c*) satisfactory from the standpoint of taste or consumer acceptability; and (*d*) appropriate therapeutically from the standpoint of its time-action profile.

Acetaminophen Prodrugs II

Effect of Structure and Enzyme Source on Enzymatic and Nonenzymatic Hydrolysis of Carbonate Esters

By L. W. DITTERT*, G. M. IRWIN, C. W. CHONG, and J. V. SWINTOSKY*

Hydrolysis rates are reported for acetaminophen prodrugs with the structure CH_3CONH-ϕ-OCOOR at pH 7.4 in phosphate buffer alone or containing 1% human plasma or serum from several animal species. The hydrolysis rates in buffer decreased as the electrophilic character of the R group decreased. Dilute plasma or serum accelerated the hydrolysis; and the number of carbon atoms, the degree of chain branching, aromaticity, and chlorine substitution in the R group variously affected the degree of acceleration. In general, the sera of small rodents (mouse, guinea pig, and rat) were more potent catalysts of the hydrolyses of all types of acetaminophen carbonates than that of other animals (cat, dog, sheep, and rabbit) or human plasma.

THE METHODS of preparation and the physical properties of a series of carbonate esters of acetaminophen have been previously reported (1). These compounds were found to hydrolyze at various rates in dilute (2% v/v) human plasma solutions, and some of them had analgesic activity on the order of acetaminophen in rats. It was postulated that the analgesic activity was due to free acetaminophen released in the blood streams of the rats following oral administration of the prodrugs.

This report discusses the influence of the structure of acetaminophen carbonate prodrugs on the nonenzymatic hydrolysis of the compounds at pH 7.4 and on the enzymatic hydrolysis of the compounds catalyzed by blood plasma from

humans and blood sera from various animal species.

EXPERIMENTAL

Frozen citrated human blood plasma (Type O^+) was obtained in approximately 100-ml. quantities from single donors through the Philadelphia Serum Exchange. Frozen pooled animal sera were obtained from Colorado Serum Company, Denver, Colorado.

Half-lives for the hydrolysis of the acetaminophen carbonates at 37° in pH 7.4 phosphate buffer (0.1 *M*), with and without human plasma or animal serum, were determined by direct UV analysis in the thermostatted cell compartment of a Cary model 15 spectrophotometer. Fifty milliliters of the plasma or serum solution was warmed to 37° in a 125-ml. glass-stoppered conical flask and a portion placed in the spectrophotometer reference cell. One-half milliliter of 95% ethanol containing an appropriate amount of the acetaminophen carbonate was injected by means of a hypodermic syringe, and the flask was swirled gently until mixing was complete. A portion of this mixture was transferred to the sample cell of the spectrophotometer and the absorbance followed until no further change was observable. In cases in which the reactions were very slow, the final absorbance values were calculated. The half-lives were determined from plots of log Δ absorbance *versus* time (see Fig. 1). In most cases, the spectrophotometer was set at 240 mμ (the absorbance maximum of the esters), where a decrease in absorbance reflected the disappearance of the ester. In several experiments, the spectrophotometer was set at 300 mμ (the absorbance maximum of acetaminophen), where an increase in absorbance reflected the appearance of acetaminophen. For a given ester in a given enzyme system, the same half-lives were obtained at the two wavelengths.

RESULTS AND DISCUSSION

Half-lives for the hydrolysis of 11 carbonate esters of acetaminophen in pH 7.4 phosphate buffer (0.1 *M*), with and without 1% (v/v) human plasma, are shown in Table I. The rates of nonenzymatic cleavage of acetaminophen carbonate esters of straight-chain alcohols decreased with increasing chain length to four carbons; thereafter, they remained essentially constant at a minimum value.

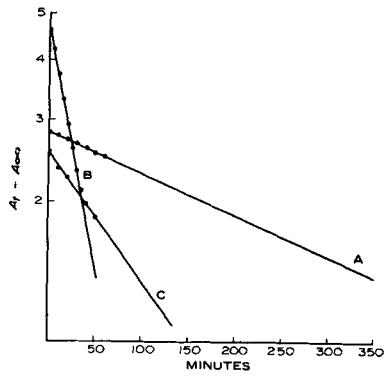

Fig. 1—Representative plots showing the first-order nature of the hydrolysis of carbonate esters of acetaminophen in pH 7.4 phosphate buffer (0.1 M*) containing 1% (v/v) human plasma at 37°. Absorbances were determined at 240 mμ, the absorbance maximum of the esters.* (A_t = *absorbance at time* t; A_∞ = *absorbance when the reaction is apparently complete.*) The *half-lives are as follows*—A, *methylcarbonate*, $t_{1/2}$ = *345 min.;* B, *butylcarbonate*, $t_{1/2}$ = *30 min.;* C, *isopropylcarbonate*, $t_{1/2}$ = *111 min.*

[a] With and without 1% v/v human plasma (37°).

These results are in agreement with the findings of Gordon *et al.* (2), who studied the effect of the carbon chain length of aliphatic alcohols on the ammonolysis of their acetate esters. They found that the rate of ammonolysis decreased to a constant minimum value at alcohol carbon chain lengths of about five. These results suggest that the hydrolysis of the acetaminophen carbonates is subject to essentially the same electronic effects as the hydrolysis of carboxylic acid esters and of other carbonate esters (3); that is, the alkyl groups tend to act as "electron pumps" depolarizing the carbonyl group and making it less susceptible to nucleophilic attack. As with carboxylic acid esters, this inductive effect levels off at alkyl chain lengths of about four or five carbons.

The rates of enzymatic cleavage of the acetaminophen carbonates of straight-chain alcohols in 1% human plasma increased with increasing chain length up to about six carbons. The figures shown in Table I in the column headed $t_{1/2}$ buffer/$t_{1/2}$ enzyme, which indicate the degree of enzyme catalysis relative to the nonenzymatic rate, follow the same pattern. Adams and Whittaker (4), in studies on human plasma cholinesterase, reported that the optimum chain length for either the acyl group or the alkyl group in a homologous series of carboxylic acid esters is four carbons. Hofstee (5) found that esters of fatty acids with seven carbons in the acyl chain are more susceptible to chymotrypsin catalyzed hy-

[a] Containing 1% serum from animals or 1% human plasma (37°). [b] The numbers in parentheses are $t_{1/2}$ buffer/$t_{1/2}$ enzyme ratios which represent the degree of enzymatic catalysis.

drolysis than esters of other fatty acids. The enzymes in human plasma responsible for the hydrolysis of acetaminophen carbonate esters appear to behave in a similar way. However, since human plasma contains a mixture of esterolytic enzymes, at least part of the dependence of the enzymatic rates on structure may be attributed to variations in the contributions made by the several plasma enzymes to the overall hydrolysis rates of the esters.

Half-lives for the hydrolyses of two acetaminophen carbonate esters of branched chain aliphatic alcohols are also shown in Table I. Branching slows both the nonenzymatic and the enzymatic hydrolysis reactions slightly, but the effect is less pronounced in the isobutyl than in the isopropyl case. The slowing effect of branching is probably due to inductive electronic effects similar to those observed by Gordon *et al.* (2) in their studies of the ammonolysis of acetate esters of ethanol, butanol, isopropanol, and isobutanol. Their results show a direct parallel with the nonenzymatic cleavage data for the corresponding acetaminophen carbonate esters shown in Table I.

Chain branching apparently has comparatively little effect on the degree of enzymatic catalysis of the acetaminophen carbonates by human plasma as shown by the closeness of the $t_{1/2}$ buffer/$t_{1/2}$ enzyme values for the ethyl and isopropyl derivatives and for the butyl and isobutyl derivatives. Thus, it would appear that branching in the aliphatic alcohol chain has much less of an effect on the human plasma catalyzed hydrolysis reaction than does the total number of carbons in the chain. This is an important finding with regard to the selection of derivatives for the preparation of carbonate ester prodrugs. Derivatives of branched alcohols generally have lower melting points and higher aqueous and nonaqueous solubilities than those of straight-chain alcohols (1). Since branching seems to have little effect on the hydrolysis of the carbonates, branched derivatives with their greater aqueous solubilities might be more rapidly available for oral absorption but equally susceptible to enzymatic hydrolysis as the straight-chain derivatives.

Table I shows hydrolysis data for the phenyl- and the *p*-acetaminophenylcarbonates of acetaminophen. The results suggest that aromatic groups apparently affected both the electronic state and the affinity of human plasma enzymes for these molecules. The phenolic carbonates were much more rapidly hydrolyzed in pH 7.4 buffer than the hexylcarbonate, probably because of the electrophilic character of the aromatic rings which polarize the carbonyl group and make it more susceptible to nucleophilic attack. The phenolic carbonates, however, were much less susceptible to enzymatic cleavage than is the hexylcarbonate, possibly because the hexyl group has a greater affinity for the catalytic sites on the esterolytic enzymes of human plasma.

The influence of chlorine substitution on the enzymatic and nonenzymatic hydrolysis of the ethylcarbonate of acetaminophen is illustrated in Table I. These data show that increasing chlorine substitution beta to the carbonate linkage progressively increased the nonenzymatic hydrolysis rate. The effect was quite pronounced in going from the ethyl to the monochloroethyl derivative and was apparently due to the capacity of chlorine to act as an "electron sink" causing increased polarization of the carbonyl

group. On the other hand, progressive chlorine substitution appears to decrease the susceptibility of the ethylcarbonate ester to enzymatic hydrolysis. Again this effect might be due either to deteriorating enzyme substrate "fit," or to changes in the contributions made by the various enzymes to the overall hydrolysis rate as chlorine substitution is increased.

The results of the studies on the phenolic carbonates and the chlorine substituted ethylcarbonates of acetaminophen suggest that prodrug carbonates of phenols and of alcohols containing electrophilic substituents are relatively more susceptible to nonenzymatic cleavage but relatively less susceptible to enzymatic cleavage than prodrug carbonates of aliphatic alcohols. Thus, phenols and electrophilic alcohols may form carbonate ester prodrugs which are less stable pharmaceutically and less labile to enzymatic cleavage *in vivo* than those formed by aliphatic alcohols.

Table II shows half-lives for the hydrolysis of eight carbonate esters of acetaminophen in pH 7.4 phosphate buffer (0.1 *M*) containing 1% blood serum from seven animals or 1% human plasma. Values for $t_{1/2}$ buffer/$t_{1/2}$ enzyme for each of the enzyme systems are shown in parentheses. The results show that serum from all the animals contains esterases capable of catalyzing the hydrolysis of the acetaminophen carbonate esters, although in several instances the catalysis is very weak.

For almost every species, the aliphatic carbonate esters can be ranked in the following order of susceptibility to enzymatic attack: butyl $\cong$ isobutyl > isopropyl $\cong$ ethyl > methyl. In serum from small rodents (mouse, guinea pig, and rat) the phenyl- and 2,2,2-trichloroethylcarbonates were about equally susceptible to enzymatic attack and the *p*-acetaminophenylcarbonate was somewhat less susceptible. In serum from the other animals and in human plasma, the *p*-acetaminophenylcarbonate was somewhat more susceptible to enzymatic attack than the phenyl- and 2,2,2-trichloroethylcarbonates.

For almost every compound, the sera of the animals can be ranked in the following approximate order of catalytic potency: mouse > guinea pig > rat > cat > human > rabbit > dog > sheep, although in several cases guinea pig and mouse could be interchanged in this ranking.

Augustinsson (6) reported wide species differences in both the concentrations and the specificities of the esterases normally found in the sera of animals and man. Since serum contains several esterolytic enzymes, each with its own specificities for the substrates, at least part of the dependence of the enzymatic rates on structure in a given sample of serum may be attributed to variations in the contributions made by the plasma enzymes to the overall hydrolysis rates. The specificities and the concentrations of the enzymes in the serum vary from species to species, and are probably largely responsible for the various hydrolysis rates observed for a given substrate in the sera of various animals.

Thus, it is not surprising that it is difficult to make broad generalizations based on the data of Table II. However, the following conclusions can be drawn: (*a*) if an acetaminophen carbonate ester has a comparatively large $t_{1/2}$ buffer/$t_{1/2}$ enzyme ratio in the serum of one species, it will probably also have comparatively large $t_{1/2}$ buffer/$t_{1/2}$ enzyme ratios in the sera of all species, and (*b*) the sera of small rodents seem to possess either higher concentrations of esterases, or esterases which have a greater affinity for acetaminophen carbonate esters than the sera of the other animals or human plasma.

All the compounds hydrolyzed in 1% human plasma. It would be expected that all would release free acetaminophen in the blood of humans fairly rapidly if they indeed reached the blood intact following oral administration. In almost every case, the compounds were hydrolyzed more rapidly in the serum of common laboratory test animals (except rabbit and dog) than in human plasma, and it would be expected that free acetaminophen would be rapidly released following oral absorption in these animals. Thus, human plasma is a convenient test system for studying the hydrolysis of carbonate ester prodrugs because hydrolysis in this system suggests that hydrolysis would also occur in the blood of humans and laboratory test animals *in vivo*. Lack of hydrolysis in dilute human plasma, however, would not necessarily mean that hydrolysis in the tissues of laboratory test animals and humans is not possible.

Basically Substituted Dioxolanes and Dioxanes

By OLE GISVOLD and H. V. MAULDING, JR.*

The synthesis of a group of basically substituted 1,3-dioxolanes and 1,3-dioxanes is reported. Cyclic acetals and ketals were prepared by the acid catalyzed, azeotropic distillation method, utilizing either a 1,2- or a 1,3-diol and either *p*-nitrobenzaldehyde or *p*-nitroacetophenone as the carbonyl compound, followed by catalytic reduction of the aromatic nitro group to the corresponding primary amine. All members of this series have a *p*-amino-phenyl substituent at position 2 of the dioxolane or dioxane ring in order to conform structurally as closely as possible to the sulfonamide and procaine prototypes. These compounds exhibited no antibacterial action *in vitro*. One compound had local anesthetic activity.

REPLACEMENT OF ESTERS by either substituted or unsubstituted 1,3-dioxolanes and/or 1,3-dioxanes has upon occasion led to effective medicinal agents. Bovet's acetal (1) is one of the most active muscarinic agents ever found. Blicke and co-workers (2–4) produced potent antispasmodics by replacement of the —CHCOO— of adiphenine with basically substituted 1,3-dioxolane and 1,3-dioxane rings. Recently, Hardie and co-workers (5) have reported on the local anesthetic and spasmolytic properties of a series of 4-(2-piperidyl)-1, 3-dioxolanes.

The ester linkage usually found in the procaine prototype is not a necessity as aminoalkyl ethers of the general formula $ArO(CH_2)_3NR_2$ (6) are efficient local anesthetics. Thus it was hoped that dioxolanes and dioxanes of the general formulas (I) and (II) might possess some degree of local anesthetic activity, as they closely resemble procaine and the alkylamino benzoates, with substitution of the ester group by the oxygenated ring representing the major structural modification.

Although there are certain general requirements for anti-*p*-aminobenzoic acid activity these stipulations are not nearly so specific as they may appear at first glance. The structural features requisite for antagonism of PAB are basically: (*a*) a primary aromatic amino group, and (*b*) an electronegatively charged group *para* to the amine (7). Sulfur is not necessary as the sodium *p*-amino-phenyl-arsonate (8) and diaminobenzil (9) are antimetabolites of the acid. As the critical distances between (*a*) the two ring oxygens and (*b*) the ring oxygens and the hydrogens of the primary aromatic amine in the dioxolanes (I) and the dioxanes (II) are quite similar to those stated for sulfanilamide and the *p*-aminobenzoate anion (7) (about 2.4 and 6.8 Å., respectively), it was thought that they might possess some degree of anti-*p*-aminobenzoic acid activity.

The intermediate halodioxolanes and halodioxanes (Tables I and II) required for the synthesis of the corresponding amino compounds were prepared by condensation of the aldehyde or ketone with glycerol-α-monobromohydrin or 2-methyl-2-bromomethyl-1,3-propanediol (10) in the presence of *p*-toluenesulfonic acid according to the procedure of Salmi (11). The nonhalogenated dioxolanes were prepared in the same manner using the appropriate 1,2-glycol. As it had been found previously that 5-methyl-5-bromomethyl-1,3-dioxanes reacted sluggishly with secondary amines, the bromo dioxane was converted to the iodo derivative (12) so as to obtain the wanted amines.

The 4-aminomethyl-1,3-dioxolanes (Table I) and the 5-methyl-5-aminomethyl-1,3-dioxanes (Table II) were produced by heating the intermediate halo compound, the amine and benzene in a pressure bottle on either a steam bath or in an oven for 6 to 7 days (2–4). In the case of the intermediate amino dioxolanes, these compounds were oils which decomposed on attempted distil-

[a] Uncorrected melting points were taken on a Thomas Hoover capillary melting point apparatus. [b] Microanalytical data were provided by the University of Minnesota Microanalytical Laboratory, Minneapolis. [c] Recrystallized from ethanol. [d] *Reference 24.* [e] Previously reported as an oil, (b.p. 150°, 1 mm.), *Reference 25.* [f] Mixture of diastereoisomers. [g] Analyzed as picrate. [h] Yield of base. [i] All primary aromatic amines in this series with the exceptions of compounds 2, 4, and 11 were isolated as p-nitrobenzylidene derivatives due to their instability in the free form. [j] Piperidino. [k] Analyzed as methiodide. [l] Morpholino. [m] 1-Methylpiperidino.

lation and were isolated as picrates or methiodides for analytical purposes.

The 2-p-aminophenyl dioxolanes and dioxanes (Tables I and II) were obtained by reduction of the corresponding 2-p-nitro-compounds using platinum oxide as the catalyst (13–15). In all cases where the 2-p-aminophenyl group was present, the compounds showed some degree of instability with the dioxolanes apparently being less stable than the dioxanes. All attempts at salt formation with the reduced substances failed resulting in a yellow polymeric material which was possibly due to the hydrolysis of the acetal or ketal to p-aminobenzyaldehyde and its subsequent Schiff base self-condensation (16, 17).

The Schiff bases were quite easily formed by treatment of the 2-p-aminophenyl-dioxanes and dioxolanes with p-nitrobenzaldehyde (18, 19). They were stable and the only method by which some of the primary aromatic amino compounds could be isolated without decomposition.

It should be noted that in all cases where the possibility of diastereoisomerism existed in preparation of these compounds it appeared to occur. However, upon preparation of methiodides or picrates from the mixture of isomers a sharp melting point was shown indicative of molecular compound formation (20, 21).

EXPERIMENTAL

The compounds prepared are listed in Tables I and II. The general preparative procedures are illustrated with specific examples.

2-p-Nitrophenyl-5-methyl-5-bromomethyl-1,3-dioxane(II,1)—A mixture of 16.5 Gm. (0.1 mole) of p-nitrobenzaldehyde, 20 Gm. (0.11 mole) of 2-methyl-2-bromomethyl-1,3-propanediol (10),

TABLE II—PHYSICAL CONSTANTS OF 1,3-DIOXANES

[a] Uncorrected melting points were taken on a Thomas-Hoover capillary melting point apparatus. [b] Microanalytical data were provided by the University of Minnesota Microanalytical Laboratory, Minneapolis. [c] Recrystallized from ethanol. [d] A second fraction, m.p. 52–76°, was isolated which gave correct analysis and was presumably the second diastereoisomer. [e] Primary aromatic amines isolated as stable p-nitrobenzylideneanilino-derivatives. [f] Yield based on weight of compd. 3 used in reduction. [g] Piperidino. [h] Recrystallized from methanol. [i] Morpholino.

one crystal of p-toluenesulfonic acid, and 100 ml. of benzene was refluxed (11, 22) for 20 hr. in a flask to which a Dean Stark water trap (23) was attached. The warm mixture was filtered and shaken out three times with 10% sodium carbonate followed by distilled water. The benzene was removed *in vacuo* and the resultant solid dissolved in 350 ml. of ethanol. The precipitate was collected and recrystallized from ethanol yielding 17.0 Gm. (46.5%), m.p. 111–112°.

2-p-Nitrophenyl-4-diethylaminomethyl-1,3-dioxolane (I, 6)—A solution of 14.4 Gm. (0.05 mole) of 2-p-nitrophenyl-4-bromomethyl-1,3-dioxolane and 14.6 Gm. (0.20 mole) of diethylamine in 50 ml. of benzene was heated in a pressure bottle on a steam bath for 6 days (2–4). The diethylamine hydrobromide was removed by filtration and the solvent and excess diethylamine evaporated. The resultant oil was taken up into 100 ml. of benzene followed by extraction with 10% citric acid. The acidic extracts were neutralized with solid sodium carbonate. The oily amine was again dissolved in benzene and the preceding acid-base extraction repeated twice more. The amine was taken up in ether and dried with anhydrous sodium sulfate. Upon evaporation of the ether 9.9 Gm. (70%) of a yellow oil, n_D^{21} 1.5262, was obtained which was found to decompose on attempted distillation (0.5 mm.). A picrate (m.p. 165°) was prepared for analysis by adding dropwise an ethanolic solution of picric acid to a solution of the amine in ethanol.

2-p-Aminophenyl-4-(1-piperidylmethyl)-1,3-dioxolane (Not Isolated)—A solution of 2.1 Gm. of 2-p-nitrophenyl-4-(1-piperidylmethyl)-1,3-dioxolane in 50 ml. of absolute ethanol with 100 mg. of platinum oxide (13) was reduced on the Parr hydrogenator (15) at 30 lb. pressure and the shaking stopped when the calculated amount of hydrogen had been taken up. The catalyst was removed by filtration, the solvent removed *in vacuo*, and the pale yellow oil used immediately for preparation of the Schiff base. All attempts at salt preparation failed.

2-[4-(N-4'-Nitrobenzylideneanilino)]-4-(1-piperidylmethyl)-1,3-dioxolane (I, 9)—An equimolar quantity of p-nitrobenzaldehyde (995 mg.) was added to the 2-p-aminophenyl-4-(1-piperidylmethyl)-1,3-dioxolane obtained from the preceding step and the mixture heated under reduced pressure on a water bath (18, 19). After 15 min. the oil had turned bright orange. It was removed from the water bath and refluxed for 20 min. with 10 ml. of ethanol. The Schiff base began to crystallize as bright gold needles on cooling to room temperature and on recrystallization from absolute ethanol yielded 1.5 Gm. (55%), m.p. 90–105°.

2-p-Aminophenyl-4-(4-morpholinomethyl)-1,3-dioxolane(I, 11)—A solution of 6.35 Gm. of 2-p-nitrophenyl-4-(4-morpholinomethyl)-1,3-dioxolane in 30 ml. of absolute ethanol with 100 mg. of platinum oxide (13) was reduced on the Parr hydrogenator (15) at 30 lb. pressure until hydrogen uptake ceased (about 10 min.). The resulting mixture was filtered through a sintered-glass filter to remove catalyst and the filtrate placed in the deep freeze. After 2 weeks a white crystalline precipitate was noted which was removed and recrystallized three times from absolute ethanol, yielding 4.8 Gm. (82.5%) of small white plates, m.p. 104–114°. The infrared spectrum showed the presence of a primary aromatic amino group.

MICROBIOLOGY AND PHARMACOLOGY

These series of compounds were subjected to microbiological screening on *E. coli*, *S. aureus*, two

species of Mycobacteria, *S. cerevisiae*, *C. albicans*, and *G. candidum*. None showed appreciable inhibition of any test organisms at concentrations of 100 mcg./ml.

None of the compounds had surface anesthetic activity when tested in the rabbit's eye.

Intracutaneous injection of a 0.25% solution of compound 13 (Table I) in guinea pigs caused anesthesia of 30 min. duration.

Dissolution Rates in Surfactant Solutions Under Stirred and Static Conditions

By M. GIBALDI, S. FELDMAN, R. WYNN, and N. D. WEINER*

The dissolution rate of benzoic acid was determined in water and solutions of polyoxyethylene (23) lauryl ether by the rotating disk and static disk methods. The results under stirred and static conditions substantially deviated from the Noyes-Whitney equation. Dissolution rates in surfactant solutions were much less than anticipated on the basis of solubilization data. The ratios of dissolution rate in surfactant solution to that in pure solvent were found to be significantly greater under static conditions as compared to the ratios determined under stirred conditions, suggesting a possible change in dissolution mechanism. Certain aspects of dissolution rate theory are explored to explain this unusual phenomenon.

THE INFLUENCE of interacting colloids such as polymers or micellar aggregates on drug solubility has been investigated extensively and the literature contains numerous reports concerning drug solubilization in colloidal systems. However, only a limited amount of information is available on the influence of solubilization on dissolution rate.

Taylor and Wurster (1) found significant increases in both the solubility and dissolution rate of various forms of prednisolone in 0.1% solutions of sodium lauryl sulfate. Since this concentration is considerably below the critical micelle concentration (CMC) and since the extent of solubiliza-

tion appeared to be related to the activity of the crystal form, the authors suggested that a cooperative phenomenon was responsible for the increased solubility. Furthermore, a major factor in the increased dissolution rate appeared to be an apparent increase in the interfacial rate constant by virtue of the surfactant assisting in the release of surface molecules through interfacial tension lowering. Hence, the influence of micellar solubilization, if any, on the dissolution rate of prednisolone is this study cannot be assessed.

Bates, Gibaldi, and Kanig (2) reported substantial increases in the dissolution rates of griseofulvin and hexestrol in micellar solutions of bile salts. In each case, because of the extremely low solubility of both drugs, dissolution rate was followed in a concentration region which was above the saturation solubility in water.

Until recently the influence of interacting colloids on dissolution rate in a drug concentration region below saturation solubility had received only theoretical consideration. Higuchi (3) presented a theoretical analysis pertinent to the dissolution of solids in colloidal solutions. The equations resulting from this analysis predict that the effect on dissolution rate as a function of colloidal solubilizer concentration will be far less than the effect predicted by the Noyes-Whitney relationship (4). The latter suggests a direct proportionality between dissolution rate and total solubility. The Higuchi equations (3) further predict that substantial effects on dissolution rate will be observed only when the drug concentration in solution approaches or exceeds saturation solubility. This prediction is in agreement with the findings of Bates *et al.* (2) and the earlier findings of Wurster and Polli (5).

Experimental evidence confirming the theoretical predictions were presented in a recent review (6). The dissolution rate of benzocaine in various concentrations of polysorbate 80[1] was found to be in agreement with the diffusional model proposed by Higuchi rather than the Noyes-Whitney equation. Higuchi (6) has further suggested that the magnitude of effects of interacting colloids on dissolution rates could be used for the differntiation of dissolution mechanism.

The present report concerns a study of the solubilization and dissolution rate of benzoic acid in solutions of a nonionic ether-type surfactant. Dissolution rate was followed under stirred and static conditions. It is the purpose to demonstrate that the effect of micellar solubilization on dissolution rate cannot be predicted by the Noyes-Whitney equation and to propose that different mechanisms of dissolution may be operative under stirred and static conditions.

EXPERIMENTAL

Materials—Baker analyzed reagent benzoic acid was used as the dissolving solid and polyoxyethylene (23) lauryl ether,[2] served as the solubilizing agent.

Solubility Determinations—Benzoic acid solubility was determined in a series of aqueous solutions containing various concentrations of polyoxyethylene (23) lauryl ether. In each case, an amount of benzoic acid in excess of the amount required for saturation solubility was added to the surfactant solutions contained in 25-ml. culture tubes. The tubes were sealed, placed in a Metabolyte incubator shaker (New Brunswick Scientific Co., N.J.), and equilibrated at 37° for 3–5 days. Equilibrium was determined by repetitive sampling.

Determination of Dissolution Rate—Dissolution rates were determined at 37° by the rotating disk (7, 8) and static disk (9) methods, using 300 ml. of water or aqueous solutions of polyoxyethylene (23) lauryl ether. Speed of rotation for the rotating disk experiments was 100 r.p.m.

Assay—Aliquot samples were passed through a Millipore filter (0.45 μ pore size), when necessary, and appropriately diluted with 0.1 *N* HCl. Benzoic acid concentration was determined spectrophotometrically at 230 mμ using a Beckman DB-G recording spectrophotometer. In each case, an appropriate concentration of surfactant was contained in the blank to avoid interference.

RESULTS AND DISCUSSION

Figure 1 shows the saturation solubility of benzoic acid as a function of surfactant concentration. The results describe a typical solubilization curve with a linear relation between solubility and polyoxyethylene (23) lauryl ether concentration above the CMC. Solubilization studies at low surfactant concentrations indicate a CMC of less than 0.1 Gm./100 ml.

According to the Noyes-Whitney relationship (4), under sink conditions and with constant surface area, dissolution rate (*d.r.*) may be described by the following equation:

$$d.r. = KC_s \qquad \text{(Eq. 1)}$$

where K is a constant and C_s is the solubility. In nonmicellar systems, $K = D/h$ where D is the solute molecule diffusion coefficient, and h is the effective diffusion layer thickness. If one assumes that both D and h remain invariant if the drug is dissolved in a medium containing colloidal solubilizer, then it may be deduced from Eq. 1 that

$$R = \frac{Cs^*}{Cs} \qquad \text{(Eq. 2)}$$

where R is the ratio of dissolution rate in surfactant solution to that in pure solvent and Cs^* is the drug solubility in surfactant solution.

Using the solubility data obtained in the present

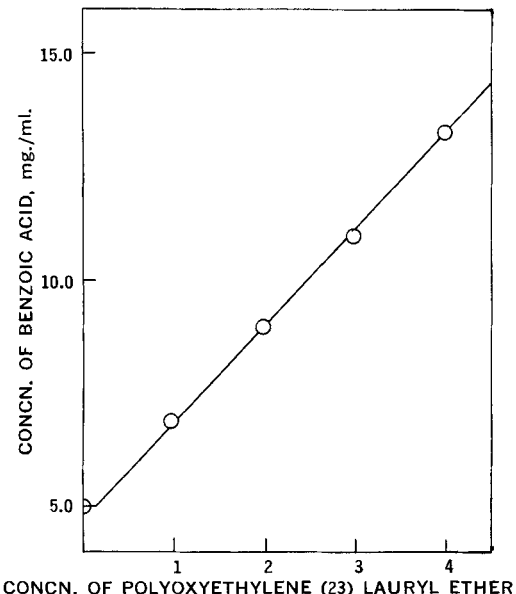

Fig. 1—Saturation solubility of benzoic acid as a function of surfactant concentration.

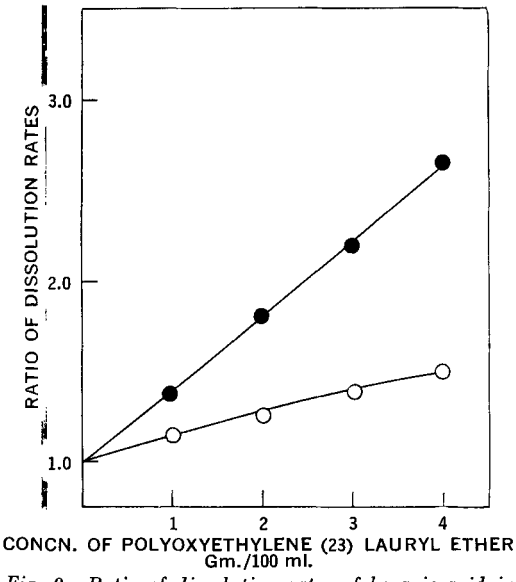

Fig. 2—Ratio of dissolution rates of benzoic acid in surfactant solution to that in water. Key: ●, upper curve was constructed by means of the Noyes-Whitney equation and solubility data: ○, lower curve represents experimental dissolution rate data.

study the theoretic dissolution rate ratios employing Eq. 2 were determined. The results are shown in Fig. 2 in contrast to the experimental dissolution rate ratios determined at 100 r.p.m. The curves in Fig. 2 clearly demonstrate that the Noyes-Whitney relation fails to predict dissolution behavior in systems containing colloidal solubilizers. Dissolution rates of benzoic acid in solutions containing polyoxyethylene (23) lauryl ether are substantially less than anticipated on the basis of solubilization data and the application of the Noyes-Whitney equation.

The dissolution of a drug in the presence of an interacting colloid such as a micelle involves consideration of two diffusing species, *viz.*, the free drug and the drug–micelle interaction product (3). In view of the large difference in molecular weight between the drug molecule and the micellar species, one anticipates a significant difference with respect to the diffusion coefficient of each species. For this situation, the diffusion layer theory gives the following equation (3):

$$d.r. = \frac{DCs}{h} + \frac{D'Cs'}{h} \qquad \text{(Eq. 3)}$$

where D' is the diffusion coefficient of the micelle-solubilized drug and Cs' is the solubility increase due to solubilization. If we assume that h, D, and D' are independent of the concentration of colloidal solubilizer then the following ratio (R) of dissolution rate in surfactant solution to that in pure solvent is predicted by diffusion layer theory.

$$R = \frac{DCs + D'Cs'}{DCs} \qquad \text{(Eq. 4)}$$

As indicated in Eq. 4 the greater the difference between D and D' the greater the negative deviation of R from the ratio value predicted by the Noyes-Whitney equation.

If one assumes that the data under stirred conditions adheres to the diffusion layer theory, a theoretic diffusion coefficient for the micelle-solubilized drug may be determined. Using the experimental R values, the appropriate solubilization data, and a value of 1.2×10^{-5} cm.²/sec. as the diffusion coefficient for benzoic acid (10), an apparent mean diffusion coefficient of 3.8×10^{-6} cm.²/sec. for the micelle-solubilized benzoic acid was calculated.

The ratios predicted by the diffusion layer theory are shown as the dashed line in Fig. 3. The predicted curve fits the experimental data reasonably well. The fit suggests, in agreement with Higuchi (3, 6), that a diffusion layer model can be used to explain the effect of colloidal solubilizers on dissolution rate.

The dissolution studies under static conditions were prompted by the possibility that different mechanisms of dissolution exist under extremely low agitation conditions and under stirred conditions. The results of these studies were used to calculate dissolution rate ratios which are plotted in Fig. 3. At each polyoxyethylene (23) lauryl ether concentration studied the ratio under static conditions was significantly higher than the ratio under stirred conditions.

An advantage of studying dissolution in systems involving interacting materials which result in diffusing species with significantly different diffusion coefficients is the possibility of mechanism differentiation (6). For example, if hydrodynamic conditions are maintained constant, dissolution rate ratios as a function of solubilizer concentration will be the same regardless of the intensity of agitation. A change in the magnitude of a dissolution rate ratio suggests a change in the hydrodynamics of the system and a possible change in the dissolution mechanism. Thus, the difference in dissolution rate ratios observed under static conditions provides evidence for the existence of different dissolution mechanisms.

An alternative to the diffusion layer theory to consider in describing dissolution rate mechanism

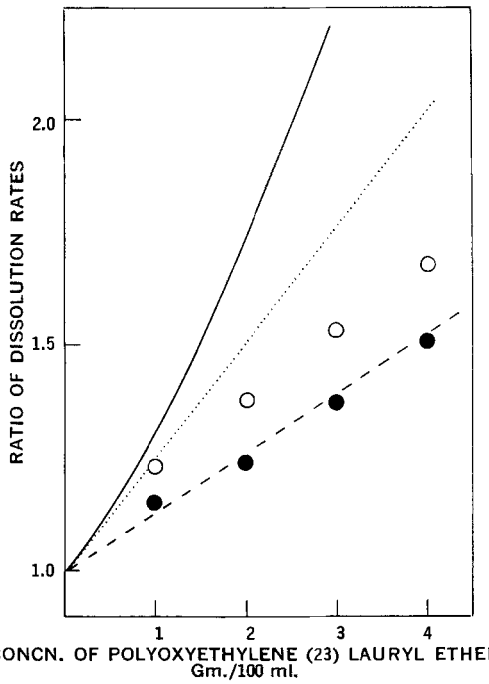

Fig. 3—Ratio of dissolution rates of benzoic acid in surfactant solution to that in water under static (○) *and stirred conditions* (●). *Key: theoretical ratios predicted by Noyes-Whitney theory* (——); *Danckwerts' theory* (· · ·); *and diffusion layer theory* (– – –).

under static conditions is one originally proposed by Danckwerts (11) to describe dissolution phenomenon under turbulent conditions. This model envisions macroscopic packets of solvent impacting the solid-liquid interface by eddy diffusion. Uptake of solute into the packet occurs upon impaction and these saturated surface elements are continually replaced by new packets of solvent. Although the Danckwerts' model was proposed originally to explain dissolution under turbulent conditions, a type of eddy diffusion may exist under static conditions and a transference of concept may be possible.

The appropriate rate expression for dissolution rate per unit area under sink conditions in accord with the Danckwerts' model is

$$d.r. = S^{1/2}D^{1/2}Cs \qquad \text{(Eq. 5)}$$

where S is the mean rate of production of fresh surface. When considering dissolution of a material in a medium of colloidal solubilizer, Higuchi (6) has shown that Danckwerts' theory leads to the following rate equation:

$$d.r. = S^{1/2}\sqrt{(Cs + Cs')(DCs + D'Cs')} \qquad \text{(Eq. 6)}$$

where the terms have the same meaning as previously described. If we assume that S, D, and D' are independent of concentration of solubilizer, then the following ratio of dissolution rate in surfactant solution to that in pure solvent is predicted by Danckwerts' theory.

$$R = \frac{\sqrt{(Cs + Cs')(DCs + D'Cs')}}{D^{1/2}Cs} \qquad \text{(Eq. 7)}$$

Theoretical values of R were calculated from Eq. 7 using an apparent mean diffusion coefficient of 3.8×10^{-6} cm.²/sec. for the micelle-solubilized benzoic acid. The theoretical relation of R and concentration of surfactant is shown as the dotted line in Fig. 3. It is apparent that the Danckwerts' model fits the static dissolution data only at the 1% level. At higher concentrations of polyoxyethylene (23) lauryl ether, progressive deviation is observed.

Several possibilities may be explored to rationalize the lack of agreement of the experimental data with the model. One possibility is that surface renewal rate is dependent on the surfactant concentration, *i.e.*, $S^{1/2} \alpha 1/(\text{surfactant})$. The dependence could involve viscosity or some other physical-chemical property of the system which is a function of polyoxyethylene (23) lauryl ether, concentration.

A second possibility is that the mechanism of dissolution under static conditions involves a combination of the diffusion layer and Danckwerts' models. Such a combination has been termed the film-penetration model (12). This model is similar to the Danckwerts' model except that solvent packets impact a diffusion layer rather than the solid-liquid interface. Interestingly, the film-penetration model has been shown to predict dissolution under turbulent conditions, more accurately than the Danckwerts' model (12).

A further possibility which cannot be ruled out is that dissolution under static conditions actually adheres to Dankwerts' theory, while dissolution under stirred conditions (under the present experimental conditions) manifests negative deviation from the results predicted by this model. The evidence, to date, that dissolution under stirred conditions follows diffusion layer theory is strictly empirical. There has been no independent verification of the model, as for example, by the independent determination of the diffusion coefficient of the drug-micellar species. Hence, the various possibilities cannot be resolved without further investigation.

BIOLOGIC IMPLICATIONS

The present report describes certain dissolution phenomena which may have an important bearing on dissolution in the gastrointestinal tract as well as on the general area of *in vivo-in vitro* correlation. The most successful methodology employed to date to relate *in vitro* dissolution rate with *in vivo* absorption has been described by Levy (13–15) and appears to involve a dissolution mechanism describable by diffusion layer theory. By means of this dissolution method Levy *et al.* (16) have reported quantitative correlation of gastrointestinal absorption in man of aspirin from three markedly different types of dosage forms. The correlation may be expressed as

$$\%\text{ – absorbed at time } T = \%\text{ – dissolved in } \frac{T - \text{lag time}}{2}$$

There is no doubt as to the precision of the correlation. However, in terms of absolute amounts, about twice the amount of drug was dissolved *in vitro* than was absorbed *in vivo* over the same time period. Correlation was observed at 50–60 r.p.m. and failed to exist at higher or lower r.p.m. Thus, it is not possible to correct the correlation in absolute

terms by simply decreasing the agitation rate.

It is proposed that the problem we face in developing *in vivo-in vitro* correlations could involve the mechanism of dissolution as well as the intensity of agitation. The nature of the dissolution mechanism in the gastrointestinal tract is not at all clear. In view of the type of agitation a dissolving solid encounters in the tract as a result of gastrointestinal motility, it is quite conceivable that dissolution will not follow pure diffusion layer theory. The process may be obscured by periodic and irregular diffusion currents which could result in a highly complex dissolution mechanism. Perhaps a combination of diffusion layer and Danckwerts' mechanisms may be operative. A great deal of further experimentation on dissolution is required to resolve these questions.

Kinetics of Reaction of Dehydroacetic Acid II

Reaction With Primary Amines

By S. GOTO, A. KONO, and S. IGUCHI

It was concluded that the conversion of 2,6-bis-(phenethylamino)-2,5-heptadiene-4-one (BPH) into *N*-phenethyl-lutidone (PL) in 80 percent ethanol is accounted for in terms of aminolysis reaction. In general, the aminolysis reaction proceeds *via* a two-step reaction path involving a *gem*-diamine as an intermediate. The first step in the above reaction of BPH becomes reversible by the addition of excess β-phenethylamine (PE-NH). The mechanistic pathway was discussed. Moreover, it was supported with kinetic investigation using an analog computer that BPH is the most important intermediate in the conversion of 3-(1-phenethylamino)ethylidene-6-methyl-3*H*-pyran-2,4-dione (Schiff's base) to PL in the presence of large excess PE-NH.

IN A PREVIOUS paper (1), the kinetic study of Schiff's base formation between dehydroacetic acid (DHA) and β-phenethylamine (PE-NH) has been shown. A further kinetic investigation on the transformation of Schiff's base to *N*-phenethyllutidone (PL)[1] is described, and also an attempt was made to confirm kinetically the reaction mechanism that was proposed by Iguchi *et al.* (2).

EXPERIMENTAL

Materials—Ethanol of superior special grade for precision analysis was used. PE-NH (Wako pure reagent) was redistilled twice (b.p. 178–179°). DHA (Taito Pfizer Co.) was recrystallized from ethanol–water, m.p. 109–110°. Commercial acetic acid was redistilled, and sodium acetate and sodium chloride of pure reagent grade were used for the kinetic studies.

Preparation of 3-(1-Phenethylamino)ethylidene-6-methyl-3H-pyran-2,4-dione (Schiff's Base)—DHA (10 Gm.) was dissolved in 15 ml. ethanol solution containing an equivalent mole of PE-NH and the solution was warmed on a steam bath. After 30 min. the solvent of reaction mixture was distilled *in vacuo*, the residue was washed once with ethyl ether, and recrystallized from ethyl ether–benzene, m.p. 89–91°.

Preparation of 2,6-Bis-(phenethylamino)-2,5-heptadiene-4-one (BPH)—To 5 ml. of ethanol solution of DHA (3.4 Gm.) was added an excess of

[1] The final product of this series of the reaction.

terms by simply decreasing the agitation rate.

It is proposed that the problem we face in developing *in vivo-in vitro* correlations could involve the mechanism of dissolution as well as the intensity of agitation. The nature of the dissolution mechanism in the gastrointestinal tract is not at all clear. In view of the type of agitation a dissolving solid encounters in the tract as a result of gastrointestinal motility, it is quite conceivable that dissolution will not follow pure diffusion layer theory. The process may be obscured by periodic and irregular diffusion currents which could result in a highly complex dissolution mechanism. Perhaps a combination of diffusion layer and Danckwerts' mechanisms may be operative. A great deal of further experimentation on dissolution is required to resolve these questions.

Kinetics of Reaction of Dehydroacetic Acid II

Reaction With Primary Amines

By S. GOTO, A. KONO, and S. IGUCHI

It was concluded that the conversion of 2,6-bis-(phenethylamino)-2,5-heptadiene-4-one (BPH) into *N*-phenethyl-lutidone (PL) in 80 percent ethanol is accounted for in terms of aminolysis reaction. In general, the aminolysis reaction proceeds *via* a two-step reaction path involving a *gem*-diamine as an intermediate. The first step in the above reaction of BPH becomes reversible by the addition of excess β-phenethylamine (PE-NH). The mechanistic pathway was discussed. Moreover, it was supported with kinetic investigation using an analog computer that BPH is the most important intermediate in the conversion of 3-(1-phenethylamino)ethylidene-6-methyl-3*H*-pyran-2,4-dione (Schiff's base) to PL in the presence of large excess PE-NH.

IN A PREVIOUS paper (1), the kinetic study of Schiff's base formation between dehydroacetic acid (DHA) and β-phenethylamine (PE-NH) has been shown. A further kinetic investigation on the transformation of Schiff's base to *N*-phenethyllutidone (PL)[1] is described, and also an attempt was made to confirm kinetically the reaction mechanism that was proposed by Iguchi *et al.* (2).

EXPERIMENTAL

Materials—Ethanol of superior special grade for precision analysis was used. PE-NH (Wako pure reagent) was redistilled twice (b.p. 178–179°). DHA (Taito Pfizer Co.) was recrystallized from ethanol–water, m.p. 109–110°. Commercial acetic acid was redistilled, and sodium acetate and sodium chloride of pure reagent grade were used for the kinetic studies.

Preparation of 3-(1-Phenethylamino)ethylidene-6-methyl-3H-pyran-2,4-dione (Schiff's Base)—DHA (10 Gm.) was dissolved in 15 ml. ethanol solution containing an equivalent mole of PE-NH and the solution was warmed on a steam bath. After 30 min. the solvent of reaction mixture was distilled *in vacuo*, the residue was washed once with ethyl ether, and recrystallized from ethyl ether–benzene, m.p. 89–91°.

Preparation of 2,6-Bis-(phenethylamino)-2,5-heptadiene-4-one (BPH)—To 5 ml. of ethanol solution of DHA (3.4 Gm.) was added an excess of

Received September 25, 1967, from the Faculty of Pharmaceutical Sciences, Kyushu University, Fukuoka, Japan.
Accepted for publication January 18, 1968.
[1] The final product of this series of the reaction.

PE-NH and kept at room temperature for 24 hr. After the solvent was evaporated, the residue was washed once with ethyl ether and then recrystallized, m.p. 115–116°.

Preparation of *N*-Phenethyl-lutidone (PL)—One gram of BPH was dissolved in 20 ml. of water, and a few drops of hydrochloric acid or acetic acid were added. After 10 hr. heating, the reaction solution was dried *in vacuo*. The residue was recrystallized from aqueous methanol, m.p. 167–168°.

Kinetic Studies—BPH was dissolved in 80% v/v ethanol which had previously been adjusted to the desired pH with the addition of acetate buffer solution. The pH values were determined with a Hitachi-Horiba pH meter using glass-saturated calomel electrodes. The ionic strength of the solution was adjusted to 0.1. The solution was transferred to a glass 100-ml. volumetric flask and placed in a constant temperature bath maintained at 60°. Aliquots (1 ml.) were withdrawn at regular time intervals, and the reaction was quenched by cooling in ice water and diluted with distilled water. The progress of the reaction was determined by measuring the samples for residual BPH spectrophotometrically. The products, intermediate (X) and PL, were also determined spectrophotometrically. In the case of conversion reaction of BPH or Schiff's base in the presence of excess PE-NH, the sample solutions were prepared by dissolving substrates in various concentrations of PE-NH (0.0–1.0 *M*).

Calculations of Amounts of Products, BPH, and Schiff's Base—The absorbances of the sample solution were measured against a blank solution at 266 mμ, 322 mμ, and 370 mμ. The calculations are based on the relations;

$$A_{266} = \epsilon^{PL}_{266}(PL)$$

$$A_{322} = \epsilon^{X}_{322}(X) + \epsilon^{BPH}_{322}(BPH)$$

$$A_{370} = \epsilon^{BPH}_{370}(BPH) + \epsilon^{X}_{370}(X)$$

Molar absorptivity values are $\epsilon^{PL}_{266} = 19{,}900$, $\epsilon^{X}_{322} = 20{,}000$, $\epsilon^{BPH}_{322} = 3{,}600$, $\epsilon^{BPH}_{370} = 41{,}600$, $\epsilon^{X}_{370} = 2{,}500$,

where $A\lambda$ is the absorbance at a wavelength λ in mμ for the sample solution, and (PL), (X), and (BPH) are molar concentrations of PL, intermediate, and BPH, respectively. The molar absorptivity value of intermediate could be estimated from the initial concentration of BPH, the molar absorptivity value of BPH, and the absorbances of the sample solution at 322 mμ and 370 mμ in the initial reaction time when the formation of PL was not observed.

In the case of conversion reaction of Schiff's base in the presence of excess PE-NH, the absorbances of the sample solution were measured at 266 mμ, 310 mμ, and 370 mμ. The calculations for each compound follow:

$$A_{266} = \epsilon^{PL}_{266}(PL) + \epsilon^{S}_{266}(S)$$

$$A_{310} = \epsilon^{S}_{310}(S) + \epsilon^{BPH}_{310}(BPH)$$

$$A_{370} = \epsilon^{BPH}_{370}(BPH)$$

Molar absorptivity values are: $\epsilon^{S}_{266} = 1{,}800$, $\epsilon^{S}_{310} = 16{,}100$, $\epsilon^{BPH}_{310} = 2{,}600$. Other values were already described, where (S) is the concentration of Schiff's base in the aliquot. The percentage deviation for above analytical procedure was ±4%. The existence of PE-NH did not interfere with their determinations.

Thin-Layer Chromatographic Analysis—The thin-layer plates (5 × 20 cm.) were coated with a 0.5-mm. layer of Silica Gel B-5 (Wako pure reagent). After the sample solution was spotted on the plates, the plates were developed with ethyl ether. The solvent front was allowed to advance 13 cm. When the developed plates were exposed to iodine vapor in a sealed glass box, the visible spots with R_f values corresponding to BPH (0.47) and PL (0.0) were recognized. When acetone was used, the R_f value of PL ascended 0.15. In the case of the reaction between Schiff's base and PE-NH, the R_f value for Schiff's base was 0.22. Unfortunately, it was impossible to get an R_f value for the intermediate on the developed plates.

Computer Analysis—A Beckman Instrument Inc., Ease analog computer was utilized for this investigation.

RESULTS AND DISCUSSION

Conversion of 2,6-Bis-(phenethylamino)-2,5-heptadiene-4-one (BPH) in Acetate Buffer Region—An attempt was made at first to investigate the conversion of BPH to PL in acetate buffer region. The apparent first-order rate constants for the loss of BPH decreased rapidly with the increase of experimental pH as shown in Table I.

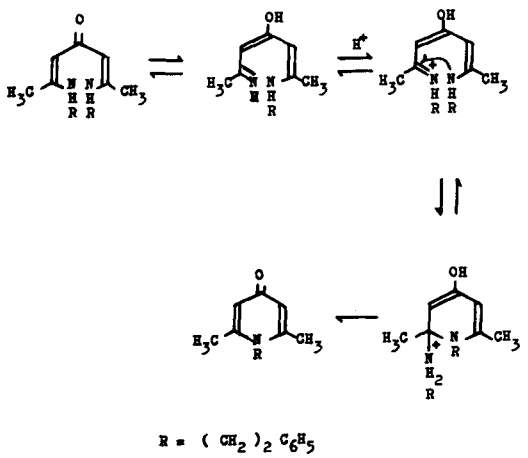
The conversion of BPH was followed by the loss of spectrophotometric absorbance. Because absorbance at 370 mμ decreased with time concurrent with increase in absorbance over the region 322 to 266 mμ, the following route was postulated:

$$\text{BPH} \xrightarrow{k_1} \text{intermediate (X)} \xrightarrow{k_2} \text{PL}$$

TABLE I—APPARENT FIRST-ORDER RATE CONSTANT FOR THE CONVERSION OF BPH IN ACETATE BUFFER REGION AT 60°[a]

Observed pH	k_1	k_2
4.82	...	7820
6.41	...	226
7.11	630, 620[b]	46.0, 46.0[b]
7.53	219	22.0
8.18	51.3, 54.5[c]	8.80, 8.80[c]
8.50	25.1, 27.0[d]	2.00, 2.00[d]
9.85[e]	6.97	1.13
10.1[f]	7.00	3.37

[a] $10^4\ k_1$ and $10^6\ k_2$ in sec.$^{-1}$. Initial concentration: BPH, 0.8 to 3.0 × $10^{-3}M$. The ionic strength was adjusted to 0.1 by the addition of sodium chloride. [b] When the concentration of acetate buffer solution was at twofold ranges, no significant differences in the apparent rate constants were observed. [c] When the concentration of acetate buffer solution was at a half range, no significant differences in the apparent rate constants were observed. [d] When the concentration of substrates was twofold ranges, no significant differences in the apparent rate constants were observed. [e] No acetate buffer solution was used. [f] Sodium acetate was used.



R = $(CH_2)_2C_6H_5$

Scheme I—Proposed route for the conversion of BPH into PL.

The first-order rate constants for the conversion of BPH at pH values below 6.4 were quite large. The reason for this behavior is considered as follows. Under more acidic conditions, all BPH is predominantly protonated and the intramolecular amine attached to the protonated carbon atom becomes an important reaction pathway, and it is expected that the conversion rate of BPH is related to the existence of protonated BPH. The pH-independent region for k_1 is observed under a weakly basic condition and the rate becomes small in this region. It is probably the consequence of the minimum protonated BPH existence. These results may be accounted for in terms of intramolecular aminolysis reaction that is the replacement of the amine component by another amine in the same molecule. Numerous papers (3–5) have mentioned that the imines, particularly when existing in cationic form $\left(\diagup C{=}\overset{+}{N}\diagdown\right)$, readily react with various nucleophilic reagents involving water and amines, and that the reaction is accelerated with an addition of hydrogen ions or an increase in negative charge of nucleophilic reagents. The conversion mechanism of BPH to PL was proposed as shown in Scheme I.

The reaction proceeds *via* a two-step reaction path involving a *gem*-diamine as an intermediate. Such an intermediate is analogous to the carbinolamine for hydrolysis and formation of Schiff's base. Moreover, the formation and decomposition of the *gem*-diamine are expected to be a function of pH. Koehler *et al.* (3) have stated "although the existence of an intermediate in the aminolysis reaction of Schiff's base has yet to be demonstrated, the nature of the reaction almost certainly required that they proceed via a two-step reaction path involving a gem-diamine as intermediate." In our experiment, the existence of the intermediate was not shown by the thin-layer chromatogram. But it is expected that the absorbance at 322 mμ may show the existence of the intermediate.

Conversion of 2,6-Bis-(phenethylamino)-2,5-heptadiene-4-one (BPH) in the Presence of Excess β-Phenethylamine (PE-NH)—The first step in BPH conversion reaction became reversible in the presence of excess PE-NH. When a great excess of PE-NH was added, the equilibrium constant (K) governing the formation of the intermediate (X) from BPH was smaller than in the presence of small excess PE-NH. It may be explained by the acceleration of reverse reaction (X → BPH) in more basic conditions because it was observed that the reverse reaction rate became quite large in a 0.04 N NaOH solution. The conversion rate of the intermediate (X) into PL was also accelerated proportionally to the increasing PE-NH. This fact may be rationalized in terms of the general acid catalytic reaction by the protonated PE-NH in this step. Therefore, the process of the conversion of BPH to PL can be described as follows:

$$\text{BPH} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \text{intermediate (X)} \overset{k_2}{\longrightarrow} \text{PL}$$

Based on the assumption, $k_1 + k_{-1} \gg k_2$, the molar concentrations of BPH, intermediate (X), and PL over the whole reaction period can be described by approximate equations (6) as shown in the following:

$$(\text{BPH}) = \frac{k_{-1}}{(k_1 + k_{-1})} \cdot e^{-\frac{k_1}{(k_1 + k_{-1})} \cdot k_2 t} \quad \text{(Eq. 1)}$$

$$(\text{X}) = \frac{k_1}{(k_1 + k_{-1})} \cdot e^{-\frac{k_1}{(k_1 + k_{-1})} \cdot k_2 t} \quad \text{(Eq. 2)}$$

$$(\text{PL}) = 1 - e^{-\frac{k_1}{(k_1 + k_{-1})} \cdot k_2 t} \quad \text{(Eq. 3)}$$

Where (BPH), (X), and (PL) are the molar concentrations of BPH, intermediate, and PL, respectively. The k_1 and k_{-1} are the rate constants for forward and reverse reactions, respectively, and k_2 is the rate constant for formation of PL from the intermediate. The equilibrium constant ($K = k_1/k_{-1}$) shown in Table II, can be estimated from experimental results.

Under the experimental condition (BPH: $1 \times 10^{-2}M$, PE-NH: 1.0 M) in which PE-NH is

				$\widetilde{k_{app.}}$[b]	

[a] k in hr.$^{-1}$. [b] $k_{app.}$ represents the apparent first-order rate constant for the conversion of BPH into PL.

greatly in excess of substrate, the reaction appearance has been changed, that is, the concentration of the intermediate (X) was maintained quite small or almost zero over the entire experimental period of kinetic run. On the other hand, it was determined experimentally that the amount of PL formed was not equal to the amount of BPH decreased. Based on the above result, another route must be established. Three pathways are considered:

$BPH \rightleftharpoons X \rightarrow PL$, with $BPH \rightarrow C$ (Route 1)

$BPH \rightleftharpoons X \rightarrow PL$, with $X \rightarrow C$ (Route 2)

$BPH \rightleftharpoons X \rightarrow PL \rightarrow C$ (Route 3)

But Route 3 should be neglected because no degradation was observed for PL over the entire experimental time. The selection of a suitable route was conducted by using an electronic analog computer. Since the equilibrium between BPH and the intermediate (X) is quickly formed at the initial stage of conversion reaction, the rate constant in each reaction step can be easily estimated. When their validity was checked by the analog computer, a good agreement was found between the computer calculated concentration-time curves and the experimental results in the case of Route 1. And the Route 2 may be omitted. The sign C shows the overall products except PL and they are assumed to be mainly various condensation products. The obtained values for rate constants and equilibrium constants are shown in Table III.

Conversion of Schiff's Base in the Presence of Excess β-Phenethylamine (PE-NH)—The experimental condition of treating a great excess of PE-NH (1.0 M) over the Schiff's base (1×10^{-2} M) was selected for the purpose of deciding on a major reaction route. The route for the conversion of Schiff's base to BPH would be attacked by an amine molecule on 6 position of carbon atom, opening the pyronl ring and continuous decarboxylation. But, unfortunately, no intermediates in the above reaction route could be isolated synthetically and spectrophotometrically. Based on the assumption that the concentrations of intermediates are almost zero, the apparent first-order rate constant on the conversion of Schiff's base into BPH was calculated. Typical changes of the spectral curves as a function of time are given in Fig. 1.

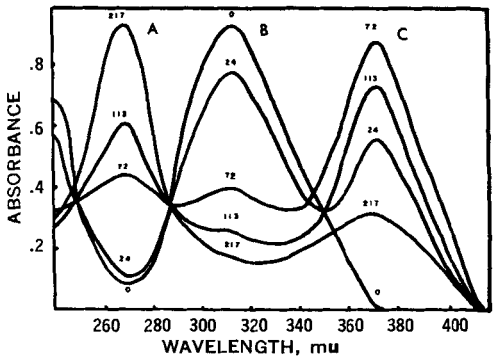

Fig. 1—The spectral changes of the reaction between Schiff's base and excessive β-phenethylamine in 80% ethanol at 60°. Initial concentration: Schiff's base, 1×10^{-2}M; β-phenethylamine 1.0 M. Key: A, PL; B, Schiff's base; C, BPH. The time of the readings after the start of the reaction is given in hours.

The changes of maximum absorbance at 310 mμ are characteristic of the first-order conversion of Schiff's base, because the intermediate (X) ($\lambda_{max.}$ = 322 mμ) formed remains almost zero during the solution conversion. The obtained first-order rate constant for loss of Schiff's base is adapted to Eqs. 4–7 together with the rate constants which were calculated in the previous section for BPH conversion in the presence of a great excess of PE-NH.

Schiff's base (S) $\xrightarrow{k}$ (0.0145 hr.$^{-1}$) BPH $\xrightarrow{k'}$ (0.019 hr.$^{-1}$) PL; BPH $\xrightarrow{k''}$ (0.007 hr.$^{-1}$) other products (C)

Therefore, the differential equations for the above route are:

$$d(S)/dt = -k(S) \quad \text{(Eq. 4)}$$

$$d(BPH)/dt = k(S) - k'(BPH) - k''(BPH) \quad \text{(Eq. 5)}$$

$$d(PL)/dt = k'(BPH) \quad \text{(Eq. 6)}$$

$$d(C)/dt = k''(BPH) \quad \text{(Eq. 7)}$$

The circuit diagram used in an electronic analog computation for the above equations is shown in Fig. 2.

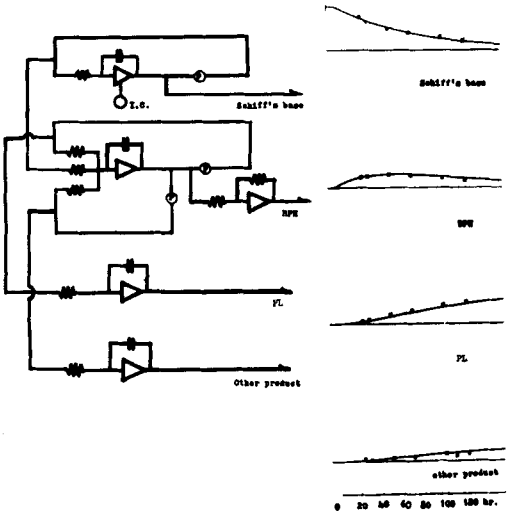

Fig. 2—Block diagram and computer curves obtained by computer analysis. Key: ——, obtained curve; •, experimental value

The agreement between the obtained and experimental values supports the idea that the reaction proceeds on the strength of the above mechanism represented by the simplified scheme and that BPH is the most important intermediate in the conversion route of Schiff's base into PL in the presence of a great excess of PE-NH.

Thiry-Vella Dog as a Biologic Model for Evaluation of Drug Absorption from the Intestinal Mucosa

By R. G. SAMPLE, G. V. ROSSI, and E. W. PACKMAN

The Thiry-Vella fistula dog was found to provide a quantitative and reproducible pharmacometric system for the evaluation of drug absorption from the intestinal mucosa. Instillation of buffered solutions of *N*-acetyl-*p*-aminophenol (acetaminophen) into the *in situ* jejunal loop resulted in rapid and essentially complete absorption. Within the range examined (75, 150, 300, and 450 mg.), an increase in dose was reflected by a commensurate increase in the plasma concentration of *N*-acetyl-*p*-aminophenol. Plasma concentration curves for each dosage level were parallel over a 2-hr. postadministration period. The Thiry-Vella fistula provides a stable, readily accessible segment of intestinal mucosa with blood, nerve, and lymph supplies intact. The chronicity of the fistula preparation permits each animal to serve as its own control and to be used repeatedly to compare the absorption characteristics of the same drug at different dosage levels, as well as different drugs at the same or alternate dosage levels.

A WIDE VARIETY of *in vivo* and *in vitro* techniques have been employed in the study of intestinal absorption depending fundamentally on the objectives and preferences of the investigator. Although many methods have been introduced, there has not been developed a relevant and reproducible biologic model for the study of factors relating to drug absorption from the intestinal mucosa, and for evaluation of concepts established principally in *in vitro* systems.

Accepted for publication January 9, 1967.
This research was supported in part by a grant from Smith Kline & French Laboratories, Philadelphia, PA 19101
The authors wish to express their appreciation to Dr. J. T. Doluisio, University of Kentucky College of Pharmacy, and Dr. E. T. Sugita, Philadelphia College of Pharmacy and Science, for their valuable suggestions during the course of this research.

The Thiry-Vella dog (1) provides a chronic *in situ* loop preparation consisting of a segment of small intestine, isolated with its blood, nerve, and lymph supplies intact, in which both the oral and aboral ends of the segment are exteriorized through the abdominal wall and sutured in place. Thus there is formed a readily accessible U-shaped loop of intestine having considerable physiologic integrity. With proper postsurgical care the fistula remains patent, enabling each animal to be used repeatedly and to serve as its own experimental control, thus providing a high degree of stability and reproducibility. Previous investigations utilizing the Thiry-Vella loop have been concerned primarily with the study of intestinal secretions (2, 3), the absorption of nutrient factors (4–8), and the effect of drugs on the motility of intestinal smooth muscle (9). The basic objective of the research described in this report was to explore the feasibility of the Thiry-Vella preparation as a biologic model for the evaluation of the absorption of drugs from the intestinal lumen.

EXPERIMENTAL

Preparation of Thiry-Vella Fistulae—Five male and 7 female mongrel dogs (9–13.6 Kg.) were used in the various phases of this investigation. Eight of these animals were surgically prepared with a Thiry-Vella fistula according to the procedure described by Markowitz (10). A postsurgical period of not less than 3 weeks elapsed prior to investigational use of each animal. All animals were maintained on a standard laboratory diet, and housed in temperature-, humidity-, and, light-controlled quarters.

Intestinal Instillation—Solutions for intestinal instillation contained either 75, 150, 300, or 450 mg. of *N*-acetyl-*p*-aminophenol (SKF ISO No. 141819) in 25 ml. of phosphate buffer at pH 5.8. Following anesthetization (sodium pentobarbital, 35 mg./Kg., intravenously) of the test animal, previously fasted for 18–24 hr., the fistula was washed with normal saline solution, warmed to 37° to remove any secretion or particulate matter. Washing was continued until the effluate was clear. Thirty minutes after termination of washing, clamped polyethylene tubing was inserted 2 cm. into each end of the fistula. One clamp was opened and a 25-ml. volume of *N*-acetyl-*p*-aminophenol buffered solution, warmed to 37°, was introduced into the fistula. The tubing was again clamped. Care was taken to insure that none of the instilled fluid was lost through leakage. Venous blood samples were obtained prior to and 6, 12, 18, 24, 30, 60, and 120 min. after instillation, and analyzed for total *N*-acetyl-*p*-aminophenol in the plasma.

Oral Administration—Gelatin capsules, containing either 75, 150, 300, or 450 mg. of *N*-acetyl-*p*-aminophenol, were administered orally. Immediately after swallowing the capsule, the test animal was anesthetized. Blood samples were obtained prior to and 15, 30, 60, 120, 180, 240, 300, and 360 min. after oral administration and analyzed for total *N*-acetyl-*p*-aminophenol in the plasma.

Intravenous Administration—Solutions for intravenous administration contained either 75, 150, 300, or 450 mg. of *N*-acetyl-*p*-aminophenol in 25 ml. of 0.9% saline. After anesthetization of the test animal, 25 ml. of the solution, previously warmed to 37°, was injected over a period of 30 sec. Blood samples for analysis were obtained prior to and 15, 30, 60, 120, 180, and 240 min. after injection.

Analytical Procedures—The blood plasma volume of each animal was determined by means of an isotope dilution technique using radio-iodinated (^{131}I) serum albumin (11). A modification (12) of the method of Brodie and Axelrod (13) was employed in assaying the total *N*-acetyl-*p*-aminophenol content of plasma samples.

RESULTS AND DISCUSSION

A critical consideration in the laboratory evaluation of new drugs and new dosage formulations intended for oral administration is the availability of feasible and relevant methodology with which to assess gastrointestinal absorption. Although various *in vitro* and *in vivo* techniques have contributed fundamentally to an understanding of the physicochemical principles involved in the absorption process, the applicability, and predictive value of current methodology in this field leaves much to be desired. Theoretical considerations led us to explore the Thiry-Vella dog as a potential pharmacometric system and, in our opinion, this research has provided support for the utility of the fistula preparation as a biologic model for the evaluation of drug absorption from the intestinal mucosa.

One of the technical problems requiring resolution was the method of administration of drug solution into the *in situ* intestinal loop. Constant rate perfusion of drug solution through the Thiry-Vella loop was found to produce swelling and distention of tissue which did not occur following introduction of relatively small fixed volumes into the isolated intestinal segment. Furthermore, pressure exerted on the intestinal wall, as occurs during perfusion, may artificially facilitate drug absorption. Comparative studies indicated that maintenance of the physiological integrity of the intestinal mucosa could best be achieved by the instillation of fixed volumes of solution.

Selection of *N*-acetyl-*p*-aminophenol as a tool for studying the feasibility of the Thiry-Vella dog as a biologic model for evaluation of drug absorption was based primarily on two considerations: availability of a quantitative procedure for the determination of *N*-acetyl-*p*-aminophenol in biological fluids and the predicted physical state of the compound at the pH of the mucosal segment. The pH of the jejunum in the dog has been reported (2) to range from pH 4 to 7.6. Under the conditions of this study, the pH of the Thiry-Vella jejunal loop was found to be pH 5.3 to 6.3. *N*-Acetyl-*p*-aminophenol has a pKa in excess of 12 and therefore would not be appreciably ionized at pH 5.8, the pH selected for the buffered solution of drug to be instilled in the Thiry-Vella loop. In view of the well-established concepts of the relative lipid solubility of the unionized moiety, it could be anticipated that the compound would be effectively absorbed from the jejunal loop at pH 5.8.

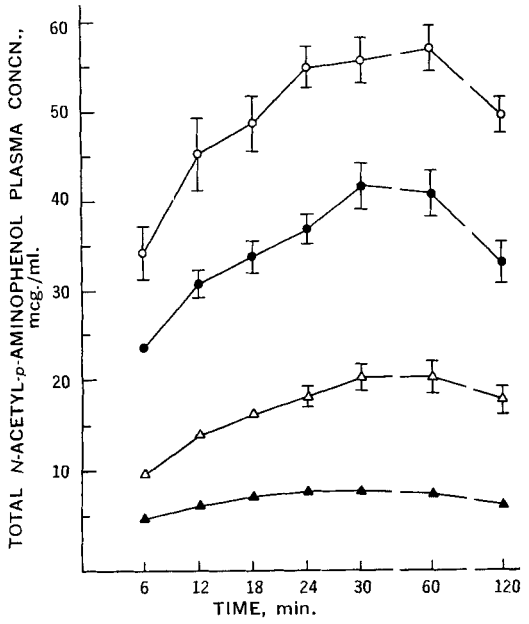

Fig. 1—Total N-*acetyl*-p-*aminophenol plasma concentration (mcg./ml.) in Thiry-Vella dogs following intestinal instillation of designated doses. Key:* ▲, *75 mg.;* △, *150 mg.;* ●, *300 mg.;* ○, *450 mg. in 25 ml. of phosphate buffer (pH 5.8). Each point represents the mean (± S.E.) response of 2 trials in each of 4 dogs. Where not indicated, the S.E. values are equivalent to less than 2 mcg./ml.*

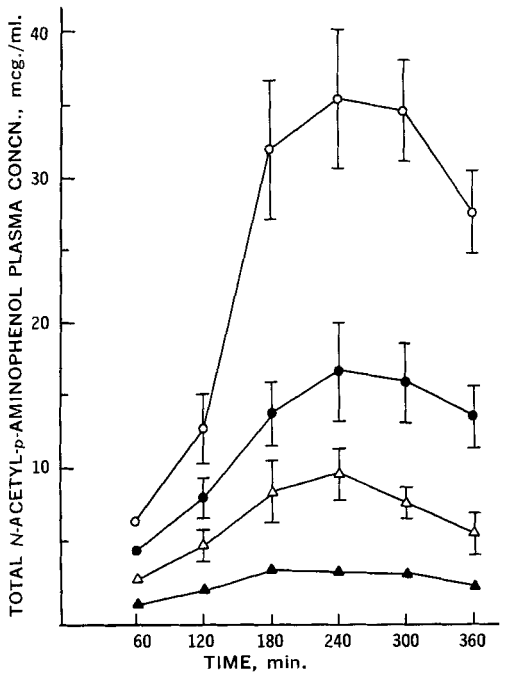

Fig. 2—Total N-*acetyl*-p-*aminophenol plasma concentration (mcg./ml.) in dogs without a Thiry-Vella fistula following oral administration of designated doses. Key:* ▲, *75 mg.;* △, *150 mg.;* ●, *300 mg.;* ○, *450 mg. Each point represents the mean (± S.E.) response of 2 trials in each of 4 dogs. Where not indicated, the S.E. values are equivalent to less than 2 mcg./ml.*

Since absorption was estimated as a function of the concentration of drug in the plasma, and since the blood plasma volume percent was essentially identical (4.35 ± 0.25%) in those animals prepared for this investigation, the experimental drug was administered on a mg./animal basis rather than on a mg./Kg. basis.

Following intestinal instillation of buffered solution of *N*-acetyl-*p*-aminophenol into the chronic Thiry-Vella fistula dog, absorption was initiated within the first 6 min., and the plasma concentration reached a peak within 30–60 min. Graphical representation of the data (Fig. 1) shows that within the dosage range examined, an increase in dose was reflected by an increase in the concentrations present in the plasma commensurate with the dose increments, and that the curves representing the plasma concentrations at the various posttreatment time periods for doses of 75, 150, 300, and 450 mg. were parallel. Therefore, as the dose of the experimental drug was increased the amount absorbed into the blood was increased indicating that the model quantitatively reflects drug absorption from the intestinal mucosa.

The apparent differences in the resulting plasma concentrations of *N*-acetyl-*p*-aminophenol among the various dosage levels were established by analysis of variance as being statistically significant (P = 0.01–0.001). Statistical analysis also indicated no lack of parallelism among the time-response curves.

Analysis of the plasma samples following intravenous injection revealed that the rate of disappearance of *N*-acetyl-*p*-aminophenol from the blood was relatively slow. A comparison of the plasma concentrations following intestinal instillation and those occurring subsequent to intravenous injection of identical doses indicated that, for the dosage range examined, from 80 to 98% of the drug introduced into the intestinal fistula was absorbed.

The characteristics of the Thiry-Vella fistula suggested that drug absorption from this relatively standardized mucosal segment would be subject to fewer variables than encountered upon exposure of the drug to the entire gastrointestinal tract. Therefore, it was of interest to compare absorption following instillation of the experimental drug into the *in situ* loop with that occurring after oral administration. Plasma levels subsequent to the oral administration of *N*-acetyl-*p*-aminophenol to dogs without a Thiry-Vella fistula evidenced (Fig. 2) substantially greater variability than those observed after instillation of identical doses of drug into the intestinal loop.

The applicability of the Thiry-Vella dog to the study of the kinetics of drug absorption is apparent. Following instillation, simultaneous sampling of the blood and the contents of the intestinal loop may be performed to determine the extent of retention, if any, of test agent in the intestinal compartment. Further, the drug may be injected intravenously and periodic samplings taken subsequently from the *in situ* loop. Thus, by determining the concentration of drug in the blood, that which remains in the loop, and that which may be transferred from the blood into the intestinal loop, it may be possible to

establish the kinetics of the absorption phenomena in this biologic model.

Although major abdominal surgery is required, the chronicity of the fistula dog permits each animal to serve as its own control. The same animal can be used repeatedly to compare the absorption characteristics of the same drug at different dosage levels, as well as different drugs at the same and alternate dosage levels. It may also be possible to evaluate absorption from various dosage formulations such as solutions, suspensions, single dose, and sustained-release solid dosage forms. Investigations of the interactions of drug combinations with regard to intestinal absorption are also feasible because the animal is serving as its own control. This is in contrast to other techniques, such as the ligated rat intestine, where the viability of the isolated segment is in question after a relatively short period of time.

Furthermore, the animal and *in situ* loop may be considered essentially identical for each experiment. The uniformity of the absorbing surface (*i.e.*, the loop) does not vary in a given animal as contrasted with the use of different animals. The mucosal epithelium, the blood, lymph, and nerve supplies remain essentially constant from one experiment to another.

The absorbing surface of the intestinal mucosa of the dog is closely related to that of man. Thus, preliminary investigations using Thiry-Vella dogs can provide data from which at least semi-quantitative predictions may be made of the absorption of a compound in man.

Factors Affecting the Dissolution Rate of Medicaments from Tablets I

In Vitro Dissolution Rate of Commercial Phenobarbital Tablets

By JAMES T. JACOB* and ELMER M. PLEIN

An *in vitro* dissolution test method is described and 42 lots of commercial phenobarbital tablets produced by 24 manufacturers were evaluated by means of the test. Thirteen lots of tablets showed incomplete dissolution within 30 min., six of which failed to release 100 percent of the drug in 1 hr. The dissolution rate data are compared with those obtained by the USP XVII tablet disintegration procedure. No correlation existed between the two tests.

THE IMPORTANCE of determining physiological availability of medicaments from tablets was recognized only recently. Even though the USP tablet disintegration test is not designed to show a measure of physiological availability of medicament, this test is used by manufacturers, as well as drug control agencies, as one of the criteria in determining the quality of tablets. There is evidence in the literature that this test leaves much to be desired as a control test in the production of tablets (1–3).

Nelson (4) reported that dissolution rate was the rate-determining factor in absorption of

tetracycline, provided that the dosage form restricted the initial surface area. He reported also that absorption of benzylpenicillin and of acetylsalicylic acid was proportional to the dissolution rate of the drugs in the gastrointestinal tract (5). Levy (6) has pointed out that the dissolution rate of a drug in particulate form is determined by a number of factors including intrinsic dissolution rate, particle size distribution, speed and type of agitation, anisotropism, and presence of other solids.

A variety of techniques is used to determine *in vitro* dissolution rates of medicaments from tablets. Levy and Hayes (7) used a beaker method to determine the dissolution rates of nationally advertised brands of aspirin. Later Levy devised the oscillating tube method and the rotating disk method (8). A revolving plastic dialysis cell containing a paper membrane was used by Marlowe and Shangraw (9) to determine dissolution rate of sodium salicylate from tablets. Schroeter and Wagner (10) used an automatic dissolution apparatus consisting of a USP tablet disintegration apparatus connected through a flow cell to a spectrophotometer, with attachments for filtration and dilution of solution. Several solid dosage forms were studied by this procedure.

A survey of recent literature shows several instances of clinical ineffectiveness of commercial tablets which met USP requirements including disintegration tests. These reports include prednisone tablets evaluated by Campagna *et al.* (3), studies by Carter (11), by Levy (12), and Brudney *et al.* (13) of tolbutamide tablets, and a study by Lozinski (14) of bishydroxycoumarin tablets. In each case the *in vitro* dissolution rate of the drug was found to be poor.

An *in vivo* dissolution and absorption test would likely give a more complete evaluation of a tablet formulation than could an *in vitro* test; however since an *in vivo* test would involve such factors as individual and species variation in absorption as well as tablet dissolution, interpretation of the results of such tests is very complex. Whereas *in vitro* dissolution tests do not register physiological availability of a drug *per se*, yet carefully designed *in vitro* dissolution tests can be used as an index of the physiological availability of active constituents from tablets. Different formulation and manufacturing procedures are known to influence the disintegration rate and the dissolution rate of tablets. The objectives of this study were (*a*) to determine the USP disintegration rate and the *in vitro* dissolution rate of a generic name product, namely phenobarbital tablets manufactured by several companies and (*b*) to study how some variable factors in manufacture and storage affect the availability of phenobarbital from the uncoated tablet. This portion of the report is concerned with commercially available tablets.

Phenobarbital is supplied in tablets of various strengths by a number of different pharmaceutical companies. Phenobarbital is a weak acid with a pKa of 7.5. It is readily absorbed from stomach, small intestine, rectum, and intramuscular sites. The mechanism of absorption from gastrointestinal sites is by nonionic diffusion (15).

EXPERIMENTAL

Commercial Phenobarbital Tablets—Forty-two lots of uncoated phenobarbital tablets of various strengths (1/4 gr., 1/2 gr., and 1 1/2 gr.) manufactured by 24 different pharmaceutical concerns within the United States were purchased either directly from the manufacturer or from wholesale drug suppliers. The dissolution rate of each lot of tablets was determined. The USP disintegration test was carried out on those lots of tablets which showed poor dissolution rate in the acid medium.

In Vitro Dissolution Test—A modified oscillating tube method originally designed by Levy (8) was used. The modified apparatus consisted of an oscillating tube which was a Plexiglas cylinder (19 cm. in length and 1.9 cm. in diameter) with a 40-mesh stainless steel screen fused to one end and a wire hook attached to the other end. The cylinder was attached to the basic unit of USP tablet disintegration apparatus by means of the wire hook (oscillating tube replacing basket-rack assembly). The cylinder was inserted through the opening of a plastic lid into a 400-ml. beaker containing 300 ml. of 0.1 *N* HCl of pH 1.2 (acid medium) or a buffer solution[1] (alkaline medium) of pH 9.5 maintained at 37° ± 0.5°. A 2-blade stirring shaft was introduced into the beaker through another opening in the plastic lid. The shaft was attached to a variable speed external stirrer.[2] The apparatus was set in motion, and a weighed tablet was dropped into the cylinder. At the end of 5 min. the apparatus was stopped, the cylinder was detached and gently raised above the level of the medium. The solution was then stirred at 600 r.p.m. for 30 sec. and 5 ml. was pipeted for analysis. The oscillating tube was then slowly immersed into the medium and the apparatus was set in motion once again. Five milliliters of medium was added to the solution in the beaker to replace that amount withdrawn. Samples were taken similarly at 10-, 20-, 30-, and 60-min. intervals and analyzed. Three runs were made on each lot of tablets and their average was recorded. If readings were not within 2% of average, then the experiment was repeated three more times and the average of the six readings was recorded.

Analytical Method—Phenobarbital was determined spectrophotometrically with a Beckman

[1] The buffer solution (boric acid–potassium chloride–sodium hydroxide) was prepared according to the method described by Mattson (16).

model DU spectrophotometer. Solutions were filtered through Whatman No. 41 filter paper and were diluted appropriately with buffer solution of pH 9.5 and the absorbance was measured at 240 mμ.

Disintegration Test—The USP XVII tablet disintegration test with and without disks was carried out on 13 lots of tablets which showed poor dissolution rates in acid medium. Actual disintegration times were recorded.

RESULTS AND DISCUSSION

Dissolution—Twenty lots of tablets out of 42 lots studied released 100% phenobarbital within 5 min., 4 lots within 5–10 min., 3 lots within 10–20 min., and 2 lots within 20–30 min. when a 0.1 *N* HCl bath was used. Thirteen lots of tablets failed to release 100% phenobarbital into the acid medium within 30 min. (Table I). At the end of 60 min. of test, 3 out of the 13 lots of tablets did not release at least 50% of the drug. A comparison of dissolution pattern of 12 out of these 13 lots of tablets is illustrated in Fig. 1. One lot (manufacturer I, 1 1/2 gr.) showed considerable tablet-to-tablet variation in dissolution rate. In order to get an approximation of the dissolution rate of the tablets in the intestinal tract, the 13 lots of tablets were subjected to dissolution test in an alkaline medium consisting of a buffer solution of pH 9.5. Despite the fact that phenobarbital is highly soluble in buffer solution of pH 9.5, 11 out of the 13 lots of tablets did not release 100% phenobarbital in 30 min. In some cases the dissolution rate in alkaline medium was slower than in acid medium (manufacturers J, K, L, and M). In most cases the tablets broke apart into fairly large pieces, but failed to disintegrate any further, thereby failing to release phenobarbital into the medium. The failure of medium to penetrate the granules may be attributed to formulation factors such as types and concentrations of binder, disintegrant, filler, and lubricant, and hardness of compression.

Another interesting finding from the dissolution study in the acid medium was the great difference in dissolution rate of phenobarbital from tablets of various strengths manufactured by the same company (Table II). The difference in dissolution rates of these tablets was thought possibly to be due to several factors such as size, hardness, shape, whether scored or unscored, quantity of excipients, *etc.*, but Table II seems to indicate that these properties were not responsible for the variable rates. Since the two lots of tablets were formulated separately, it has to be presumed that some of the formulation factors have influenced the dissolution rate of these tablets.

Disintegration—The USP XVII tablet disintegration test with and without disks showed remarkable difference in results. From Table I it can be seen that all lots of tablets except one passed the test with disks, whereas 12 lots of tablets failed the test without disks. There was absolutely no correlation between disintegration times (with disks) and dissolution rates. The tablet that disintegrated within 4 min. (manufacturer K, 1 1/2 gr.) had released only 61% of the drug into acid medium in 30 min., whereas the same lot of tablets took 202 min. to disintegrate completely when disks were not used in the test. The disks exerted a slight pounding action on tablets and resulted in fast and fairly uniform disintegration times. Although it can be generalized that tablets which took a long time to disintegrate (without disks) had relatively poor dissolution rates, no quantitative correlation can be made between the two tests. Tablets which dis-

integrate into particles small enough to pass through 10-mesh screen may still contain drug within the cores which may not be released into the medium.

Experimental data indicated usefulness of test apparatus for determining *in vitro* availability of active ingredients from tablet bases. It was found that stirring the solution using an external stirrer (not by movement of oscillating tube alone) was essential to get accurate and reproducible results. Since the solution was maintained at 37°, covering the beaker during the experiment also helped to obtain more reproducible results.

SUMMARY AND CONCLUSIONS

A modification was made in the dissolution, apparatus described by Levy, and this apparatus was used to determine the *in vitro* dissolution rate of phenobarbital from tablets. Forty-two lots of commercial phenobarbital tablets from 24 companies were tested. Thirteen out of the 42 lots of tablets failed to release 100% phenobarbital in 30 min. when 0.1 *N* HCl was used as the medium. Out of these 13 lots 11 lots failed to release 100% of the drug in 30 min. when the acid medium was replaced by an alkaline medium. The dissolution rate in the two media differed markedly and this fact has to be taken into consideration in evaluating the physiological availability of the drug. Since the dissolution rates of tablets of different strengths made by the same manufacturers showed considerable variation, factors such as types and concentrations of diluent, binder, disintegrant, and lubricant, as well as hardness of compression, should be considered in the formulation of tablets.

There was absolutely no correlation between the dissolution rate and the disintegration time (with and without disks). The USP disintegration test should be replaced by a dissolution test and the limits of dissolution rate should be based on *in vitro* determination or *in vitro-in vivo* correlations (wherever possible to determine) specific for the drug in question and the type of the tablet.

Factors Affecting Dissolution Rate of Medicaments from Tablets II

Effect of Binder Concentration, Tablet Hardness, and Storage Conditions on the Dissolution Rate of Phenobarbital from Tablets

By JAMES T. JACOB* and ELMER M. PLEIN

A series of formulations is described in which several binders are used in varying proportions and the tablets are compressed at different pressures. Results show the effects of these variables on dissolution rates of phenobarbital tablets in an acid medium of pH 1.2. Some data on the effects of storage of tablets under controlled conditions are presented.

IN ORDER that a clinical response be elicited by administration of a tablet, not only should the tablet contain the labeled amount of medicament, but also the medicament should be fully available to the body. When drugs are administered in dosage forms other than solutions, the rate at which the dosage form releases the medicament into gastrointestinal fluid may be more important than the effective surface area of the absorbing agent. For this reason with solid dosage forms (tablets, capsules, powder, *etc.*) the absorption of medicament may depend upon the dissolution rate of the formulation and/or the medicament (1).

Several workers have studied the effects of various formulation factors on dissolution rates of medicaments from compressed tablets. Sunkes (2) found an inverse relationship between the amount of salicylamide dissolved from granules and the percent of granulating agent used in preparing these granules. He found also that tablets released salicylamide at a faster rate than did granules from which tablets were made. An opposite observation was reported by Harris (3) who found that granules released medicament faster than did tablets made from the same granules. Henderson's (4) studies indicated that the effect of particle size upon either tablet hardness or dissolution time is characteristic of a particular compound and that no general prediction could be made as to quantitative correlation among these factors for all drugs. Levy *et al.* (5) studied effects of granule size, starch concentration, and compression pressures on the dissolution rate of salicylic acid from granules prepared by double compression. They found that the dissolution rate increased with decreasing granule size, with increasing starch content, and with increasing precompression pressures. Levy and Gumtow (6) in a study of the effect of lubricants on the dissolution rate of salicylic acid from tablets reported that a hydrophobic lubricant (magnesium stearate) retards dissolution rate, whereas a water-soluble surface-active agent (sodium lauryl sulfate) increases dissolution rate. Yen (7) conducted an extensive study on various factors affecting the dissolution rate of triamterene tablets and concluded that besides studying individual factors affecting the dissolution rate the combination of various factors should be considered for a true evaluation. Parrot *et al.* (8) reported that when neutral, ionic, and nonionic organic compounds were employed as additives, the dissolution rate of benzoic acid was linearly dependent upon its solubility in the particular solvent system.

In a study of commercial phenobarbital tablets it was found that several lots of tablets showed poor dissolution rates in an acid medium and also in an alkaline medium (9). Since one or more various formulation factors could contribute to the slow dissolution rate of these commercial tablets, this investigation was undertaken to study two factors, in particular—namely, binder concentration and compression hardness. Effects of certain storage conditions on dissolution rate also were studied. Fumed silicon dioxide[1] which is used chiefly as a free flowing agent and arabinogalactan[2] which is a natural gum exudate were evaluated for their tablet-binding properties.

Received November 17, 1967, from the University of Washington, College of Pharmacy, Seattle, WA 98105

Accepted for publication January 2, 1968.

Presented to the Basic Pharmaceutics Section, APhA Academy of Pharmaceutical Sciences, Las Vegas meeting, April 1967.

Portions of this paper are abstracted from a dissertation submitted by James T. Jacob to the Graduate School, University of Washington, Seattle, in partial fulfillment of the Doctor of Philosophy degree requirements.

This investigation was supported in part through grants provided by the Washington Initiative 171 funds for research in biology and medicine.

EXPERIMENTAL

Formulation of Tablets—A number of batches of phenobarbital tablets was manufactured by wet granulation (approximately 250 tablets to a batch). Each tablet was made to contain 100 mg. of phenobarbital and 100 mg. of excipients composed of varying quantities of binders. Besides fumed silicon dioxide and arabinogalactan, a few commonly used binders also were used (acacia, gelatin, ethyl cellulose,[3] and hydroxyethyl cellulose[4]). Various concentrations of fumed silicon dioxide and arabinogalactan were used either as powders or as solutions or gels in water to make the tablets. Tablets were compressed from 20/40-mesh granules on a Stokes single-punch machine model 511-5 using $^1/_{16}$-in. (~0.8 cm.) die and standard concave punches.

Hardness—Tablets were compressed at various pressures maintaining a minimum hardness of 5 Strong-Cobb units.

Dissolution Test—Rate of release into 0.1 *N* HCl (pH 1.2) was determined by the use of the test method previously described (9).

USP XVII tablet disintegration test with and without disks was carried out only on those batches of tablets which did not release 100% phenobarbital in 30 min.

Aging—Six tablets from each batch were kept in an open 2-dram (~10 ml.) vial in an oven set at 55° for 16 days and then were tested for hardness and dissolution rate at the end of the storage period.

Humidity Studies—Six tablets from each batch containing fumed silicon dioxide or arabinogalactan were stored at 98% relative humidity in a desiccator containing a saturated solution of potassium dichromate kept at 25° (10), for 30 days, and the following tests were carried out: amount of absorbed moisture (tablets were weighed before and after storage in the desiccator), hardness, and dissolution rate. The dissolution rates were determined immediately after removing the tablets from the desiccator and also after exposing them to room temperature for 24 hr. during which time they lost moisture and attained constant weight.

RESULTS AND DISCUSSION

Table I gives the dissolution rates of phenobarbital from tablets manufactured using fumed silicon dioxide or arabinogalactan as a binder. Granules made with fumed silicon dioxide in concentrations of 2% and 5% as a gel in water and 5% as powder possessed good binding qualities and produced smooth, shiny tablets of satisfactory hardness and fast dissolution rates (maximum dissolution time 60 sec.). Arabinogalactan was found to be a good binder when used in concentrations of 2–5%. An increase in concentration of arabinogalactan, however, resulted in a decrease in dissolution rate, especially when the binder was used in the form of a gel in water (dissolution time 3600 sec.).

Table II shows effect of hardness on dissolution rates of phenobarbital tablets prepared with 5% arabinogalactan added as a powder and granulated with water or used as a solution in water to granulate the powder mixture.

Tests on tablets formulated with acacia, gelatin, ethyl cellulose, and hydroxyethyl cellulose used as binders in various concentrations clearly indicate how dissolution rates can be affected by altering the concentration of binder as well as hardness of the tablet (Table III). Satisfactory tablets were obtained with acacia or gelatin as a binding agent, although differences in hardness of the tablets affected their dissolution rates. An increase in hardness by 2 Strong-Cobb units was responsible for about 50% reduction in dissolution rate of tablets prepared with acacia (Batch No. 9A and 9B). Hardness of tablets is also a factor in dissolution rates of tablets prepared with 2% gelatin (Batch No. 10A and 10B), with 4% gelatin (Batch No. 11A and 11B), and perhaps with 5% ethyl cellulose. The effects of concentration of gelatin and hardness of compression

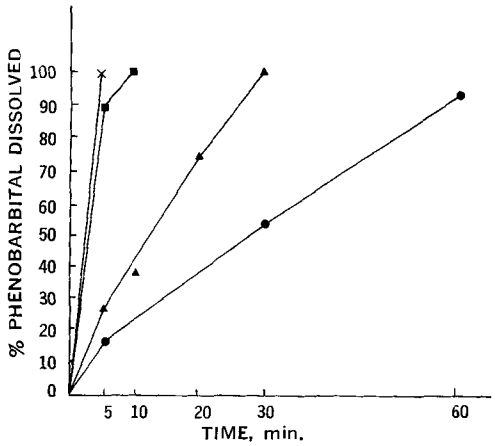

Fig. 1—Dissolution rates in 0.1 N HCl, of phenobarbital tablets made with gelatin as a binder. Key: ×, 2% gelatin (No. 10A) compressed at a hardness of 6.5 Strong-Cobb units; ■, 2% gelatin (No. 10B) compressed at a hardness of 10.0 Strong-Cobb units; ▲, 4% gelatin (No. 11A) compressed at a hardness of 6.5 Strong-Cobb units; ●, 4% gelatin (No. 11B) compressed at a hardness of 13.0 Strong-Cobb units.

on dissolution rates of tablets are illustrated in Fig. 1. Ethyl cellulose and hydroxyethyl cellulose possess good binding properties and produced tablets with good physical appearance; however, the poor dissolution rates shown in Table III indicate they are unsatisfactory binding agents in these formulations.

The USP tablet disintegration test with and without disks was carried out on tablets with slow dissolution rates in 0.1 *N* HCl and the results are shown in Table III. A comparison of dissolution rates and disintegration times (with and without disks) showed no correlation between the two tests. Tablets formulated with 1% ethyl cellulose took 60 min. to release 98% of the drug into acid medium, but the disintegration time in water was only 30 sec. (No. 12, Table III). This great disparity can be attributed to the fact that tablets swelled on contact with water and broke apart into small particles, whereas in the acid medium no such swelling was observed.

The results of aging tablets at 55° for 16 days, which storage time is approximately equivalent to a storage time at room temperature for 2 yr. (11), showed slight increase in tablet hardness (Table IV). This observation substantiates earlier reports found in the literature (12, 13). There was no decrease in dissolution rates as a result of increased hardness due to aging.

Considerable quantities of moisture were absorbed by tablets when they were exposed to 98% relative humidity for 30 days as a result of which the dissolution rates of these tablets were markedly decreased. A comparison of data in Tables I and V shows the differences in the dissolution rates. The quantity of moisture absorbed and retained depended upon the type and concentration of binder used. Tablets made with arabinogalactan absorbed more moisture than did those made with fumed silicon dioxide (Table V). The quantity of absorbed moisture was directly proportional to the concentration of binder used. There were remarkable differences in dissolution rates of tablets determined immediately after removal from the humidity chamber and after they had lost most of the absorbed moisture. Tablets made with fumed silicon dioxide clearly indicated this variation (Batch No. 6, 7, and 8, Table V). The absorbed moisture retarded the dissolution rates of drug by preventing the acid solution from penetrating into the tablets. After losing most of the absorbed moisture (by evaporation at

[a] Dissolution rate determined immediately after removal from the humidity chamber. [b] Dissolution rate determined following storage in the humidity chamber and after the tablet had been exposed to room temperature to a constant weight.

room temperature) the tablets were more vulnerable to penetration of 0.1 *N* HCl resulting in an increased dissolution rate. However, the increased dissolution rates were considerably lower than the dissolution rates of the same tablets prior to their storage in the humidity chamber.

SUMMARY AND CONCLUSIONS

1. Fumed silicon dioxide and arabinogalactan in concentrations of 2–5% possess good tablet-binding qualities.

2. Increase in binder concentration and hardness of compression resulted in a decrease in the dissolution rates of phenobarbital tablets. Selection of binder, its concentration, and hardness at which tablets are compressed are important factors which should be properly controlled so that the medicament will be completely released for quick physiological availability.

3. No apparent change in dissolution rate was observed when phenobarbital tablets were aged at 55° for 16 days.

4. Depending upon type and concentration of binder, phenobarbital tablets absorbed varying quantities of moisture when exposed to 98% relative humidity for 30 days. As a result of moisture absorption, dissolution rates of phenobarbital from those tablets were considerably decreased. An increased dissolution rate was observed when the moist tablets were tested after exposure to room temperature for 24 hr. during which time they lost most of the absorbed moisture. However, this increased dissolution rate was much lower than the original dissolution rate of the tablet.

5. No correlation was found between dissolution rate and USP tablet disintegration test with and without disks.

Identification of Antibiotics in Sensitivity Disks

By LOLA G. WAYLAND and PETER J. WEISS

Identity tests for antibiotic sensitivity disks have been developed. Suitable tests previously reported in the literature have been modified and adapted to the microquantities involved in these disks. Once a system of testing had been established, it was screened for interference from all other disk antibiotics. Penicillins are identified generally by an iodometric method and specifically by thin-layer chromatography (TLC). The polypeptide antibiotics are differentiated by TLC in combination with nitration, reduction, and diazotization to further distinguish colistin from polymyxin. Lincomycin, oleandomycin, and kanamycin are identified by TLC systems, the tetracyclines by paper chromatography. Under varying conditions of solvents and wavelengths, streptomycin, erythromycin, nystatin, vancomycin, novobiocin, cephalothin, and viomycin are identified spectrophotometrically. Color tests have been devised for chloramphenicol, dihydrostreptomycin, and neomycin.

THE FIRST antibiotic disks, made by Bondi *et al.* in 1947, were widely recognized as "diagnostic aids for the rapid determination of the susceptibility of microorganisms to antibiotics" (1). Since then, they have proved as valuable as anticipated, and have widespread use in hospitals and clinical laboratories throughout the world. Because of the reliance placed upon information elicited from their use, confirmatory evidence of the labeled identity of the antibiotics in the disks is of great importance. This paper describes laboratory procedures developed for this purpose.

Regulations describing the tests and methods of assay and requirements for certification of antibiotic disks are published in the Code of Federal Regulations, title 21, chapter 1, part 147. Table I lists the antibiotic disks now included in these regulations with references to the applicable identity tests described in this paper.

Although antibiotic disks are tested by a "performance" method for inhibitory response against specific microorganisms and are compared with control disks of known potencies, the zone of inhibition obtained does not always specifically identify the antibiotic. For example, from microbiological assay alone, positive differentiation cannot be made between colistin and polymyxin, and between chloramphenicol and the tetracyclines; among the various tetracyclines, and among the various penicillins; between kanamycin and neomycin, and between dihydrostreptomycin and streptomycin, particularly if the potencies deviate greatly from the label claims. While it may not be of the utmost medical importance to differentiate one tetracycline from another, it is important to distinguish a tetracycline from chloramphenicol, or a semisynthetic penicillin from cephalothin or penicillin G. Some antimicrobial agent other than an antibiotic may conceivably be present and under certain conditions may be undetected by microbial assay. Therefore, a system of chemical identity tests for antibiotics in disks was established to supplement the quantitative information obtained by microbiological assay techniques.

Received August 22, 1967, from National Center of Antibiotics and Insulin Analysis, Bureau of Science, Food and Drug Administration, Washington, DC 20204

Accepted for publication January 22, 1968.

The standard disks used in developing these tests were kindly supplied by Mary Ann Garth and the Special Investigations Branch of the Division of Antibiotics and Insulin Certification.

IDENTIFICATION PROCEDURES

I. Penicillins—(*a*) *Iodometric Test*—This general screening procedure for penicillin and cephalothin involves a modification of the iodometric assay method (2). Place enough disks in each of two tests tubes to provide 30 mcg. of sodium cephalothin, 20 units of penicillin G, or 4 mcg. of other penicillins. To both tubes add 1 ml. of 1% phosphate buffer (pH 6) and shake well. To one tube, add 1 ml. of 1 *N* sodium hydroxide, shake, and let stand 15 min. Then add 1 ml. of 1.2 *N* hydrochloric acid and 0.2 ml. of 0.001 *N* iodine solution; after 15 min. add 1 drop of starch indicator solution. To the second tube add 2 ml. of distilled water, 0.2 ml. of iodine solution, and 1 drop of starch indicator solution. If penicillin or cephalothin is present, the first tube remains colorless, while the second develops the characteristic blue of the starch–iodine complex.

(*b*) *Chromatography*—Blend 30 Gm. of cellulose MN 300 without binder (Macherey, Nagel, Westbury, N.Y.) with 200 ml. of distilled water at high speed for 15 min. Apply this slurry to 20 × 20 cm. glass plates with a Brinkmann-Desaga applicator set for a film depth of 0.250 mm. Air dry the plates overnight and use without preactivation. Place enough disks to provide not less than 10 mcg. of penicillin in a sintered-glass microfi ter. Pipet 1.0 ml. of methanol onto the disks and allow to steep, with occasional stirring, for 5 min. Then apply suction and collect the filtrate in a small, flat-bottomed vial (15 × 75 mm.). Evaporate the extract to dryness under a stream of air, and redissolve in 50 μl. of methanol. Spot this solution on a TLC plate in 1-μl. increments until 1 mcg. has been applied.

Prepare a standard for each antibiotic from standard disks and spot each on the plate in the same manner. Standard and sample extracts may be spotted both individually and as a mixture to

insure homogeneity. Use only freshly extracted solutions. When the plate has been spotted, place it in a rectangular tank lined with heavy filter paper saturated with the solvent system, a 0.1 *M* sodium chloride solution (3). Place a glass trough in the bottom of the tank with solvent and allow the plate to rest directly in it. Allow the solvent front to travel 10 cm. from the starting line, then remove the plate from the development tank and allow to air dry. Lightly spray the plate with a freshly prepared solution of 2 parts 10% aqueous ferric chloride, 1 part 5% aqueous potassium ferricyanide, and 7 parts 20% sulfuric acid. After 5 min. for color development, the penicillins appear as blue spots on a green background. Directly compare the positions of the sample spots with the standards. The average R_f values of 10 runs are: sodium nafcillin, 0.45; cloxacillin, 0.62; sodium oxacillin, 0.68; potassium phenethicillin, 0.76; penicillin G, 0.85; and methicillin 0.89.

The tetracyclines have R_f values from 0.50 to 0.65 but are yellow before the color reagent is applied and in addition, yield negative iodometric reactions. Vancomycin hydrochloride appears at an R_f of about 0.90, but also yields a negative iodometric test.

(*c*) *Ninhydrin Test*—Ampicillin is the only penicillin that reacts with ninhydrin. After identifying it as a penicillin by the iodometric test, staple one disk to a sheet of Whatman No. 1 chromatographic paper, and apply one drop of ninhydrin reagent (1% ninhydrin in 100 ml. of water-washed *n*-butanol containing about 1 ml. of pyridine). Dry and heat the disk with a hot-air gun. Ampicillin yields a characteristic purple color.

II. Bacitracin, Colistin Sulfate, Kanamycin Sulfate, Neomycin Sulfate, and Polymyxin B Sulfate—(*a*) *Chromatography*—Apply Silica Gel G on glass plates (20 × 20 cm.) manually with a Brinkmann-Desaga applicator to a depth of 0.250 mm. Air dry overnight. Commercial TLC sheets may also be used.

Extract the antibiotics from the disks in the manner described for the penicillins, using water instead of methanol. Extract a minimum of 20 mcg. from the disks so that, when the residue is dissolved in 50 µl. of water, a total of 4 mcg. will be spotted on a TLC plate. For each antibiotic, extract standard disks and spot the extracts on the plate. Prepare the tank in the manner described for the penicillins, and use the same type of tank. The two-phase resolving system consists of chloroform–methanol–17% ammonia (40:25:20) (4), and the portion in the glass trough must be freshly prepared for each run. Both phases are used together. After the plate has been placed in the tank to develop, seal the lid with masking tape. When the solvent front has moved 10 cm. (in about 1 hr.), remove the plate from the tank and allow it to air dry. Spray the plate with ninhydrin reagent (see Ic) or use a commercial aerosol containing 0.3% ninhydrin in ethanol. Heat the plate with a hot-air gun to make the spots visible. Bacitracin yields a very characteristic spot at the front. The R_f values are: colistin sulfate, 0.80; polymyxin B sulfate, 0.70; kanamycin sulfate, 0.50; and neomycin sulfate, 0.30.

(*b*) *Diazotization*—Since phenylalanine is one of the decomposition products of polymyxin B sulfate but not of colistin sulfate, one may be differentiated from another by nitration, reduction, and diazotization of this aromatic moiety (5). Extract 10–15 polymyxin B sulfate 50-unit or colistin sulfate 10-mcg. disks with 1 ml. of water into a 50-ml. conical flask and evaporate the extract to dryness under a stream of air. Simultaneously evaporate 1.0 ml. of solution containing 10 mcg. of phenylalanine. Add 1.0 ml. of fuming nitric acid to each flask, cover with a watch glass, and heat on a vigorously boiling steam bath for 30 min. Remove from heat and add 10 ml. of water, 2 ml. of concentrated ammonium hydroxide, and about 50 mg. of sodium hydrosulfite. Mix and allow to stand 20 min. Then cool the flasks in a large evaporating dish containing crushed ice. Add 5.0 ml. of a 5% sodium nitrite solution and 1.5 ml. concentrated hydrochloric acid. Let stand 30 min., maintaining the temperature below 5°. Add 10 ml. of 5% sulfamic acid, shake, and dispel the nitrous oxide fumes with a current of air. Add 4.0 ml. of freshly prepared 0.8% solution of *N*-(1-naphthyl) ethylenediamine dihydrochloride. If polymyxin B sulfate is present, a red-purple color similar to that of the phenylalanine will develop. Colistin sulfate will remain colorless or only faintly pink tinged.

Bacitracin gives a positive result in this test, but may be identified by the TLC system described for group II*a*. Ampicillin yields a positive reaction with ninhydrin and diazotization; it also moves with the solvent front in the TLC system for group II*a*, but may be distinguished from them by the iodometric test for penicillin.

III. Tetracyclines—*Chromatography*—Extract the disks in the same manner described for the penicillins, using methanol as solvent. Extract enough disks to yield 50 mcg. in 50 µl. Subject the solutions, along with appropriate standards, to ascending paper chromatography, using the method of Selzer and Wright (6). Use a stationary phase of MacElvaine's buffer (pH 3.5) and a solvent system of chloroform–nitromethane–pyridine (10:20:3). The resulting spots are visible under ultraviolet light in the presence of ammonia fumes. No interference arises from any of the other 23 antibiotics listed in Table I.

IV. Lincomycin Hydrochloride and Oleandomycin Phosphate—*Chromatography*—Extract ten 2-mcg. disks in the manner described for penicillins, but with 0.05% phosphate buffer (pH 6) instead of methanol. After evaporation, dissolve the residue in 50 µl. of the buffer and apply ten 1-µl. spots to a TLC plate prepared as for procedure II*a*. Treat standard disks in the same manner. Use the resolving system, methylethyl ketone–acetone–water (9.3:2.6:1), developed by Brodasky and Lummis (7). Develop the chromatogram and air dry the plate. Place the plate in an iodine atmosphere (a closed rectangular glass tank containing a small beaker with several iodine crystals warmed on a steam bath) until yellow spots appear. Remove the plate from the tank, allow it to stand several minutes, and then spray it lightly with starch indicator solution until the lincomycin hydrochloride or oleandomycin phosphate shows up as a dark purple spot. Make direct comparisons of the positions of the spots with the standards.

All the penicillins give two spots in this system. Cloxacillin, methicillin, penicillin G, potassium phenethicillin, sodium nafcillin, and sodium oxacillin

TABLE I—IDENTIFICATION PROCEDURES FOR ANTIBIOTIC SENSITIVITY DISKS

Antibiotic	Usual Potency Level[a] Low	High	Identification Procedure
Ampicillin	2	10	I*a,c*
Bacitracin	2 units	10 units	I*a*,II*a*
Sodium cephalothin	30	...	XI
Chloramphenicol	5	30	VI
Chlortetracycline hydrochloride	5	30	III
Sodium cloxacillin	1	...	I*a,b*
Colistin sulfate	2	10	II*a,b*
Demethylchlortetracycline hydrochloride	5	30	III
Dihydrostreptomycin sulfate	2	10	VIII*a,b*
Erythromycin	2	15	XIII
Kanamycin sulfate	5	30	II*a*
Lincomycin hydrochloride	2	...	IV
Methacycline hydrochloride	5	30	III
Methicillin	5	...	I*a,b*
Sodium nafcillin	1	...	I*a,b*
Neomycin sulfate	5	30	II*a,V*

Tetracycline hydrochloride	5	30	III
Vancomycin hydrochloride	5	30	XII
Viomycin sulfate	2	10	X

[a] Potency is given as mcg./disk unless otherwise stated.

have R_f values ranging from about 0.35–0.44 for the major spot, while ampicillin has its major spot at 0.16. Sodium cephalothin has one spot at R_f 0.35; the tetracyclines and nystatin all have one or two spots which are yellow *before* being exposed to iodine; and oleandomycin phosphate has one spot at R_f 0.24. Lincomycin hydrochloride is readily distinguished from all these, since it yields a single spot at an R_f of 0.56.

V. Neomycin Sulfate—Extract enough disks with 1 ml. of water to give at least 75 mcg. of antibiotic. Collect the filtrate in a 50-ml. round-bottom distillation flask. Add 5 ml. of 40% sulfuric acid; reflux for 100 min. and cool. Transfer the solution to a glass-stoppered test tube and extract with 2.5 ml. of xylene. Transfer the upper xylene layer with a syringe with a cannula tip to a second tube. Add 2.5 ml. of *p*-bromoaniline reagent (8), and shake vigorously. If the disks contain neomycin sulfate, a pink color develops on standing.

No other disk antibiotic has been found to interfere in this test but the pink color will not develop in the presence of water.

VI. Chloramphenicol—Steep at least four 30-mcg. disks in 1 ml. of methanol with occasional stirring for 2 min. Filter with suction into a test tube and wash into a 50-ml. glass-stoppered centrifuge tube with 10 ml. of water. Add 10 ml. of 12 *N* sodium hydroxide and 10 ml. of α-naphthol reagent (a 2 mg./ml. solution in 6 *N* sodium hydroxide, freshly prepared) (9). Heat the tube for 30 min. in a boiling water bath, cool in tap water for about 5 min., and dilute to mark with methanol. Immediately upon the addition of the methanol a blue color appears which deepens slightly upon standing.

None of the other 27 antibiotics in Table I gives a blue color.

VII. Sodium Novobiocin—Extract enough disks with 2 ml. of methanol to give 40 mcg. of novobiocin. Evaporate to dryness under a stream of air and dissolve the residue in 2 ml. of 0.1 *N* sodium hydroxide. Record the UV spectrum from 200 to 400 mμ in 1-ml. cells. A characteristic absorption curve is obtained with a maximum at 305 mμ, shoulders at 288 and 248 mμ, and a minimum at 260 mμ. Standard disks are similarly treated for comparison.

VIII. Streptomycin Sulfate and Dihydrostreptomycin—(*a*) Place single disks of sample and standard side by side on a spot plate. Add one drop of oxidized nitroprusside reagent to each disk (10). With either streptomycin sulfate or dihydrostreptomycin a red-orange color develops rapidly. Viomycin sulfate gives a faint response. None of the other disk antibiotics interferes. If a ninhydrin spot test on a single disk (method I*c*) is negative, viomycin sulfate is eliminated.

(*b*) Differentiate streptomycin sulfate from dihydrostreptomycin by extracting 60 mcg. from disks into a test tube with 2 ml. of water. To the extract add 0.4 ml. of 1 *N* sodium hydroxide. Place the same solution in both 1-ml. cells and, with a double-beam spectrophotometer, record the spectrum from 300 to 350 mμ. Return the contents of the cell to the tube and heat it in a boiling water bath for 5 min. Cool the tube to room temperature and record the spectrum from 300 to 350 mμ with the unheated solution in the reference cell. Streptomycin sulfate produces a broad maltol peak at 320 mμ (11). The ferric chloride color of this method (11) is too faint to be visible at this concentration.

No other antibiotic in Table I gives this maltol reaction; however, the lower potency streptomycin sulfate disks give inconclusive results, possibly

because of methylcellulose interference from the higher proportion of paper.

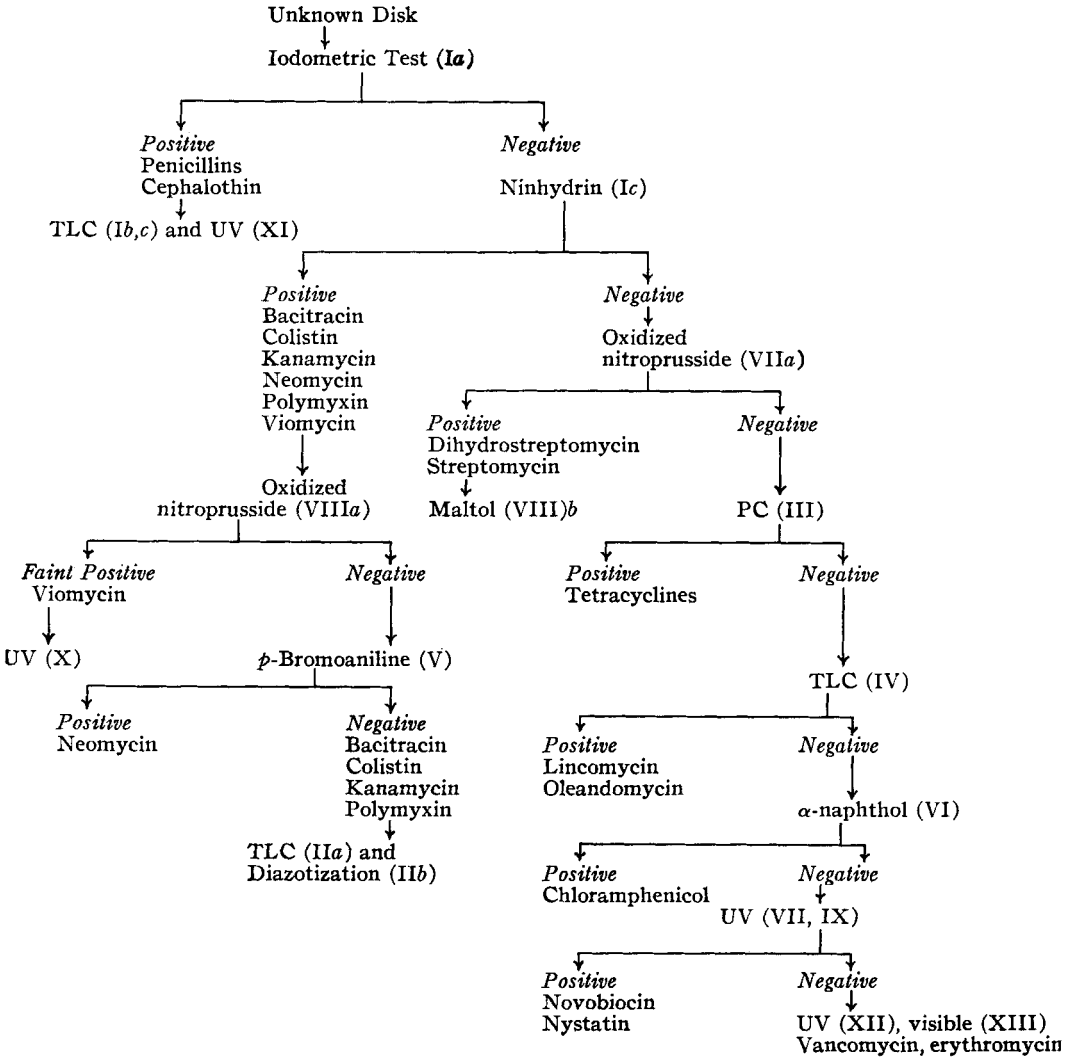
IX. Nystatin—Extract one 100-unit disk with three 1-ml. portions of methanol; collect and dilute to volume with methanol in a 5-ml. volumetric flask. Record the UV spectrum from 210 to 400 mμ. Characteristic peaks occur at 318, 304, and 291 mμ. Treat standard disks in a similar manner and compare spectra. No other antibiotic has a UV spectrum closely resembling that of nystatin.

X. Viomycin Sulfate—Extract five 10-mcg. or ten 2-mcg. disks with 1 ml. of 0.05% phosphate buffer, pH 6.0 Record the UV spectrum from 250–350 mμ against a buffer blank, using 1-ml. cells. Viomycin sulfate has a strong absorbance at 268 mμ. Although potassium phenethicillin absorbs at this wavelength, it is 10 times weaker in magnitude, and the shape of the potassium phenethicillin curve is more complex.

XI. Sodium Cephalothin—Extract four 30-mcg. disks with 1 ml. of water. Wash the disks with two additional 1-ml. portions of water and collect all filtrates in a 5-ml. volumetric flask. Dilute to 5 ml. with water and record the UV spectrum from 220 to 310 mμ. Treat standard disks similarly. Sodium cephalothin yields a peak at 237 mμ and a shoulder at 265 mμ. No other antibiotic in Table I gives this spectrum.

XII. Vancomycin Hydrochloride—Extract enough disks to yield 50 mcg. in 1 ml. of water. Evaporate the extract to dryness under a stream of air and redissolve in 1 ml. of 0.02 *N* sulfuric acid. Record the UV spectrum from 250–350 mμ, using water in the 1-ml. reference cell. With vancomycin hydrochloride a peak occurs at about 278 mμ.

Extract the same number of disks, evaporate the extract to dryness, and redissolve in 1 ml. of 0.02 *N* sodium hydroxide. Record the UV spectrum from 250–350 mμ, using 1-ml. cells. The vancomycin hydrochloride absorption peak shifts to about 302 mμ. In each case standard disks are similarly treated. This acid-base shift in absorbance wavelength is characteristic only of vancomycin hydrochloride (12) among the antibiotics listed in Table I.



XIII. Erythromycin—Extract two to four 15-mcg. disks with 1 ml. of chloroform, evaporate the extract to dryness under a stream of air, and redissolve in 1 ml. of 40% sulfuric acid. Heat in a water bath at 50° for 30 min. and cool to room temperature. Treat standard disks in the same manner. Record the visible spectrum from 450–500 mμ, using water in the 1-ml. reference cell. Erythromycin has a strong absorbance at about 482 mμ (13). Under these conditions none of the other 27 antibiotics listed in Table I absorbs strongly at 482 mμ.

DISCUSSION

The system of chemical testing outlined in the flow chart (Scheme I) and described here in detail can completely identify an unknown disk sample, if enough disks (80–100) are available. Four unknown disk samples were carried through this identification system and successfully identified as colistin, kanamycin, nafcillin, and oxytetracycline.

In practice, testing begins from the labeled identity and proceeds to confirm or deny the label. In the identification system described, as in many others, positive reactions to any single test may not be sufficient to characterize definitively the compound in question. The composite picture from supplemental chemical tests, in combination with microbiological response and potency data, results in satisfactory identification. For example, ampicillin and bacitracin react with ninhydrin, move with the solvent front in the TLC method for group II*a* antibiotics (although bacitracin has a very distinctive spot), and undergo the nitration, reduction, and diazotization procedure for the differentiation of colistin sulfate and polymyxin B sulfate. The iodometric test would identify a properly labeled ampicillin disk as a penicillin, but if an ampicillin disk were labeled as bacitracin and tested as such, the error might not be discovered. Because of this possibility, the iodometric test is carried out on bacitracin disks routinely. However, the discrepancy would be detected by microbial assay, because in that test the responses of ampicillin and bacitracin are very different.

The identity tests described have been applied satisfactorily to 250 lots of disks received as part of the antibiotic certification program. Each antibiotic was represented at least twice. Often these disks are color coded with dyes. Thus far, none of the dyes has been found to interfere in the tests.

This system of identity tests applies to those antibiotics presently in use in sensitivity disks but the use of new antibiotics may bring new problems. If such new antibiotics are closely related to the ones now in use, some of these identity tests may not be as specific as at present. The special problems of antibiotic sensitivity disk identity testing, dealing with microgram quantities of highly complex, related materials on a paper matrix, require frequent reevaluation for the possible improvement of the existing tests. Nevertheless, the system of methods just described should serve as a useful starting point for developing new test methods as the need arises.

Kinetics of Degradation of Glutethimide

By J. W. WESOLOWSKI*, SEYMOUR M. BLAUG, TING-FONG CHIN, and JOHN L. LACH

The hydrolysis of glutethimide (2-ethyl-2-phenyl-glutarimide) in buffered aqueous solutions in the pH range 1.5–8.0 has been studied. This region exhibited specific base catalysis. The overall rate may be expressed by the equation, rate = k' (glutethimide) at constant pH. The energy of activation, corrected for heat of ionization of water, was calculated. A mechanism of hydrolysis is proposed.

GLUTETHIMIDE is a widely used nonbarbiturate sedative hypnotic (1). It belongs to a relatively new medicinal group of compounds, the glutarimides, which exhibit CNS depressant as well as stimulant properties (2–4). A review of the literature showed that very little kinetic work has been done on glutarimides (5–8). In view of the increasing importance of this group of compounds it was felt that a quantitative investigation of the hydrolysis rate of glutethimide was warranted.

Investigations on the hydrolysis of succinimide (9) and phthalimide (10, 11) have shown that the ionization of the imide has a strong effect on the course of hydrolysis. In the acid region where the imide is undissociated, specific base catalysis has been observed. The presence of the imide anion causes a decrease in the hydrolysis rate. A complex rate expression has been derived to explain the observed effect (10).

Glutethimide hydrolyzes in weakly basic solution to 4-ethyl-4-phenyl glutaramic acid (EPG) (8, 12, 13) and to the corresponding glutaric acid in 40% potassium hydroxide (12). In the pH range studied, 1.5–8.0, it was expected that glutethimide ionization would be very small and that the predominant product of hydrolysis would be EPG.

An ion-exchange procedure was used to follow the course of glutethimide degradation. A strongly basic quaternary amine anionic-exchange resin specially purified (washed with 10% phosphoric acid and with methanol), was used to separate the glutethimide from EPG. The glutethimide was then eluted from the column by methanol and assayed spectrophotometrically at 257.5 mμ.

EXPERIMENTAL

Reagents and Apparatus—Glutethimide, recrystallized m.p. 85–86°; glutethimide NF reference standard; EPG m.p. 156–157° (prepared by refluxing glutethimide in a 10% sodium hydroxide solution for 1 hr.); sodium hydroxide, sodium chloride, C.P. Merck; monobasic, dibasic, and tribasic sodium phosphate; anhydrous methanol, reagent grade, Mallinckrodt; orthophosphoric acid, reagent grade, Allied Chemical; Anion-exchange (Cl), 50 mesh, analytical reagent grade resin[1]; Beckman DU spectrophotometer and 5-cm. cells; glass columns, 1 × 20 cm. with a glass stopcock at one end and a 100-ml. reservoir at the other end; glass columns, 2 × 45 cm. with Teflon stopcocks (Fisher); constant temperature bath with Sargent heater, circulator, and regulator, Model No. S-PN-2770; thermometer calibrated to 0.1°.

The buffers used in this study were: pH 1.5—0.4 *M* phosphoric acid; pH 2.35, 3, 4, and 5—0.4 *M* Na_2HPO_4–0.4 *M* H_3PO_4; pH 6, and 6.5—0.4 *M* Na_2HPO_4–0.4 *M* NaH_2PO_4; pH 7, 7.5 and 8—0.4 *M* Na_3PO_4–0.4 *M* NaH_2PO_4. All buffer solutions were adjusted with the aid of a Beckman model H2 pH meter. The same phosphate buffer system was used throughout the study in that the pH of this buffer is relatively independent of temperature.

Procedures—The following general procedure was used for studying the effect of pH and temperature on the rate of hydrolysis of glutethimide.

An accurately weighed glutethimide stock solution was prepared in anhydrous methanol, such that 5 ml. contained 100 mg. of glutethimide. The buffer solutions were preheated to the temperature at which the particular run was made. A 100-ml. volumetric flask was filled with 50 ml. of the preheated buffer and 5 ml. of the methanolic glutethimide stock solution was pipeted in with constant swirling. The solution was diluted with buffer to volume, mixed, and placed in the bath. After a lapse of 10 min. to allow the solution to thermally equilibrate, 5 ml. representing the zero hour sample was withdrawn, transferred onto a column of the anion-exchange resin, and 20 ml. of cold deionized water was added to the column. The sample was passed through the column at the rate of 1.5 ml./min. When the solution level reached the top of the resin, anhydrous methanol was added as the eluent and the flow rate was increased to 5–7 ml./min. One-hundred milliliters was collected in a volumetric flask and assayed spectrophotometrically at 257.5 mμ, using the eluent collected from a blank column as a blank.

Samples were removed from the volumetric flask at definite time intervals and analyzed by this procedure.

pH and Temperature Effect on the Rate of Hydrolysis—In order to study the effect of pH and

Received April 14, 1967, from College of Pharmacy, University of Iowa, Iowa City, IA 52240
Accepted for publication January 12, 1968.
* Present address: Squibb International, Kingston, Jamaica, W. I.

[1] Dowex 2-4x. Obtained from J. T. Baker Chemical Co.

temperature on the rate of hydrolysis of glutethimide, the reaction was carried out at the different temperatures, in buffer solution, as follows: 50°—pH 6, 6.5, 7, 7.5, and 8.0; 60°—pH 5, 6.5, 7, 7.5, and 8.0; 65°—pH 6, 6.5, 7, 7.5, and 8.0. Since glutethimide solutions at pH's 1.5 to 5.0 show insignificant degradation after 90 hr. at 65°, the data are not included.

Effect of Ionic Strength—The effect of ionic strength on the rate of hydrolysis was determined by studying the hydrolytic rate at 65° of a solution of glutethimide in 0.4 *M* phosphate buffer at pH 7.5 and comparing the rate of hydrolysis with a solution of glutethimide of the same concentration containing 1% potassium chloride. The effect of buffer concentration on hydrolytic rate was also studied by following the hydrolysis rate at 65°–pH 7.5 in 0.2 *M* phosphate buffer.

Effect of Glutethimide Concentration—Solutions of glutethimide containing 2.217×10^{-4}, 1.915×10^{-c}, and 1.495×10^{-4} moles/L. in 0.4 *M* phosphate buffer of pH 7.5 were prepared and the rate of hydrolysis followed at 65° in the manner described.

DISCUSSION

In the pH range 5–8 studied (Figs. 1–3), the hydrolysis of glutethimide appears to be base

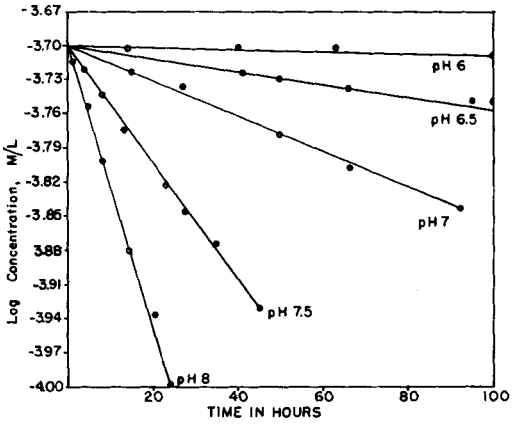

Fig. 1—Log of concentration of glutethimide against time at 50° at various pH's.

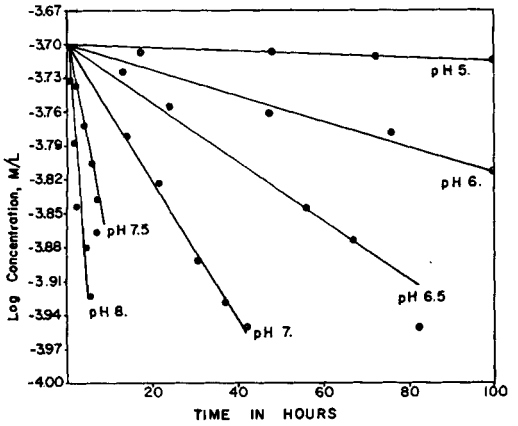

Fig. 2—Log concentration of glutethimide against time at 60° at various pH's.

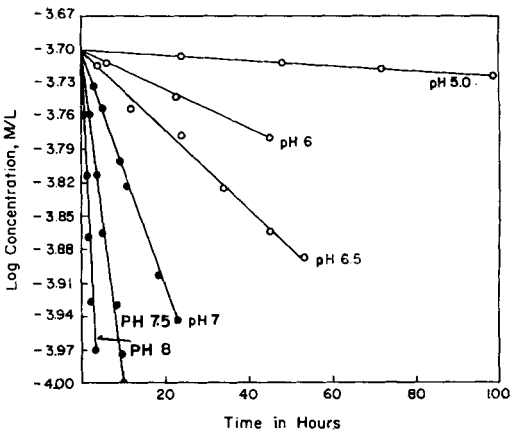

Fig. 3—Log concentration of glutethimide against time at 65° at various pH's.

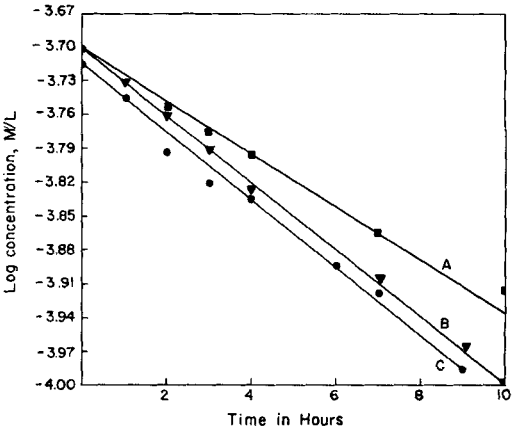

Fig. 4—Effect of buffer concentration and ionic strength on the hydrolysis rate of glutethimide at 65° in phosphate buffer at pH 7.5. Key: A, 0.4 M buffer + 1% KCl; B, 0.4 M buffer; C, 0.2 M buffer.

catalyzed. Figure 4 shows that although the phosphate buffer system was the only one used in this study, no discernible change in the hydrolytic rate was observed when the reaction was carried out in 0.2 and 0.4 *M* buffer solutions, suggesting a specific base catalysis.

It has been reported that the rate of hydrolysis of succinimide (9) and phthalimide (10, 11) is dependent upon the concentration of ionized as well as unionized form of the cyclic imide. Therefore, a decrease in the rate should be observed as the proportion of dissociated to undissociated imide increases. The imide anion is not readily attacked by the hydroxyl ion, in that greater energy would be required to overcome the electrostatic repulsive forces present in such a system.

In a previous work (10) a general second-order rate expression was reported which took into consideration the contribution of the ionized as well as the unionized species on the rate observed. Since the present work dealt with the lower pH region, k_a was considered negligible in comparison to the hydrogen ion concentration since the anionic species is insignificant in this pH range.

The hydrolysis rate is first order with respect to glutethimide since a straight line is obtained when

the logarithm of concentration is plotted against time (Figs. 1–3). This can be further verified (Fig. 5) by plotting the effect of initial glutethimide concentration on the hydrolysis rate. The plot shows the first-order dependence of the reaction with respect to glutethimide, the rate of the reaction being directly proportional to the concentration of the substrate.

The order of the reaction with respect to hydroxyl ion concentration can be determined from the relationship

$$\log k = \log C + n\text{pH}$$

A plot of log *k' versus* pH should give a straight line with a slope of *n*. Figure 6 shows that the slope, 0.897, is not in agreement with the expected value of 1.0. The deviation may be due to the analytical

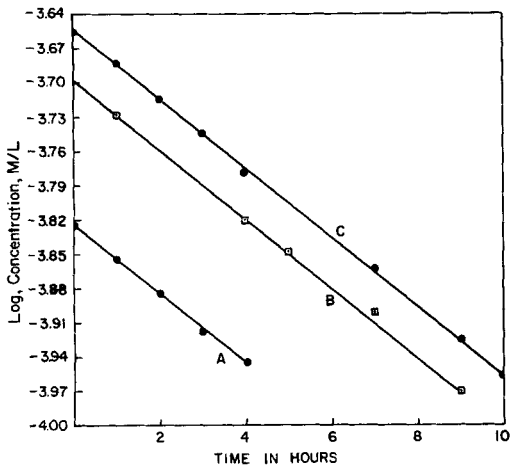

Fig. 5—Effect of initial concentration on the hydrolysis rate of glutethimide at 65°, pH 7.5. Key: A, *1.495 × 10⁻⁴ moles/L.;* B, *1.915 × 10⁻⁴ moles/L.;* C, *2.217 × 10⁻⁴ moles/L.*

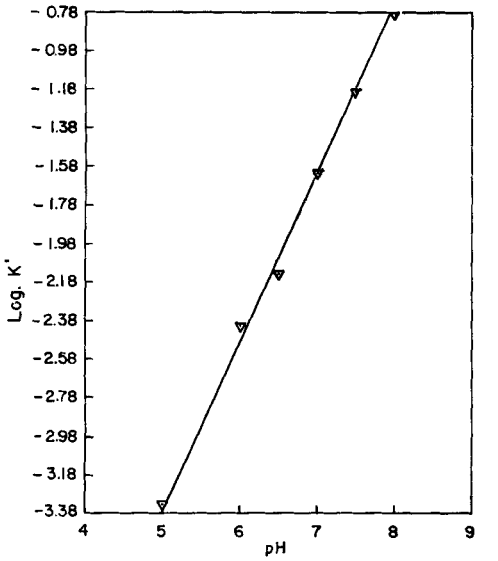

Fig. 6—Log K', the specific reaction constant against pH at 65°.

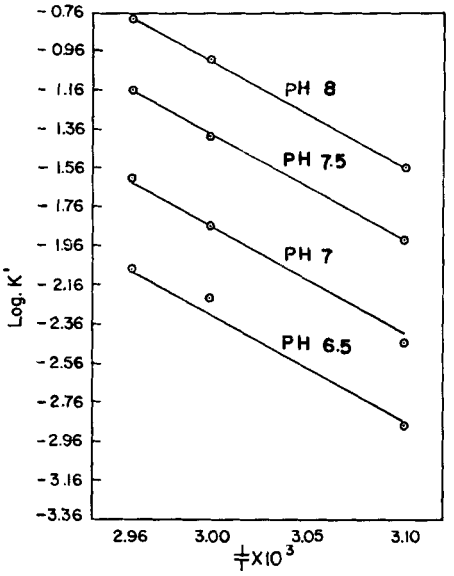

Fig. 7—Plot of log K' versus 1/T showing the temperature dependence of the rate of hydrolysis of glutethimide at various pH's.

procedure, *i.e.*, ion-exchange separation of glutethimide from EPG.

Although the ionic strength in 0.4 *M* phosphate buffers is beyond the limits of the Debye-Hückel limiting law (14), it nevertheless was desired to determine whether primary salt effects existed in the hydrolysis of glutethimide. The slight decrease in rate observed upon the addition of 1% potassium chloride (Fig. 4) cannot be unequivocally explained at this time. A plausible explanation may be that a "salting-out" effect on the slightly soluble glutethimide was brought about due to the increased electrolyte concentration.

The Arrhenius plot (Fig. 7) of log *k' versus* 1/*T* was found to give a straight line with a constant apparent energy of activation, E_a, of 25.86 Kcal. The apparent energy of activation, E_a, for the three temperatures, corrected for the ΔHi of water by the method of Harned and Hamer (15) are listed in Table I. The half-lives, $t_{1/2}$, of glutethimide at different pH were calculated for 25° by the Clausius-Clapeyron equation and are listed in Table II. A plot of log $t_{1/2}$ *versus* pH (Fig. 8) shows that below pH 5 glutethimide is very stable since at pH 1.0 and 5.0 the rate is independent of hydrogen ion concentration.

Mechanism of Hydrolysis—The hydrolysis of glutethimide probably involves a bimolecular (S_N2) mechanism (16) with direct attack by the hydroxyl ion being the rate-determining (slow step) step of hydrolysis as shown in Scheme I.

Bimolecular mechanisms have been known to be

TABLE I—ENERGY OF ACTIVATION CORRECTED FOR HEAT OF IONIZATION OF WATER[a]

50°—13.47 Kcal.
60°—13.92 Kcal.
65°—14.15 Kcal.

[a] Heats of ionization of water calculated according to Harned and Hamer (15) were found to be: 50°—12.39 Kcal., 60°—11.936 Kcal., and 65°—11.71 Kcal.

TABLE II—HALF-LIFE PERIODS, $t_{1/2}$, FOR THE HYDROLYSIS OF GLUTETHIMIDE AT DIFFERENT pH'S AND AT 25°

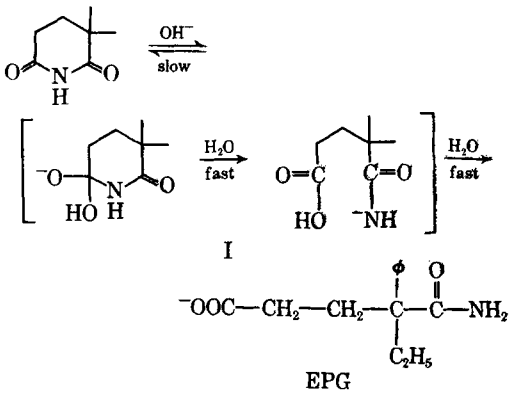
subject to steric hindrance. The rear of the carbon where displacement of the C—N bond is occurring must be unhindered in order to permit facile entrance of the attacking hydroxyl group for the formation of the reaction intermediate (I). Therefore, the reaction may be expected to be sensitive to steric hindrance at the site of reaction but relatively insensitive to electronic effects.

Fischer-Hirschfelder models of glutethimide and of the postulated intermediate in the hydrolysis mechanism (I) were prepared. Steric hindrance due to the 2-ethyl-2-phenyl substituents appears to be quite effective on the 1-carbonyl carbon. The 5-carbonyl carbon is comparatively unhindered for attack by the hydroxyl ion, and 4-ethyl-4-phenyl glutaramic acid would be the main product from such an attack. Further hydrolysis to the corresponding dicarboxylic acid should occur only under adverse conditions due to the same steric retardation. This view is substantiated by a report (12) indicating that 40% potassium hydroxide is necessary for the amide cleavage.

No attempt was made to isolate the postulated degradation product, 4-ethyl-4-phenyl glutaramic acid (EPG), in the kinetic study. However, using thin-layer chromatography, EPG was found to be the degradation product of glutethimide. EPG



Scheme I

was prepared by refluxing a 5-Gm. sample of glutethimide in 50 ml. of a 10% sodium hydroxide solution for 2 hr. The solution was cooled and acidified with concentrated hydrochloric acid to a Congo Red end point. The precipitated solid was collected on a Büchner funnel and washed with deionized water. The compound recrystallized from 20% ethanol had a m.p. 156–157°.

Anal.—Calcd. for $C_{13}H_{17}NO_3$: C, 66.32; H, 7.28; N, 5.95. Found: C, 66.81; H, 7.39, N, 6.01.

A solution containing 100 mg./100 ml. of glutethimide, adjusted to pH 8.0 with phosphate buffer, was prepared. The solution was heated in a constant temperature bath adjusted to 65°. After 24 hr. the solution was cooled and a sample was spotted on a prepared thin-layer plate beside a sample taken from a solution containing ungraded glutethimide plus EPG. A methanol–acetone–triethanolamine solvent was used for development and Dragendorff's reagent for visualization. The sample taken from the glutethimide solution that had been heated for 24 hr. showed two spots which corresponded to the two spots obtained from the sample containing undegraded glutethimide and EPG.

Recent work on the hydrolysis kinetics of phthalimide and *ortho*-carboxyphthalimide (17) shows that a small region in the very low pH range exists where acid catalysis occurs at 100°. However, similar acid catalysis was unobserved in the pH ranges and temperatures employed in this study.

SUMMARY AND CONCLUSION

The degradation of glutethimide in buffer solution of pH's ranging from 5.0–8.0 at 65, 60, and 50° has been studied. The degradation of glutethimide in aqueous solutions appears to be a base-catalyzed reaction, since the contribution of ionized species to the reaction rate in the pH range studied is very small. The rate is first order with respect to the concentration of glutethimide.

The apparent energy of activation, E_a, for the degradation of glutethimide at pH 8.0 was found to be of the order of 25.86 Kcal. Corrections were made for the apparent energy of activation, E_a, for the heat of ionization of water in the temperature range studied.

The half-lives at 25° for glutethimide in aqueous solutions were determined from the calculated specific reaction constants for reactions at different pH's and at 25°. The $t_{1/2}$ of glutethimide in a

buffered solution of pH 5 was calculated to be 28.3 years at 25°. The use of water-soluble hydrochloride glutethimide is recommended due to high solubility and high stability.

A mechanism is proposed which involves direct attack by a hydroxyl ion on the unhindred carbonyl of the glutethimide, followed by cleavage of the ring to 4-ethyl-4-phenyl glutaramic acid.

Some Pharmacological and Toxicological Properties of Several Phthalimidoaldehydes

By A. M. BURKMAN*, G. L. RINGHAM†, and M. H. WEINSWIG

Four phthalimidoaldehyde derivatives were prepared and several parameters of pharmacological activity were examined: acute toxicity, coordination deficit, ability to alter barbiturate-induced "sleep" in mice, provoke lacrimation and chromodacryorrhea in rats, and influence contractility of excised guinea pig ileum. Gamma-phthalimidobutyraldehyde and α-phthalimido-β-methylbutyraldehyde, the more toxic members of the group, significantly prolonged hexobarbital sleep time. The most intense lacrimatory effects were produced by α-phthalimido-β-methylbutyraldehyde while the most pronounced contractile response in isolated gut was provoked by phthalimidoacetaldehyde. The two latter responses were blocked by atropine premedication. None of the compounds produced chromodacryorrhea.

ALTHOUGH A variety of aldehyde derivatives and acyclic ketones have been examined for hypnotic activity since the introduction of chloral hydrate by Liebreich in 1869 (1), few remain prominent today as therapeutic agents. Most of these substances proved to be less desirable in terms of toxicity or effectiveness than other available hypnotics (2, 3) although chloral hydrate itself still occupies a preeminent position as a highly regarded and widely used soporific (4). In the search for and evaluation of aldehydic substances having potential hypnotic activity, attention was directed toward a group of phthalimidoaldehydes whose biological activity had never been investigated. Although the compounds to be described in this communication are known substances, that is, their syntheses have been reported (5–7), no pharmacological information is available from the literature. It was our intent to prepare and examine several phthalimidoaldehyde derivatives for gross CNS depressant activity. The nature of the responses displayed by animals during an initial toxicity screen would then dictate other pharmacological tests to be pursued.

METHODS

Synthesis—The phthalimidoaldehydes were all prepared using the Rosenmund reduction procedure

(8). This involved, in all cases, a three-step sequence of reactions in which (*a*) a phthalimido acid was formed by interaction of phthalic anhydride and one of four amino acids, (*b*) conversion of the acid to the acid chloride, and (*c*) reduction of the acid chloride to the aldehyde. Glycine, β-alanine, γ-aminobutyric acid, and valine were used as amino acid reactants and thus the following compounds were formed: phthalimidoacetaldehyde, β-phthalimidopropionaldehyde, γ-phthalimidobutyraldehyde, α-phthalimido-β-methylbutyraldehyde.

Preparation of Drugs for Biological Testing—The compounds, which were all sparingly soluble in water, were administered to animals as an aqueous suspension or, in the case of α-phthalimido-β-methylbutyraldehyde, an emulsion. The vehicle contained 0.25% methylcellulose, 1,500 cps. For the *in vitro* experiments, the drugs were dissolved in polyethylene glycol 200.

Acute Toxicity—Median lethal doses and their 95% confidence intervals were determined in female albino mice[1] using the intraperitoneal route of administration. For each drug three doses, six mice per dose, were used to estimate the position of the dose-lethality line (9).

Coordination Deficit—The method of Dunham and Miya (10) was employed to examine the drugs' ability to alter coordinated motor activity in mice. Animals were placed on a 2.5-cm. diameter horizontal rod rotating at a constant rate of 5 r.p.m. Mice that remained on the rod for 3 min. on each of two consecutive trials were selected for subsequent experimentation. Approximately 96% of the mice drawn from a stock colony met this criterion. Groups of six experimental mice were injected i.p. with doses of the compounds ranging from 50 to 400 mg./Kg. and reexamined for coordination deficit at intervals of 15 min. from injection until 3 hr. had elapsed and at 30-min. intervals thereafter until 6 hr. had elapsed. Animals that failed to remain on the rod *more* than once out of two consecutive trials were judged to suffer from a drug-induced neurological deficit. Twenty-four mice were used for each drug.

Potentiation of Barbiturate Sleep Time—For each of the phthalimidoaldehydes a fixed dose, equivalent to 1.06 mmoles/Kg., was administered to groups of mice. This dose, held constant to facilitate a comparison among drugs, represented no more than one-third the LD_{50} of the most toxic compound. Phthalimidoacetaldehyde was injected into seven groups of six mice. An eighth group of six, which served as a control, received only saline. Sodium hexobarbital, 120 mg./Kg., i.p., was administered to the groups at intervals of 0, 15, 30, 60, 90, 120, and 180 min. from aldehyde injection. "Sleep time" was recorded as that period during which the righting reflex was abolished. An animal was not credited with recovery until it was able to right itself twice within 15 sec. The results were subjected to an analysis of variance and Dunnett's test (11). This protocol was repeated for each aldehyde.

Lacrimation and Chromodacryorrhea—The method described by Malone *et al.* (12), was employed to detect and quantify muscarinic-like activity. Two female albino rats were used to test each of two dose levels of phthalimidoaldehyde. Saline was employed as a "blank" control and methacholine chloride, 10 mg./Kg., as a "positive" control. Lacrimation and chromodacryorrhea scores were assigned at 15-min. intervals for a period of 1 hr. following i.p. injection of the drugs. In subsequent experiments, the drugs' muscarinic activity was similarly evaluated in rats pretreated with atropine sulfate, 1 mg./Kg., i.p.

Contractility of Guinea Pig Ileum—Segments of terminal ileum were excised, suspended in aerated Tyrode's solution (13), and subjected to varying concentrations of the aldehydes which had been dissolved in appropriate amounts of polyethylene glycol 200. Smooth muscle activity was recorded electromechanically *via* an isotonic myograph. The glycol vehicle alone was included among the drugs tested. A single gut segment was used to evaluate the peripheral activity of *each* drug. The segments were initially challenged with two or three small doses of acetylcholine (ACH) chloride (0.001–0.004 mcg./ml. of bath) until stable, reproducible contractile responses were obtained. After the stabilization period, a dose of 0.004 mcg./ml. evoked a "standard" response (for each segment) against which aldehyde responses were subsequently compared. During the course of the experiment gut segments were periodically challenged with acetylcholine Cl, 0.002 mcg./ml. of bath, and atropine sulfate, 0.02 mcg./ml. of bath.

RESULTS AND DISCUSSION

Synthesis—The four phthalimidoaldehydes were successfully prepared in good yields and their melting points, along with those described in the literature, are summarized in Table I. The α-phthalimido-β-methylbutyraldehyde obtained as a viscous oil could not be crystallized. Similar difficulties were evidently encountered by others (7).

Biological Activity—Table II lists the 24-hr. LD_{50}'s of the four compounds along with their 95% confidence intervals. Phthalimidoacetaldehyde (PIA) and α-phthalimido-β-methylbutyraldehyde (APIM) were the least and most toxic compounds, respectively. The dose-lethality lines for β-phthalimidopropionaldehyde (BPIP) and γ-phthalimidobutyraldehyde (GPIB) were virtually superimpossible and thus their LD_{50}'s did not differ significantly. The dose-lethality lines for all four compounds, having a combined slope of approximately 16.8 probits/log unit, did not deviate significantly from parallelism.

Although PIA was least toxic in terms of lethal dose requirements, it was the only member of the series that elicited clonic convulsions in mice at high doses in the lethal range. Animals usually died in the midst of a convulsive seizure or during a period of extreme excitability which often followed convulsions. No other compound possessed convulsive activity. On the contrary, animals receiving drugs other than PIA usually lapsed into a gradually progressive depression terminating in death or slow recovery. Animals that survived remained markedly depressed for about 24 hr.

At sublethal concentrations each of the drugs, including PIA, was observed to suppress locomotor activity lasting for several hours without loss of the righting reflex. This apparent depressant activity was not reflected in any recognizable coordination deficit. When subjected to doses up to 400 mg./

[1] In this and all subsequent mouse experiments, female albino mice (Harlan ICR strain), 18–22 Gm. were employed.

TABLE II—ACUTE MEDIAN LETHAL DOSES OF PHTHALIMIDOALDEHYDES IN MICE

Compd.	Intraperitoneal LD_{50} and 95% Confidence Interval mg./Kg.	mmoles/Kg.
PIA	1725 (1531–1932)	9.1 (8.1–10.2
BPIP	1055 (942–1182)	5.2 (4.6–5.8)
GPIB	1055 (942–1182)	4.9 (4.3–5.5)
APIM	800 (721–888)	3.4 (3.0–3.7)

Kg., mice continued to successfully maintain their position on the rotating rod. At no time during the 6-hr. observation period did they fail the test.

In order to assess the subtler aspects of the drugs' CNS depressant action, the compounds' ability to alter hexobarbital-induced depression was investigated. The results are presented in Table III. Analysis revealed that using a fixed dose of 1.06 mmoles/Kg. of each drug only GPIB and APIM produced significant prolongation of sleep time. The dose employed was purposefully chosen so as not to exceed one-third the LD_{50} of the most toxic derivative (APIM). In spite of its relative insolubility significant hexobarbital potentiation was observed for GPIB even when the substance was administered at the same time as hexobarbital (0 premedication time). Although potentiating action could be demonstrated even when the hexobarbital injection was delayed for 120 min., GPIB's influences were apparently dissipated by 180 min. A significant but much less impressive potentiating effect was seen following APIM administration. Significant prolongation of hexobarbital sleep time could be demonstrated only after 60 min. had elapsed between APIM premedication and hexobarbital administration. This suggests that GPIB may be not only intrinsically more active than APIM, but more efficiently absorbed as well. The potentiating activities of GPIB and APIM are not, of course, necessarily reflections of direct CNS action. Their ability to influence hexobarbital sleep could be due to a wholly peripheral effect (*e.g.*, inhibition of barbiturate metabolizing enzymes). Furthermore, failure of the phthalimidoaldehydes to influence rotating rod performance clearly demonstrates that the compounds lack potent depressant activity. This, coupled with the fact that the depression of spontaneous locomotor activity may have been due to peritoneal irritation, leads to the inescapable suspicion that these compounds' central actions are weak at best.

At comparatively high doses the phthalimidoaldehydes were frequently observed to produce lacrimation, salivation, and flushing of the paw pads and ears. These observations prompted experiments designed to evaluate the drugs' cholinomimetic action *in vivo* and *in vitro*. Chromodacryorrhea, the secretion of porphyrin pigments by the Harderian gland (14) first described by Freud (15), was characteristically evoked by muscarinic stimulants. Although the response was readily provoked by methacholine, it was not elicited by any of the aldehydes (Table IV).

All compounds, except GPIB, increased lacrimatory responses and premedication of the animals with atropine successfully abolished these effects. APIM was responsible for the most intense lacrimation at a dose level of 2.1 mmoles/Kg. These cholinergic-like effects are not manifested until fairly high doses are attained and at these concentrations all animals were distinctly sedated.

			5.0×10^{-4}	−9.5	−0.95	...[d]

[a] Adjacent segments, each approximately 1 cm. in length, were cut from a 5-cm. section of terminal ileum. [b] The "standard" response evoked by acetylcholine chloride, 0.004 mcg./ml. of bath; in mm. of polygraph pen deflection. [c] Contractile dose 50: the interpolated dose of aldehyde producing a contractile response one half that evoked by the "standard" dose of ACH [d] Only depression of gut tone was observed.

PIA provoked the most intense contractile response in isolated gut (Table V). BPIP and GPIB were considerably less active as spasmogens while APIM produced only a sustained relaxation of ileal musculature. Both the stimulant and depressant effects were dose-dependent and inspection revealed that the log dose-percent response lines closely approached parallelism. A comparatively long onset time (about 20–25 sec.) was associated with the stimulant response while APIM's depressant action was seen within 3–5 sec. of drug administration. Contractions could be prevented by the prior introduction of atropine into the tissue bath. Responsiveness of depressed tissues to ACH remained essentially unaltered. Control vehicle, polyethylene glycol 200, produced no observable responses in the doses used.

SUMMARY

(*a*) Four phthalimidoaldehydes were prepared and examined for biological activity: phthalimidoacetaldehyde (PIA); β-phthalimidopropionaldehyde (BPIP); γ-phthalimidobutyraldehyde (GPIB), and α-phthalimido-β-methylbutyraldehyde (APIM).

(*b*) The order of decreasing i.p. toxicity in mice was APIM, BPIP (GPIB), PIA.

(*c*) PIA, alone among the aldehydes, produced hyperactivity and convulsions in mice when administered in lethal or near-lethal concentrations. At lower doses all compounds produced distinct sedation in both rats and mice. The sedative action expressed itself primarily as a depression of spontaneous locomotor activity. Sedated mice, however, did not exhibit any coordination deficit as

determined by their ability to maintain their position on a rotating rod.

(*d*) The most pronounced prolongation of hexobarbital sleep time in mice was produced by GPIB. Less impressive, but nonetheless significant, was the sleep potentiating effect of APIM. In equimolar concentrations neither PIA nor BPIP exhibited any influence on barbiturate depression.

(*e*) At comparatively high doses, the aldehydes were frequently observed to produce lacrimation, salivation, and flushing of the paw pads and ears, observations that prompted examination of the drugs for possible cholinomimetic activities.

(*f*) The estimated order of decreasing activity as lacrimatory stimulants in rats was APIM, BPIP (PIA), GPIB. This action was blocked by atropine premedication.

(*g*) None of the aldehydes provoked chromodacryorrhea in rats.

(*h*) PIA and BPIP and GPIB evoked short-lived tonic contractions in isolated guinea pig ileum that could be blocked by atropine. APIM produced only mild gut relaxation. There appears to be little relationship between the aldehydes' spasmogenic properties and their ability to stimulate lacrimation.

Thin-Layer Chromatography and IR Spectrophotometry of Commercial Sodium Sulfobromophthalein Solutions

By F. BARBIER and G. A. DEWEERDT

Techniques and results of analysis of some commercially available sulfobromophthalein (phenoltetrabromphthalein disulfonate) solutions by means of TLC and IR spectrophotometry are reported. The IR spectra of sulfobromophthalein and sulfobromophthalein-like compounds are presented and discussed. Three of the additional fractions found could be identified as phenoltetrabromphthalein and its mono- and trisulfonate derivatives. These impurities probably are due to imperfections in the synthesis of sulfobromophthalein. With but one exception they represent less than 1 percent of the total absorbance at 578 mμ. Such low concentrations do not interfere with the clinical use of sulfobromophthalein.

DESPITE THE WIDE use and established value of sulfobromophthalein (phenoltetrabromphthalein disulfonate) in the diagnosis of liver disease, little information is available on the composition of the dye solutions for intravenous use (1–5). The purpose of this study was to analyze some sulfobromophthalein solutions, commercially available in Belgium, with the aid of thin-layer chromatography (TLC) and IR spectrophotometry.

Received January 6, 1967, from the Policlinic of Internal Medicine, University of Ghent, Gent, Belgium.
Accepted for publication October 12, 1967.

METHODS

Sulfobromophthalein solutions for intravenous use and marketed by the following laboratories were analyzed: Vitarine Co., lot 9364; E. Merck, lots R493, R879, R959, and T959; Hynson, Westcott and Dunning, lots P_{23}, R_{96}, T_{47}, and U_{28}; and Simes, lot 3E29.

Thin-layer Chromatography—TLC was carried

determined by their ability to maintain their position on a rotating rod.

(*d*) The most pronounced prolongation of hexobarbital sleep time in mice was produced by GPIB. Less impressive, but nonetheless significant, was the sleep potentiating effect of APIM. In equimolar concentrations neither PIA nor BPIP exhibited any influence on barbiturate depression.

(*e*) At comparatively high doses, the aldehydes were frequently observed to produce lacrimation, salivation, and flushing of the paw pads and ears, observations that prompted examination of the drugs for possible cholinomimetic activities.

(*f*) The estimated order of decreasing activity as lacrimatory stimulants in rats was APIM, BPIP (PIA), GPIB. This action was blocked by atropine premedication.

(*g*) None of the aldehydes provoked chromodacryorrhea in rats.

(*h*) PIA and BPIP and GPIB evoked short-lived tonic contractions in isolated guinea pig ileum that could be blocked by atropine. APIM produced only mild gut relaxation. There appears to be little relationship between the aldehydes' spasmogenic properties and their ability to stimulate lacrimation.

Thin-Layer Chromatography and IR Spectrophotometry of Commercial Sodium Sulfobromophthalein Solutions

By F. BARBIER and G. A. DEWEERDT

Techniques and results of analysis of some commercially available sulfobromophthalein (phenoltetrabromphthalein disulfonate) solutions by means of TLC and IR spectrophotometry are reported. The IR spectra of sulfobromophthalein and sulfobromophthalein-like compounds are presented and discussed. Three of the additional fractions found could be identified as phenoltetrabromphthalein and its mono- and trisulfonate derivatives. These impurities probably are due to imperfections in the synthesis of sulfobromophthalein. With but one exception they represent less than 1 percent of the total absorbance at 578 mμ. Such low concentrations do not interfere with the clinical use of sulfobromophthalein.

DESPITE THE WIDE use and established value of sulfobromophthalein (phenoltetrabromphthalein disulfonate) in the diagnosis of liver disease, little information is available on the composition of the dye solutions for intravenous use (1–5). The purpose of this study was to analyze some sulfobromophthalein solutions, commercially available in Belgium, with the aid of thin-layer chromatography (TLC) and IR spectrophotometry.

Received January 6, 1967, from the Policlinic of Internal Medicine, University of Ghent, Gent, Belgium.
Accepted for publication October 12, 1967.

METHODS

Sulfobromophthalein solutions for intravenous use and marketed by the following laboratories were analyzed: Vitarine Co., lot 9364; E. Merck, lots R493, R879, R959, and T959; Hynson, Westcott and Dunning, lots P_{23}, R_{96}, T_{47}, and U_{28}; and Simes, lot 3E29.

Thin-layer Chromatography—TLC was carried

out on chromatoplates (20 × 20 cm.) prepared by the technique of Stahl (thickness of the absorptive layer of Silica Gel G, Merck, 250 μ) with two solvent systems: butanol–acetic acid–water (30:7.5:12.5 v/v) and butanol–propionic acid–water (30:20:7.5 v/v). When the solvent front reached a height of 10 cm., the plate was removed, dried in air, and developed in ammonia vapors. The fraction corresponding with phenoltetrabromphthalein disulfonate was located with bromsulfalein Fuka. [The other reference compounds (phenoltetrabromphthalein and its mono- and tetrasulfonate derivatives) were kindly provided by N. B. Javitt, New York, N.Y.] All these compounds develop a purple color on alkalization. The fractions obtained were scraped off the plate, eluted with 0.1 *N* NaOH, and centrifuged. The absorptions in the visible range of the spectrum (wavelength scan from 320 to 750 mμ) of each fraction were scanned on a Beckman DB recording spectrophotometer. The percentage of each fraction was estimated from its absorbance at 578 mμ.

IR Spectrophotometry—All IR spectra were obtained with a Perkin-Elmer NaCl Infracord using the potassium bromide pellet technique.

Prior to preparative TLC of the fast-running fractions, RI and RII, 400 ml. of sulfobromophthalein solution (Simes) was alkalized with 1 Gm. of KOH and extracted twice with butanol. To this extract HBr was added till the purple color disappeared. Next the extract was washed twice with distilled water, evaporated *in vacuo* until saturation, and chromatographed on MN Silica Gel N-HR/UV 254 (Macherey, Nagel and Co.) absorptive layers of 500-μ thickness. Fraction RI was isolated with butanol–acetic acid–water (12:4.5:5.5 v/v) and fraction RII with hexane–butanol (20:1 v/v). Both fractions were visualized under UV light (wavelength of 254 mμ), scraped off the plate, and eluted with ethanol.

Sufficient amounts of pure fraction SII were obtained from lot P23 of Hynson, Westcott and Dunning and lot 3E29 of Simes. The dye solutions were chromatographed on MN Silica Gel N-HR with *tert*-butanol–water–butanol (32:10:5 v/v), visualized with KOH spray, scraped off the plate, eluted with water, concentrated *in vacuo*, and finally filtrated on Sephadex G 25.

RESULTS

Commercial sulfobromophthalein solutions always proved to be separable into several fractions by TLC (Table I). After alkalization, a total of eight additional purple fractions was demonstrated. In both chromatographic systems the R_f of the fastest running fraction (RII) corresponds with phenoltetrabromphthalein, and that of the other fast-running fraction (RI) with phenoltetrabromphthalein monosulfonate. No fraction corresponding with phenoltetrabromphthalein tetrasulfonate was found.

Table II shows the percentages of the fractions found in the sulfobromophthalein solutions. With the exception of the sulfobromophthalein, Simes lot 3E29, the additional fractions always represent less than 1% of the total absorbance at 578 mμ.

The visible spectra of sulfobromophthalein and all additional fractions were indistinguishable; so this technique is unable to characterize the multiple fractions eluted from the chromatogram. Fortunately IR spectrophotometry gives more gratifying results.

The phthalein compounds studied differ by the number of Br atoms linked to the phthalide group, and the number and the localization of the sulfonate substituents on the hydroxyphenyl groups (Fig. 1).

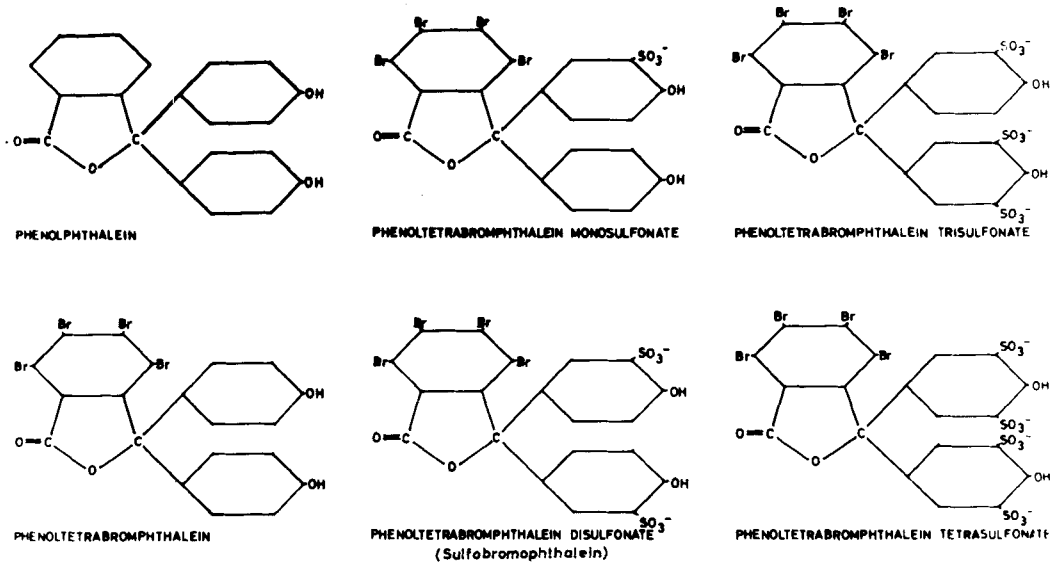

Fig. 1—Structural formulas of some of the phthalein dyes examined.

Phenolphthalein (Table III)—The band at 5.7 μ can be assigned to the —C=O group in the phthalide nucleus. This absorbance is present in all compounds examined and sufficiently individualized to provide reliable measurements of the concentration of the compound in the KBr pellet. Aromatic ring vibrations: in most cases three peaks are found (6.2, 6.6, and 6.9 μ); a fourth peak at 6.85 μ is perhaps due to the aromatic ring in the phthalide group. The strong 12-μ band arises from the adjacent pairs of H atoms on the phthalide group.

Phenoltetrabromphthalein (Fig. 2, Table III)—The halogenation has the following effects on the IR spectrum: absence of the band at 13.2 μ, and the mass increase induces a lowered vibrational frequency of the aromatic ring of the phthalide group and hence shifts its absorption from 6.85 μ toward longer wavelengths (7.4 μ).

Phenoltetrabromphthalein Monosulfonate (Fig. 2, Table III)—The introduction of one sulfonate substituent results in the following changes: (*a*) the band at 9.7 μ, which can be assigned to the sulfonate substituent, is very well individualized and provides a simple means of estimating the number of sulfonate substituents on comparing to the absorbance at 5.7 μ. (*b*) The site of the new substituent causes the loss of one adjacent pair of H atoms (decrease at 12 μ) which is replaced by one isolated H atom (weak absorption at 11 μ). (*c*) The mass increase in one hydroxyphenyl group lowers its frequency and shifts the aromatic ring absorption toward longer wavelengths. As only one group is involved, a reduplication of these bands results (6.6 and 6.7 μ; 6.9 and 7.1 μ).

Phenoltetrabromphthalein Disulfonate (Sulfobromophthalein) (Fig. 3, Table III)—The introduction of a second SO_3^- substituent restores the symmetry of the hydroxyphenyl groups. Hence, the reduplication of the aromatic ring peaks disappears and an absorption is now found only at 6.7 and 7.1 μ; the SO_3^- band at 9.7 μ doubles in comparison to the absorbance at 5.7 μ, and another adjacent H pair is replaced by an isolated H atom (further decrease at 12 μ, increase at 11 μ).

Phenoltetrabromphthalein Tetrasulfonate (Fig. 3, Table III)—Two more SO_3^- substitutents are introduced, resulting in a more pronounced shift of the aromatic ring peaks toward 6.9 μ (and perhaps 7.4 μ?); once more a doubled absorbance at 9.7 μ, four SO_3^- substituents now being present in one molecule; and since all adjacent H atoms are eliminated, the absorption at 12 μ disappears while the intensity of the band at 11 μ is much enhanced.

Fraction RII (Table III)—The very low concentration of this compound resulted in tedious isolation and difficult purification. Two spectra were obtained but the purification was still incomplete. Nevertheless some conclusions were possible: (*a*) the phthalide group is present as a Br derivative (7.4 μ instead of 6.85 μ). A four-Br derivative is most likely, as the corresponding H atoms would give supplementary bands in the region 11–13 μ. (*b*) The hydroxyphenyl groups are symmetrical (6.6 and 6.9 μ); neither presence of SO_3^- groups (no absorption at 9.7 μ) nor of other substituents (strong band at 11.9 μ, no band at 11 μ). (*c*) The region 12–15 μ is identical with that of phenoltetrabromphthalein. Therefore it is concluded that compound RII is identical with phenoltetrabromphthalein.

Fraction RI (Table III)—A tetrabromphthalide group is present (7.4 μ). Asymmetry of the hydroxyphenyl groups (6.6 and 6.7 μ; 6.9 and 7.1 μ) related to the presence of one SO_3^- substituent (absorption at 9.7 μ) in one molecule (ratio of the absorbance at 5.65 μ to the absorbance at 9.7 μ) and a weak absorption at 11 μ suggest the replacement of one adjacent H pair by an isolated free H atom. The region 12–15 μ is identical with that of phenoltetrabromphthalein monosulfonate. It is concluded that fraction RI is identical with phenoltetrabromphthalein monosulfonate.

Fraction Sulfobromophthalein (Table III)—A tetrabromphthalide group is present (7.4 μ); hydroxyphenyl groups are symmetrical but shifted (6.75 and 7.15 μ); two SO_3^- substituents are present (ratio of the absorbance at 9.7 μ to the absorbance at 5.7 μ); adjacent pairs of H atoms are diminished but still present (12 μ); isolated free H atoms are present, indicating a substitution in the hydroxyphenyl groups (11.0 μ). The region 12–15 μ is identical with that of sulfobromophthalein. The conclusion is that fraction sulfobromophthalein is identical with phenoltetrabromphthalein disulfonate.

Fraction SIII (Table III)—The ratio of the absorbance at 9.7 μ (SO_3^- group) to the absorbance at 5.65 μ argues for the presence of three sulfonate substituents in one molecule. The number of Br atoms in the phthalide group cannot be clearly stated, as a (inconstant) band at 7.2 μ (NH_4^+?) obscures the region of 7.4 μ. The most probable number is four, as there is a little shoulder appearing at 7.4 μ. The band at 11 μ (isolated H atom in the hydroxyphenyl ring) is stronger, and the band at 12 μ (adjacent free H atoms) is weaker as compared to sulfobromophthalein. This argues for the presence of only two adjacent free H atoms in one molecule.

Phthalide groups with 2 adjacent H atoms as found in 3,6-dibromo-, 3,4-dibromo-, and 3,6-dichloroderivatives absorb at 11.6 μ (unpublished data). The absorbance of this band from the spectrum of fraction SIII suggests that the adjacent H atoms are situated on one of the hydroxyphenyl groups, which obviously contains only one of the sulfonate substituents. A similar type of hydroxyphenyl group is found in sulfobromophthalein and results in absorptions at 6.7 and 7.1 μ (shifted aromatic ring vibrations) and at 9.15 μ (SO_3^- substituent).

As a matter of course the other hydroxyphenyl group contains the two remaining sulfonate substituents and two free isolated H atoms. The latter type of hydroxyphenyl group is found in the tetrasulfonate derivative and results in absorptions at 6.85 and 7.15 μ (aromatic ring) and at 8.9 μ (SO_3^- substituent).

In fraction SII, the corresponding bands are found at 6.75 and 6.85 μ (aromatic ring); 7.1 and 7.15 μ, obscured (aromatic ring); 9.0 and 9.15 μ (SO_3^- group). This configuration is very well explained by the presence of both kinds of hydroxyphenyl groups in one molecule. Therefore this is most probably phenol (tetra ?) bromphthalein trisulfonate.

Fractions SI, SII, SIV, SV, and SVI were not obtained in sufficient amounts for IR analysis. Finally, the stability of aqueous solutions of phenoltetrabromphthalein and its mono-, di-, and tetrasulfonate derivatives was investigated. Chromatograms developed 1, 2, 3, and 4 months after preparing the solution revealed no additional fractions. Chromatograms of an aqueous solution of sulfobromophthalein (50 mg./ml.) autoclaved at 120° during 20 min. showed only one band, comparable in R_f to the standard dye.

DISCUSSION

TLC having a greater resolving power than paper and column chromatography successfully separates several sulfobromophthalein-like impurities in commercial sulfobromophthalein solutions. The chemical structure of two of the additional fractions was defined by IR spectrophotometry as phenoltetrabromphthalein and phenoltetrabromphthalein monosulfonate, whereas the third fraction has been tentatively identified as phenoltetrabromphthalein trisulfonate.

These investigations suggest that the additional fractions are due to imperfections in the synthesis of sulfobromophthalein. Because these impurities represent less than 1% of the total absorbance at 578 mμ in all but one of the sulfobromophthalein solutions for intravenous use examined, their influence on the disappearance rate of the dye from plasma must be negligible. Of paramount importance is the possible influence of these impurities on the number and composition of the sulfobromophthalein conjugates found in blood and bile. Indeed, Javitt (6, 7) demonstrated that phenolsulfodibromphthalein and phenolsulfotribromphthalein (8) are recovered mostly in bile, primarly as a glucuronide, and that conjugation of phenoltetrabromphthalein monosulfonate occurs mainly with glutathione although a glucuronide conjugate has also been found.

Phenoltetrabromphthalein tetrasulfonate and phenol 3,6-dibromphthalein disulfonate (9), on the other hand, formed no conjugates. At the present time no data are available about the fate of injected phenoltetrabromphthalein trisulfonate. Based on a considerable body of evidence (1–3, 10–12), it is now known that at least three of the four major ninhydrin-positive sulfobromophthalein compounds appearing in the bile consist of cleavage products and isomers of a conjugate of sulfobromophthalein and glutathione. In contrast to paper and column chromatography, TLC separates trace amounts of one to three additional sulfobromophthalein-like compounds in bile and blood of most patients (13).

It seems unlikely that these additional compounds have their origin in the tiny quantities of sulfobromophthalein-like impurities found in the dye solutions. Anyhow, free sulfobromophthalein and its major conjugates form the bulk of the dye appearing in the bile. Thus, the present investigation indicates that the small quantities of sulfobromophthalein-like impurities found in most commercial dye solutions for intravenous use do not interfere with the clinical use of the dye.

Relationship Between Sputum Viscosity and Total Sialic Acid Content

By R. MUNIES, T. C. GRUBB, and R. E. CALIARI

Sputum samples collected from patients suffering from pulmonary diseases were hand homogenized, and the viscosity of the samples determined by measuring the flow time through a No. 100 Cannon-Fenske capillary viscometer at 37°. Total sialic acid content (free plus bound) was determined on an aliquot of each sample. In some patients producing an insufficient volume, samples from different patients were pooled and the data obtained treated separately. A sputum model was developed, and the viscosity and sialic acid content were determined in the same manner as the sputum. The data show a statistically significant linear relationship between viscosity and sialic acid concentration, until a point is reached where the acid content approaches a maximum and then plateaus, although the viscosity continues to increase.

VISCOSITY measurements of sputum have frequently been used for evaluating mucolytic or expectorant action of drugs. This measurement alone does not adequately describe the physicochemical properties of sputum. Measurements of adhesiveness and tensile strength of fibers should provide a more complete evaluation. However, reduction in viscosity is the prime objective to make the sputum more easily eliminated from the respiratory tract. Unfortunately "viscosity" is a term applied to homogeneous systems and is inappropriate for sputum, which is nonhomogeneous. Therefore, what is the appropriate measurement of viscosity to provide meaningful results?

Sputum viscosity has been measured in many different ways. Basch *et al.* (1) used a narrow glass tube and measured flow under pressure. However, Forbes and Wise (2) using the same technique could not obtain consistent readings on the same specimen. They, therefore, used a torque viscometer which measures viscosity by its dampening effect on the rotation of a metal cylinder suspended in it by a torsion wire. This instrument has limited use, because not less than 25 ml. is needed for each measurement and only fairly viscid samples can be measured accurately. In a study comparing the action of various expectorant drugs Simon and Harmon (3) blended the sputum specimens by vigorously stirring at

Relationship Between Sputum Viscosity and Total Sialic Acid Content

By R. MUNIES, T. C. GRUBB, and R. E. CALIARI

Sputum samples collected from patients suffering from pulmonary diseases were hand homogenized, and the viscosity of the samples determined by measuring the flow time through a No. 100 Cannon-Fenske capillary viscometer at 37°. Total sialic acid content (free plus bound) was determined on an aliquot of each sample. In some patients producing an insufficient volume, samples from different patients were pooled and the data obtained treated separately. A sputum model was developed, and the viscosity and sialic acid content were determined in the same manner as the sputum. The data show a statistically significant linear relationship between viscosity and sialic acid concentration, until a point is reached where the acid content approaches a maximum and then plateaus, although the viscosity continues to increase.

VISCOSITY measurements of sputum have frequently been used for evaluating mucolytic or expectorant action of drugs. This measurement alone does not adequately describe the physicochemical properties of sputum. Measurements of adhesiveness and tensile strength of fibers should provide a more complete evaluation. However, reduction in viscosity is the prime objective to make the sputum more easily eliminated from the respiratory tract. Unfortunately "viscosity" is a term applied to homogeneous systems and is inappropriate for sputum, which is nonhomogeneous. Therefore, what is the appropriate measurement of viscosity to provide meaningful results?

Sputum viscosity has been measured in many different ways. Basch *et al.* (1) used a narrow glass tube and measured flow under pressure. However, Forbes and Wise (2) using the same technique could not obtain consistent readings on the same specimen. They, therefore, used a torque viscometer which measures viscosity by its dampening effect on the rotation of a metal cylinder suspended in it by a torsion wire. This instrument has limited use, because not less than 25 ml. is needed for each measurement and only fairly viscid samples can be measured accurately. In a study comparing the action of various expectorant drugs Simon and Harmon (3) blended the sputum specimens by vigorously stirring at

constant speed and measuring the viscosity in an Ostwald viscometer. In this study it was necessary to dilute some samples with water and extrapolate the viscosity to zero dilution.

Since sputum is non-Newtonian, some investigators feel any measurement of viscosity must be made with an instrument which can measure and vary the velocity gradient and tangential stress separately (4). Rotational viscosimeters fill this need but also have their shortcomings. A cone and plate rotational viscosimeter has the disadvantage that the small quantity of sputum which can be measured may not be representative. In addition, lumps in the sample may not always fill the gap between the cone and vessel floor, thus the values of corresponding tangential stresses are not comparable.

All current methods appear to have some shortcomings, however, if a positive relationship between viscosity and a common ingredient of sputum can be established, chemical assay of this component may then avoid this dilemma.

It is generally accepted that glycoproteins are mainly responsible for the physical properties of mucous secretions and that the terminal unit of the carbohydrate prosthetic groups is in many instances sialic acid (5). The naturally occurring sialic acids are substituted neuraminic acid derivatives (*N*-acetyl, *N*-glycol, *N,O,*-diacetylneuraminic acid). However, in man only the *N*-acetylneuraminic acid is found.

Sialomucins are regular components of the mucoid material covering the epithelial surfaces of the respiratory, digestive, and urogenital tracts. Their relationship to the viscosity of mucous secretions has been alluded to by several investigators. Atassi *et al.* (6) reported that the bronchial secretions from patients with chronic bronchitis contained increased levels of sialic acid. Hoskins and Zamcheck (7) tested the serous saliva and mucoid saliva from one subject and found that the fucose and sialic acid content relative to hexosamine was less in the thinner material. Sialic acid was also more abundant in mucoid saliva than in gastric juice from the same subject. This work is supported by additional evidence in which relatively high ratios of concentrations of sialic acid to fucose were found in jelly from pseudomucinous ovarian cysts compared to that from pseudomyxomatous cysts (8). In the former, the cyst contains a viscoelastic gel. Gibbons (9) found a significant difference in sialic acid concentration between estrus and pregnancy samples of bovine cervical mucin. The thick plasto-elastic gel secreted during pregnancy had a higher sialic acid content than the thinner material secreted at estrus suggesting that the content of this acid is one of the factors affecting the viscosity of mucin.

The work cited above provides a theoretical framework for the hypothesis that there is a correlation between the viscosity of mucus secretions and the carbohydrate complex, namely the sialomucins synthesized and discharged from the mucus-secreting glands. The authors are unaware of any previous study with a sufficient number of samples to determine if a statistically significant positive correlation exists. Therefore, the purpose of this study was to quantitate both variables (viscosity and sialic acid) simultaneously to determine if this relationship for sputum does exist.

EXPERIMENTAL

Sample Collection—Sputum was obtained from patients with bronchiectasis, bronchial asthma, or pulmonary emphysema with the majority of samples from the latter two conditions.[1] No attempt was made to identify sample with disease.

The method used to obtain these samples was a modification of that described by Bickerman *et al.* (10). Essentially this consisted of having patients inhale a mixture of 0.2 ml. of 2.25% racemic epinephrine[2] and 1.0 ml. of 0.25% phenylephrine hydrochloride. Following this the patients inhaled a warm normal saline aerosol generated in a high flow nebulizer by means of an air pump. All of the material expectorated, during and for 10 min. following the aerosol inhalation, was collected and immediately frozen. Mucoid material recovered in this manner is reported to be from the tracheobronchial passageway (10).

Viscosity Determination—The frozen samples were brought to ambient temperature and passed through a Logeman hand homogenizer with the gap adjusted to the smallest permissible size. The homogenate was warmed to 37° and 8.0 ml. was transferred to a No. 100 Cannon-Fenske capillary viscometer positioned in a 37° constant temperature water bath, and allowed to equilibrate for 12–20 min. before the flow time was measured. The viscometer was washed in a chromic acid solution at the beginning of each day of use and rinsed with water and acetone and air-dried between each viscosity measurement. Viscosity calculations were based on a distilled water standard. Samples from different patients producing insufficient volume for viscosity measurements were pooled.

Sialic Acid Assay—The analytical procedure employed for determining total sialic acid content (free plus bound) measured as *N*-acetylneuraminic acid was that of Warren (11). The method is based upon periodate oxidation of sialic acids to form β-formylpyruvic acid, which is combined with thiobarbituric acid to form a chromophore that is extracted in cyclohexanone, and measured spectrophotometrically. Though there is some interference from 2-deoxyribose present in sputum, this can be readily compensated for as described by Warren.

[1] The authors are indebted to Dr. Hylan A. Bickerman for supplying all clinical material used in this study.
[2] Trademarked as Vaponephrine.

The above assay only measured free sialic acids. Therefore, 1.0 ml. of each sputum homogenate (pooled and unpooled) was diluted with 1.0 ml. of distilled water and heated at 80° in 2.0 ml. 0.2 *N* H_2SO_4 for 1 hr. in order to hydrolyze the bound acids. Then 0.2 ml. of the hydrolyzate, representing 0.05 ml. of sputum was assayed for total sialic acid.

Sputum Model—A partially purified mucoprotein preparation derived from commercial hog gastric mucin was prepared in the manner described by Sheffner (12). Colloidal suspensions ranging from 0.25–2.50% were prepared from this tan spongy material and their viscosity and sialic acid content determined.

RESULTS AND DISCUSSION

The authors are of the opinion that capillary viscometry is well suited to this investigation. If a relationship exists between viscosity and sialic acid content, it is a reasonable assumption that, although the viscosity values reported here may differ from the numerical values obtained when using a different measuring technique, the comparative relationship would still be valid. Even the best rotation viscometry remains a semiexact method for measuring the viscosity of sputum, and it is far from suitable for the determination of absolute values.

Although homogenization alters the integrity of mucoproteins and mucopolysaccharides, the writers concluded that homogenization would still be acceptable for investigating the relationship between viscosity and sialic acid content.

It was also concluded that though the patients had a variety of diseases, were on different drug therapy, or may have had slightly different concentrations of saline in their bronchial passages, it was unlikely that these factors could influence the interpretation of the results.

Unpooled Sputum—The sialic acid content reported is in μmole per 0.1 ml. of sputum.

Table I is a summary of the data obtained on unpooled sputum. The data graphically depicted in Fig. 1 show that there is a linear relationship between viscosity and sialic acid concentration until a point is reached where the acid content appears to approach a maximum and then plateaus, although the viscosity continues to increase. A linear relationship is evident until a viscosity of approximately 2 cps. is reached. This linearity is supported by a correlation coefficient of 0.979 obtained from samples 1–10 whereas a much lower coefficient is obtained by using the data from all the samples. Unfortunately only a few samples are on the plateau portion of the curve, so the maximum sialic acid value can only be estimated to be between 0.11 and 0.12 μmole.

TABLE I—UNPOOLED SPUTUM SAMPLES

Sample No.	Viscosity, cps.	μ moles, Sialic Acid/ 0.1 ml.
1	0.818	0.012
2	1.089	0.021
3	1.125	0.036
4	1.186	0.028
5	1.311	0.029
6	1.322	0.042
7	1.398	0.048
8	1.914	0.079
9	2.022	0.075
10	2.131	0.092
11	2.326	0.075
12	2.739	0.110
13	3.700	0.109
14	5.453	0.118

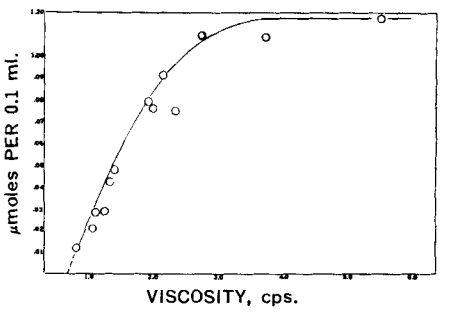

Fig. 1—Relationship between the viscosity and sialic acid concentration of unpooled sputum.

TABLE II—POOLED SPUTUM SAMPLES

Sample No.	Viscosity, cps.	μmoles, Sialic Acid/ 0.1 ml.
1	1.177	0.079
2	1.192	0.090
3	1.549	0.102
4	2.175	0.172
5	2.280	0.176
6	2.429	0.180
7	2.475	0.157
8	2.622	0.194
9	3.470	0.190
10	4.902	0.220
11	26.820	0.240

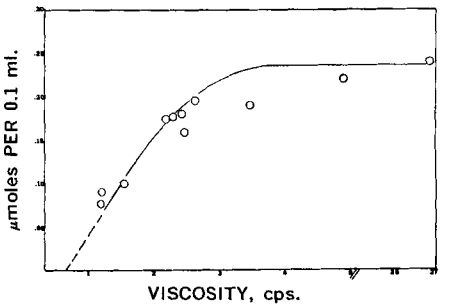

Fig. 2—Relationship between the viscosity and sialic acid concentration of pooled sputum.

It is significant that when the curve is extrapolated to the *X* axis, (that is, sialic acid equals 0.00 μmoles), the interscept is 0.70 cps.—the viscosity of water at 37°.

Pooled Sputum—There was a greater percentage of high viscosity sputums in the pooled specimens (Table II) than in the unpooled. Figure 2 shows that the relationship between viscosity and sialic acid is the same for pooled and unpooled sputum. A sample with an extremely high viscosity (26.82 cps.) is five and one-half times greater than its nearest neighbor, yet there is a difference of only 0.02 μmole in sialic acid content. Though there is only one sample on this high end of the viscosity scale, it does emphasize the leveling of the acid concentration with a concomitant rise in viscosity above

TABLE III—SPUTUM MODEL

% Muco-protein	Viscosity, cps.	μmoles, Sialic Acid/ 0.1 ml.
0.25	0.94	0.007
0.50	1.26	0.014
0.75	1.66	0.023
1.00	2.22	0.028
1.50	3.00	0.043
2.00	4.00	0.055
2.50	5.00	0.069

2 cps. The correlation coefficient for the lower portion of the curve is 0.988, again indicating a linear relationship. When the curve is extrapolated to the X axis, it too intersects at 0.70 cps.

The major difference between the pooled and unpooled data is the magnitude of the sialic acid concentration relative to the same viscosity. Though the shapes of the curves are quite similar, the sialic acid content of the pooled samples is higher, with the plateau value approximately double that of the unpooled.

Sputum Model—The authors developed a simulated biological model in which some of the variables could be controlled. Gastric mucin was first selected because it represents a crude source of mucoprotein; however, the sialic acid content of the material available was quite low, and the viscosity of a standard suspension was difficult to duplicate on a day-to-day basis. A partially purified mucoprotein substrate which met the practical conditions needed for the model was used (12). The data are tabulated in Table III.

Because this model is a series of uniform aqueous suspensions, the curve has been drawn so that it is forced to intersect the X axis (sialic acid = 0.000) at the viscosity of water at 37°. The similarity of this curve (Fig. 3) to the two mucous curves is evident. Although the sputum model does not closely simulate natural mucus because it utilizes a lyophilized, partially purified mucoprotein, which disperses readily in water, it lends considerable weight to the relationship under study.

While it is premature to attempt to quantitate the viscosity of sputum in terms of sialic acid content, it appears that within limits and with continuing research this will be possible. The plateau seen

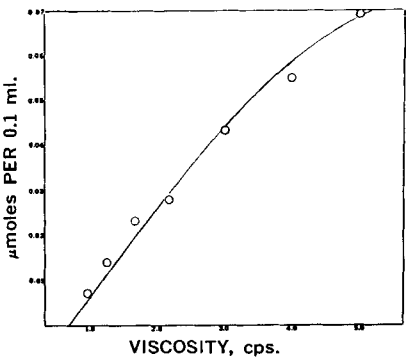

Fig. 3—Relationship between the viscosity and sialic acid concentration of sputum model.

in all three sets of data suggest, as expected, that there are other factors besides sialic acid affecting the viscosity of sputum.

Carbonate Ester Prodrugs of Salicylic Acid

Synthesis, Solubility Characteristics, *In Vitro* Enzymatic Hydrolysis Rates, and Blood Levels of Total Salicylate Following Oral Administration to Dogs

By L. W. DITTERT*, H. C. CALDWELL, T. ELLISON†, G. M. IRWIN, D. E. RIVARD, and J. V. SWINTOSKY*

The methods of synthesis, solubilities, and partition coefficients for the ethyl-, butyl-, hexyl-, and 2,2,2-trichloroethylcarbonate esters of salicylic acid are reported. The solubility and partitioning characteristics of the ethyl- and trichloroethylcarbonates were similar to those of aspirin, whereas the butyl- and hexylcarbonates were more lipid soluble than aspirin. The *in vitro* hydrolysis rates of the compounds were also determined. The hydrolysis of the carbonate esters of salicylic acid were only slightly accelerated by 2 percent human plasma, and aspirin hydrolysis was not accelerated at all by this enzyme system. In the pseudocholinesterase and α-chymotrypsin systems, the hydrolysis of the butyl- and hexylcarbonates were accelerated to a much greater degree than those of the ethylcarbonate and aspirin. The results suggest that carbonates with 4 or 6 carbon alkyl chains fit the active sites of these esterolytic enzymes better than a carbonate with a 2 carbon alkyl chain or an acetate ester. Aspirin and the butyl-, hexyl-, and trichloroethylcarbonates were administered orally to dogs and the plasma levels of total salicylate were followed for 8 hr. The resulting blood level curves were virtually superimposable; all peaked at about 2 hr. and fell off at about the same rate. These results suggest that the prodrug carbonate esters are as readily absorbed as aspirin despite their different aqueous and lipid solubilities and that all the drugs including aspirin are converted to a common form, *i.e.*, free salicylate, within 2–3 hr. after oral administration.

FECAL BLOOD loss studies (1, 2) have shown that approximately 70% of persons taking aspirin experienced occult gastric bleeding averaging 5 ml. of blood per day, and Kelly (3) has reported that patients taking aspirin for long periods of time may develop severe iron deficiency anemia due to fecal blood loss. The mechanism by which aspirin causes gastric hemorrhage is a matter of considerable controversy (4). There is little doubt, however, that at least part of the problem is due to local irritation of gastric mucosa (5).

It was the purpose of our studies to seek prodrug derivatives of salicylic acid which would be nonirritant, would be readily absorbed, and which would be rapidly hydrolyzed in blood and other tissues to release free salicylate in the human blood stream. It was reasoned that carbonate esters of salicylic acid which are readily hydrolyzed by dilute human plasma, but which are less soluble in water and more soluble in lipids than aspirin, might be distributed and absorbed over a broader area of the gastrointestinal tract and might be less irritating to the gastric mucosa than aspirin.

This paper presents the synthesis, solubility, and partitioning properties, and *in vitro* hydrolysis rates of four carbonate ester prodrugs of salicylic acid. It also presents the blood levels of total salicylate following oral administration to dogs of three of the carbonate esters compared with aspirin.

EXPERIMENTAL

Chemical Synthesis—Melting points were determined in capillary tubes on a Thomas-Hoover apparatus and are uncorrected. Reported yields are of pure compound.

The following general procedure for synthesizing the compounds was adapted from the method of preparation of the methylcarbonate reported by Fischer (6). To an ice-cooled mixture of 85 Gm. (0.61 mole) of salicylic acid and 155 ml. (1.22 moles) of dimethylaniline in 500 ml. of dry benzene, the appropriate chloroformate (0.61 mole) was added over a period of 15 min. The ice bath was removed, and the mixture was stirred at room temperature for 2 hr. and washed with six 100-ml. portions of 10% HCl and three 100-ml. portions of water. The benzene solution was dried over anhydrous magnesium sulfate, and the solvent was removed. The remaining material was purified by crystallization from the appropriate solvent system (see Table II) after treatment with activated charcoal.

Particle Size Reduction—The purified compounds were micronized by one or more passes

Received January 9, 1968, from Smith Kline & French Laboratories, Philadelphia, PA 19101

Accepted for publication February 2, 1968.

The authors wish to acknowledge the assistance of the following: Mr. Philip Goldman and Mr. Ralph Matz for preparing the compounds; Mrs. Elisabeth Rattie for assistance with assays, and Miss Margaret Carroll and staff for microanalysis.

* Present address: College of Pharmacy, University of Kentucky, Lexington, KY 40506

† Present address: Riker Laboratories, Northridge, CA 91324

through a fluid energy mill (Trost Jet Mill, Helme Products, Inc., Helmetta, N. J.). This procedure produced particles in the 2–20 μ size range.

Solubilities—The saturation solubilities of the compounds at 37° were determined in 0.1 *N* HCl and spectral grade cyclohexane (Fischer) in rotating bottles utilizing an assembly that has been described previously (7). HCl (0.1 *N*) was used to assure that the compounds were completely unionized and to reduce the degree of hydrolysis of the compounds during equilibration. The aqueous samples were rotated for 6 hr., and the cyclohexane samples were rotated for 16 hr. (overnight). Samples of the clear supernatant saturated solutions were withdrawn into hypodermic syringes through Millipore filters held in Swinney filter adapters (Millipore Filter Corp.). The samples were analyzed spectrophotometrically.

Partition Coefficients—The partition coefficients of the compounds between cyclohexane and 0.1 *N* HCl at 25° were determined using a method and apparatus previously described (8). Since 0.1 *N* HCl was used as the aqueous phase in these experiments, the partition coefficients shown in Table III are "true partition coefficients" of the unionized compounds.

In Vitro Hydrolysis Rates—Half-lives for hydrolysis of the compounds at 37° in 0.1 *M* phosphate buffer with and without enzymes were determined by a spectrophotometric method previously described (9). Frozen human blood plasma (Type O^+) was obtained in approximately 100-ml. quantities from single donors through the Philadelphia Serum Exchange. Purified human pseudocholinesterase was obtained from Sigma Chemical Co., and α-chymotrypsin (salt free from EtOH) was obtained from Nutritional Biochemicals Co.

Blood Levels of Total Salicylate in Dogs—Purebred beagle dogs were used in a 4 × 4 crossover study with aspirin and the butyl- and trichloroethylcarbonates of salicylic acid. Each dog received an equimolar dose of drug per Kg. body weight according to Table I.

The drugs were administered *via* a stomach tube in single doses of finely ground powder suspended in 20 ml. of 0.5% tragacanth. Blood specimens were collected at 0, 15, 30, 60, 120, 240, 360, and 480 min. following drug administration, and total salicylate in the plasma was determined by the method of Cosmides, Stemler, and Miya (10).

Table I—Dosing Schedule

Compound	Mol. Wt.	Dose, mg./Kg.	Dosing Schedule[a] Day 1	4	8	11
Aspirin	180.16	75	A	B	C	D
Trichloroethyl[b]	313.54	130	B	C	D	A
Butyl[b]	238.24	90[c]	C	D	A	B
Hexyl[b]	266.30	111	D	A	B	C

[a] Dog weights: A = 12.8 Kg.; B = 8.6 Kg.; C = 8.1 Kg.; D = 12.0 Kg. [b] Carbonate of salicylic acid. [c] The dose of the butyl carbonate is 10% less than equimolar.

RESULTS AND DISCUSSION

The molecular weight, yields, melting points, elemental analyses, and recrystallization solvents for the four carbonate ester prodrugs of salicylic acid used in this study are shown in Table II. The ethyl derivative has been reported previously (11) but the others are new compounds. All are white

[a] 0.1 *N* HCl was used in these experiments to assure that the compounds were completely unionized in the aqueous phases and to reduce the degree of hydrolysis in the aqueous phase during equilibration. [b] The numbers in parentheses are $t_{1/2}$ buffer (pH 7.4)/$t_{1/2}$ enzyme ratios which represent the degree of enzymatic catalysis.

crystalline, somewhat waxy, solids in their pure forms.

The solubilities of the carbonate esters and aspirin in 0.1 *N* HCl and in cyclohexane at 37° are shown in Table III along with the corresponding cyclohexane–0.1 *N* HCl partition coefficients at 25°. In these studies, 0.1 *N* HCl was used in place of water to assure that the compounds would not hydrolyze appreciably during equilibration and that they were completely unionized in the aqueous phases. Thus, the solubilities shown in Table III are those of the unionized compounds and the partition coefficients are "true partition coefficients."

As expected, the solubilities of the aliphatic carbonate esters decrease in 0.1 *N* HCl and increase in cyclohexane with increasing chain length. The measured partition coefficients show the expected increase with increasing chain length. The trichloroethyl derivative is less soluble in cyclohexane and much less soluble in water than the ethyl derivative. It might have been expected that the cyclohexane solubility of the trichloroethyl derivative would be greater than it is, since trichloroethyl groups tend to be more lipophilic than ordinary ethyl groups, but the trichloroethylcarbonate of salicylic acid has a higher melting point than the other derivatives indicating a stronger crystal lattice which tends to reduce solubility in all solvents.

Predictions of the relative availabilities of the compounds for oral absorption based on the solubilities and partition coefficients shown in Table III must take into account the fact that they probably do not have precisely equivalent pKa values; therefore, at pH's near their pKa's, some of the compounds might show relatively higher or lower apparent partition coefficients than would be expected on the basis of the true partition coefficients shown in Table III. Also, because the compounds are weak acids, the aqueous solubilities will increase with increasing pH. However, the fact that solubilities shown in Table III are of a reasonable order of magnitude suggests that if the drugs are finely ground and properly wetted by water, they should all be readily absorbed following oral administration.

If the solubilities and partition coefficient of aspirin are compared with those of the carbonates, it might be predicted that the ethyl derivative would have gastrointestinal absorption characteristics similar to those of aspirin. In subsequent tests (12) it was found that the ethyl derivative was almost as irritating to the gastric mucosa of rats as aspirin itself. It would seem that salicylate derivatives with relatively high aqueous solubilities and relatively low lipid solubilities are more irritating to the gastric mucosa than those which are less soluble in water and more soluble in lipids.

Table III also shows enzymatic and nonenzymatic hydrolysis data for the four carbonate esters and aspirin. The aliphatic carbonates are more stable toward hydrolysis in buffer than aspirin. The trichloroethylcarbonate is less stable, probably because the chlorine atoms act as good "electron sinks" drawing electrons away from the carbonyl carbon and making it susceptible to nucleophilic attack.

In 2% human plasma in pH 7.4 buffer, the aliphatic carbonates and aspirin are very slowly hydrolyzed. The values for $t_{1/2}$ buffer/$t_{1/2}$ enzyme, shown in parentheses in Table III, represent the degree of enzymatic catalysis and show that the esterases of human plasma have very little catalytic effect on the hydrolysis of these compounds. Even though the hydrolysis of the trichloroethylcarbonate derivative is relatively rapid, the degree of enzymatic catalysis is practically nil. In 0.05% "purified" human pseudocholinesterase and 0.05% α-chymotrypsin (from bovine pancreas) the ethylcarbonate derivative and aspirin are hydrolyzed relatively slowly and the degree of enzymatic catalysis in each case is relatively small. On the other hand, the butyl- and hexylcarbonates are hydrolyzed relatively rapidly by these enzymes and the degree of enzymatic catalysis is considerably larger. These prodrugs, however, are not nearly as susceptible to enzymatic hydrolysis by these enzymes as is 4-acetamidophenyl 2,2,2-trichloroethyl carbonate. For this carbonate ester prodrug of acetaminophen, the $t_{1/2}$ buffer/$t_{1/2}$ enzyme values were 1680 for 0.05% human pseudocholinesterase and 646 for 0.05% α-chymotrypsin (12). Of all the enzymes studied, these two were the most powerful catalysts for the hydrolysis of carbonate esters of acetaminophen, but they are apparently much weaker catalysts for the hydrolysis of carbonate esters of salicylic acid.

Augustinsson and Nachmansohn (13) reported the presence of an aspirin esterase in human blood which is clearly different from the pseudocholinesterase of serum. Morgan and Truitt (14) studied the *in vitro* hydrolysis of aspirin in serum from various species of laboratory animals and humans, and they reported that the aspirin esterase activity of human blood is very weak. The esterases of human blood, having a somewhat greater affinity for carbonate esters, than for aspirin, hasten the hydrolysis of these esters.

The *in vitro* enzyme hydrolysis studies suggested that free salicylate might be released at different rates following oral administration of aspirin and the carbonate prodrugs, but there are many esterolytic enzymes and many sites in the body other than the blood stream where hydrolysis of these compounds might occur. To investigate the release rates and sites of hydrolysis and to study the influence of the physical properties of the carbonate prodrugs on their *in vivo* performance, the prodrugs and aspirin were administered orally to dogs, and the blood levels of salicylate were followed. The analytical method employed (10) converts the carbonate esters and aspirin to free salicylate, therefore, the blood levels were obtained in terms of total salicylate.

The average total salicylate plasma levels in dogs following oral administration of aspirin and the butyl-, hexyl-, and trichloroethylcarbonates of salicylic acid are shown in Fig. 1. The curves in Fig. 1 show that the drugs are nearly identical with respect to the plasma salicylate levels they produce in dogs. All curves reach a peak near 20 mg. % at 2 hr. and then fall off at about the same rate. The minimum and maximum individual blood levels for all drugs overlap at all time points.

These results suggest that the solubility and partitioning properties of these prodrug carbonate esters did not grossly affect their gastrointestinal absorption rates. A possible exception is the hexyl derivative which appears to have a somewhat slower absorption rate than the others. However, the absorption rate of this compound is apparently fast.

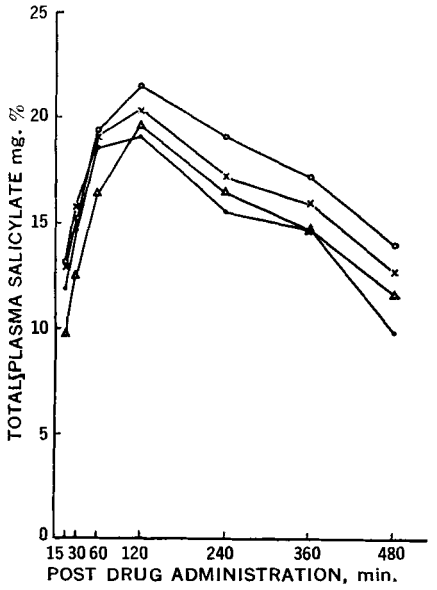

Fig. 1—Plot showing plasma levels of total salicylate in purebred beagle dogs following oral administration of equimolar doses of aspirin (.—., 75 mg./Kg.); trichloroethylcarbonate of salicylic acid (○—○, 130 mg./Kg.); butylcarbonate of salicylic acid (×—×, 90 mg./Kg.); and hexylcarbonate of salicylic acid (Δ—Δ, 111 mg./Kg.). The study was carried out according to a 4×4 crossover plan, and each point represents the average of four plasma levels. The minimum and maximum individual plasma levels overlapped for all drugs at all time points.

enough to catch up with the other carbonates and aspirin at the 2-hr. point. The fact that all the blood levels follow the same pattern and fall off at about the same rate suggests that beyond 2 or 3 hr., aspirin and the carbonate prodrugs of salicylic acid are all in the same form, that is, they have been completely converted to free salicylate. Thus, it would appear that aspirin and the three carbonates are rapidly converted to free salicylate *in vivo*, and it might be expected that the pharmacologic activities of the three carbonates would be very similar to those of aspirin.

Based on these findings, extensive pharmacologic evaluations of the butyl-, hexyl-, and trichloroethylcarbonates were undertaken. Future publications in this series will deal with their analgesic, antipyretic, and anti-inflammatory activities and their gastrointestinal irritation liabilities compared with aspirin.

Dissolution of Salicylic Acid and Polyvinylpyrrolidone from Compressed Mixtures

By MILO GIBALDI and HOWARD WEINTRAUB

The present study was initiated to describe quantitatively the dissolution mechanism of a polyphase mixture of drug and water-soluble polymer. The release pattern of both salicylic acid and polyvinylpyrrolidone (PVP) was described quite well by the theoretical model for the dissolution of two noninteracting phases. The PVP dissolution rates from various mixtures, as determined by a weight-loss method, were in excellent agreement with a model describing dissolution of nonbarrier solid. The dissolution rates of salicylic acid over a wide composition range were essentially invariant but lower than the intrinsic dissolution rate of salicylic acid.

THERE IS considerable pharmaceutic interest in the dissolution of drugs from solid mixtures. The various mathematical theories and physical models presented in the reports of T. Higuchi (1–3) and the more recent efforts of W. I. Higuchi (4, 5) form the basis for much of the current research on diffusion-controlled dissolution phenomena.

A recent report from this laboratory was concerned with the dissolution of drugs dispersed in polyvinylpyrrolidone (6). The observed dissolution phenomenon was not consistent with the anticipated release rate of solute from a hydrophilic matrix (2). Hence, the present study was initiated to describe quantitatively the dissolution mechanism of a polyphase mixture of drug and polyvinylpyrrolidone (PVP).

The release pattern of both salicylic acid and the hydrophilic polymer from compressed mixtures was described quite well by the theoretical model for the dissolution of two noninteracting phases (5). These findings are of particular interest in that: (*a*) there is evidence of significant physical-chemical interaction between salicylic acid and PVP (7), (*b*) the PVP/salicylic acid solubility ratio probably exceeds the limit suggested by Higuchi (4), and one might anticipate that dissolution would adhere to the models developed for solute release from an inert matrix, and (*c*) a previous report by Lapidus and Lordi (8) demonstrated that the release of chlorpheniramine maleate from a compressed hydrophilic methylcellulose matrix follows the theoretical relationships proposed for solid drugs in solid matrices (2) rather than the models proposed for simple polyphase mixtures (5).

EXPERIMENTAL

Determination of Dissolution Rates—Salicylic acid and PVP,[1] each with a particle size <250 μ, were blended thoroughly, in various ratios, in a mortar. The blend was then compressed at 10,000 lb. load for 10 sec. on a laboratory model Carver hydraulic press using a 1.2 cm. (0.5-in.) flat-faced punch and die. Tablet thickness was about 5 mm.

Initial dissolution rates[2] were determined by the rotating disk method (9, 10) using 250 ml. of 0.1 *N* HCl at 37° and 100 r.p.m. One-milliliter samples were withdrawn at various times and diluted with 0.1 *N* HCl. Salicylic acid concentration was determined spectrophotometrically at 303 mμ using a Beckman DB-G recording spectrophotometer. Preliminary studies indicated no need to correct for PVP interference at this wavelength under the experimental conditions.

The initial dissolution rate of PVP was estimated by measuring weight loss of the tablet as a function of time, and correcting the weight loss for the previously observed dissolution rate of salicylic acid. Tablets of the desired composition were prepared as described above and the dissolution rate studies were run in a manner similar to that described for salicylic acid with the following exceptions. At selected time intervals the stirring was stopped, the Plexiglas holder was withdrawn from the dissolution medium, and the holder surface wiped with a tissue. The entire unit was placed in an oven at 45° for 5 min. and then immediately weighed on a Mettler H-15 balance. After weighing, the Plexiglas unit was returned to the dissolution apparatus and the procedure repeated at appropriate intervals.

Preliminary studies indicated that further drying for 1 hr. beyond the 5-min. period resulted in minimal weight loss (about 4 mg./hr.) as compared to the initial weight loss of residual water (about 130 mg./hr.). Moreover, the apparent retention of water after the 5-min. drying period was independent of the total length of time the disk was exposed to the dissolution medium. This additional dehydration essentially reflects the loss of the normal moisture content of the PVP rather than the penetration of dissolution fluids into the matrix. Drying of disks of pure PVP under identical conditions for 1 hr. showed a rate of loss of about 3 mg./hr. Hence, penetration of water into the tablet (beyond a surface phase) does not occur to a significant extent. These

[2] The term "initial dissolution rate" in this context indicates steady-state dissolution under essential sink conditions.

data also indicate that the weight-loss method provides a valid measure of the dissolution of PVP.

Solubility Studies—Salicylic acid solubility was determined in a series of aqueous solutions of PVP in 0.1 *N* HCl. In each case, 200 mg. of salicylic acid was added to 20 ml. of solution contained in 25-ml. culture tubes. The tubes were sealed, placed in a Metabolyte shaker (New Brunswick Scientific Co., N. J.), and equilibrated at 37°. The solutions were sampled periodically by means of a filter pipet, diluted, and assayed for total salicylate to determine equilibrium. Under the conditions of the study, PVP gave no spectral interference.

A limited study was conducted on the behavior of salicylic acid in PVP solution as a function of time according to the method of Bates *et al.* (11). A 2.5-Gm. quantity of salicylic acid was added to 250 ml. of 2% PVP solution in 0.1 *N* HCl at 37°. The system was stirred at 100 r.p.m. by means of a Teflon blade. Samples were withdrawn at various intervals and assayed for total salicylic acid.

RESULTS

The initial dissolution rates of both PVP and salicylic acid followed apparent zero-order kinetics in accord with the experimental conditions of constant dissolution surface area and apparent sink conditions. Representative plots at various compositions are shown in Figs. 1 and 2. The PVP data in Fig. 1 were corrected for an initial time lag to yield a zero intercept in each case.

The use of the weight-loss method manifested a lag of 2 to 3 min. before the occurrence of apparent zero-order kinetics. The initial time lag may reflect a surface hydration phenomenon (a presteady-state condition), and the mild drying employed between sampling was apparently insufficient to dehydrate completely the tablet surface, since the lag is noted initially but not between drying periods.

Figure 3 shows the dissolution rates of PVP and salicylic acid as a function of the composition of the biphasic mixture, as determined from the apparent zero-order dissolution rate plots. At each composition studied the dissolution rate of salicylic acid is essentially constant and somewhat lower than the intrinsic dissolution rate of salicylic acid. The dissolution rate of PVP was found to increase with increasing proportions of PVP in the mixture.

The results of the solubility studies at 37° are presented in Fig. 4. These findings must be considered preliminary in that an exceedingly long period was required for apparent equilibrium. The early sampling period provided results which indicated a decreased apparent solubility of salicylic acid at low PVP concentrations. Apparent solu-

TABLE I—COMPOSITION OF "COMPLEXES" ISOLATED FROM 2% PVP SOLUTION AT 37°

Determination	Molar Ratio (PVP Repeating Unit/Salicylic Acid) Stirrer Solid	Bulk Solid
1	1.81	0.68
2	1.87	0.69

bility increased with time at each PVP level and "equilibrium" appeared to be established after about 2 weeks. The equilibrium solubility plot indicates a continuous increase in apparent solubility of salicylic acid as a function of PVP concentration up to about 8%. Twenty-four hours after incubation, no crystalline salicylic acid was observable in any tube. Each tube contained an amorphous, plastic precipitate.

The concentration of salicylic acid in 2% PVP solution as a function of time is shown in Fig. 5. A maximum occurs at about 40 min. and thereafter the concentration of drug in solution decreases. After 48 hr., stirring was stopped and two distinct amorphous solid phases were observed. No crystalline salicylic acid was noted. One phase was a transparent glass material concentrated about the stirring shaft (in the region of the system where the vortex had existed). The second phase was an opaque amorphous material occurring at the bottom of the flask. A sample of each solid phase was dried to constant weight and the stoichometry determined by chemical assay. The composition of each phase is reported in Table I.

DISCUSSION

The PVP and salicylic acid dissolution rate data were consistent with the models recently presented to describe the dissolution rate behavior of polyphase mixtures (5). The PVP data were in agreement with the simplest of these models which describes the dissolution of nonbarrier solid from a mixture of two noninteracting solid phases.

For a two-phase mixture of components A and B, Higuchi (5) has proposed the following model. Upon exposure to solvent, A and B dissolve initially at rates proportional to their solubilities and diffusion coefficients. If the ratio of amounts in the mixture, *i.e.*, N_A/N_B, exceeds the ratio of the product of diffusion coefficient (D) and solubility (C^0), *i.e.*, $D_AC^0_A/D_BC^0_B$, then after a short time, component B will become depleted from the solid–liquid interface region of the dissolving solid. Consequently, a surface layer of pure component A is formed.

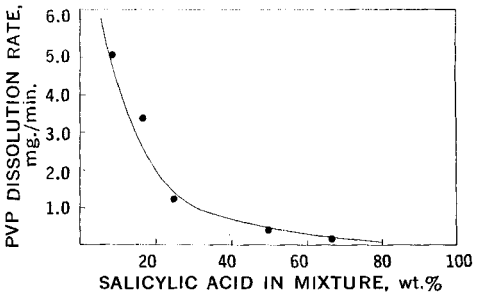

Fig. 6—Comparison of theoretical and experimental dissolution rates of PVP as a function of mixture composition. Key: ——, theoretical; ●, experimental.

Estimates of the magnitude of the ratio of diffusion coefficients and solubilities of PVP and salicylic acid (SA) indicate that $D_{SA}C^0_{SA}/D_{PVP}C^0_{PVP} < 0.1$. Hence, in mixtures with $N_{SA}/N_{PVP} > 0.1$, PVP would be expected to behave in a manner similar to component B described above.

Accordingly, when $N_A/N_B > (D_AC^0_A)/(D_BC^0_B)$, the dissolution rate of component B from the mixture is described by the following equation (6):

$$(DR)_B = \frac{N_B}{N_A}(DR)^0_A \qquad \text{(Eq. 1)}$$

where $(DR)^0_A$ is the intrinsic dissolution rate of component A.

Figure 6 shows a comparison of the theoretic dissolution curve of PVP *versus* mixture composition, as determined from Eq. 1 and the experimental data. Good agreement is observed despite the fact that solubility studies suggest significant interaction of PVP with salicylate. Apparently the formation of complex in the diffusion layer contributes little to the overall dissolution rate of PVP from the nonbarrier phase. The diffusion of the complex will be discussed in greater detail below.

The physical model employed to describe the PVP dissolution rate predicts that the dissolution rates of salicylic acid over the composition range studied should be constant and equal to the intrinsic dissolution rate of salicylic acid, since this component represents the barrier phase. As shown in Fig. 3, the dissolution rates of salicylic acid over a wide composition range is essentially invariant but somewhat lower than the intrinsic dissolution rate of salicylic acid. The regression line fitted to the six data points gave a slope of essentially zero ($\sim 10^{-4}$). The data provide no indication of the contribution of a salicylate–PVP complex to the dissolution process. In fact, the results are somewhat lower than those predicted by the noninteracting model.

Although the dissolution rate studies of various PVP–salicylic acid mixtures provide little evidence for the existence of solution interaction, the solubility data indicate definite interaction of PVP and salicylic acid. The nature of the complex is not clear at present but probably could be represented by PVP–$(SA)_n$ where n is a variable depend-

ent upon the PVP concentration and temperature. The maximum value of n is likely to be in the order of 360. This would be consistent with a complex containing one salicylic acid molecule bound to each vinylpyrrolidone repeating unit. Previous studies (12) of the interaction of phenol with PVP report a value for bound phenol of 0.94 moles $L.^{-1}$/equiv. of PVP $L.^{-1}$ corresponding to a 1:1 complex of phenol with the repeating unit.

Significant existence of a 1:1 complex with the vinylpyrrolidone repeating unit in the salicylic acid system is unlikely except at very low concentrations of PVP (<0.5%). The formation of the 1:1 complex may be limited by the poor solubility and precipitation of less substituted complexes at 37°. The initial increase in apparent solubility noted in Fig. 5 may be due to the formation of soluble complexes of PVP–$(SA)_n$ where n has a relatively low order of magnitude. It is likely that n increases with time and the resulting higher molecular weight complexes precipitate from solution.

The complex isolated from the stirrer shaft probably represents precipitated complex. The bulk complex was found to have a salicylic acid:vinylpyrrolidone repeating unit ratio exceeding unity, which suggests the possible physical inclusion of unbound, undissolved salicylic acid. The apparent absence of undissolved salicylic acid from the stirrer solid may reflect the turbulent conditions in the vortex which would minimize the presence of drug particles. Further studies are in progress to characterize more clearly the PVP–salicylic acid interaction.

Regardless of the nature of the complex which exists in the diffusion layer during dissolution, it would appear likely that the large molecular weight and presumably small diffusion coefficient of the complex precludes a significant contribution of this species to the diffusion process. Since the complex species is expected to contribute little to the dissolution phenomenon, the dissolution of PVP and salicylic acid from the biphasic mixture adheres to a simple model developed for two noninteracting phases rather than the more complex case where the phases demonstrate solution interaction.

The decreased dissolution rate of salicylic acid from the barrier phase of the mixtures, as compared to the intrinsic dissolution rate of salicylic acid may reflect the increased viscosity in the diffusion layer of the dissolving solid due to the presence of high concentrations of PVP. The diffusion coefficient and hence the dissolution rate of the drug is an inverse function of viscosity in the diffusion layer. The presence of PVP in the diffusion layer would, therefore, tend to decrease the dissolution rate of the drug. Alternatively, a film of a high-molecular weight PVP–salicylic acid complex may form at the interface and depress the salicylic acid dissolution rate while minimally affecting the more rapidly dissolving PVP.

Effect of a Nonionic Surface-Active Polymer on Passage of Hydrocortisone Across Rat Intestine *In Vitro*

By WITOLD SASKI

Employing the Crane and Wilson everted sac technique, the passage of hydrocortisone cortisol—in micellar solutions of oxyethylated tertiary octylphenol polymethylene polymer (tyloxapol)—from the mucosal to the serosal side of the rat intestinal membrane was studied. It was determined that the mechanism by which cortisol passes across the membrane is that of diffusion. However, it was found that the relative rate of passage of cortisol dissolved in micellar solutions of tyloxapol is a function of concentration of the solubilizing agent used and is inversely proportional to the concentration of tyloxapol and viscosity of the solution tested.

THE SCIENCE of biopharmaceutics has been well advanced in recent years and excellent reviews on the subject have been published (1–5). However, the part surface-active agents may play in the passage of drugs across biological membranes is far from being understood at the present time. The use of surfactants in the formulation of solubilized systems in pharmacy is rather common, and their effect upon the absorption and biological activity of drugs is of paramount importance.

Originally described by McBain (6), solubilized systems are those in which the solubility of materials otherwise insoluble, or only poorly soluble, in a given medium is increased due to the prior presence of particles of colloidal dimensions, termed micelles. Solubilized systems in pharmacy were reviewed by Swarbrick (7) and Mulley (8). Reports concerning the effects of surface-active agents on drug absorption have been conflicting. As Levy (1) has indicated, enhancement as well as inhibition of the gastrointestinal absorption and the pharmacologic activity of drugs has been observed when amphiphilic compounds were added to a medication. These varied effects may have been due to such factors as the possible interaction with the drug and modification of the physical properties of the dosage form, or possible effects on the absorbing membrane. Recently, the effect of various concentrations of the nonionic surfactant, polysorbate 80,[1] on the absorption of a number of alcohols and barbiturates by goldfish has been studied (9). The absorption rate of the barbiturates was increased significantly in the presence of low concentrations of polysorbate 80, and decreased by higher concentrations of the surfactant. The absorption rate of the alcohols studied was not significantly affected by the surfactant. The retardation of barbiturate absorption at higher polysorbate 80 concentration was interpreted as being indicative of the absence of a dissociating effect of the biologic membrane on the drug–micelle complex. By kinetic analysis, the authors have shown that the modification of barbiturate absorption by polysorbate 80 represents the net effect of enhanced absorption and decreased thermodynamic activity of the drug due to micellar complexation. Kakemi *et al.* (10) reported a decrease of the rectal absorption of sulfonamides by addition of various nonionic surface-active agents, polysorbate 80 included. These workers ascribed the decrease to an entrapment of the drug in micelles. However, contrary to the notion that the only form in which the drug passes the membrane is free drug and not drug in micelle (11), the authors found that the drug in micelle was also absorbed to some extent, and therefore, an overall enhancement of drug absorption was obtained by solubilization. They presented a new model illustrating the proposed mechanism, and developed a formula mathematically expressing the absorption rate of the solubilized drug.

Steroids have been reported to be absorbed by diffusion (12), the more lipoidal the compounds, the greater the absorption rate; the more polar and water-soluble the compound, the less absorption rate. However, there has been no information available as to the effect of amphiphilic, preferably nonionic, compounds on the absorption of steroids. Kavanau (13) suggested that the amphiphilic agents may exert some striking effects by their penetration into the lipid phase of membranes with a consequent alteration of the lipid phase state, the membrane configuration, the rates of transformation of the membranes, and the ability of the membranes to transform between

I

different configurations. The penetration of amphiphiles which loosen the liquid-condensed structure of the "bimolecular" disks probably would tend to lead to an increase in the pore size. In some cases, concluded Kavanau, these amphiphiles would tend to promote a localized, or perhaps even an extensive, transformation of membranes to the open configuration and a decreased stability of the lipid–lipoprotein–protein complex. Such compounds, of course, would tend to increase permeability.

The present author set out to investigate the effects a nonionic solubilizer would have on the absorption of poorly soluble corticosteroids. Cortisol (hydrocortisone) was chosen as a representative of the group and, as a solubilizing agent, an oxyethylated tertiary octylphenol polymethylene polymer,[2] better known under its generic name of tyloxapol (14). Tyloxapol was selected as the agent of choice on the basis of its record as practically nonhemolytic (15) and otherwise innocuous to the biologic membranes. It is used as a solubilizer in a sterile ophthalmic solution[3] of cortisol (2 mg./ml.) and in other pharmaceutical preparations. The structure of tyloxapol is shown in I: where $n \simeq 10$ and $p \simeq 4$, and the average molecular weight ($n = 10$, $p = 4$) is 2,812 (16).

The Crane and Wilson (17) everted sac technique seemed well suited for the investigation. Although this method does not give an estimate of the rate of absorption *in vivo*, it can provide useful information about the kinetics of the absorptive process, in addition to showing whether it is active or passive. Several established criteria (18) for adequate characterization of the mode of passage of substances across the biological membrane have been observed in this study. They were, the concentration-effect curve, the time-effect curve, the capacity of the system to transfer both with and against a concentration gradient, experimental conditions such as kind and quantity of added substances, surface tension, viscosity, pH, ionic strength, and verification of the viability or biological integrity of the membrane under the conditions of the study of transfer.

EXPERIMENTAL

Apparatus—Eberbach water bath shaker, Beckman DB spectrophotometer with Sargent SR recorder, Central Scientific Co. du Nouy 70545 tensiometer, Federal Pacific Electric Co. Wilhelmy plate tensiometer, Ostwald viscometer, Beckman Zeromatic pH meter, Burrell wrist-action model DD shaker, thermostatically controlled incubator, Crane and Wilson apparatus.

Materials and Reagents—Cortisol (Nutritional Biochemicals Corp., dried at 70° for 24 hr.); tyloxapol (obtained from Ruger Chemical Co., Inc.); triphenyltetrazolium Cl (TTC, Nutritional Biochemicals Corp.), freshly prepared 0.5% solution in aldehyde-free dehydrated ethanol; tetramethylammonium hydroxide 10% solution (Eastman Kodak), freshly diluted 1:10 with aldehyde-free dehydrated ethanol; 1,2-dichloroethane, purified; sodium chloride, reagent grade (Fisher Scientific Co.); benzopurpurin 4B, biological stain grade (Matheson Coleman and Bell).

Preparation of Solutions—Predetermined amounts of cortisol were dissolved in the aqueous solutions of tyloxapol at concentrations of this polymer varying from 0 to 10% w/v. Each solution was made isotonic with the body fluids by the addition of sodium chloride. The solutions were freshly prepared for each experiment using the Eberbach water bath shaker at 37°. The solubility of cortisol in aqueous solutions of tyloxapol has been reported previously (19).

Intestinal Absorption Study—Everted sac technique of Crane and Wilson (17) was used and further perfected in a few important details. Female Sprague-Dawley rats weighing about 250 Gm. were fasted for 24 hr. but had access to drinking water at all times. The animal was killed by a blow on the head and the abdomen cut open by a midline incision, care being taken not to damage the small intestine. The intestine was completely cut across in the region of the upper duodenum and at the ileocecal junction. A 20-ml. syringe cannula was then inserted into the upper end of the intestine and the lumen cleared of its contents by allowing oxygenated saline at room temperature to pass through under moderate pressure. The washed out length of intestine was removed from the animal by carefully stripping off the mesentery at the line of its attachment to the intestine. For the eversion of the intestine, a glass rod of an appropriate length and diameter with a slightly flattened end was used. The intestine was then sleeved onto the glass rod and everted. A tie made with thread at the end of the intestine segment helps the process considerably. Upon completion of eversion a loop was made of the distal end of the sac, and an additional tie using catgut was applied beneath the loop. These precautionary measures practically

exclude the possibility of a leakage. Two segments of approximately 13 cm. length each were obtained from the upper intestinal tract of each animal. Proximal ends of the sacs were attached to the cannula of the Crane and Wilson apparatus.

The sacs were filled with 1–2 ml. of oxygenated saline termed "serosal fluid." Each sac was suspended in 45 ml. of cortisol in saline or cortisol in tyloxapol–saline solution ("mucosal fluid") maintained at 37° and aerated continuously with a mixture of 95% oxygen and 5% carbon dioxide. At indicated times, the total serosal fluid was withdrawn by means of a syringe with a polyethylene cannula attached and the sac rinsed once with about 2 ml. of saline. A fresh 1–2-ml. portion of saline was then placed in the sac. Both serosal and mucosal fluids were assayed each time. Retention within the intestinal wall was low.

The object of everting the sac is twofold. Eversion, with slight distension of the sac, stretches the mucosa and improves its oxygenation. The small volume of fluid inside the sac causes passage of any solute from the mucosal to the serosal side producing a relatively large increase in its concentration in the serosal fluid. This facilitates the detection of transport against the concentration gradient (20).

Analytical Methods—The withdrawn serosal fluid and washing were combined in a separator, boric acid–sodium hydroxide buffer, 0.5 ml. per 5 ml. of solution was added (12), and the fluid extracted twice with 20 volumes of ethylene dichloride, using the Burrell wrist-action shaker for 5 min. each time. The extract was evaporated to dryness in a Petri dish in a stream of hot air. The residue was dissolved in aldehyde-free dehydrated ethanol, transferred to a 10-ml. volumetric flask, and brought up to volume with ethanol. This alcoholic solution was transferred to a 15-ml. capped test tube and 1 ml. of tetramethylammonium hydroxide 10% solution, freshly diluted 1:10 with aldehyde-free dehydrated ethanol, was added, followed by 1 ml. of 0.5% triphenyltetrazolium chloride solution in aldehyde-free dehydrated ethanol. The test tube, after gentle inverting to ensure a thorough mixing, was placed in a dark room (incubator set at 25°) for exactly 25 min. A respective blank solution treated in the identical way served as a control. Color, developed by the reduction of triphenyltetrazolium chloride to form the formazan in a solution buffered with tetramethylammonium hydroxide, was read in a Beckman DB spectrophotometer at 485 mμ. Cortisol concentration was calculated by reference to the respective standard Beer's law curve previously prepared. The effect of air, water, and the concentration of tetramethylammonium hydroxide, have been discussed by Johnson *et al.* (21) and their paper should be consulted to ensure the reproducibility of the tetrazolium assay.

Determination of the Critical Micelle Concentration (CMC) for Tyloxapol—Surface tension method employing a du Nouy tensiometer (22) and a Wilhelmy plate tensiometer (23), and a spectral absorption benzopurpurin 4B method (24) using a Beckman DB spectrophotometer were applied.

Determination of the Viscosity—Relative, absolute, and specific viscosities of the solutions of tyloxapol in physiologic saline at 37° were determined by means of an Ostwald viscometer in a constant-temperature water bath. Densities of the solutions were determined using a pycnometer.

RESULTS AND DISCUSSION

In preliminary experiments, it was found that the integrity of the rat intestine was not impaired by immersion of the everted sac in 1.0% tyloxapol oxygenated saline solution for 30–60 min. in a water bath at 37°. The sacs so treated were subsequently used in several experiments with the mucosal solution containing 0.10 and 0.20 mg./ml. solutions of cortisol in saline (no tyloxapol present). The results obtained were nearly identical with those obtained with the sacs which were not so treated. At rather elevated concentrations of tyloxapol, far above the critical micelle concentration (CMC) of the solubilizing agent, it was found that the relative rate of passage of cortisol is a function of concentration of the surface-active polymer and is inversely proportional to its concentration. This fact served as direct evidence that the membrane did not change so as to allow for the enhancement of passage of cortisol across it.

In an initial series of experiments, the concentration of 200 mcg. of cortisol per ml., that is below the limit of its water solubility, was used while the concentrations of tyloxapol were 0, 0.005, 1.0, 3.0, and 5.0% w/v. The rates of passage of cortisol were observed to be consistently a function of concentration of the surfactant and inversely proportional to its concentration.

The concentration of 0.005% w/v of tyloxapol was included to see whether this amount—below the CMC—would be of any consequence. No significant changes in the rate of passage of cortisol were observed at this concentration of the surfactant. It is conceivable that by means of more accurate methods, such as the use of labeled radioactive cortisol molecules, the effect of the minute amounts of the solubilizing agents could be evaluated more precisely.

The CMC of tyloxapol determined by surface tension measurements was found to be about 0.04 Gm./dl. However, employing the benzopurpurin 4B spectral absorption method, the first sharp inflection indicative of the CMC formation was detected at the concentration of 0.01 Gm./dl.

Detailed data are presented for the series of experiments involving cortisol actually solubilized. Concentration of 500 mcg./ml. was used throughout the series, the only variable being the concentration of tyloxapol, *i.e.*, 1.0, 2.0, 5.0, and 10.0% w/v. The pattern of diffusion of cortisol across the rat intestine is clearly demonstrated by the time-effect curve (Fig. 1) as a function of the concentration of tyloxapol. $C_{serosal}/C_{mucosal}$ on the ordinates denotes the concentration ratio of cortisol passed in a given time from the serosal to mucosal fluid. Number of runs with each particular concentration is indicated, and so are standard deviations for each time interval within each group of the runs, in Table I.

To determine the relative rates of passage, expression of the results in terms of Fick's law was used:

$$\frac{d(C_o - C_i)}{dt} = -P(C_o - C_i) \quad \text{(Eq. 1)}$$

where t is time, and P is permeability coefficient

which is a measure of the relative ease with which the drug crosses the membrane. C_0 represents the drug concentration in the outside (mucosal) fluid, and C_i that in the inside (serosal) fluid. When C_o is made for all practical purposes constant by suspending the everted sac with a very small volume of saline in a relatively large volume of mucosal fluid, the equation may be integrated to give:

$$Pt = -\ln\left(1 - \frac{C_i}{C_o R}\right) \qquad \text{(Eq. 2)}$$

where R is the ratio C_i/C_o at the steady state (25). If R is assumed to be 1, on substituting the absorbed concentration ratios in the equation, and plotting the values of the right-hand side of the equation against time, straight lines are obtained (Fig. 2.). The permeability coefficient P (or the relative rate of penetration of cortisol) as a function of concentration of tyloxapol is given by the slope

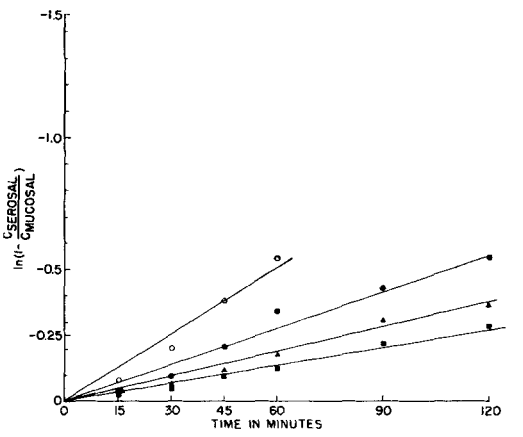

Fig. 2—The relative rates of passage of solubilized cortisol (0.50 mg./ml.) as a function of concentration of tyloxapol. Key: Tyloxapol % w/v—○, 1.0; ●, 2.0; ▲, 5.0; ■, 10.0.

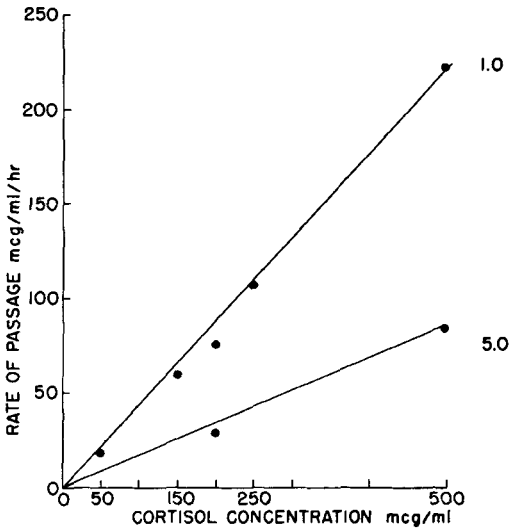

Fig. 3—Effect of concentration of the solubilizing agent on the amount of cortisol passed across the rat intestine in vitro *as a function of the initial concentration solubilized in 1.0 and 5.0 % tyloxapol solution after 1 hr. of incubation.*

of the respective line, $-\ln(1 - C_i/C_oR)/t$. The slopes vary dramatically depending on the concentration of the solubilizer present.

The cortisol concentration effect is illustrated in Fig. 3. It can be seen that the absolute amount of the drug absorbed is directly proportional to its initial concentration, in agreement with the concept of simple diffusion (26). However, it is evident that the amount of the drug absorbed is a function of concentration of the solubilizing agent. The higher concentration of tyloxapol, the lesser amount of cortisol absorbed. It is also evident that the fraction (ratio) of cortisol entering the sac is independent of the concentration of the drug in the outside solution. In other words, the amount passing across the rat intestine is directly proportional to the concentration gradient in accord with the law of simple diffusion. Indeed, it can be seen

from Fig. 3, that the C_i/C_o cortisol ratio in the case of 1.0% tyloxapol is consistently about 0.4 for all five cortisol concentrations, and in the case of 5.0% tyloxapol the ratio is about 0.15.

This series of experiments was carried out in such a way as to minimize variables inherent in using everted sacs from different animals. In one case, the concentrations of cortisol used were 50, 150, 250, and 500 mcg./ml., solubilized in 1.0% solution of tyloxapol, and the determination of cortisol which passed from the mucosal to the serosal side of the sac was consecutively made using the same sac at 1-hr. intervals. Upon repeating the experiment, employing a second segment obtained from the same animal, close results were obtained and averages of the two experiments plotted. A point corresponding to the 200 mcg./ml. concentration plotted on the 1.0% tyloxapol curve was derived from two other experiments involving another rat. Two separate experiments were carried out to obtain the data for the 5.0% tyloxapol curve.

Surface tension of the solutions used throughout the investigation did not seem to play any significant role in the process of cortisol across the rat intestine, differing by a fraction of 1 dyne/cm. in the 1.0–10.0% tyloxapol range (38.7–39.3 dynes/cm. at 21°). The rate of transfer of cortisol from the solutions containing no tyloxapol or just a minute amount of it (below the CMC) was the greatest.

The pH seemed to play no significant part either, although the solutions used were not adjusted to any specific pH. Those containing no tyloxapol were rather close to neutrality (pH 6.5 ± 0.2), while those with tyloxapol had a pH of about 5. The reasons for not adjusting the pH were twofold, cortisol is a nonionizing compound as is tyloxapol, thus, pH-partition theory does not apply. The other reason for not buffering the solutions was a reluctance to introduce ions that might conceivably alter the absorption rates. The ionic strength imparted by sodium chloride used for the sake of tonicity of the solutions was practically uniform throughout the investigation.

The Einstein equation (27) directly relates diffusion to viscosity of the diffusion medium:

$$D = \frac{RT}{N} \cdot \frac{1}{6\pi r\eta} \qquad \text{(Eq. 3)}$$

where D is the diffusion coefficient, N is Avogadro's number, R is the gas constant, T is the absolute temperature, r is the radius of the diffusing molecule, and η is the viscosity.

If it is assumed that except for viscosity all other factors are kept constant, the Eq. 3 may be written:

$$D = K \cdot \frac{1}{\eta} \qquad \text{(Eq. 4)}$$

Absolute, relative, and specific viscosities of 1.0, 2.0, 5.0, and 10.0% w/v of tyloxapol in saline solution at 37° were determined (Table II). When the logarithm of specific viscosity is plotted against tyloxapol concentration, a steep straight line is obtained. It is apparent that the diffusion coefficient of cortisol is inversely proportional to viscosity of the diffusion medium.

According to the views summarized by Levine and Pelican (18), only changes in the biological barrier can influence the rate of absorption of a particular molecular species of a drug transferred by passive diffusion. However, the rate of absorption of a species of a drug molecule which is transferred by facilitated diffusion may be increased or decreased by changes in, or on, the membrane, or by the presence of certain solutes. Consideration of the latter, as the present experiments would indicate, may have important consequences in the therapeutic use of a drug or combination of drugs administered orally. As Stein (28) pointed out, we have no clear idea as to the mechanism of action of facilitated diffusion as yet. At least in part, this is due to our ignorance of the detailed structure of the cell membrane and of the physical chemistry of such a system. In any event, active transport seems to have no place in the system studied since the attempts to detect a movement of solubilized cortisol against the concentration gradient (placing the solutions of the same concentration on both sides of the everted sac) failed.

Physicochemical study of micellar complexation of tyloxapol with cortisol and other steroids, which may throw more light on the mechanism of the passage of these compounds in micellar solutions across the biological membranes, is being carried out in this laboratory.

TABLE II—VISCOSITY OF TYLOXAPOL SOLUTIONS IN SALINE AT 37°

	Absolute, cps.	Relative	Specific
Water	0.6947	...	...
Tyloxapol 1.0% w/v	0.7139	1.0277	0.0277
Tyloxapol 2.0% w/v	0.7754	1.1161	0.1161
Tyloxapol 5.0% w/v	0.8967	1.2910	0.2910
Tyloxapol 10.0% w/v	1.3126	1.8895	0.8895

Effect of Amines and the Particular Role of Position 3

By DONALD B. McCORMICK and WERNER FÖRY

The base-catalyzed hydrolysis of flavins was investigated in 50 percent water–methanol with excess sodium hydroxide or excess amines at different temperatures. Rate constants for the pseudo first-order cleavage of the pyrimidine portion of the isoalloxazine systems were measured and with sodium hydroxide shown to increase from lumiflavin to 3-ethyllumiflavin to 3-carboxyamido(phenylalanyl)lumiflavin. With amines, the size as well as basicity is of prime importance since the general order in efficacy of the nucleophile for hydrolysis of flavins is ethylamine > diethylamine > triethylamine > benzylamine > tributylamine. In general, alkylation of the 3-imino function of the flavin increases its lability because of inability to ionize and undergo resonance stabilization of the anionic tautomers. Moreover, the special case where a 3-carboxyamido function is present allows intramolecular polarization, *via* hydrogen bonding of the amide hydrogen to 4-carbonyl oxygen, which causes a marked increase in hydrolysis rate in sodium hydroxide. From the temperature dependencies of the rates of hydrolysis, the calculated values for energies of activation indicate the decrease expected upon 3-alkylation and further upon intramolecular enhancement with the 3-carboxyamido group. The calculated values for entropies of activation are large and negative in accord with considerable loss of degrees of freedom in the activated complexes formed in the bimolecular mechanism.

FLAVINS CAN undergo hydrolytic decomposition of their isoalloxazine nucleus, particularly in alkaline solution. Kuhn and Rudy (1) isolated urea and 1,2-dihydro-1,6,7-trimethyl-2-keto-3-quinoxaline carboxylic acid from the degradation of lumiflavin in alkaline medium. These results were confirmed by Surrey and Nachod (2) and extended by Svobodova (3) and Wada *et al.* (4) who noted several other unidentified products. Farrer and MacEwan (5) studied the kinetics for hydrolysis of riboflavin over a wide range of pH and showed the reaction to be general acid-base catalyzed. More recently Guttman and coworkers have examined the influence of complexing agents in decreasing the rates for hydrolysis of flavins (6–8) and the intermediates formed following cleavage of the pyrimidine portion of the isoalloxazine system (9–11).

Since most of the earlier studies on the hydrolysis of flavins involved only the use of hydroxyl ion as the attacking species, it seemed desirable to investigate more thoroughly the effects of size and basicity of other nucleophiles such as amines. Also the rate of hydrolysis of a 3-substituted flavin in aqueous sodium hydroxide had been observed to be faster than that of unsubstituted flavin (8), but the primary cause for the difference had not been reported. Furthermore, though such compounds as purines which complex with flavin by planar overlap of their ring systems (12–14) cause a decrease in rate of hydrolysis of flavin (6, 7), certain other types of molecular as-

Base-Catalyzed Hydrolysis of Flavins

Effect of Amines and the Particular Role of Position 3

By DONALD B. McCORMICK and WERNER FÖRY

The base-catalyzed hydrolysis of flavins was investigated in 50 percent water–methanol with excess sodium hydroxide or excess amines at different temperatures. Rate constants for the pseudo first-order cleavage of the pyrimidine portion of the isoalloxazine systems were measured and with sodium hydroxide shown to increase from lumiflavin to 3-ethyllumiflavin to 3-carboxyamido(phenylalanyl)lumiflavin. With amines, the size as well as basicity is of prime importance since the general order in efficacy of the nucleophile for hydrolysis of flavins is ethylamine > diethylamine > triethylamine > benzylamine > tributylamine. In general, alkylation of the 3-imino function of the flavin increases its lability because of inability to ionize and undergo resonance stabilization of the anionic tautomers. Moreover, the special case where a 3-carboxyamido function is present allows intramolecular polarization, *via* hydrogen bonding of the amide hydrogen to 4-carbonyl oxygen, which causes a marked increase in hydrolysis rate in sodium hydroxide. From the temperature dependencies of the rates of hydrolysis, the calculated values for energies of activation indicate the decrease expected upon 3-alkylation and further upon intramolecular enhancement with the 3-carboxyamido group. The calculated values for entropies of activation are large and negative in accord with considerable loss of degrees of freedom in the activated complexes formed in the bimolecular mechanism.

FLAVINS CAN undergo hydrolytic decomposition of their isoalloxazine nucleus, particularly in alkaline solution. Kuhn and Rudy (1) isolated urea and 1,2-dihydro-1,6,7-trimethyl-2-keto-3-quinoxaline carboxylic acid from the degradation of lumiflavin in alkaline medium. These results were confirmed by Surrey and Nachod (2) and extended by Svobodova (3) and Wada *et al.* (4) who noted several other unidentified products. Farrer and MacEwan (5) studied the kinetics for hydrolysis of riboflavin over a wide range of pH and showed the reaction to be general acid-base catalyzed. More recently Guttman and coworkers have examined the influence of complexing agents in decreasing the rates for hydrolysis of flavins (6–8) and the intermediates formed following cleavage of the pyrimidine portion of the isoalloxazine system (9–11).

Since most of the earlier studies on the hydrolysis of flavins involved only the use of hydroxyl ion as the attacking species, it seemed desirable to investigate more thoroughly the effects of size and basicity of other nucleophiles such as amines. Also the rate of hydrolysis of a 3-substituted flavin in aqueous sodium hydroxide had been observed to be faster than that of unsubstituted flavin (8), but the primary cause for the difference had not been reported. sociations could be expected to facilitate the hydrolysis rate.

The purposes of the present investigation were to circumscribe more thoroughly the efficacy of amines in the base-catalyzed hydrolysis of flavins, to ascertain the effect of substitution in position 3 of the flavin nucleus, and to indicate how intramolecular polarization can enhance the rate of hydrolysis.

Lumiflavin and its analogs were chosen as they are much less susceptible to photolytic decomposition (15) and because the absence of a polyhydroxy side chain precludes certain complicating behavior observed with riboflavin (7). A solution of 50% water–methanol was used as solvent to be compatible with solubility of both flavin and the larger aliphatic amines. The rate of loss of the flavin yellow color ar 450 mμ was used as a satisfactory index for cleavage of the pyrimidine portion of the flavins (6). Rate constants were determined for hydrolysis effected by sodium hydroxide as well as by a series of amines, the relative effectiveness of which is shown to be dependent upon size and basicity. Alkylation of position 3 in the flavin increases the rate for hydrolysis as resonance stabilization through tautomerization is lost. A further increase in rate is caused by interaction of amide-linked amino acid ester in this position due to polarization of flavin carbonyl 4 *via* hydrogen bonding with the amide function. The temperature dependency for hydrolysis in aqueous sodium hydroxide was measured for lumiflavin to compare with the energy of activation previously reported (6) and additionally for ethylamine-catalyzed hydrolyses of lumiflavin and its 3-substituted analogs the latter of which have lower values for activation energies. The entropies of activation then were calculated and found to be large and negative and thereby reflect greater loss of translational and rotational freedom in the activated complexes of 3-substituted flavins, especially with a 3-carboxyamido function.

EXPERIMENTAL

Materials—Lumiflavin (7,8,10-trimethylisoalloxazine) was synthesized according to Hemmerich (16). The 3-ethyl and 3-carboxymethyl derivatives were prepared following the general method of Hemmerich (17) by alkylation of lumiflavin in *N,N*-dimethylformamide with potassium carbonate and the appropriate iodide. The 3-carboxymethyllumiflavin was activated with *N,N'*-carbonyldiimidazole after the procedure of Staab *et al.* (18) to yield the flavin imidazolium amide which was then reacted with L-phenylalanine methyl ester according to the method of Anderson and Paul (19) to form the 3-carboxyamido(phenylalanyl)lumiflavin [3-carboxyamido-(L-phenylalanine methyl ester)-7,8,10-trimethylisoalloxazine].

Usual reagents and other chemicals were obtained from commercial sources.

Methods—Flavins were dissolved in methanol and diluted with water plus base such that the final concentrations of reactants in 25 ml. were 5×10^{-5} *M* flavin and base at a specified concentration, usually 0.1 *M*, in 50% (v/v) water–methanol. These aerobic solutions were heated at a specified temperature controlled by a rheostat and heating mantle or a Haake model F constant temperature circulator. Aliquots of 2 ml. were taken at intervals and the concentration of remaining flavin determined by measuring the absorbance at 450 mμ in a Beckman DU spectrophotometer.

Infrared spectra of flavin compounds were run in potassium bromide pellets (1 mg. flavin per 300 mg. KBr) with a Perkin-Elmer Infracord spectrometer set for slow scan.

Calculations—Under the conditions employed (excess base and water) for the pseudo first-order hydrolysis of the pyrimidinoid portion of the flavin ring system, the apparent rate constants, *k*, were determined by multiplying by 2.303 the initial slopes of lines obtained in plots of log A_{450} *versus* min. where

$$\log A_{450} = \left(\frac{k}{2.303}\right) t + \text{constant} \quad \text{(Eq. 1)}$$

The heats of activation, ΔHa, were calculated from the rate constants at different temperatures using the differential expression of the Arrhenius equation integrated between limits

$$\log \frac{k_2}{k_1} = \left(\frac{\Delta Ha}{2.303R}\right) \frac{T_2 - T_1}{T_2 T_1} \quad \text{(Eq. 2)}$$

The entropies of activation, ΔSa, were calculated from a rate constant at a particular temperature and the heat of activation, where from the Eyring equation

$$\Delta Sa = 2.303R \log \frac{kNh}{RT} + \frac{\Delta Ha}{T} \quad \text{(Eq. 3)}$$

RESULTS AND DISCUSSION

Rate constants for the sodium hydroxide-catalyzed hydrolysis of flavins are given in Table I. From the rate constants at 75 and 50° which indicate the thermal dependency for hydrolysis of lumiflavin, the energy (heat) of activation was calculated to be 20.2 Kcal. which is in good agreement with the value of 20.0 reported previously (6). The entropy of activation was calculated to be −16 e.u. (cal. deg.$^{-1}$) which is reasonable for a bimolecular reaction where decrease in entropy is expected in passing to an activated complex with loss of translational and rotational freedom before rupture of the flavin ring system. Alkylation of the 3-imino function of a flavin

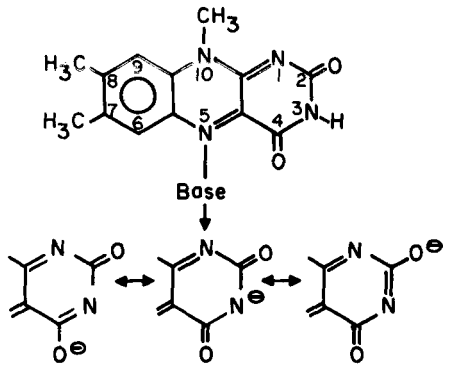
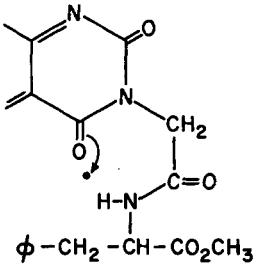
3-Carboxyamido(phenylalanyl)-lumiflavin	5	1.02



Scheme I

leads to a considerable increase in the rate of hydrolysis as can be seen by comparing the rate constants for lumiflavin and its 3-ethyl derivative, both at 50°. Flavins unsubstituted in position 3 can undergo tautomerization between the 3-imino and 2- and 4-carbonyl functions. In the alkaline medium used for hydrolysis, the isoalloxazine system is ionized, as it is well above its pKa near 10 (20). Thus, as shown in Scheme I, lumiflavin exists as resonance-stabilized anionic forms in strongly basic solution and is less susceptible to nucleophilic attack.

Because the acidic proton in position 3 is lacking, ionization cannot occur with 3-alkylated flavins. The pyrimidine portion of their isoalloxazine systems is more electron deficient and hydrolysis resulting from nucleophilic attack occurs more readily. The exceedingly rapid rate for hydrolysis of 3-carboxyamido(phenylalanyl)lumiflavin in aqueous sodium hydroxide even at 5° must reflect an additional cause for lability. Not only is this 3-substituted flavin not able to form resonance-stabilized anions, but also space-filling molecular models indicate the possibility for intramolecular interaction of the flavin carbonyl functions with the amino acid group. As with lumiflavin and 3-ethyllumiflavin, increasing the concentration of sodium hydroxide increases the rate of hydrolysis of the 3-carboxyamido derivative in agreement with the bimolecular mechanism for hydrolysis. Hence, a unimolecular process such as would occur if the amide nitrogen served as the nucleophile can be excluded as a single-step mechanism. However, this does not exclude such a mechanism as hydrolysis of a function followed by an intramolecular attack by the generated nucleophile. As shown by the infrared spectra in Fig. 1, the band for the 4-carbonyl stretch vibration at 1710 cm.$^{-1}$ in lumiflavin and at 1700 cm.$^{-1}$ in 3-ethyllumiflavin is considerably diminished in the 3-carboxyamido derivative, while the amplitude of the 2-carbonyl band remains approximately the same near 1660 cm.$^{-1}$ for all three compounds. These assignments agree well with those reported earlier for lumiflavin and other derivatives (21). Therefore, it appears that the hydrogen of the amide function intramolecularly bonds to the 4-carbonyl oxygen and, as shown in the formula below, thereby polarizes this function in a manner favorable for hydrolysis.



The decomposition of lumiflavin as a function of time in 0.1 *M* bases at 75° is shown by the data in Fig. 2. A "hard" base such as sodium hydroxide is most effective in the base-catalyzed hydrolysis, but facile degradation is also effected with small aliphatic amines. Molecular size of the amine is quite important as ethylamine (pKb = 3.25) is somewhat less basic than diethylamine (pKb = 2.90), but the rate of hydrolysis with the former is somewhat greater. Further decrease in hydrolysis rate is seen with the larger triethylamine (pKb = 3.25) and more yet with tributylamine (pKb = 3.50). Also the latter is more basic than benzylamine (pKb = 4.70), but its greater size leads to a slightly decreased rate. Aniline (pKb = 9.42) is too weak a base and *N,N*-diethylaniline is too large to be effective. Thus the

	Benzyl-	0.99

steric factors which limit the approach of an amine as nucleophile are of major importance even when basicity is favorable. As the hydrolysis proceeds, accumulation of intermediate breakdown products leads to deviation from pseudo first-order kinetics with a curving of lines after 1 or 2 hr.

Rate constants for the initial pseudo first-order amine-catalyzed hydrolysis of flavins are listed in Table II. As with lumiflavin, the relative effectiveness of the amine as nucleophile for hydrolysis of the 3-substituted flavins is markedly dependent upon size. An additional steric restriction imposed by the 3-alkyl group may be manifest, as a greater proportional decrease in hydrolysis rate is seen in going from the triethyl- to tributylamine with 3-ethyllumiflavin than with lumiflavin. Also as with sodium hydroxide, the rates for hydrolysis of 3-ethyllumiflavin with small amines is somewhat greater than found for hydrolysis of lumiflavin. As explained before, lack of the acidic hydrogen on position 3 of 3-alkyl flavins causes greater lability toward hydrolytic degradation. The absolute rates for amine-catalyzed hydrolysis of 3-carboxyamido(phenylalanyl)lumiflavin are lower than those for lumiflavin or its 3-ethyl analog.

The heats and entropies of activation for the hydrolysis of flavins with ethylamine are presented in Table III. Values of ΔHa and ΔSa for lumiflavin with this base are similar in magnitude to the respective values obtained with sodium hydroxide as given above. The energies (heats) of activation required for ethylamine-catalyzed hydrolysis of the 3-alkyl flavins are lower and their entropies of activation more negative than lumiflavin. Especially noteworthy is the very large ΔSa value calculated for 3-carboxyamido(phenylalanyl)lumiflavin. This appears to reflect the large orientation factors expected in this bulky, intramolecularly hydrogen-bonded compound upon forming an activated complex with the amine.

Quantitative Gas Chromatographic Determination of Methapyrilene Fumarate, Ephedrine Hydrochloride, and Codeine Phosphate in Syrup

By HAROLD J. WESSELMAN and WILLIAM L. KOCH

A method for determining methapyrilene fumarate, ephedrine hydrochloride, and codeine phosphate simultaneously by gas chromatography is described. Temperature programming plus the use of an internal standard provide a simple and rapid method for separating and determining the three components in a syrup. Precision and accuracy studies are included.

BROCHMANN-HANSSEN AND Svendsen (1) determined ephedrine by gas chromatography in 1962. At about the same time Fales and Pisano (2) reported the determination of ephedrine as did Parker, Fontan, and Kirk (3). The latter authors (4) also determined codeine as did Massingill and Hodgkins (5) and Mule (6). Later Fontan, Smith, and Kirk (7) and Mac Donald and Pflaum (8) were able to determine methapyrilene. All of these determinations were qualitative in nature.

The quantitative determination of methapyrilene was performed by Celeste and Turczan (9) while the quantitative determination of codeine was done by Schmerzler *et al.* (10).

While the syrup can be assayed using an infrared or a combination spectrophotometric and titrimetric procedure, these methods leave much to be desired as several interdependent correction factors must be applied to the infrared and ultraviolet absorbance values obtained from tediously prepared extracts. In the present method, a simplified extraction procedure is combined with gas chromatography to give a rapid assay.

EXPERIMENTAL

Equipment—A linear programmed-temperature gas chromatograph (F and M Scientific Corp., model 402), equipped with a flame-ionization detector, was used for the experimental work. The detector signal was fed to a Honeywell Electronic 16 1-mv. recorder with a chart speed of 15 in./hr. and a 1-sec. full scale response. Samples were injected with a 10-μl. Hamilton, No. 701, syringe.

Materials—Helium was used as a carrier gas, while electrolytic hydrogen and oxygen were used in the detector. The stationary phase was 3.8% Linde W-98 silicone gum applied by the solution technique of Horning *et al.* (11) to Diatoport S (80–100 mesh) and packed in dual borosilicate glass columns (91 cm. × 6.4 mm.). Chloroform (analytical reagent grade) was used to dissolve the free bases obtained from the commercially available methapyrilene fumarate, ephedrine hydrochloride, and codeine phosphate.

Operating Conditions—The column temperature was programmed from 145–255° at a heating rate of 10° per min. At the end of each programmed run, the column oven was cooled for exactly 10 min. and then equilibrated for exactly 10 min. at 145° before injecting the next sample. These times were selected to keep the assay within practical limits of time and precision. The helium flow rate was 55 ml. per min. with an inlet pressure of 40 psig. Oxygen and hydrogen flow rates were 300 and 35 ml./min., respectively. The sample injection port and the detector block were maintained at 285°. One-microliter injections of all samples were used throughout. The electrometer range was 10 with an attenuation of 256.

Quantitative Analysis—The internal standard technique of Ray (12) was used because of its accuracy. In this method amobarbital is employed as the internal standard.

A 10.0-ml. sample of the syrup is placed into a 125-ml. separator containing 15 ml. water. Then add 1.5 ml. 1:1 sodium hydroxide to make the mixture basic. Extract the mixture with four 25-ml. portions of chloroform and filter the extracts through anhydrous sodium sulfate into a 150-ml. beaker. Using a stream of dry air and a water bath, evaporate the chloroform to a volume of about 3 ml. Transfer quantitatively the extracts to a 10-ml. volumetric flask, add exactly 2.0 ml. of chloroform containing 20.0 mg. amobarbital, and dilute to volume with chloroform. In a like manner prepare a standard solution by extracting 20.0 mg. codeine phosphate, 10.0 mg. ephedrine hydrochloride, and 27.0 mg. methapyrilene fumarate dissolved in 25.0 ml. water.

Chromatograph the standard and the sample solutions and measure the peak heights of each com-

Received October 31, 1967, from the Analytical Development Department, Eli Lilly and Company, Indianapolis, IN 46206

Accepted for publication January 26, 1968.

ponent. Calculate the amounts of each component in the syrup by using the following formulas:

$$\frac{\text{standard amobarbital peak height/standard ephedrine peak height}}{\text{sample amobarbital peak height/sample ephedrine peak height}} \times 1.0 = \text{mg. ephedrine hydrochloride/ml. syrup}$$

$$\frac{\text{standard amobarbital peak height/standard methapyrilene peak height}}{\text{sample amobarbital peak height/sample methapyrilene peak height}} \times 2.7 = \text{mg. methapyrilene fumarate/ml. syrup}$$

$$\frac{\text{standard amobarbital peak height/standard codeine peak height}}{\text{sample amobarbital peak height/sample codeine peak height}} \times 2.0 = \text{mg. codeine phosphate/ml. syrup}$$

PRECISION AND ACCURACY

To determine the precision and accuracy of the method, a freshly prepared solution of the three components in distilled water was used as the standard solution. This solution was chromatographed five times and the peak height ratios for each component were averaged to obtain values which were then used in the calculations for the sample solution. The relative standard deviations for ephedrine, methapyrilene, and codeine are ±3.76, ±2.38, and ±2.02%, respectively. Since the ratios for the standard solution are fairly constant and reproducible, this solution need be chromatographed only two times when routine assays are performed. The sample solution was prepared by dissolving the same three components in a freshly made syrup blank. These studies were carried out in accordance with the suggestions of the Advisory Board of Analytical Chemistry (13) and the recommended nomenclature is used. Table I shows the results of these studies.

The precision of the method was also examined by having another analyst assay a production lot of the syrup. Each of five replicate extractions was chromatographed five times. The relative standard deviation values could probably be improved if a longer equilibration period is allowed before beginning the programmed temperature run. The results of this study are recorded in Table II.

Theory mg./ml.	1.00	2.90	2.00
Lot No.			
A[a]	1.01	2.93	1.98
B[b]	1.05	2.85	2.05
C[b]	1.01	2.82	2.00
D[c]	1.01	2.92	2.00
E[c]	1.01	2.94	2.00

[a] Average of 10 determinations; RSD values similar to those of Table II. [b] Average of 5 determinations. [c] Average of 3 determinations.

The results indicate that while the precision is less than anticipated, it is better than conventional methods which are combinations of spectrophotometric and titrimetric procedures. This method has the important advantage of being specific for each component. Efforts are being made to increase the precision of the method by improving the temperature programming technique.

RESULTS AND DISCUSSION

A typical chromatogram of a mixture of methapyrilene, ephedrine, codeine, and amobarbital is shown in Fig. 1. Table III shows the results of the assay of five production lots of the syrup. The overall time for determining the standard and the sample amounts to approximately 1.5 hr.

CONCLUSION

A simplified method for determining methapyrilene fumarate, ephedrine hydrochloride, and codeine phosphate by means of gas chromatography is presented. The use of temperature programming plus an internal standard result in a good separation

of the three components which have widely spaced boiling points.

Quantitative Determination of Some Single and Multiple Component Drugs by Gas-Liquid Chromatography

By BOBBY R. RADER and EMMA S. ARANDA

A gas-liquid chromatographic procedure has been developed to separate and quantitate various drug mixtures. The samples are extracted by various techniques and determined by the use of a polar (4 percent cyclohexanedimethanol succinate) or a polar–nonpolar (1 percent cyclohexanedimethanol succinate plus 10 percent SE 52 silicone gum rubber) gas-liquid column. Retention data relative to pentobarbital are presented for 50 drug materials. Quantitative data are presented for 25 different drugs found in 19 commercial preparations, and for 7 synthetically prepared drug combinations. Recoveries ranged from 96 to 106 percent.

GAS-LIQUID CHROMATOGRAPHY (GLC) has been used to successfully separate antihistamines (1–5), barbiturates (6–11), and alkaloids (12–14) where several of the same class occur together. Many multiple component drugs, however, are not confined to a single class of ingredient (*e.g.*, barbiturates only) but have a variety of active ingredients. The purpose of this study was to find appropriate column materials for GLC which could be used to separate various classes of drugs in a single dosage form.

Previous reports on drug separation by GLC (2, 5, 11, 12) indicate that columns containing either polar or polar–nonpolar liquid phases give more symmetrical peaks for a larger number of drugs than nonpolar liquid phases. Peak symmetry is desirable for accurate quantitation of drugs. Two such columns were investigated in this study.

Received November 1, 1967, from Food and Drug Administration, Los Angeles District, Department of Health, Education, and Welfare, Los Angeles, CA 90015
Accepted for publication January 3, 1968.

Nineteen commercial drug preparations were analyzed. These drugs were in several dosage forms including tablets, capsules, liquids, and lotions. They contained from one to ten active ingredients each, but a maximum of six ingredients was analyzed in any one sample.

Seven synthetic drug mixtures were also analyzed. These mixtures were prepared, in most cases, with the concentration of active ingredients and excipients (starch, lactose, and magnesium stearate) equivalent to commercial drug preparations.

EXPERIMENTAL

Column Preparation

A mixed column of 1% HI-EFF-8BP (cyclohexanedimethanol succinate) + 10% SE 52 (a methylphenyl silicone gum rubber) on Gas Chrom Q (Column A) and a polar column of 4% HI-EFF-8BP on Gas Chrom Q (Column B) were prepared and conditioned in the following manner.

Column A—Into a 600-ml. beaker, 200 mg. of HI-EFF-8BP (Applied Science Laboratories) and

of the three components which have widely spaced boiling points.

Quantitative Determination of Some Single and Multiple Component Drugs by Gas-Liquid Chromatography

By BOBBY R. RADER and EMMA S. ARANDA

A gas-liquid chromatographic procedure has been developed to separate and quantitate various drug mixtures. The samples are extracted by various techniques and determined by the use of a polar (4 percent cyclohexanedimethanol succinate) or a polar–nonpolar (1 percent cyclohexanedimethanol succinate plus 10 percent SE 52 silicone gum rubber) gas-liquid column. Retention data relative to pentobarbital are presented for 50 drug materials. Quantitative data are presented for 25 different drugs found in 19 commercial preparations, and for 7 synthetically prepared drug combinations. Recoveries ranged from 96 to 106 percent.

GAS-LIQUID CHROMATOGRAPHY (GLC) has been used to successfully separate antihistamines (1–5), barbiturates (6–11), and alkaloids (12–14) where several of the same class occur together. Many multiple component drugs, however, are not confined to a single class of ingredient (*e.g.*, barbiturates only) but have a variety of active ingredients. The purpose of this study was to find appropriate column materials for GLC which could be used to separate various classes of drugs in a single dosage form.

Previous reports on drug separation by GLC (2, 5, 11, 12) indicate that columns containing either polar or polar–nonpolar liquid phases give more symmetrical peaks for a larger number of drugs than nonpolar liquid phases. Peak symmetry is desirable for accurate quantitation of drugs. Two such columns were investigated in this study.

Received November 1, 1967, from Food and Drug Administration, Los Angeles District, Department of Health, Education, and Welfare, Los Angeles, CA 90015
Accepted for publication January 3, 1968.

Nineteen commercial drug preparations were analyzed. These drugs were in several dosage forms including tablets, capsules, liquids, and lotions. They contained from one to ten active ingredients each, but a maximum of six ingredients was analyzed in any one sample.

Seven synthetic drug mixtures were also analyzed. These mixtures were prepared, in most cases, with the concentration of active ingredients and excipients (starch, lactose, and magnesium stearate) equivalent to commercial drug preparations.

EXPERIMENTAL

Column Preparation

A mixed column of 1% HI-EFF-8BP (cyclohexanedimethanol succinate) + 10% SE 52 (a methylphenyl silicone gum rubber) on Gas Chrom Q (Column A) and a polar column of 4% HI-EFF-8BP on Gas Chrom Q (Column B) were prepared and conditioned in the following manner.

Column A—Into a 600-ml. beaker, 200 mg. of HI-EFF-8BP (Applied Science Laboratories) and

2.0 Gm. of SE 52 (Analabs, Inc.) were weighed, then dissolved in 350 ml. of benzene–toluene (1 + 2) by heating on the steam bath with mixing. To this solution, 20 Gm. of 80–100 mesh Gas Chrom Q (Applied Science Laboratories) was added.

Column B—Into a 600-ml. beaker, 800 mg. of HI-EFF-8BP was weighed, then dissolved in 350 ml. of benzene by heating on the steam bath with mixing. To the solution, 20 Gm. of 80–100 mesh Gas Chrom Q was added.

The solvent in each case was removed by evaporation on a steam bath with frequent stirring. The packing material was slowly added to a 1.8 m. × 63 mm. (6 ft. × 1/4 in. i.d.) glass coiled column, using vacuum and tapping. The columns were conditioned overnight at 250° with a flow rate of nitrogen of about 50 ml./min.

Apparatus

A Packard model 7621S gas chromatograph equipped with a hydrogen flame ionization detector and a 1-mv. recorder was used with the following conditions: Column temperature, 200–250°; inlet temperature, 280°; detector temperature, 250°; voltage, 250; carrier gas, nitrogen at 100 ml./min.; sensitivity, 1×10^{-7} to 1×10^{-10} amp. full scale.

Because of the concentration range of the components in some of the drugs, the concentrations in the sample solutions to be analyzed ranged from 0.2 to 3 mg./ml. Column temperatures and instrument sensitivity were varied to obtain adequate separation and response for quantitation.

Preparation of Standard Solution

A weighed amount of the drug to be determined was diluted with chloroform or methanol to approximate the same concentration as that in the sample solution (0.2–3 mg./ml.).

Barbiturates as sodium salts used as standards were extracted in the same manner as the sample.

Sample Preparations

For tablets, 20 tablets were weighed and powdered; then a portion was weighed for assay. For liquids, an aliquot was pipeted. For lotions, the density was determined and a sample was weighed for analysis.

Extraction Procedures

In the first stage of sample analysis, the active ingredients were extracted from the inert materials by one of three techniques: direct solution in an appropriate solvent, liquid-liquid extraction using a separator, or liquid-liquid partition column chromatography. The purpose of these procedures was not necessarily to separate one component from another but to isolate the active ingredients for subsequent chromatographic separation.

The following extraction procedures were used. (The ether and chloroform used in Procedures 3 and 4 were water-saturated just before use.)

Procedure 1—A sample aliquot was diluted to a suitable volume with chloroform or methanol and mixed.

Procedure 2—The solvent was added by pipet to an accurately weighed portion of the powdered sample. The sample was placed in an ultrasonic bath for 10 min. to aid solution, then mixed, and filtered.

Procedure 3—The sample was mixed with 3–4 ml. of 1 *N* NaOH and 4–5 Gm. of acid-washed diatomaceous earth[1] and transferred to a chromatographic column. The beaker and funnel were rinsed with 1 Gm. of acid-washed diatomaceous earth, which was also added to the column. The column was topped with a piece of glass wool, then eluted with one or two of the following: (*a*) 200–300 ml. of ether; (*b*) 200–300 ml. of chloroform; (*c*) 10 ml. of 10% acetic acid in chloroform, followed by 100 ml. of 1% acetic acid in chloroform; (*d*) 100 ml. of 1% triethylamine in chloroform; (*e*) 5 ml. of 20% triethylamine in chloroform, followed by 100 ml. of 1% triethylamine in chloroform.

Procedure 4—The sample was treated as in Procedure 3, except that water was used instead of 1 *N* NaOH.

Procedure 5—The sample was transferred to a separator, diluted to approximately 20 ml. with distilled water, and made either (*a*) basic with 1 *N* NaOH, or (*b*) acid with HCl and extracted 6–8 times with 25-ml. portions of chloroform.

All extracted sample solutions in Procedures 3, 4, and 5 were evaporated nearly to dryness, then dissolved in an appropriate solvent and transferred to a volumetric flask.

When multiple components in a drug were determined, the drug with the lowest concentration was determined first; then appropriate dilutions were made for assay of the other drugs present in greater concentrations.

The actual extraction method used for a given sample can be determined from Table I. For example, the extraction for a drug mixture (No. 7) of orphenadrine citrate, caffeine, and phenacetin (with aspirin) is listed in the table as *3 bd*. This sample was extracted on the NaOH–diatomaceous earth column, and eluted with solution *b* (chloroform), followed by solution *d* (1% triethylamine in chloroform).

Injection Technique

From 1–3 μl. of solvent was drawn into a 10-μl. syringe, followed by 1–3 μl. of air and then by 5 μl. of the sample solution. The plunger was drawn back, and the volume of sample solution was read and injected.

This technique allows the entire sample in the syringe to be injected, and eliminates the need for an internal standard (15).

Quantitation of Peaks

A number of methods can be used to quantitate chromatographic peaks (16). In this study, calculations were based on peak heights for drugs with retention times of less than 5 min., because it was difficult to accurately measure the width of sharp, narrow peaks. For peaks with retention times greater than 5 min., quantitation was based on peak area obtained by triangulation.

To obtain accurate results, an amount of standard was injected to produce a peak area within ±20% of sample peak area. Peak heights were between 20 and 90% of full-scale deflection.

DISCUSSION

The experimental conditions used were selected to allow the analysis of a variety of multiple component

[a] Authentic samples only were analyzed.

drugs. Hence, the specified conditions may not be the optimum conditions for the analysis of a single drug material.

Different extraction procedures were necessary because of the variety of dosage forms and interferences from tablet excipients. A simple extraction with

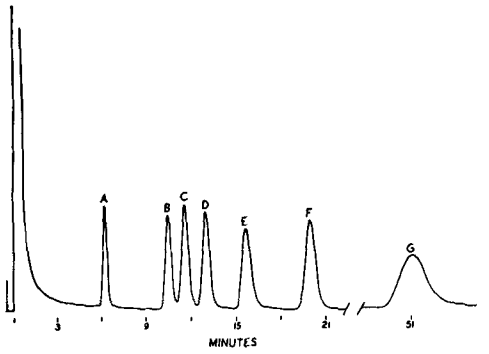

Fig. 1—Separation of barbiturates using a 1.8-m. (6-ft.) 1% HI-EFF-8BP + 10% SE 52 column on Gas Chrom Q 80–100 mesh at 220°. Key: A, *barbituric acid;* B, *butabarbital;* C, *amobarbital;* D, *pentobarbital;* E, *secobarbital;* F, *mephobarbital; and* G, *phenobarbital.*

chloroform or methanol is preferable when interferences are not encountered.

The 1% HI-EFF-8BP + 10% SE 52 column (Column A) is preferred for analysis since it gives sharper chromatographic peaks and can separate a greater variety of drugs. Figures 1, 2, and 3 show the separation of analgesics, barbiturates, and antihistamines. Figure 4 shows the separation of mixed classes of drugs by this polar–nonpolar type of column.

Retention times on the 4% HI-EFF-8BP column (Column B) in some cases are considerably different from those by the mixed column; thus, some drugs which are not separated by one can often be assayed and identified by the other. Figure 5 shows the separation of drugs by this column.

Relative retention times for 50 drugs were obtained and are listed in Table II. Some of these drugs were not determined quantitatively; they did, however, give good response and symmetrical peaks by one or both columns, indicating that quantitation would be possible.

No study was made of the stability of the drugs on the gas chromatographic columns used. This proce-

dure is not recommended for the isolation of a pure drug prior to additional analysis (such as infrared or mass spectrophotometry).

CONCLUSION

The quantitative and qualitative determination of 25 different drugs in 19 commercial preparations and seven synthetic samples was accomplished by a fast, reasonably accurate method. The quantitative results of these analyses are shown in Table I. Recoveries from the synthetic samples ranged from 96 to 106%, with most recoveries between 98 and 103%. Analysis of commercial preparations containing one active ingredient by ultraviolet spectrophotometric methods showed good agreement with GLC results.

Automated Analysis of Tertiary Amines

By NORBERT R. KUZEL

An automated method for the analysis of tertiary amines has been developed using a basic automatic analyzer arrangement. The method is based on a modification of the familiar dye complex extraction method for amines. The method is simple and is not subject to adsorption of the dye on components of the analytical train. A new technique for automated extraction is also described as part of the method. The specificity of the method can be highly controlled by suggested changes in the dye reagent formulation enabling certain amines to be analyzed in the presence of other amines. The method has been designed for the analysis of solid samples.

A LARGE NUMBER of commercially useful compounds are tertiary amines. These compounds traditionally involve difficult and exacting assay procedures. A simple, general automated method for these compounds would be very desirable. It would be of even greater value if a controllable degree of specificity could be incorporated into the automated method since many of these compounds are produced or formulated as mixtures with other amines. The work described in this paper in large measure achieves these objectives.

The majority of published analytical methods for tertiary amines (1–13) are based on some modification of a dye complex formation with a halogenated acid dye as first observed by LaMer and Downes (14) and later supplemented by Griffiths (15). Prudhomme (11) was the first to utilize this principle as the basis of his method for the determination of quinine with eosin. Lehman and Aitken (8) used bromothymol blue to form their amine complex which was extracted into benzene and then reextracted into aqueous alkali. Brodie and Udenfriend (2) used methyl orange, and Cronheim and Ware (3) were the first to use bromocresol purple.

EXPERIMENTAL

Apparatus—The analytical system consisted of the following modules[1]: (*a*) automatic solid sampler; (*b*) proportioning pump; (*c*) photoelectric colorimeter (15-mm., tubular flow cell); (*d*) linearized recorder.

Preliminary Investigations—Since bromothymol blue is most often used in dye complex methods for tertiary amines, it was investigated for its suitability in an automated system. A basic automatic analyzer[2] with the previously mentioned modules was set up for evaluation. The analytical train was equipped with a Technicon glass-bead extractor and Acidflex tubing for all tubes exposed to chloroform. Bromothymol blue reagent was used at a pH of 7.8 and the reagent was extracted in the glass-bead extractor with chloroform. The reagent was decolorized in the system followed by a heavy build-up of yellow dye in the glass-bead extractor. The concentration of dye was increased until some blue color remained, but very high and variable blanks were observed. Other extraction solvents such as methylene chloride, ethylene dichloride, carbon tetrachloride, chlorobenzene, and mixtures of these with methanol, ethanol, propanol, butanol, acetonitrile, dioxane, and tetrahydrofuran were evaluated with very little improvement in performance. Coating the extractor with silicone offered only slight improvement. Mixtures of chloroform with ethanol showed the best response, but results continued to be variable and a pronounced base line drift still occurred.

Methyl orange at a pH of 5.0 and 8.0 was substituted for bromothymol blue with very little improvement. During these studies it was observed that as the dye solutions were made more acidic, dye retention decreased. Several halogenated sulfonphthalein dyes such as bromocresol green, bromophenol blue, bromochlorophenol blue, chlorophenol red, cresol red, iodophenol blue, metacresol purple, phenol red, and thymol blue were evaluated for their performance in acid solutions, and bromocresol purple was selected as the dye of choice. It was shown to have a high sensitivity to certain tertiary amines even in highly acid solutions and, because of its sensitivity, reextraction into alkali was considered unnecessary for most applications. Bromocresol purple also showed very little retention in the analytical train and the base line was only slightly elevated over that observed without reagent.

Reagents—(*a*) Bromocresol purple[3]; (*b*) dye solution—200 mg. of bromocresol purple dissolved in 1,000 ml. of 2% v/v glacial acetic acid; (*c*) Dow Antifoam B added to the wash solution pumped into the automatic sampler.[4]

Procedure—Fig. 1 shows a flow diagram of the

analytical train including all tubing sizes. The automatic sampler was programmed to operate at 20 samples per hr. A 0.5 ml./min. sample is pumped from the automatic sampler and segmented with air. The sample stream is mixed with reagent and about 15% of the mixed stream is resampled and pumped back through the pump. Chloroform is pumped through Acidflex tubing into a PCI pulse chamber. The two phases are joined in a Teflon coil extractor and the aqueous dye complex is extracted with the chloroform. The phases are separated in a BO phase separator, and a portion of the chloroform extract is drawn through the flow cell by pumping from the cell. The extract is measured in the colorimeter equipped with 420-mμ filters and the absorbance recorded on a linearized recorder. A 10-roller chain is used on the proportioning pump to provide smooth flow of the pumped solutions. A small glass wool filter is placed in the chloroform line as it emerges from the pump to filter out shreds of Acidflex tubing that are produced in the proportioning pump. The system is started by pumping ethanol through the Acidflex tubing before any aqueous solutions are pumped. The ethanol is replaced by chloroform and after all the ethanol has been purged, the aqueous solutions are started. This technique has provided excellent base line stability and has prevented contamination of the flow cell with aqueous solutions. Dow Antifoam B is used in the wash solution to provide uniform air segmentation.

RESULTS AND DISCUSSION

The method was evaluated primarily for its application to the analysis of propoxyphene hydrochloride (16) (dextro)-4-dimethylamine-1,2-di-phenyl-3-methyl-2-propionoxybutane hydrochloride.

The response follows Beer's law over an absorbance range of 0–0.9 and relative standard deviations of an average of five observations are typically 0.5–1.2%. Figure 2 shows typical recordings of the response of the system to five replicate standards of propoxyphene hydrochloride. Inspection of the curve shows a stable base line, good reproducibility, symmetrical peaks, and no sample interaction. Comparative results between the automatic method and a manual nonaqueous titration method are shown in Table I. The results by the automatic method represent an average of

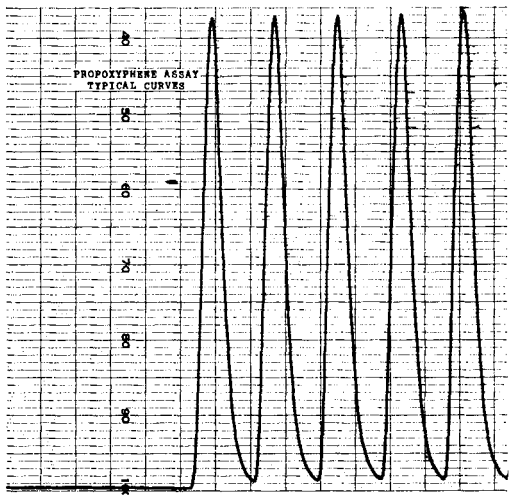

Fig. 2—Response of replicate standards of propoxyphene hydrochloride.

Table I—Comparative Data on Propoxyphene Hydrochloride Samples Between Manual and Automated Methods

Lot	Manual mg./dose	Automated mg./dose	
1	66.2	66.3	(20)
2	65.0	64.4	(20)
3	65.0	64.9	(20)
4	33.6	32.6	(10)
5	32.8	32.8	(10)
6	33.2	32.9	(10)

the indicated number of single-dose assays, while the manual method represents the result obtained on a composite sample of 10 doses. Considering that the same doses were not assayed by both methods, the correlation is very good. This data was obtained on multicomponent mixtures in both capsule and tablet formulations.

The method is shown using an automatic sampler since the majority of the tertiary amines analyzed in our laboratory are assayed as solid samples, primarily as multicomponent tablets or capsules. Tablets are placed directly in the cups of the automatic sampler and capsules are emptied into the cups and the empty capsules are discarded. Standard solutions of the amine are normally dissolved in the appropriate solvent and aliquots of these solutions are pipeted into the sample cups. A correction is made in the absorbance of the standard to account for the volume change resulting from the use of liquid standards. Sample size differences are accommodated by changing the amount of solvent delivered by the automatic sampler or by changing to an alternate size pump tube. Alternate pump tubes are placed in the proportionating pump manifold and tube connections are changed without opening the pump platen.

The concentration of the dye required in the reagent was determined by adjusting the concentration until linearity was obtained throughout the desired concentration range. An additional 50% excess of dye was used since large increases in dye concentration increase the reagent blank slightly. The acidity was adjusted for highest sensitivity to

propoxyphene hydrochloride. The acid concentration can be varied from 1.5 to 3% glacial acetic acid without significant change in response. Eastman bromocresol purple provides a much higher response to the amines tested than some of the other brands, but the reason for this difference in response was not investigated.

The automatic sampler was evaluated for its performance characteristics by analysis of potassium permanganate tablets. These tablets were selected since they provide a relatively stable, highly colored sample which can be traced throughout the system and their tablet weight is essentially equivalent to their content of potassium permanganate. Use of these tablets vividly emphasizes any localized problems in sampling, mixing, sample interaction, and wash characteristics. Hydroxylamine hydrochloride is run through the system occasionally to clean out any traces of manganese dioxide formed in the analytical train. This technique pointed up two serious problems in the use of the automatic sampler. Sample interaction was significant and solvent delivery was erratic. The source of the eratic solvent delivery was found to be due to faulty check valves in the sampler, thus allowing variable amounts of air to be delivered along with the solvent. This problem was solved by replacing the valves with check valves[5] which provide a very positive action and result in precise dispensing of solvent in the sampler. The conventional system of withdrawing a sample from the automatic sampler resulted in too large a sample interaction for precise work and a new sampling device was designed. This consisted of a small rectangular Lucite block with a 0.89-mm. (0.35-in.) hole drilled through its long axis and 2 side ports. The device was placed in the sample line adjacent to the blender compartment of the sampler. The side port nearest the sampler was connected to the wash pump tube. This tube is selected to provide at least twice as much wash volume as is withdrawn by the sample pump tube. During sampling the wash tube is bypassed and has no effect on the system. During the rinse part of the cycle the wash solution divides so that a portion flows into the sample pump tube and the remainder flows into the blender compartment of the sampler, effectively blocking off any leakage of sample from the blender. The other side port is connected to the air pump tube and all air segmentation occurs at this point during both sample and rinse cycles. With this arrangement a uniformly segmented stream, originating near the blender, is always pumped. Positive and precise sampling is obtained with no evidence of sample interaction.

The glass-bead extractor was found to provide inconsistent and erratic extraction in the described system. Base line drift was encountered and significant sample interaction was observed. Several other extractor designs were evaluated with only moderate improvement in results. One of the critical factors in automatic extractions is the method of introduction of the two phases. If one phase is allowed to lag or lead the other or if one phase is allowed to pool in the extractor, erratic results are obtained. An excellent, yet simple extractor was designed to eliminate these problems. It consisted of a coil of 0.96-mm. (0.38-in.) i.d. Teflon spaghetti tubing wound around a 2.54-cm. (1-in.) diameter cylinder. One end of the Teflon coil is simply connected to the pulse chamber containing chloroform by a short length of Acidflex tubing. A piece of 0.8-mm. (0.030-in.) o.d. stainless steel tubing is inserted into the side of the Acidflex tubing so that one end of the stainless steel tube enters the end of the Teflon coil extractor in a coaxial arrangement. The other end of the extractor coil is connected to a small volume phase separator by another short piece of Acidflex tubing. The aqueous phase is introduced through the stainless steel tube and is swept into the extraction coil by the chloroform. Because of the small diameter of the Teflon extraction tubing and the high velocities of flow, the aqueous phase is separated into small discrete segments and remains segmented throughout the entire extraction coil resulting in excellent sample separation. The aqueous stream is debubbled prior to introduction into the extractor and the aqueous phase in effect replaces the air bubble for segmentation. Since this extractor is free of violent agitation, essentially no emulsion formation has been observed. This allows the use of small volume phase separators, and clean phase separations are obtained as a result of the uniform floating off of the very small segments of the lighter phase as it exits from the extraction coil. Because of the segmentation, the length of the extraction coil can be adjusted for optimum extraction efficiency without affecting sample interaction.

SPECIFICITY

A limited investigation was made into the specificity of the method as described. About 100 amines and related compounds were evaluated for their response in the system. Some of the results are shown in Table II. As can be seen, the method in

general responds to aromatic tertiary amines while showing very little or no response to primary and secondary amines or to amides. This response is quite different from that reported by Woods *et al.* (13) in their work with bromocresol purple which did not depend on extraction of the dye complex from acid solutions. The lack of response to quaternary ammonium salts was probably due to adsorption in the analytical train since a positive response was seen in a manual extraction procedure. Special techniques for prevention of adsorption in the analytical train might allow the method to be used for analysis of certain quaternary amines.

Some of the compounds which did show response were further evaluated for their response to changes in dye reagent formulation. Reagents were made up at a pH of 5.0 with citrate-phosphate buffer, pH 2.2 with 2% glacial acetic acid, and pH 1.2 with 1% sulfuric acid. Table III shows some of the results. The results are expressed as molar extinction values calculated from sample size, dilution in the automated system, and the absorbance obtained. Molar extinction values reported here are about 30% lower than those obtained by manual extraction and measurement in a suitable spectrophotometer. A very interesting spectrum of response was observed and considerable change in specificity was observed with changes in reagent.

ANALYTICAL POTENTIAL

The described method should prove very useful in the precise analysis of large numbers of tertiary amine samples such as might be encountered in single-dose analysis profiles of production lots of pharmaceutical formulations. Appropriate process samples, both solid and liquid, could also be analyzed in large numbers. Modifications of the dye reagent such as those indicated might allow analysis of the desired amine in the presence of other amines while still retaining satisfactory sensitivity. The described specificity could also be effectively utilized in manual adaptations of this method. The new extractor design provides the possibility of repetitive extractions or scrubbing with immiscible solvents without significant loss of sample separation or increase of sample interaction. Decreased emulsion problems could lead to an increased sensitivity in repetitive extraction procedures since this would allow a larger volume of the desired phase to be retained for the next step of analysis. All of these advantages could be utilized in the application of this method to analysis of natural products, feeds, or fermentation samples.

Urinary Excretion of Chlorpheniramine and Its *N*-Demethylated Metabolites in Man

By PETER KABASAKALIAN, MARILYN TAGGART, and EDWARD TOWNLEY

The *N*-demethylated metabolites of chlorpheniramine, *N*-desmonomethylchlorpheniramine, and *N*-desdimethylchlorpheniramine were found in the urine of males using a repetitive dosage schedule.

CAVALLITO, CHAFETZ, AND MILLER (1) studied the urinary excretion of chlorpheniramine[1] on four humans who orally took 10.2-mg. chlorpheniramine maleate in gelatin capsules. The total 24-hr. urinary excretions fluctuated from 12 to 57% of the ingested dose among the four subjects. Their analytical method, however, was nonspecific, and their high results were above the upper limits found by Beckett and Wilkinson (2).

Beckett and Wilkinson (2) studied the influence of urine pH and flow rate on the renal excretion of chlorpheniramine. They found that renal excretion rates vary with both urinary pH and the rate of urine flow. When an aqueous solution of 14.2 mg. of chlorpheniramine maleate was orally administered to male subjects, the excretion rates fluctuated from 4.5 to 11.5% in 24 hr. When the urine was maintained acid (pH 5.0 ± 0.5) by the administration of ammonium chloride, 20.0 to 26.5% was excreted, whereas when the urine was maintained alkaline (pH 8.0 ± 0.5) by the administration of sodium bicarbonate, 0.3 to 0.4% was excreted. They also found that under constant acid urine conditions a high urine flow rate increased the excretion rate. The volume-dependent fluctuations became negligible when (by water loading the subjects) the urine rate was maintained above 150 ml./hr.

Since the data of Beckett and Wilkinson (2) suggested that chlorpheniramine is extensively metabolized, its probable *N*-demethylated metabolites were sought in this work. The multiple-dosage regimen appeared to be ideally suited to the problem of locating these metabolites. All one had to do was to find urinary excretion products which increased, leveled off, and declined with the dosage regimen.

EXPERIMENTAL[2]

Protocol—A male subject under a normal diet with no urine pH or fluid intake control was used in this study.

Single-Dose Regimen—The subject orally took a single dose of 12 mg. of chlorpheniramine maleate in tablet form (three 4-mg. chlorpheniramine maleate tablets). Urine was collected normally for 5.5 days and combined into 12-hr. samples.

Multiple-Dose Regimen—The same subject orally took 4 mg. of chlorpheniramine maleate in tablet form daily for 29 days. Urine was collected normally for 39 days and combined into 12-hr. samples.

Analytical Methods—The urine was analyzed by the general method of Beckett and Wilkinson (2) which involved extraction with ether at pH 10, concentration, and subsequent gas chromatography on a 5% potassium hydroxide coated Anakrom ABS column[3] containing 3% polyethylene glycol 20M[4] as liquid phase and operating at 180°C. A 76.2-cm. (2.5-ft.) column exhibited 1,500 theoretical plates for chlorpheniramine.

Free chlorpheniramine had a retention time of 6.0 min. Quantitative determinations were made using a chlorpheniramine reference standard. Isolation by thin-layer chromatography on alumina (3) and subsequent mass spectroscopy (4) showed an *m/e* value of 58 for $CH_2{=}N(CH_3)_2$ indicative of a tertiary amine and *m/e* values of 203, 202, and 167 which are characteristic of the *p*-chlorobenzyl-2-pyridyl group. It did not form derivatives either with cyclopentanone or acetone using the procedure of Capella and Horning (5) or with acetic anhydride (6).

Metabolite X had a retention time of 10.8 min., identical to that of an authentic sample of *N*-desmonomethylchlorpheniramine. Quantitative determinations were made using the authentic sample as a calibration standard. Isolation by thin-layer chromatography on alumina (3) and mass spectroscopy (4) showed *X* to be a secondary amine with an *m/e* value of 44 for $CH_2{=}NH(CH_3)$ and the *m/e* values of 203, 202, and 167 of the *p*-chlorobenzyl-2-pyridyl group. It formed a derivative (retention time >30 min.) with cyclopentanone (indicative of primary and secondary amines), but none with acetone (indicative of the absence of a primary amine) using the procedure of Capella and Horning (5). It formed a derivative with acetic anhydride (6) (retention time >30 min.).

Metabolite Y had a retention time of 14.8 min., identical to that of an authentic sample of *N*-desdimethylchlorpheniramine. Quantitative determinations were made using an authentic sample as a calibration standard. Isolation by thin-layer chromatography on alumina (3) and subsequent mass spectroscopy (4) showed *Y* to be a primary amine with an *m/e* value of 30 for $CH_2{=}NH_2$ and the *m/e* values of 203, 202, and 167 of the *p*-chlorobenzyl-2-

pyridyl group. It formed derivatives, indicative of a primary amine, with cyclopentanone (retention time = 26 min.) and with acetone (retention time = 17 min.) using the procedure of Capella and Horning (5). It formed a derivative with acetic anhydride (6) (retention time >30 min.).

RESULTS AND DISCUSSION

Single-Dose Regimen—The urinary excretion of free chlorpheniramine by the subject on the single-dose regimen is shown in Table I.

The amount of unchanged chlorpheniramine excreted by the single subject in the first 24 hr. was 5.2% of the ingested dose. This is well within the range (4.5 to 11.5%) found by Beckett and Wilkinson (2) for several subjects who were not under pH or fluid intake control. The total estimated excretion of free chlorpheniramine was about 12% of the ingested dose.

Multiple-Dose Regimen—The urinary excretion of free chlorpheniramine by the subject in a multiple-dose regimen is listed in Table II.

The 12-hr. urinary excretion rate varies with time in a "saw-tooth" manner. The peaks and valleys increased with time until a "steady state" (repetitive 24-hr. excretion pattern) was reached. The minimum values or valleys occur prior to the repetitive drug ingestion and the peaks following ingestion. The gradually increasing pattern indicates that chlorpheniramine was building up in the body.

In the steady state, the input of the drug to the body should equal the output from the body. Large fluctuations were observed during the steady-state condition and were probably caused by either the variance in the daily fluid intake, urine pH, or the

Chlorpheniramine	CH_3	CH_3
Metabolite *X*	CH_3	H
Metabolite *Y*	H	H

diurnal excretion pattern. The calculated *average* daily excretion rate was 0.502 mg., or 12.6% of the repeated 4-mg. chlorpheniramine dose. This compares favorably with the 12% that was estimated from the single-dose experiment.

On termination of the drug-intake regimen, the chlorpheniramine excretion rate decreased. From the total amount of free chlorpheniramine excreted after the last dose is taken on day 28.0, and using the average 0.502 mg. of chlorpheniramine excreted per 4-mg. dose, one can calculate the equivalent amount of chlorpheniramine maleate present in the subject immediately after the last dose. This calculation yields a figure of 9.3 mg. of chlorpheniramine maleate (equivalent to 2.4 tablets, each containing 4 mg. of chlorpheniramine maleate).

Metabolites X and Y—The *N*-dealkylation reaction, especially of monomethyl and dimethyl-substituted primary amines is a major pathway of drug metabolism (7). If these metabolites were present, the gas chromatographic method of Beckett and Wilkinson (2) should have revealed them, albeit with much higher retention times (6, 8) than the parent compounds. Unfortunately, in the single dose regimen, it is difficult to differentiate the desired metabolites from other constituents of urine. The metabolites, *X* and *Y*, which were found to be *N*-desmonomethylchlorpheniramine and *N*-desdimethylchlorpheniramine, respectively (Table III), built up, leveled off, and declined like chlorpheniramine but more slowly.

During the steady-state condition, an *average* of 0.510 mg. of *N*-desmonomethylchlorpheniramine and 0.216 mg. of *N*-desdimethylchlorpheniramine were excreted daily (13.2% and 5.8% of the repeated 4-mg. oral dose). Together with the free chlorpheniramine excreted daily, this accounts for 32% of the dose, leaving the fate of the remaining 68% still unaccounted for.

SUMMARY AND CONCLUSIONS

A repetitive dosage regimen using a commercially available pharmaceutical dosage of chlorpheniramine has been successfully used to identify two metabolites of chlorpheniramine, *N*-desmonomethylchlorpheniramine and *N*-desdimethylchlorpheniramine, in the urine of a single human subject.

ADDENDUM

Kamm and Van Loon (9) have recently reported the presence of the metabolites, *N*-desmonomethylchlorpheniramine and *N*-desdimethylchlorpheniramine, in the urine of the rat and the dog.

A Micro-Extraction Technique with Compounds Isolated from Thin-Layer Chromatograms

By ALMA L. HAYDEN, WILSON L. BRANNON, and NEUMAN R. CRAIG

A micro-apparatus is described for the extraction of drugs and related compounds from thin-layer or paper chromatograms by continuous elution with 1 ml. solvent. The sample, after extraction, is ground with KBr, mounted on a micro potassium halide plate, and placed in the center of a paper frame with a window area for infrared analysis. Spectra can be determined on 5- or 10-mcg. samples without beam condensers, ordinate expanders, or micro-dies.

RECENT INVESTIGATIONS in this laboratory have involved structure characterization and identification of microgram quantities of drugs and related materials by infrared spectroscopy. Most often, these have been polar compounds which have been isolated from thin-layer and paper chromatograms where impurities from the matrix and eluting solvent may interfere. To minimize these effects while

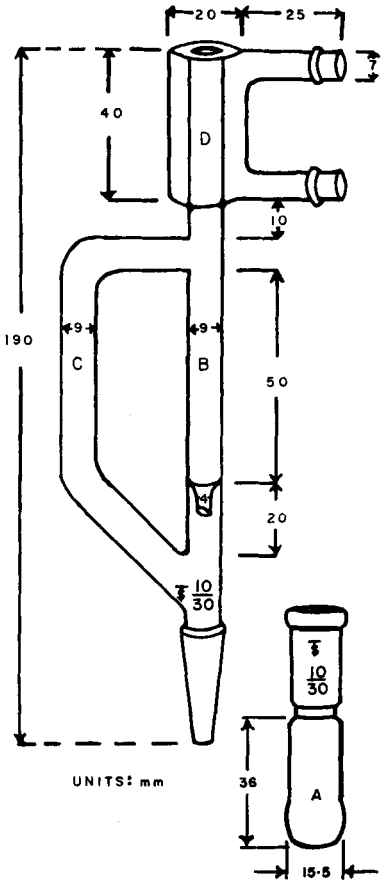

Fig. 1—A continuous extractor with flask (A), column (B), delivery tube (C), and condenser (D).

obtaining spectra on generally available equipment, the development of micro-sample handling techniques has been required.

The potassium halide disk technique can be easily modified, since the matrix is simply a means of mounting the sample. By localizing the compound in the center of the disk to approximate the final slit size of the beam, the required quantity of sample can be reduced significantly (1, 2). In this way, identifiable infrared spectra have been obtained in this laboratory without the aid of beam condensers or ordinate expanders on as little as 5 mcg. of a pure compound. As little as 10 mcg. of material isolated from a thin-layer chromatogram can be identified when this technique is used in combination with a continuous extractor (3). A further 5–10-fold reduction in sample size is possible if beam or signal intensifiers are used.

In previous reports of greater sample sensitivity (0.05–1.0 mcg.), other sampling and pelleting techniques were combined with beam condensers, ordinate expansion, and micro-dies (4–6). Bisset *et al.* (2) obtained similar results by using a reflecting microscope. The technique described here should be of particular interest when the above-mentioned accessories are not available.

The extraction apparatus shown in Fig. 1 operates efficiently with 1 ml. of solvent. The extractor consists of a boiling flask (A), a small column (B) with a side-arm delivery tube (C), and a condenser (D). The side-arm is wrapped with asbestos tape; the condenser is water or air cooled.

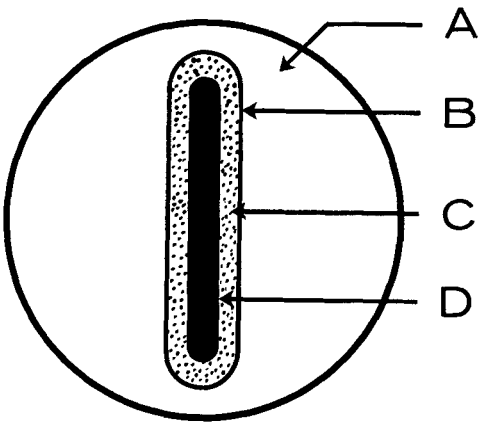

Fig. 2—Micro-plate in paper frame: A, frame; B, window; C, KBr periphery; D, KBr sample mixture.

In operation, the chromatographic zone or sample is placed in the column, which contains a pledget of glass wool. The zone may be prewashed with a solvent if desired. The apparatus is then assembled and about 1 ml. of the extracting solvent is poured through the column and collected in the flask. Single or mixed solvents may be used. The solvent is refluxed and the condensate continuously elutes the compound from the column. The cycle is continued until the extraction is completed. The extract or solution containing the compound is cooled and filtered through chloroform-washed fine filter paper or glass wool into a 50-mm. millite mortar. The filtrate is evaporated to dryness under nitrogen and the crystalline residue is dried in a vacuum over phosphorus pentoxide.

A pressed paper or cardboard frame[1] (12.7 mm. in diameter, 0.6 mm. in thickness) containing a 2 × 11 mm. window is placed on the anvil of a 0.5-in. potassium bromide die. The dry residue is ground by hand with 2 mg. of potassium halide, and the mixture is aligned vertically (1 × 10 mm.) in the center[2] of the window area of the paper frame. Approximately 25 mg. of potassium halide powder is used to rinse the mortar and then to fill in the remaining window area. The die is assembled and evacuated, and the micro-plate is pressed in the usual manner. After pressing, the micro-plate with paper frame (Fig. 2) is mounted in the micro-sample position of a double-beam spectrophotometer. Perkin-Elmer models 21 and 237 were used in this laboratory to record the spectra.

Figure 3 shows the spectra of 1-methylhydantoin: A is 10 mcg. isolated from a thin-layer chromatogram, B is 10 mcg. crystallized directly from chloroform. Both spectra were obtained on micro-plates. For comparison, a standard 0.5% disk (C) is included. Figure 4 shows a spectrum, obtained as described above, of 5 mcg. of 1-methylhydantoin recrystallized from chloroform. In the reference beam, an attenuator was used for the 10-mcg.

[1] Supplied as 13-mm. frames from Limit Research Corp., Darien, Connecticut.

[2] For use with a beam condenser, the mixture is pressed in a 1 × 1 mm. central area of the window.

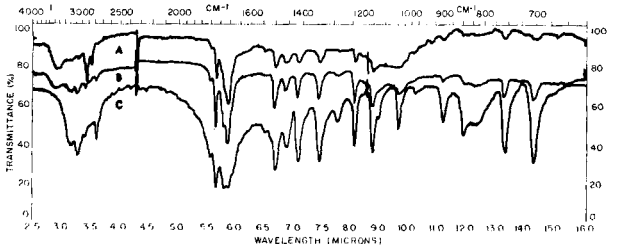

Fig. 3—Spectra of 1-methylhydantoin: 10 mcg. isolated from TLC (A), 10 mcg. crystallized from $CHCl_3$ (B), and a standard 0.5% disk (C).

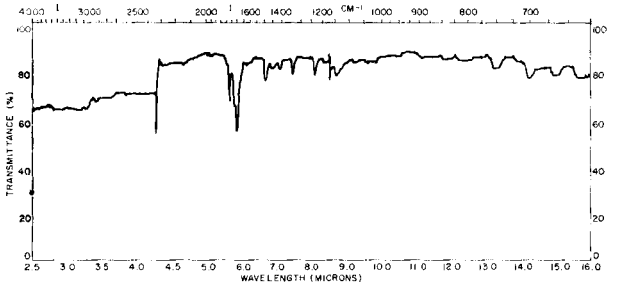

Fig. 4—Spectrum of 5 mcg. 1-methylhydantoin crystallized from $CHCl_3$.

spectra; a potassium bromide reference disk or plate was used with the 0.5% and 5-mcg. spectra. The spectra are essentially the same except for additional absorption in the C-H and 9 μ spectral regions of the sample from the thin-layer chromatogram. These spectra were recorded on a Perkin-Elmer model 237 grating spectrophotometer. Comparable, though less intense, spectra were examined in the micro-sample position of a NaCl prism spectrophotometer.

It must be emphasized that spectral identification of mcg. quantities of pure compounds depends on sample handling techniques as well as on crystal form and absorption characteristics of the molecule. In addition, the identification of materials isolated in microgram quantities from thin-layer and paper chromatograms requires adequate extraction with the inclusion of minimal solvent and substrate residues. By using the continuous extractor, microgram quantities of polar compounds can be isolated from thin-layer chromatograms with 1 ml. of solvent. However, the effects of solvent and substrate residues must be further reduced by washing glassware, thin-layer plates, and paper with the extracting solvent before use. In this application, the extraction was performed with freshly distilled, dried, and ethanol-stabilized chloroform. The extractions and disk preparations should be made on the same day. In this way, reproducible spectra of suitable intensity are obtained. Effects of excipient residues on the spectra can be further reduced by using a reference micro-plate prepared under the same conditions as the sample.

This technique has been used also in the identification of barbiturates, steroids, and other compounds isolated from thin-layer and paper chromatograms.

Osmotic Properties of Aqueous Solutions Containing Caffeine

By FRANK M. GOYAN and HANNA N. BORAZAN

An improved form of the thermoelectric osmometer developed by one of the authors has been used to study solutions of *p*-aminobenzoic acid, citric acid, sodium citrate, sodium salicylate, sodium benzoate, morphine hydrochloride, and papaverine hydrochloride alone and in combination with caffeine. The measured colligative property is plotted against concentration of caffeine. These data are described by two intersecting straight lines for each substance. The point of intersection occurs at different positions on the caffeine scale depending upon the nature and concentration of the complexing agent. The shift along the caffeine scale from the break in the pure caffeine data is divided by the concentration of the complexing agent to give a characteristic complexing capacity number. Osmotic coefficients may be calculated from tabulated slopes.

THE IDEA that the molecular forces related to the solvent effect of caffeine may be involved in attachments of biological significance was suggested by Weil-Malherbe (1). Higuchi and his colleagues (2–6) have established a relationship between the solubilizing action of caffeine and its tendency to form complexes and aggregates. The combination of these two ideas suggests that the instrumentation developed by Johnson and Goyan (7–9) may be adapted to the study of properties related to drug action.

A preliminary survey of the problem indicated the need for greater sensitivity and temperature stability. These improvements were approached on a developmental basis while measurements were in progress. The final outcome was an approximately 10-fold increase in sensitivity with considerable improvement in stability and reproducibility, compared to the same instrument before modification.

EXPERIMENTAL

The circuit and technique previously described (7–9) were not changed except that the regulated power supply (Leeds and Northrup part No. 099012) was installed in place of the battery and calibrating circuit of the Speedomax recorder. The slide wire of the recorder was connected to this power source through two 400-ohm resistors which served as end coils. A 100-ohm resistor was connected across the regulated power supply. The extemporaneous arrangement of 200-ohm precision resistors increased the sensitivity of the recorder from 10 mv. full scale to approximately 1 mv. full scale. Because of the fact that the recorder is used as a nul instrument and calibrated against the resistance box, this temporary arrangement was used throughout the course of the work. It is planned to install the recommended range card for future work.

Attempts to stabilize the temperature regulation and otherwise to improve the stability and reproducibility of the instrument continued throughout the course of the measurements. Manual adjustment and empirical uniformity of method had to be resorted to in the early phases. The following improvements are significant: (*a*) a 4-L. Dewar flask was substituted for the original 1-L. flask used to maintain water at constant temperature. (*b*) The Dewar flask was provided with an insulated metal cover to which was attached brass holders to keep the cells in a vertical position under the water. (*c*) The part of the cell extending above the cover was protected from draft by means of a plastic cylinder which was split to allow half to be removed temporarily while adding sample. (*d*) A thin glass rod less than 1 mm. in diameter was attached to the bottom of the platinum coil around the thermistor. This had the effect of maintaining nearly equal drops by drawing away excess sample. The rod extended to the lowest level of the platinum gauze. (*e*) Cells not adequately vented seemed to cause trouble. This was corrected in one case by sealing a glass tube just below the platinum gauze and bringing the open end of this tube up to the level of the top of the sample tube. (*f*) Temperature control was improved by the control of the air bath with a modified Melabs proportional temperature controller, using a thermistor sensing element. No attempt was made to heat or cool the water, except for initial manual adjustment. The stirring motor was operated from a constant voltage source. Once the correct differential between air and water was established, temperature drift was too slow to influence the readings when using the reference thermistor in the circuit. It was found necessary to improve the insulation of the air bath and to manipulate the droppers through holes draped with cloth.

Solutions were made on a molal basis using ordinary distilled water. The solid needed to make the most concentrated solution of a series was weighed out and the other concentrations made on a molal basis by dilution with the appropriate vehicle. Because of the concurrent study of the instrument it was necessary to discard preliminary results in many cases. However, all of the data included in this paper were taken after proper adjustments were made. All points fall within the circles shown on the figures. USP or equivalent quality chemicals obtained from reliable sources were used without further purification.

RESULTS

All results obtained were plotted with ΔR as ordinate and molal concentration as abscissa. It was found that intersecting straight lines could be used to express all data given in Table I within the limit of experimental error. These intersecting straight lines are of special interest because it was discovered that the point of intersection shifted as a function of the nature and concentration of the

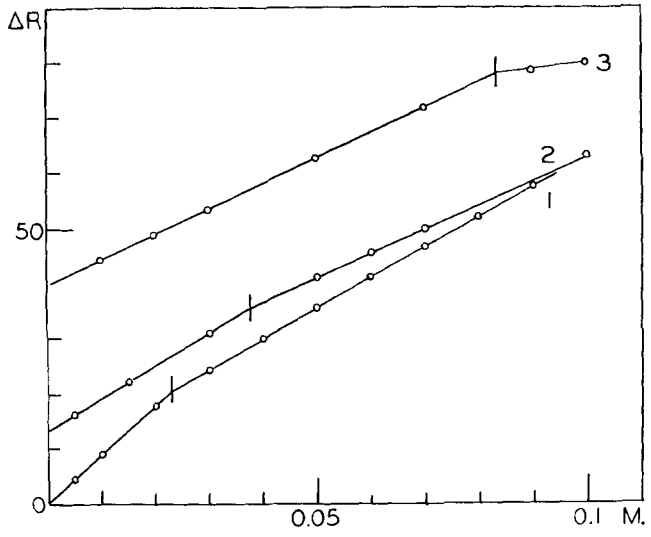

Fig. 1—Plot of measured differences in resistance in ohms plotted against molal concentration of caffeine in the following vehicles: 1, water; 2, 0.015 M *PABA; 3, 0.03* M *papaverine hydrochloride. The intersection of two straight lines is marked by a short vertical line.*

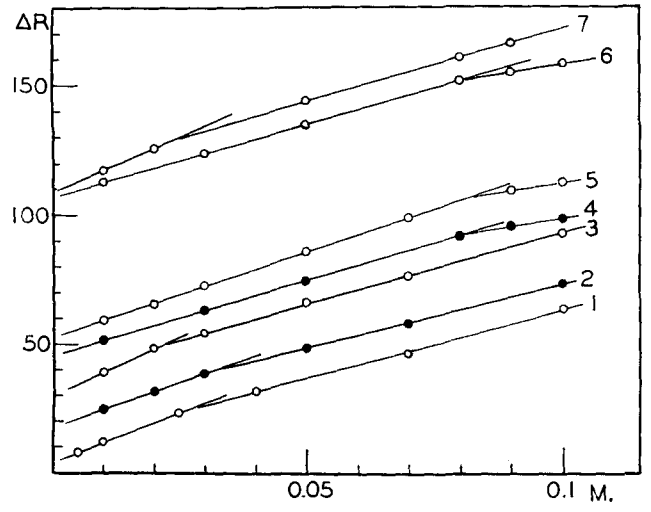

Fig. 2—Similar to Fig. 1 except that points represented by solid disks were raised 10 ohms in order to avoid crowding. Numbers refer to the following vehicles: 1, 0.005 M *PABA; 2, 0.01* M *PABA; 3, 0.01* M *sodium citrate; 4, 0.02* M *sodium salicylate; 5, 0.03* M *morphine hydrochloride; 6, 0.06* M *sodium benzoate; 7, 0.1* M *citric acid.*

compound used to prepare the vehicle. For these reasons, all slopes and intercepts shown graphically were checked by the method of least squares.

The same data are displayed in Figs. 1 and 2 to show the shift in the point of intersection of the two lines for caffeine. This difference between the intersection in water and in the solution under study is divided by the concentration of the vehicle solute to yield the complexing capacity number shown in Table II. It is difficult to estimate the accuracy of these values, but it is almost certain that the last figure shown in the column of calculated values is not significant. The close approach to simple integers suggests that these integers are in

TABLE II—COMPLEXING CAPACITY NUMBERS WITH CAFFEINE

Vehicle	Calculated from Table I	Nearest Integer	Increased Solubility Ref.
Citric acid, 0.1 *M*	0.02	0	(10)
Morphine HCl, 0.03 *M*	1.98	2	...
PABA			
0.005 *M*	0.88	1	(4, 5)
0.010 *M*	0.99		
0.015 *M*	0.89		
Papaverine HCl, 0.03 *M*	2.00	2	...
Sodium benzoate, 0.06 *M*	0.96	1	(2, 10)
Sodium citrate, 0.01 *M*	−0.18	0	...
Sodium salicylate, 0.02 *M*	2.88	3	(3, 10)

necessary to state complexing capacity numbers as integers. It is quite possible that the decimal fractions given in the first column of Table II have some significance. The important conclusion is that these numbers do exist and can be measured.

It is a well-known fact that a true colligative property of sucrose plotted against concentration does not fall exactly on a straight line (11). The treatment of the present data was indicated by interest in the complexing numbers and by the fact that the authors are not yet in a position to state absolute values based upon empirical corrections. However, all of the slopes given may be used to calculate apparent osmotic coefficients for pure substances at a concentration of 0.1 *M* by the equation:

$$\phi = \frac{S_1 C_1 + S_2(0.1 - C_1)}{88} \qquad \text{(Eq. 1)}$$

where ϕ is the osmotic coefficient, S_1 is the first slope, C_1 is the concentration at the intersection, and S_2 is the second slope of Table I. Similar equations may be derived for other concentrations. Comparison of the present work with the work of others shows some discrepancies not easily explained. Blake and Harris (12), working near the freezing point of water, have assumed that caffeine behaves as an ideal solute. Several papers combined (13–15) indicate that the osmotic coefficient of caffeine is about 0.65 as compared to a value of 0.72 calculated by Eq. 1.

TABLE III—DATA FALLING ON SINGLE STRAIGHT LINES

Variable	Vehicle	Intercept, ohms	Slope dR/dM	Last Point *M*	Number of Points
Benzoic acid	Water	0.0	880	0.025	5
Citric acid	Water	2.3	1000	0.20	6
Citric acid	Caffeine 0.01 *M*	8.8	1012	0.10	5
Citric acid	Caffeine 0.1 *M*	61.5	1075	0.10	4
PABA	Water	0.0	873	0.03	5
Salicylic acid	Water	0.0	880	0.015	3
Sodium benzoate	Water	0.0	1760	0.05	3
Sodium citrate	Water	4.2	2621	0.10	4
Sodium citrate	Caffeine 0.02 *M*	21.6	2629	0.10	4
Sodium salicylate	Water	0.0	1760	0.10	4
Sucrose	Water	0.1	882	0.20	6

some way related to the stoichiometry of complex formation.

A few other systems were studied in the hope that they might throw some light on the meaning of these complexing capacity numbers. These data are shown in Table III. The straight lines represented by slope and intercept pass through all of the measured points within the limit of experimental error. The intercepts are not experimental points. The experimental value for zero concentration is always zero because of the practice of using a drop of pure water to establish a base resistance reading before substituting drops of solution. In every case a 0.01 *M* or lower concentration was included in the series.

DISCUSSION OF RESULTS

The discovery of caffeine complexing numbers reported in this paper present new information about a few compounds. Emery and Wright (10) report that citric acid is a more effective solubilizing agent for caffeine than is sulfuric acid. The value of zero for the caffeine complexing number for citric acid and for sodium citrate shown in Table II indicates that the interaction with citric acid implied by the experiments of Emery and Wright is different from interaction with compounds of Table II known to have specific biological activity. It is not

The present work adds a new dimension to the study of caffeine complexes and is in agreement with the work of Donbrow and Jan (16) concerning the absence of aggregates in solutions of caffeine more dilute than 0.02 *M*. However, something like a critical micelle concentration may be found at 0.023 *M*. The complexing capacity number of unity for sodium benzoate may be regarded as being in agreement with Donbrow and Jan. It is interesting to speculate that the higher complexing capacity numbers found for morphine, papaverine, and sodium salicylate are in some way related to biological activity.

Triterpenic Constituents of *Lepechinia chamaedryoides*

By MARIO SILVA

Betulinic acid was isolated and identified from *Lepechinia chamaedryoides* collected in the summer, and ursolic acid was found in plant material collected in the spring.

During a current project dealing with Chilean flora (1) the author had occasion to reexamine *Lepechinia chamaedryoides* in order to study the compound isolated by Alvarez (2), and to see how constant it is in this plant during the year.

The petroleum ether-soluble fraction of plant material collected during March (summer) yielded betulinic acid (3) characterized through its derivatives. Betulinic acid was also isolated from the benzene-soluble fraction. In this plant material no other triterpenic acid could be detected.

From plant material collected in November (spring), ursolic acid (4) was obtained which gave a methyl ester with a rather peculiar melting point (105°). Therefore, it was characterized through several derivatives. Betulinic acid could be detected by thin-layer chromatography only as its methyl ester.

These different results appear to be a seasonal variation of the triterpenic constituents.

EXPERIMENTAL[1]

Isolation of Betulinic Acid—Stems and leaves of *Lepechinia chamaedryoides* collected in March near Concepción, were dried at 80° with air circulation, and 2100 Gm. of the dried and ground plant was extracted in a Soxhlet apparatus with petroleum ether (b.p. 65–75°) to exhaustion. This solution was concentrated to yield 109 Gm. of a dark green product. This product was crystallized several times from ethanol to yield 11 Gm. of a crude acid m.p. 286°.

Betulinic Acid Methyl Ester—This ester was prepared by diazomethane treatment in ether solution; crystallized from ethanol as colorless crystals with m.p. 221°, $[\alpha]_D$ +4.4° (chloroform, c 0.44), $\nu_{max.}^{Nujol}$ 3610, 1695, and 1637 cm.$^{-1}$, $\nu_{max.}^{CHCl_3}$ 1724, 1647 cm.$^{-1}$.

Anal.—Calcd. for $C_{31}H_{50}O_3$: C, 79.10; H, 10.71. Found: C, 79.34; H, 10.69.

Betulin Diacetate—The betulinic acid methyl ester on $LiAlH_4$ reduction using ether as solvent gave an noncarbonilic compound which on pyridine–acetic anhydride acetylation at room temperature gave a diacetate (5), m.p. 222°, $[\alpha]_D$ + 28.7° (chloroform, c 0.48), $\nu_{max.}^{Nujol}$ 1732, 1640, and 1250 cm.$^{-1}$, τ = 7.9 (two acetates).

Anal.—Calcd. for $C_{34}H_{54}O_4$: C, 77.52; H, 10.33. Found: C, 77.73; H, 10.53.

The betulinic acid obtained was further characterized through several derivatives.

Benzene Extract—The defatted plant material was dried and the benzene-soluble constituents were extracted. This solution was concentrated to yield 27 Gm. of product. This product through crystallizations, first from petroleum ether and later with ethanol, gave in a good yield an acid, m.p. 285–286° identical with the betulinic acid previously isolated.

Isolation of Ursolic Acid—Stems and leaves of *Lepechinia chamaedryoides*, collected in November (spring) near Concepción, were dried at 80° with air circulation, and 4611 Gm. of the dried and ground plant was extracted in a Soxhlet apparatus with benzene to exhaustion. This solution was concentrated to yield 253 Gm. of a dark green product, and 150 Gm. of this product was chromatographed over alumina grade III to give crude ursolic acid m.p. 250°, $[\alpha]_D$ + 52.8° (pyridine, c 0.35).

Ursolic Acid Acetate—Treatment of the acid with pyridine–acetic anhydride gave an acetate, m.p. 248°,

Received August 7, 1967, from the Laboratorio de Fitoquímica, Departamento de Botánica, Instituto Central de Biología, Universidad de Concepción, Concepcion, Chile.
Accepted for publication November 2, 1967.
This work was generously supported by the Comisión de Investigación Científica of the Universidad of Concepción.
The author wishes to acknowledge his indebtedness to Professor D. H. R. Barton, for making authentic samples available and for his constant help and encouragement. Also, the author is grateful to Professor P. Mancinelli for collecting the plant material.

[1] Melting points (uncorrected) were performed on a Kofler block. Rotations were measured at 20°. The microanalyses were performed by Dr. Alfred Bernhardt's Institute, Mülheim, Germany, and at the Chemistry Department, Imperial College, London, England. Ultraviolet spectra were recorded in solution in absolute ethanol on a SP 700 spectrophotometer. Infrared spectra were recorded on a Perkin-Elmer 137 spectrophotometer. Nuclear magnetic resonance spectrum was determined on a Varian A-60 spectrometer using deuterochloroform as solvent and tetramethylsilane as an internal reference.

Coumarins VII. The Coumarins of *Lomatium nuttallii*

By KUO-HSIUNG LEE and T. O. SOINE

The ether extract of the root of *Lomatium nuttallii* (A. Gray) Macbr. has been examined and has provided a number of known coumarins. These are osthol, jatamansin, pteryxin, and lomatin. The ether extract also contained a new coumarin, provisionally named *nuttallin*, which has been identified as the senecioate ester of lomatin. The methanol extract yielded the glycosidic coumarin, columbianin.

INTEREST in naturally occurring agents with potential physiological activity has led the authors, in the past, to consider the *Lomatium* genus. At least one representative of this genus has been employed extensively by the American Indians as a therapeutic agent (1) without, however, any firm rationale for such usage. Our previous examinations have encompassed *L. columbianum* Math. and Const. (2). *L. suksdorfii* (Wats.) Coulter and Rose (3), and *L. dissectum* var. *multifidum* (Nutt.) Math. and Const. (4) and it has been determined that coumarins are the principal chemical type present. That coumarins can be responsible for a variety of physiological activities is well known (5). A continuing investigation of this genus has led the authors to examine the roots of *L. nuttallii* (A. Gray) Macbr. and has resulted in the isolation of a number of known coumarins. Specifically, osthol (I), lomatin angelate (II) [*i.e.*, jatamansin (6) or selinidin (7)] pteryxin (III), lomatin (IV),[1] and columbianin (V) (2, 8) have been isolated and identified. The presence of a new coumarin, lomatin senecioate (VI), provisionally named *nuttallin*, has been demonstrated. Naturally occurring nuttallin has proved to be elusive as far as isolation is concerned but its synthesis has been easily achieved following its identification in the NMR spectrum of the jatamansin residues. The fact that the spectrum of the mixture corresponded exactly for jatamansin (*i.e.*, lomatin angelate) was expected and it was not surprising that the peaks of any contaminant as closely related as a senecioate to an angelate of the same alcohol would coincide except for the specific protonic differences in the acid portion of the ester. These differences were observed as the singlets at τ 8.13 (3H), 7.84 (3H), and 4.34 (1H) which are the typical signals for the senecioyl group (9). The synthetic senecioate of the optically active natural lomatin had the NMR spectrum predicted from the previous observations on the crude mixture, *i.e.*, it peaks at τ 8.64 (6H, s.), 8.12 (3H, s.), 7.85 (3H, s.), 4.37 (1H, s.), 6.90 (2H, t.), 4.87 (1H, t.), 3.83 (1H, d.), 3.25 (1H, d.), 2.77 (1H, d.), and 2.42 (1H, d.). With the exception of the peaks noted above the spectrum is virtually identical with that of jatamansin. Curiously, nuttallin does not crystallize, a circumstance that is analogous to a similar situation with regard to the angelate (VII) and senecioate (VIII) esters of (−)-3′-hydroxy-3′,4′-dihydroxanthyletin. In this case, however, Lemmich *et al.* (10), in spite of extensive purification, were unable to secure VII in a crystalline form whereas Hata and Sano (9) had little difficulty in obtaining crystalline VIII (*i.e.*, decursin). The reasons for such anomalous behavior are not apparent.

checked for accuracy against a set of standard samples and are uncorrected.

Ultraviolet spectra were determined on a Bausch and Lomb Spectronic 505 recording spectrophotometer.

Infrared spectra were determined on a Perkin-Elmer 237B grating infrared spectrophotometer.

Values of [α] were determined on a Perkin-Elmer 141 polarimeter.

Nuclear magnetic resonance (NMR) spectra were determined on a Varian Associates A-60 instrument in $CDCl_3$ using tetramethylsilane (TMS) as the internal standard. The authors are indebted to the School of Chemistry, University of Minnesota, for these determinations.

Silica gel for column chromatography refers to Baker Analyst No. 3405 activated at 120° and silica gel for thin-layer chromatography refers to Silica Gel G supplied by Brinkmann Instruments, Inc., Great Neck, N. J. activated at the same temperature.

Material[2]—*Lomatium nuttallii* (A. Gray) Macbr. is a species belonging to the *Umbelliferae* family of plants. It is known by the following pseudonyms: *Seseli nuttallii* (Gray), *Peucedanum graveolens* (Wats.), *P. kingii* (Wats.), *Cynamarathrum nuttallii* (Gray), and *Cogswellia nuttallii* (Gray) Jones. The present investigation was confined entirely to the roots of the plant which had been collected and identified in the summer of 1956 at an elevation of 8800 ft. in St. Charles Canyon, Bear Lake County, Idaho. The roots, which had been stored in a deep-freeze refrigerator, were reduced to a powder suitable for extraction in a Jacobsen laboratory grinder designed to keep frictional heat at a minimum.

Ether Extract—The dried and ground root (500 Gm.) was extracted with diethyl ether for several hours until only a faint fluorescence was evident in the menstruum when spotted on filter paper and examined under ultraviolet light. The marc was dried and reserved for methanol extraction (*q.v.*). Upon removal of the ethereal solvent a viscous oil remained. This oil was dissolved in 90% methanol, defatted with petroleum ether, and evaporated to give a residue weighing 30 Gm. A portion (15 Gm.) of this residue was chromatographed on silica gel (450 Gm.) impregnated with 10% of water. The column was successively eluted with benzene, benzene–chloroform, chloroform, chloroform–ethyl acetate, ethyl acetate, and ethyl acetate–methanol. Nine hundred and forty eight 20-ml. fractions were collected and the composition of the fractions determined by examining thin-layer chromatograms under ultraviolet light. The first benzene eluate (fractions 1–25) yielded only nonfluorescent, yellow-colored oily substances and was not investigated further. The subsequent fractions (26–184) contained a single spot having a purple-blue fluorescence under ultraviolet light and fractions 185–239 (0.6 Gm.) appeared to be a mixture of fluorescent compounds.

The benzene–chloroform mixture eluted the following fractions all of which contained a mixture of fluorescent compounds, *i.e.*, fractions 240–486, 487–498, 499–512, 513–524, 525–537, and 538–572.

Chloroform was used to elute fractions 573–763 which also appeared to be a mixture of fluorescent compounds.

The chloroform–ethyl acetate mixture eluted only traces of fluorescent substances in fractions 764–779 and 780–787. The same was true of the ethyl acetate and ethyl acetate–methanol fractions (788–948) and these fractions were not investigated further.

Isolation of Coumarins from the Ether Extract—The fractions containing fluorescent materials were worked up to yield the following:

(*a*) *Osthol*—The residue (4.1 Gm.) resulting from the removal of solvent from fractions 28–184 was recrystallized from a small amount of ether to provide fine, colorless needles, m.p. 81–82°; infrared spectrum (KBr disk): 3000, 2950, 2820 (triplet of aromatic OCH_3), 1721 (α-pyrone C=O), 1606, 1498, 1460 (aromatic C=C), 1563 (aromatic ring with conjugated C=C), 1272, 1245, 1120, 1085 (asymmetric and symmetric stretching of =C—O—C), and 820 cm.$^{-1}$ (1,2,3,4-aromatic substitution). The melting point of this compound was undepressed on admixture with an authentic sample of osthol and their infrared spectra were identical.

(*b*) *Jatamansin*—a blue-fluorescent oily substance (4.8 Gm.) was obtained from fractions 240–486. Thin-layer chromatography on silica gel using different solvent systems gave only one spot with the

[2] Collected and initially identified by Dr. T. G. Call, California State Polytechnic College, San Luis Obispo, California, with confirmation of the identification by Dr. Lincoln Constance, Botany Department, University of California, Berkeley. A voucher specimen has been placed in the herbarium of the Botany Department, University of Minnesota, Minneapolis.

same R_f value as that of jatamansin.[3] The oily substance (3.0 Gm.) was dissolved in a small amount of benzene and, after adding a few drops of cyclohexane, was kept in the refrigerator for 1 week. The white, crystalline semisolid that separated was removed by filtration and washed with cyclohexane to yield white crystals (83 mg.), m.p. 85–93°. Recrystallization from ether–cyclohexane provided colorless prisms (61 mg.), m.p. 90–92°; $[\alpha]_D^{25}$ −17.8° (c 1.0, $CHCl_3$); infrared spectrum (Nujol mull): 1724 (α-pyrone C=O), 1610, 1490 (aromatic C=C), 1245, 1147, 1119 (asymmetric and symmetric stretching of =C—O—C), and 847 cm.$^{-1}$ (1,2,3,4-aromatic substitution). It failed to depress the melting point of an authentic sample of jatamansin on admixture and the infrared spectra were identical.

After the isolation of jatamansin, the mother liquor was rechromatographed on silica gel impregnated with 3% of water using benzene, benzene–chloroform, and chloroform–ethyl acetate as eluants, successively. No further separations were realized and, similarly, thin-layer chromatography on silica gel failed to show any spots other than the one ascribable to jatamansin. The oily residue had an infrared spectrum quite similar to that of jatamansin but differed in minor details. The NMR spectrum agreed with that of jatamansin (6) but, in addition, had superimposed on it singlets at τ 8.13 (3H), 7.84 (3H), and 4.34 (1H). Further treatment of this fraction is deferred to a later portion of this paper (*q.v.*).

(*c*) *Pteryxin*—The orange-colored oily substance (1.66 Gm.) obtained from fractions 499–512 was rechromatographed on silica gel (50 Gm.) impregnated with 5% of water. Elution with chloroform furnished a colorless oily residue which was seeded with one small crystal of pteryxin[4] and the whole then kept in a refrigerator for 5 days. The colorless, large tetragonal crystals which formed were collected and twice recrystallized from skellysolve-B to give 21 mg. of white crystals, m.p. 81–83° undepressed by admixture with pteryxin; $[\alpha]_D^{21}$ −1.8° (c 0.69, $CHCl_3$): infrared spectrum (KBr disk): 1745 (α-pyrone C=O), 1615, 1495 (aromatic C=C), 1235, 1145 (asymmetric and symmetric stretching of =C—O—C), and 837 cm.$^{-1}$ (1,2,3,4-aromatic substitution). The infrared spectrum of this compound was identical to that of pteryxin.

(*d*) *Lomatin*—The reddish-orange oil obtained from the chloroform fractions (573–763) weighed 0.89 Gm. and was rechromatographed on silica gel (40 Gm.) impregnated with 5% of water. Elution with chloroform yielded a fraction having a single spot with the same R_f value as lomatin on examination by silica gel thin-layer chromatography. This fraction was dissolved in acetone and brought to turbidity with skellysolve-B at which time it was seeded with one small crystal of lomatin and kept in the refrigerator for 3 days. The resulting crystalline deposit was filtered and washed with benzene. Recrystallization from skellysolve-B–acetone mixture yielded colorless crystals (11.4 mg.), m.p. 179–181°; $[\alpha]_D^{28.5}$ +46.4 (c 0.44, C_2H_5OH). A mixed melting point with authentic lomatin showed no depression and the infrared spectra were identical.

Methanol Extract—The marc from the ether extraction was dried in air and extracted with methanol until a portion of the extract failed to give an appreciable residue when evaporated to dryness (7 days). This extract was allowed to concentrate spontaneously and deposited crystalline material as the volume decreased. The crystalline material was removed by filtration, rinsed with methanol, and dried, m.p. 270–275°. The filtrate and washings from these crystals was allowed to dry completely resulting in a thick reddish-brown syrupy residue. Paper chromatographic examination of this residue showed only one blue-fluorescent spot corresponding to that for the crystalline material. It was not examined further.

The crystalline material was recrystallized from hot methanol, m.p. 274–275° and showed no depression of melting point on admixture with authentic columbianin.[5] Similarly, an acetate prepared in the conventional manner, m.p. 220–222° failed to depress the melting point of authentic columbianin acetate.[5]

Hydrolysis of the Jatamansin Mother Liquors—The mother liquor, after removal of the crystalline jatamansin, was evaporated to yield a viscous, oily residue. This residue (360 mg.) was dissolved in 3 ml. of dioxane and 11 ml. of 1 *N* potassium hydroxide and left overnight at room temperature. Examination of the mixture by thin-layer chromatography showed that the faster moving fluorescent ester spot had disappeared almost completely in favor of a much slower moving fluorescent alcohol spot. The reaction mixture was diluted with an equal amount of water and acidified with 10% sulfuric acid. After standing for 45 min. it was adjusted to pH 8 with 10% sodium carbonate solution and finally extracted with chloroform. The chloroform extract, after drying and evaporation, was dissolved in benzene and chromatographed on silica gel (10 Gm.) impregnated with 5% of water. Initial elution with a mixture of chloroform–benzene (1:9) yielded a colorless, viscous oily substance (25 mg.) which had an infrared spectrum virtually identical with the starting material. Subsequent elution with chloroform afforded a crystalline material which upon recrystallization from acetone–skellysolve-B formed colorless needles (140 mg.), m.p. 180–181°; infrared spectrum (KBr disk): 3470 (free OH), 1700 (C=O), 1600, and 1484 (aromatic C=C), 1281 and 1075 cm.$^{-1}$ (OH deformation and C—O stretching). This compound showed no depression in melting point on admixture with authentic lomatin and the infrared spectra were identical. No other fluorescent materials were eluted by the use of ethyl acetate.

The aqueous phase (pH 8) was acidified with 10% sulfuric acid and extracted with ether. After drying and evaporation, the oily residue (*ca.* 110 mg.) was treated with dicyclohexylethylamine (250 mg.) and converted to the *p*-phenylphenacyl ester form according to the method of Stodola (11). The resulting white solid product (130 mg.) was then chromatographed on silica gel (10 Gm.) impregnated with 10% of water. The eluant was benzene–skellysolve-B (2:1) to which increasing amounts

[4] Obtained from the studies reported in *Reference 3*.

[5] Obtained in these laboratories from the studies reported in *Reference 2*.

of benzene were added. Unreacted *p*-phenylphenacyl bromide, a mixture of *p*-phenylphenacyl angelate and senecioate and *p*-phenylphenacyl senecioate (31 mg.), m.p. 136°, were obtained successively. The identity of the senecioate ester was established by thin-layer chromatography, infrared spectroscopy, and mixed melting point determination with an authentic sample of *p*-phenylphenacyl senecioate.

Synthesis of Lomatin Senecioate—Lomatin (200 mg.) was suspended in dry benzene (5 ml.). The suspension was added slowly to a solution of senecioyl chloride (b.p. 67°/39 mm. Hg) (230 mg.) in dry benzene (3 ml.). The mixture, protected by a calcium chloride drying tube, was refluxed on a steam bath for 16 hr. The reaction mixture was then cooled and washed with 5% sodium bicarbonate solution followed by distilled water. The benzene solution was dried over anhydrous magnesium sulfate, filtered, and the solvent removed under reduced pressure to yield a colorless, glassy substance (230 mg.). All attempts to crystallize the ester were unsuccessful. Thin-layer chromatography, however, showed only one spot with the same R_f value as noted for jatamansin and fractions 240–486. This compound was then further purified by silica gel chromatography and dried in a high vacuum to yield an amorphous, very hygroscopic substance with m.p. 58 ~ 62° $[\alpha]_D^{20}$ +75.0 (c 1.0, $CHCl_3$); ultraviolet spectrum: $\lambda_{max.}$ 326, 256, 246, and 219 mμ (log $\epsilon_{max.}$ 4.16, 3.73, 3.83, and 4.53, respectively); infrared spectrum (in $CHCl_3$) was almost identical with fractions 240–486, *i.e.*: 1724 (α-pyrone C=O), 1610, 1490 (aromatic C=C), 1140, 1115 (asymmetric and symmetric stretching of =C—O—C), and 834 cm.$^{-1}$ (1,2,3,4-aromatic substitution).

Gas-Liquid Chromatographic Determination of Dienestrol in the Presence of Methyltestosterone

By FRED L. FRICKE, STEPHEN M. WALTERS, and WILLIAM T. LAMPKIN

A gas chromatographic procedure has been developed for the determination of dienestrol in the presence of methyltestosterone. Dienestrol was extracted from tablets and quantitatively determined by gas chromatography of its bis-(trimethylsilyl)ether. The bis-(trimethylsilyl)ether of alizarin was used as an internal standard. Preliminary experiments indicate that the method is applicable in the presence of other androgens and corticosteroids.

THIS STUDY describes a rapid, specific, gas-liquid chromatographic procedure for the determination of dienestrol in the form of its bis(trimethylsilyl)ether derivative, with bis-(trimethylsilyl)acetamide as the silylating agent.

A number of analytical procedures have been reported for the determination of dienestrol. The USP XVI utilizes the Folin-Denis reagent in a colorimetric procedure. Cocking (1) also developed a colorimetric method based on a reaction of dienestrol with bromine in acetic acid, whereas Malpress (2) formed a polynitro derivative and measured the orange color produced. A method for the determination of dienestrol in biological samples, utilizing the formation and subsequent titration of the maleic acid adduct, was proposed by Smith (3). Gottlieb (4) formed nitrosophenols from various synthetic estrogens including dienestrol and measured the colors produced, while Gry (5) determined the nitroso derivative of dienestrol polarographically. Summa and Graham (6) determined dienestrol both by a polarograpic method, which is the basis of the NF XII assay, and by measurement of a yellow color [first observed by Banes (7)] that is formed with ultraviolet irradiation of dienestrol. In applications of gas chromatography as the determina-

Gas-Liquid Chromatographic Determination of Dienestrol in the Presence of Methyltestosterone

By FRED L. FRICKE, STEPHEN M. WALTERS, and WILLIAM T. LAMPKIN

A gas chromatographic procedure has been developed for the determination of dienestrol in the presence of methyltestosterone. Dienestrol was extracted from tablets and quantitatively determined by gas chromatography of its bis-(trimethylsilyl)ether. The bis-(trimethylsilyl)ether of alizarin was used as an internal standard. Preliminary experiments indicate that the method is applicable in the presence of other androgens and corticosteroids.

THIS STUDY describes a rapid, specific, gas-liquid chromatographic procedure for the determination of dienestrol in the form of its bis(trimethylsilyl)ether derivative, with bis-(trimethylsilyl)acetamide as the silylating agent.

A number of analytical procedures have been reported for the determination of dienestrol. The USP XVI utilizes the Folin-Denis reagent in a colorimetric procedure. Cocking (1) also developed a colorimetric method based on a reaction of dienestrol with bromine in acetic acid, whereas Malpress (2) formed a polynitro derivative and measured the orange color produced. A method for the determination of dienestrol in biological samples, utilizing the formation and subsequent titration of the maleic acid adduct, was proposed by Smith (3). Gottlieb (4) formed nitrosophenols from various synthetic estrogens including dienestrol and measured the colors produced, while Gry (5) determined the nitroso derivative of dienestrol polarographically. Summa and Graham (6) determined dienestrol both by a polarograpic method, which is the basis of the NF XII assay, and by measurement of a yellow color [first observed by Banes (7)] that is formed with ultraviolet irradiation of dienestrol. In applications of gas chromatography as the determina-

Accepted for publication October 24, 1967.

tive step, McGregor *et al.* (8) formed the dimethyl ether, and Luukainen *et al.* (9) prepared the trimethylsilyl ethers of steroids.

Advantages of the trimethylsilyl ethers are their easy and quantitative formation and the decrease in adsorption effects on the column. The trimethylsilyl ether derivatives have normally been prepared by the reaction of dienestrol with hexamethyldisilazane and trimethylchlorosilane in pyridine. However, complete formation of the derivative with these reagents often requires prolonged heating and removal of ammonia. Another disadvantage is that amine hydrochlorides are produced. Klebe *et al.* (10) have found that bis-(trimethylsilyl)acetamide as prepared by Birkofer *et al.* (11) is a superior silylating agent, in many respects, to the previously used reagents.

EXPERIMENTAL

Apparatus—Gas chromatograph, Packard series 7800 with flame-ionization detector and Minneapolis Honeywell recorder.

GLC Column—Glass coiled (1.8 m. × 4 mm.) packed with 5% SE-30 on Gas Chrom Q, 80/100 mesh. The column was conditioned for 8 hr. with a nitrogen flow of 60 ml./min.

Operating Conditions—Column temperature 230°; detector temperature 255°; injection port temperature 255°; hydrogen flow 90 ml./min.; air flow 750 ml./min.; nitrogen flow 100 ml./min.; sensitivity, 1×10^{-9} amp.

Reagents—Bis-(*trimethylsilyl*)*acetamide*[1]—This reagent must be stored under nitrogen to prevent destruction by atmospheric moisture. A dry box is convenient for storage.

Internal Standard Solution—Place 150 mg. of alizarin in a 50-ml. volumetric flask. Add approximately 40 ml. of ethyl acetate and shake until most of the alizarin is dissolved. Transfer to a dry box and add 2 ml. of bis-(trimethylsilyl)acetamide. Remove and heat at 60° for 5 min., cool, dilute to volume with ethyl acetate, and mix well.

Standard Dienestrol Solution—Place 4.0 mg. of NF dienestrol reference standard in a 10-ml. volumetric flask and dissolve in a small portion of ethyl acetate. Add 2.0 ml. of internal standard solution. Transfer to a dry box and add 10 drops of bis-(trimethylsilyl)acetamide. Remove the solution from the dry box and dilute to volume with ethyl acetate.

Extraction Procedure—Weigh not less than 20 tablets and grind to a fine powder. Weigh accurately a portion of the powder sufficient to give about 2 mg. of dienestrol for tablets containing 0.25 mg./tablet (or about 4 mg. for tablets containing more than 0.25 mg. of dienestrol/tablet) into a 250-ml. conical flask. Add 50 ml. of acetone, place on a hot plate with a magnetic stirrer, and boil gently with stirring for 10 min.; cool and let settle. Decant through a funnel fitted with a glass wool plug into a 250-ml. beaker. Repeat the extraction two more times with 50-ml. portions of acetone, combining the extracts in the 250-ml. beaker. Evaporate the extract on a steam bath with the aid of a current of dry air to approximately 10 ml. Transfer to a 50-ml. beaker with several small portions of acetone, using a stirring rod to break up any precipitate. Evaporate this extract just to dryness. Transfer the residue with several small portions of ethyl acetate to a 5-ml. volumetric flask if it contains 2 mg. of dienestrol (or to a 10-ml. volumetric flask if it contains 4 mg.). Then add 1.0 ml. of internal standard solution to the 5-ml. volumetric flask (or 2.0 ml. if a 10-ml. volumetric flask is used).

Etherification Step—Place the volumetric flask inside a nitrogen dry box and add an excess (about 0.5–1.0 ml.) of bis-(trimethylsilyl)acetamide. Mix

and remove from the dry box. (*Note*: If the volume is above the calibration mark, the excess may be removed with the aid of heat and a current of nitrogen.) Inject 6–7 μl. of this solution into the gas chromatograph. Make duplicate injections of both sample and standard.

Calculations—The peaks due to the bis-(trimethylsilyl)ethers of dienestrol and alizarin have retention times of approximately 6.6 min. and 11.1 min. (See Fig. 1.) Peak area is determined by multiplying the peak height times the width at half height.

The ratio of the peak areas is given by:

$$R = \frac{\text{area of bis-(trimethylsilyl)ether of dienestrol}}{\text{area of bis-(trimethylsilyl)ether of alizarin}}$$

mg. of dienestrol/tablet =

$$\frac{\text{R for sample} \times \text{standard concn.} \times \text{diln. factor} \times \text{av. wt. tablet}}{\text{R for standard} \times \text{wt. sample}}$$

RESULTS AND DISCUSSION

Table I shows the average peak area ratios (R) of the bis-(trimethylsilyl)ether of dienestrol to the bis-(trimethylsilyl)ether of alizarin of five injections of four standard solutions. These values indicate that dienestrol is linear over the concentration range used.

Simulated tablet mixtures containing all excipients including methyltestosterone and known quantities of dienestrol were taken through the entire procedure. These mixtures were chromatographed in duplicate. The results are given in Table II. These data indicate that the standard deviation for the method is 1.6. Table III shows results of the analyses of marketed products containing methyltestosterone and dienestrol.

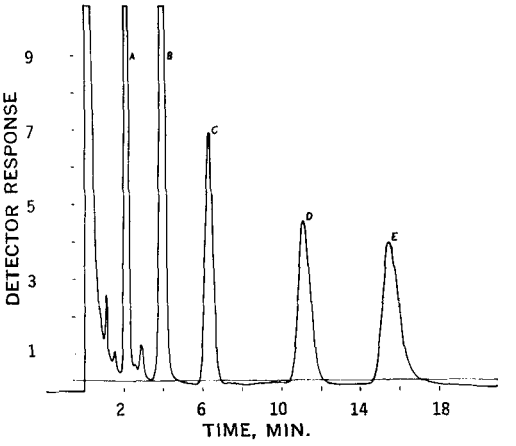

Fig. 2—A typical chromatogram of a sample. Key: A, (trimethylsilyl) ester of palmilic acid; B, (trimethylsilyl) ester of stearic acid; C, bis-(trimethylsilyl)ether of dienestrol; D, bis-(trimethylsilyl)ether of dienestrol; D, bis-(trimethylsilyl)ether of alizarin; E, methyltestosterone.

TABLE III—ANALYSIS OF DIENESTROL IN MARKETED PRODUCTS

Dienestrol found, % of Label Claim	
Preparation A: 0.5 mg./Tablet	Preparation B: 0.25 mg./Tablet
96.4	101
95.6	98.4
96.2	101
94.2	99.6
Av. 95.6	Av. 100
Std. Dev. 1.0	Std. Dev. 1.3

TABLE IV—PRELIMINARY STUDY OF SIMULATED TABLET MIXTURES CONTAINING ANDROGENS AND CORTICOSTEROIDS

Compound	Dienestrol Added, Mg.	% Recovery (Av. of 4)	Retention Time, min.
Corticosteroid			
Betamethasone acetate	3.84	98.5	133
Prednisone	3.84	99.4	13,31
Silylated prednisone	...	...	70
Prednisolone	3.84	100.0	20,44
Silylated prednisolone	...	...	107
Hydrocortisone	3.84	99.3	18,40
Silylated hydrocortisone	...	...	97
Desoxycortisone acetate	3.84	97.8	48
Androgen			
Testosterone	4.05	98.5	11.5
Silylated testosterone	...	...	14
Dromostanolone propionate	4.05	98.6	19

A typical chromatogram of a silylated mixture of stearates, dienestrol, alizarin, and methyltestosterone is shown in Fig. 2.

Preliminary experiments using simulated tablet mixtures indicate that the method is applicable in the presence of other androgens, corticosteroids, and stearates, which cause interference in many of the existing methods. The recovery data for dienestrol and the retention times of the various compounds are shown in Table IV.

The bis-(trimethylsilyl)ether of diethylstilbestrol has the same retention time as the bis-(trimethylsilyl)ether of dienestrol, but partially degraded upon injection in the chromatograph. Barbiturates were found to interfere in the silylation reaction.

In view of the results for both simulated mixtures and commercial samples, the proposed procedure appears to be suitable for determination of dienestrol in the presence of methyltestosterone.

New Developments in Antibiotic Interference Thresholds of Microbial Assays

By B. ARRET and J. ECKERT

Interference thresholds have been determined for a number of antibiotics in the microbial assays of specific antibiotics. Two aspects were considered in order to facilitate the quantitative analysis of mixtures of antibiotics: the "interference threshold," which is the concentration of an antibiotic causing a significant interference in the presence of another antibiotic in a given assay, and the "sensitivity threshold," which is the concentration of an antibiotic causing a response in the assay for a different antibiotic.

In 1957, Arret *et al.* (1) described the problems encountered in assaying pharmaceutical preparations in which two or more antibiotics are combined, and proposed solutions to these problems. If the test organism used for the assay of one antibiotic (*a*) is not affected by a second antibiotic (*b*), the assay for (*a*) is uncomplicated. But if the test organism is affected by (*b*), erroneously high or low values for (*a*) may be obtained. Consequently, methods for eliminating the effect of (*b*) were developed. In general, one of the following five methods was used: (*1*) inactivating by biological or chemical means; (*2*) using a test organism which is sensitive to (*a*) and relatively resistant to (*b*); (*3*) artificially making the organism resistant to (*b*); (*4*) separating antibiotics by differential solubility techniques; or (*5*) compensating for the presence of (*b*) by adding it to every solution of (*a*) used for the standard curve.

The analyst needs definite quantitative knowledge of the interfering effects of various antibiotics in certain widely used assay procedures. He must be aware of such effects if confidence is to be maintained in the specificity of an assay.

Since the earlier publication (1), new antibiotics have been discovered, and combinations of these antibiotics together with the older ones make it necessary to update this publication. As before, all the pertinent data are in tabular form for easy reference.

The data obtained from this work simplify the problems of assaying antibiotic combinations Although combinations of two antibiotics have specifically been considered here, the approach can be used as a general guide to the assay of combinations of three or more antibiotics.

[a] All assays are plate methods, except chloramphenicol, streptomycin-*K. pneumoniae*, tetracycline, and viomycin. Streptomycin and dihydrostreptomycin may be considered as acting identically. To find the amount of bacitracin alone which produces an inhibitory zone on *S. aureus* kanamycin plates, find "bacitracin" in the left-hand column headed "Antibiotic Tested" and follow that row horizontally across to the column headed "Kanamycin, *S. aureus*." The fig. "7" indicates that bacitracin alone (7 units/ml.) produces a minimum measurable inhibitory zone.

bination with the reference concentration of (*a*), gave a relative potency [as compared to the reference concentration of (*a*)] of greater than 110% or less than 90% has been termed the "interference threshold." These limits were selected because the 95% confidence range of an average microbiological assay is ±10%. Any assay within this range of theoretical is considered normal variation and any assay beyond this range is considered significant.

The lowest concentration of (*b*) alone which caused a measurable response in the assay procedure of (*a*) is called the "sensitivity threshold."

The interference thresholds and the sensitivity thresholds for the antibiotics and methods tested are given in Tables I and II, respectively.

DISCUSSION

The information given in Table I makes it possible to predict whether the assay of an antibiotic will be complicated by interference from a second antibiotic included in the formulation, which then must be eliminated.

Table II describes the effects of single antibiotics on various assays. The information given in this table can be applied in numerous ways, such as: (*i*) a guide to determine if interference can be expected from different antibiotics in a given assay procedure; (*ii*) a guide to the specificity of the given assay procedure; (*iii*) a means of qualitative identification of unknowns; and (*iv*) selection of an alternative organism for various antibiotics and combinations of them. In dealing with the latter, caution must be exercised, because in many cases the zones are not as clear and well defined as those usually obtained with the original method.

It was noted in many cases that (*b*) alone produced inhibition in the assay for (*a*) at a much lower concentration than that which caused interference when combined with the reference concentration of (*a*). For example (see Table II), 200 mcg./ml. of viomycin will cause inhibition in the penicillin assay without penicillin, but (Table I) more than 500 mcg./ml. of viomycin is necessary to cause interference in the assay with penicillin present. This is due to the fact that assay conditions may be more favorable to (*a*) so that they mask the effect of (*b*). Factors such as pH and ionic strength of the solvent, composition of the nutrient medium, and incubation temperature are significant. Therefore, the data should not be construed to indicate any synergistic or antagonistic relationships.

Conversion of Griseophenone A to (±)-Dehydrogriseofulvin in the Presence of Horseradish Peroxidase and Hydrogen Peroxide

By ALVIN SEGAL and ELMORE H. TAYLOR

The horseradish peroxidase catalyzed conversion of griseophenone A (I) to (±)-dehydrogriseofulvin (V) has been demonstrated. The results support a one-electron oxidative coupling mechanism previously proposed.

Barton and Cohen (1) first suggested that in the biosynthesis of the antibiotic (+)-griseofulvin (VII) (Scheme I), the chlorobenzophenone (I) could conceivably be converted to the spiran, (−)-dehydrogriseofulvin (V), *via* a 1-electron oxidative coupling mechanism proceeding through the formation of the intermediate diradical (III). Chemical synthesis of (±)-V using 1-electron oxidizing agents supports this hypothesis (2–4). The final step was the stereospecific enzymatic reduction of (−)-V to form (+)-VII (5–7).

(+)-Griseofulvin (VII) was first isolated from the mycelium of *Penicillium griseofulvum* (8). It was subsequently shown to be a metabolic product of many species of *Penicillia* (9).

The enzyme peroxidase has been demonstrated to be present in species of *Penicillia* (10), and has been implicated in the biosynthesis of fungal metabolites such as the ergot alkaloids (11). The peroxidase catalyzed O—C oxidative coupling of phenols has been reported (12). In addition, 1-electron transfer mechanisms have been proposed for coupled oxidations involving peroxidase (13). On the basis of this information the authors decided to investigate the possibility of converting I to V *via* peroxidase catalysis.

Received September 18, 1967, from the Department of Pharmacognosy, College of Pharmacy, University of Tennessee, Memphis, TN 38103

Accepted for publication November 15, 1967.

The authors wish to thank Ayerst Laboratories, Inc., New York, N. Y. for their generous donation of griseofulvin, microsize.

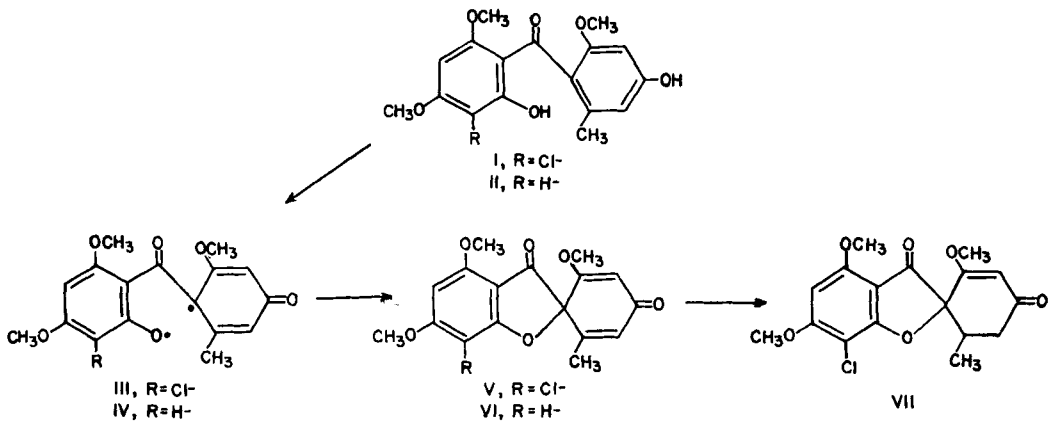
The peroxidase catalyzed O—C oxidative coupling of phenols has been reported (12). In addition, 1-electron transfer mechanisms have been proposed for coupled oxidations involving peroxidase (13). On the basis of this information the authors decided to investigate the possibility of converting I to V *via* peroxidase catalysis.

Received September 18, 1967, from the Department of Pharmacognosy, College of Pharmacy, University of Tennessee, Memphis, TN 38103

Accepted for publication November 15, 1967.

The authors wish to thank Ayerst Laboratories, Inc., New York, N. Y. for their generous donation of griseofulvin, microsize.



Scheme I

EXPERIMENTAL

Melting points were determined on a Leitz Wetzlar apparatus. Infrared spectra were determined in KBr disks using a Perkin-Elmer model 137 Infracord spectrophotometer. Ultraviolet spectra were determined in 95% ethyl alcohol using a Perkin-Elmer model 202 ultraviolet-visible spectrophotometer. NMR spectra were determined in deuteriochloroform solutions with tetramethylsilane as internal standard using a Varian A-60A spectrometer. Optical rotations were measured in acetone solutions using a Carl Zeiss polarimeter. Analytical and preparative thin-layer chromatography (TLC) were performed on plates covered with Silica Gel HF_{254} (Merck). The staining system used was 5% potassium carbonate–0.2% potassium permanganate. Solvent systems used were (*a*) butyl acetate (technical)–acetone, 4:1, and (*b*) chloroform–methanol, 98:2. Column chromatography was performed using Florisil (100–200 mesh) (Fisher Scientific Co., St. Louis, Mo.). Micro-analysis was performed by Schwarzkopf Microanalytical Laboratory, Woodside, N. Y.

(−)-Dehydrogriseofulvin (V)—This substance was prepared essentially following the method of Taub (4). A suspension of 20 Gm. of (+)-VII (m.p. 219–220.5°; pure by TLC analysis using solvent systems *a* and *b*) and 40 Gm. of selenium dioxide in 1.2 L. of *tert*-butanol was refluxed for 65 hr. The hot reaction mixture was filtered through diatomaceous earth[1] and the solvent evaporated at 45° *in vacuo* to yield a red oil. TLC analysis of the reaction mixture with solvent system *a* revealed a series of spots from the origin to the solvent front, indicating a complex mixture, and containing VII (R_f 0.49). The reaction products were suspended in 200 ml. of benzene and chromatographed on a column of Florisil (453 Gm., 77 × 3.7 cm.). The column was eluted with benzene, mixtures of benzene and chloroform, chloroform, and mixtures containing V and VII were then eluted from the column with chloroform–methanol (1–3%). A series of yellow solids (11 Gm.) which remained after evaporation of solvent melted between 260–265°. TLC analysis of the solids with solvent system *a* revealed the presence of V (R_f 0.47) and VII (R_f 0.49), with solvent system *b* the presence of V (R_f 0.65) and VII (R_f 0.68). The presence of VII could be detected (before permanganate oxidation of the plates) by its brilliant blue fluorescence under ultraviolet irradiation. An attempt was made to purify V using preparative TLC (plates 0.5 mm. thick). The product obtained was a white powder which was recrystallized from chloroform–ether and then benzene to yield white crystals, m.p. 276–279° with phase change at 262–263°; $[\alpha]_D^{25}$ −30° (c 0.5); $\lambda_{max.}$ infl. 230 mμ (ε, 25,000); 292 mμ (ε, 35,000); infl. 320 mμ (ε, 7000). [Lit. (4) m.p. 276–279° with phase change at 260°; $[\alpha]_D$ −31.6° (acetone); $\lambda_{max.}$ infl. 230 mμ (ε, 25,000); 292 mμ (ε, 33,000); infl. 320 mμ (ε, 6800).] The infrared spectrum was essentially identical to that reported for (±)-V (14).

Anal.—Calcd. for $C_{17}H_{15}ClO_6$: C, 58.21; H, 4.31. Found: C, 58.31; H, 4.52.

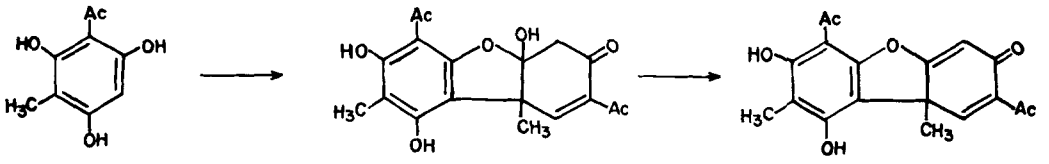
TLC analysis of the purified V (m.p. 277–279°) with solvent system *a* revealed the presence of a single spot (R_f 0.47, V) after permanganate oxidation; ultraviolet irradiation revealed a faint blue fluorescent spot of R_f 0.49 indicating a trace amount of VII. Analysis with solvent system *b* revealed the presence of a single spot (R_f 0.65, V) and ultraviolet irradiation revealed a faint blue fluorescent spot of R_f 0.68, again indicating the presence of a trace amount of VII.

Griseophenone A (I)—The method of Taub (4) was used to convert 800 mg. of (−)-V (m.p. 260–265°) to 280 mg. of I, using the zinc dust–acetic acid procedure. The yellow crystalline product melted at 212–214°; $\lambda_{max.}$ 297 mμ (ε, 18,800); 332 mμ (ε, 6300). [Lit. (4) m.p. 210–212°; $\lambda_{max.}$ 297 mμ (ε, 18,500); 332 mμ (ε, 6200).]

TLC analysis of I with solvent system *a* revealed a single spot of R_f 0.34.

(±)-Dehydrogriseofulvin (V)-From I by Enzymatic Conversion—Griseophenone A (I) (100 mg., 285 μmoles) was stirred in 2 L. of phosphate buffer (pH 7.6) containing 15 ml. of H_2O_2 (0.3%) and 100 mg. of horseradish peroxidase (200 units per mg., Nutritional Biochemical Corp., Cleveland, Ohio). The mixture was left stationary in the dark at 25° for 18 hr. and then extracted with chloroform. The chloroform extract was then concentrated to about 100 ml. and washed twice with 10 ml. of cold 2% KOH to remove 50 mg. of unreacted I. The chloroform solution was then washed with water until neutral and evaporated to dryness. The residue (40 mg.) was dissolved in acetone and streaked on three thick (0.5 mm.) TLC plates which

[1] Celite marketed by Johns-Manville Products Corp., New York, N. Y.



Scheme II

were developed with solvent system *b*. The zone corresponding in location to V was eluted with chloroform–methanol (10%) and evaporation of solvent yielded 29 mg. of a white powder. Recrystallization from benzene yielded 7 mg. of white crystals, m.p. 287–289°. [Lit. (4) m.p. 288–290°.] $[\alpha]_D^{25}$ 0° (c 0.5). The infrared, NMR, and ultraviolet spectra of (±)-V and (−)-V were congruent and (±)-V and (−)-V had identical mobilities by co-chromatography on TLC plates with solvent systems *a* and *b*, (±)-V exhibiting a single spot by ultraviolet irradiation and permanganate oxidation.

RESULTS

(+)-Griseofulvin (VII) was converted to (−)-V by selenium dioxide dehydrogenation and (−)-V was converted to I by reductive cleavage in acetic acid using powdered zinc. Griseophenone A (I) was then converted to (±)-V in a phosphate buffer (pH 7.6) containing horseradish peroxidase and hydrogen peroxide. The reaction did not take place in the absence of peroxidase and/or hydrogen peroxide. The infrared, NMR, and ultraviolet spectra of (−)-V, prepared by chemical means from (+)-VII, and (±)-V, prepared enzymatically from I, were congruent and their mobilities were identical on TLC.

DISCUSSION

The formation of (±)-V was not unexpected as Fales (12) has reported the horseradish peroxidase catalyzed conversion of methylacetylphloroglucinol (VII) (Scheme II), to the racemates, benzofuran derivative (IX), and usnic acid (X). Fales in fact reports the formation only of racemates from oxidative couplings in peroxidase systems.

The formation of racemic dehydrogriseofulvin (V) suggests the possibility that another enzyme(s) (including other peroxidases) could be involved in the *in vivo* conversion of I to (−)-V. On the other hand, it is possible that *in vivo*, peroxidase catalyzes the conversion of II to an optically active VI *via* IV, and that VI is then chlorinated to form (+)-VII. While considerable evidence exists that chlorination of II occurs in the biosynthesis of (+)-VII (15), nevertheless it has been shown that chlorination of a spiran can occur as in the biosynthesis of geodin (16).

More Convenient Syntheses of o-Azidobenzaldehyde and 2-Substituted Indazoles

By THOMAS J. SCHWAN* and CHARLES S. DAVIS†

Improved syntheses of o-aminobenzaldoxime, o-azidobenzaldehyde, and 2-substituted indazoles are described. An unequivocal synthesis of 2-(2-dimethylaminoethyl)indazole is reported.

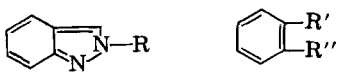
Because a series of 2-substituted indazoles (I) was desired for pharmacological evaluation, synthetic routes to these compounds were investigated. Recently there was reported the synthesis of 2-arylindazoles by the thermal decomposition in polychlorobenzenes of *o*-azidobenzylidene amines (II), which were prepared by condensation of *o*-azidobenzaldehyde (III) with the appropriate amines (1). The preparation of III by nitrous acid treatment of *o*-aminobenzaldoxime (IV) was previously reported by Bamberger and Demuth (2). Although Bamberger readily obtained IV from the aminoaldehyde (V) the synthesis of V from the nitroaldehyde (VI) required voluminous quantities of reactants and solvents. Hence, a route to large quantities of IV was sought.

Hydrogenation of *o*-nitrobenzaldoxime (VII) to IV without concomitant reduction of the oxime function was conveniently effected with 5% palladium-on-carbon in 70% yield.

Although difficulty was initially encountered in converting IV to III, it was found that III could more easily be isolated by extraction rather than by the steam distillation method reported previously (2).

Condensation of III with aniline or 2-dimethylaminoethylamine in dimethylformamide gave the intermediate Schiff base II which was not isolated by being thermally decomposed to the indazole I in refluxing dimethylformamide. This route to I allows the reaction mixture to be poured into water; the product is then easily isolated by filtration or extraction. Hence the use of water-insoluble, nonvolatile polychlorobenzenes is avoided; furthermore, isolation of the Schiff base is unnecessary.

The dimethylaminoethyl derivative (*Ib*), thus obtained, confirmed the structural assignment of Jao and Shchukina (3), who synthesized *Ib* and its 1-substituted isomer by the equivocal method of alkylating indazole with 2-dimethylaminoethyl chloride.



Ia R = C_6H_5
Ib R = $(CH_3)_2N(CH_2)_2$

II R′ = CH=N—R, R″ = N_3
III R′ = CHO R″ = N_3
IV R′ = CH=NOH, R″ = NH_2
V R′ = CHO, R″ = NH_2
VI R′ = CHO, R″ = NO_2
VII R′ = CH=NOH, R″ = NO_2

EXPERIMENTAL[1]

o-Aminobenzaldoxime (IV)—A mixture containing 97 Gm. (0.58 mole) of VII (4), 22 Gm. of 5% palladium-on-carbon (50% moisture), and 1600 ml. of ethanol was stirred with hydrogen at atmospheric pressure for 30 min., the temperature being maintained between 25 and 35° during the hydrogenation. Removal of the catalyst followed by evaporation of the solvent gave the crude product. Recrystallization from toluene gave 63 Gm. (79%) of IV, m.p. 136–136.5° [lit. (2) m.p. 132–133°].

o-Azidobenzaldehyde (III)—To a cooled stirred suspension of 4.08 Gm. (0.03 mole) of IV in 30 ml. of concentrated hydrochloric acid was added a solution of 2.28 Gm. (0.033 mole) of sodium nitrite in 4 ml. of water at 0–5°. To the solution was added 25 ml. of water followed by 60 ml. of 25% aqueous sodium hydroxide at 15–20°. The mixture was stored at room temperature for 16 hr., extracted with ether (3 × 75 ml.), the extracts dried ($MgSO_4$), and concentrated to dryness to give the crude product. Crystallization from hexane gave 2.35 Gm. (53%) of III, m.p. 29–34° [lit. (2) m.p. 35–37°].

2-Phenylindazole (Ia)—A solution of 1.47 Gm. (0.01 mole) of III, 1.03 Gm. (0.011 mole) of aniline, 0.1 Gm. of glacial acetic acid, and 20 ml. of dimethylformamide was stirred at 90–100° for 2 hr. and then refluxed for 30 min. After the mixture was cooled and poured into 400 Gm. of ice water, the product was collected and recrystallized from hexane to give 1.08 Gm. (56%) of *Ia*, m.p. 81–83° [lit. (1) m.p. 82–83°].

2-(2-Dimethylaminoethyl)indazole Dihydrochloride (Ib)—A solution of 3.11 Gm. (0.021 mole) of III, 2.21 Gm. (0.024 mole) of 2-dimethylaminoethylamine, 0.1 Gm. of glacial acetic acid, and 20 ml. of dimethylformamide was stirred at 90–100° for 2 hr. and then refluxed for 45 min. After the mixture was poured into 400 Gm. of ice water, the resulting solution was extracted with ethyl acetate (3 × 100 ml.), the extracts dried ($MgSO_4$), and concentrated to dryness *in vacuo*. Treatment of the free base with methanolic hydrogen chloride gave 2.63 Gm. (48%) of white crystals. Recrystallization from methanol gave the analytical sample, m.p. 181–191° [lit. (3) m.p. 171–181°]; the ultraviolet spectrum was identical to that reported for *Ib* (3).

Anal.—Calcd. for $C_{11}H_{15}N_3 \cdot 2HCl$: C, 50.39; H, 6.54; Cl, 27.04; N, 16.20. Found: C, 50.01; H, 6.63; Cl, 26.89; N, 16.00.

The *picrate* was prepared quantitatively from *Ib* and picric acid in ethanol; m.p. 241–243° dec. [lit. (3) 235° dec.].

Solubilization of Aminopteridines

By MILTON LAPIDUS

Aqueous solutions of a series of aminopteridines (5–10 mg./ml.) stable at physiologic pH's were prepared either by salt formation with hydrochloric acid or by complex formation with 10 percent deoxyribonucleic acid. Deoxyribonucleic acid was superior to ribonucleic acid, crystalline bovine serum albumin, human serum albumin fraction V, or gum acacia in solubilizing 4,7-diamino-2(*p*-chlorophenyl)-*N*-(2-diethylaminoethyl)-6-pteridinecarboxamide at pH 7. Potentiometric titration detected complex formation between deoxyribonucleic acid and the above aminopteridine.

In the course of preparing injectable solutions of a number of aminopteridines it was observed that very few in the series under investigation were appreciably soluble in water. The general lack of aqueous solubility of substituted pteridines has been reported as being due to substituted polar groups (OH, SH, and NH_2) (1). Pteridine (unsubstituted) was reported as being highly soluble (1 part in 7.5 parts of water at 20°).

Although classic salt formation has been used successfully to solubilize aliphatic amines, this method has limited applicability to weakly basic aminopteridines. The apparent acid solubility of triamterene (2,4,7-triamino-6-phenylpteridine) is reversed as the pH is raised to 7 (2).

Complex formation has been reported to increase the aqueous solubility of small molecules (3–5). Speculation that deoxyribonucleic acid, ribonucleic acid, serum proteins, and gum acacia may form aminopteridine complexes with enhanced solubility characteristics stimulated this study.

EXPERIMENTAL

The aminopteridines studied were synthesized by Osdene *et al.* (6, 7). Deoxyribonucleic acid-sodium (DNA-Na), ribonucleic acid-sodium (RNA-Na), and crystalline bovine serum albumin (BSA) were purchased from Nutritional Biochemical Corp., Cleveland, Ohio; human serum albumin (HA) fraction V from Pentex, Inc., Kankakee, Ill.; and USP gum acacia from S. B. Penick and Co., New York, N. Y. The standard reagents used were the best grades commercially available.

Analysis of Wy-4029—Wy-4029 [4,7-diamino-2-(*p* - chlorophenyl) - *N* - (2 - diethylaminoethyl) - 6-pteridinecarboxamide] in 0.1 *N* sulfuric acid fluoresces at 445 mμ when activated at 390 mμ. Using the Aminco Bowman spectrophotofluorometer, a linear response was obtained in the concentration range of 2–9 mcg./ml.

pH of Complete Solubility and Solubility Reversal—To 25 mg. of each of the aminopteridines suspended in 50 ml. of water increments of 1 *N* HCl were added until the soluble end point was reached. The pH was monitored with a Beckman pH meter, and pH equilibrium was established after the addition of each increment of acid. Back titration with 0.1 *N* sodium hydroxide resulted in the end point of solubility reversal.

pH Solubility Profile of Wy-4029—To a series of 500-mg. samples of Wy-4029 suspended in 20 ml. of water were added varying amounts of concentrated hydrochloric acid to obtain a constant pH of 3, 4, 5, 6, or 7. The contents of each beaker was stirred for 1 hr. at 25°. The mixtures were then filtered through a 0.45-μ Millipore filter (the standard method subsequently used) and the concentration of Wy-4029 in the filtrate was determined.

Potentiometric Evidence of Complex Formation—Solutions of Wy-4029 (50 mg./100 ml.), DNA-Na (1 Gm./100 ml.), and Wy-4029 (50 mg./100 ml.) plus DNA-Na (1 Gm./100 ml.) were adjusted to pH 3.5 with 1 *N* hydrochloric acid and titrated with 0.1 *N* sodium hydroxide, pH equilibrium being established after each addition of alkali.

Stability of Macromolecule–Aminopteridine Complex—To 25 mg. of each of the aminopteridines was added 50 ml. of a 1% solution of DNA-Na (pH 2.5), and the mixtures were triturated in a Potter-Elvehjem homogenizer until soluble (5 min.). Increments of 0.1 *N* sodium hydroxide were slowly added, pH equilibrium being established after the addition of each increment. The pH at which turbidity occurred was considered the end point of solubility reversal.

Effect of Concentration and pH of Macromolecules on Wy-4029 Solubility—To various concentrations of DNA-Na (pH 5.0), RNA-Na (pH 2.8), HA (pH 4.9), BSA (pH 5.1), and USP gum acacia (pH 4.4) in 20 ml. of water was added an excess (50–400 mg.) of Wy-4029. The mixtures were

triturated in a Potter-Elvehjem homogenizer for 5 min., stirred an additional 2 hr., adjusted to pH 7, filtered, and the concentrations of Wy-4029 determined.

Effect of Initial pH of the Macromolecule Solution on Solubility of Wy-4029—To 20 ml. of 5% solutions of DNA-Na, RNA-Na, gum acacia, and BSA adjusted with 1 *N* hydrochloric acid or 1 *N* sodium hydroxide to pH's varying from 2 to 8 was added an excess (100–400 mg.) of Wy-4029. The mixtures were triturated in a Potter-Elvehjem homogenizer for 5 min., stirred an additional 2 hr., adjusted to pH 7, filtered, and the concentrations of Wy-4029 determined.

Preparation of Wy-4029–DNA Solution—This solution as prepared by adding 10 Gm. of DNA-Na to 90 ml. of water, adjusting to pH 3.5 with dilute hydrochloric acid, making up to 100 ml., and clarifying by centrifugation at 6,000 r.p.m. for 15 min. Wy-4029 (1 Gm.) was added and complete solubility was attained by trituration in a Potter-Elvehjem glass homogenizer. Each prepared solution was vigorously stirred and slowly adjusted to pH 7 with dilute sodium hydroxide, then either sterile-filtered through a 0.45-μ Millipore filter and stored in ampules or lyophilized and stored as a powder. This powder was readily reconstituted by the addition of water.

RESULTS AND DISCUSSION

The aminopteridines investigated were all solubilized by classic salt formation (0.5 mg./ml.) with 0.1 *N* hydrochloric acid. By allowing pH equilibrium after the addition of each increment of acid, it was possible to arrive at the pH at which aqueous solubility was achieved. The compounds varied considerably in solubility pH (Table I). The individual values probably reflect the relative basicity: the weaker this basicity, the greater the difficulty of forming classic salts and the lower the pH required for solubilization.

Reversal of the apparent acid solubility of the aminopteridines, accomplished by the addition of sufficient 0.1 *N* sodium hydroxide, also occurred over a rather wide pH range (Table I). A number of aminopteridines remained soluble at 0.5 mg./ml. and pH 7.4, and for these compounds it was predicted that higher concentrations would be stable. Solutions of aminopteridines (10 mg./ml.) were then prepared by solubilization with hydrochloric acid and adjustment to pH 7.4 with alkali (Table I, footnote *c*).

To determine the effect of DNA on aminopteridine solubility, a 1% solution of DNA-Na (pH 2.5) containing 0.5 mg./ml. of an aminopteridine in solution was titrated with 0.1 *N* sodium hydroxide until solubility reversal occurred. In every example the rever-

[a] Aminopteridine, 25 mg./50 ml. water. [b] Aminopteridine, 25 mg./50 ml. of a 1% solution of DNA-Na. [c] Solubilized by salt formation, 10 mg./ml. pH 7.4. [d] Solubilized by complex formation, 5 mg./ml. in 10% DNA, pH 7.0. [e] Solubilized by complex formation, 10 mg./ml. in 10% DNA, pH 7.4. [f] Solubilized by complex formation, 5 mg./ml. in 10% DNA, pH 6.5.

sal occurred at a higher pH than had previously been determined for solutions prepared by classic salt formation (Table I). The 0.7–4.5 unit upward extension of the pH solubility range suggested the concomitant utility of complex formation by DNA as well as other macromolecules for preparing stable solutions of aminopteridines at higher concentrations than was previously possible. As shown in Table I, some aminopteridines cannot be solubilized at 10 mg./ml. and pH 7.4, probably because they are weakly basic and do not form stable hydrochlorides. Wy-4029, representative of this group, has limited solubility at pH 7 (Fig. 1). The concentration of Wy-4029 in solution was increased considerably by complex formation with macromolecules. Solutions of DNA-Na (pH 5), RNA-Na (pH 2.8), HA fraction V (pH 4.9), BSA (pH 5.1), and gum acacia (pH 4.4) at their respective natural pH's were effective in solubilizing Wy-4029 and in maintaining concentrations at pH 7 previously not considered possible (Fig. 2). Since the pH of the macromolecule solution is a variable in determining the amount of aminopteridine solubilized, a pH-solubility profile study of 5% solutions of DNA-Na, RNA-Na, BSA, and gum acacia was made. For each of the macromolecules an optimum pH for maximum solubility of Wy-4029 was determined (Fig. 3). The anticipated superiority of DNA-Na in solubilizing Wy-4029 was confirmed.

The potentiometric evidence of complex formation between Wy-4029 and DNA-Na was provided by three distinct alkali titration curves (Fig. 4) (8). Complex formation existed up to approximately pH 9. DNA-Na maintained the solubility of Wy-4029 above the pH at which solubility by salt formation failed.

A solution of Wy-4029 solubilized in 10% DNA-Na at pH 3.5 (10 mg./ml.) and then adjusted to pH 7.4 was found to be stable at 4° and 25° for a minimum of 3 months. A lyophilized powder prepared from a freshly made solution was readily reconstituted in water.

A toxicity evaluation of the aminopteridines and aminopteridine–DNA complexes (1 mg./mouse) demonstrated the protective effect of DNA in preventing skin lesions in mice at the subcutaneous site

Wy-4029 was solubilized initially at the given natural pH (shown in parentheses) of each of the macromolecules.

of injection. Dissection of the subcutaneous site failed to reveal the depot of aminopteridine usually found after injecting an aqueous solution. It seems reasonable to assume that transport of the aminopteridine away from the site of injection is accelerated when it is complexed with DNA.

Gas Chromatographic Determination of Anagestone Acetate in Fertility Control Tablets

By ARVIN P. SHROFF and R. E. HUETTEMANN

A gas-liquid chromatographic technique has been developed for the determination of anagestone acetate in tablets. A 3 percent DEGS column gave good resolution between the peaks of anagestone acetate and internal standard. The accuracy and the precision of the method are 1.97 and 0.052, respectively. Anagestone acetate does not undergo any alteration after 18 months of storage.

THE INCREASING awareness of the population "explosion" has stimulated the development of a number of oral contraceptive agents. Estrogen-progestin combinations are widely used for this purpose. Of the seven U. S. companies which offer eleven different dosage forms, the choice of estrogen is between either 17-α-ethynylestradiol (EE) or 17-α-ethynylestradiol 3-methylether (MEE). The progestational agents, however, vary in their chemical structure but they fall into two main classes. The members of one class are characterized by the absence of the C-19 methyl group and are designated as "19-nor" compounds. The other group is characterized by modification of the basic progesterone structure with different types of substitutions to form the so-called "substituted" progestins.

Estrogens in the presence of some of these progestins have been assayed by colorimetric (1, 2), ultraviolet (3), spectrofluorometric (4), and gas-liquid chromatographic (3, 5, 6) methods.

Similarly, the progestational agents of the "19-nor" and "substituted" progestin classes have been quantitated by various analytical techniques. For example, Bastow quantitated 17-α-hydroxy-19-nor-17-pregn-5(10)-en-20-yn-3-one (norethynodrel) with an ultraviolet spectrophotometric technique (7) and France and co-workers used GLC for 6-α-methyl-6-dehydro-17α-acetoxyprogesterone (6).

In the present investigation we describe the gas-liquid chromatographic determination of a new "substituted" progestin 3-desoxy-17 α-acetoxy-6-α-methylpregn-4-en-20-one(I) (anagestone acetate), in the presence of MEE (II). The determination was carried out on a 3% DEGS coated column using MEE as an internal standard. The steroids do not undergo any decomposition on the stainless steel column when proper conditions are maintained and MEE can be separated without prior acylation or trimethylsilyl etherification.

EXPERIMENTAL

Apparatus and Operational Parameters—An F&M model 1609 instrument equipped with a hydrogen flame-ionization detector and modified injection port was employed. The modified injection port was made by F&M Scientific to eliminate the potential for inlet sample splitting. The recorder was a Minneapolis Honeywell "Electronik" with a 1-mv. full-scale deflection and was operated at a chart speed of 15 in./hr. A coiled stainless steel column 39.4 in. long and 1/4 in. i.d. packed with 3% DEGS on Gas Chrom Z (100–120 mesh) was used. The column packing was prepared by the evaporation technique. The packed column was conditioned at 215° for 24 hr. with nitrogen flowing at 63 ml./min. All samples were injected by means of a 10-μl. Hamilton syringe. The operational parameters were: column temperature 215°; inlet-port temperature 235°, and detector temperature 250°. Nitrogen was used as a carrier gas flowing at 65 ml./min. Oxygen and hydrogen were maintained at about 400 ml./min. and 45 ml./min., respectively.

Standard MEE Solution—Weigh accurately 300 mg. of reference standard MEE (E 1%, 1 cm. 60–65) into a 100-ml. volumetric flask and dilute to mark with methylene chloride.

Standard Anagestone Acetate Solution—Place exactly 100 mg. of anagestone acetate into a 100-ml. volumetric flask and dilute to mark with methylene chloride.

Preparation of a Typical Standard Curve—Pipet into three different vials 1.0 ml., 2.0 ml., and 3.0 ml., of the standard anagestone acetate solution and evaporate to dryness on a steam bath and under a stream of nitrogen. Dissolve each residue with 1.0 ml. of standard MEE solution (internal standard) and inject approximately 2 μl. into the gas chromatograph. Adjust the attenuator to 320 and elute for 20 min. The first major peak is attributed to anagestone acetate and the second major peak to MEE. The areas are calculated, after drawing a tangent to both minima of each peak, by multiplying the height of the peak by the width at one-half the peak height. A plot of the ratios of areas under anagestone acetate and MEE *versus* the weight of anagestone acetate is obtained and a best straight line drawn. All the points on the curve are obtained in triplicate.

Analysis of Tablets—Two tablets (2 mg. anagestone acetate and 80 mcg. MEE per tablet) equivalent to 4.0 mg. of anagestone acetate are placed in a 21 × 50-mm. vial and treated with 2.0 ml. of distilled water and 2.0 ml. of cyclohexane. The vial is clamped to a Burrell wrist-action type shaker and allowed to shake vigorously for 0.5 hr., then centrifuged for 1 min. and 1.0 ml. of the upper phase is pipeted into another 21 × 50-mm. vial. This solution is evaporated on a steam bath and under a stream of nitrogen. The residue thus obtained is redissolved in 1.0 ml. of standard MEE solution (internal standard) and a 2-μl. injection made into the gas chromatograph. The attenuation and calculations are similar to "preparation of typical standard curve." The amount of anagestone acetate is obtained from the standard curve.

DISCUSSION AND RESULTS

Theoretically each combination tablet contains 2 mg. of anagestone acetate and 80 mcg. of MEE along with other excipients of the tablet. The anagestone acetate present is 25 times in excess of the MEE.

The efficiency of using MEE as an internal stan-

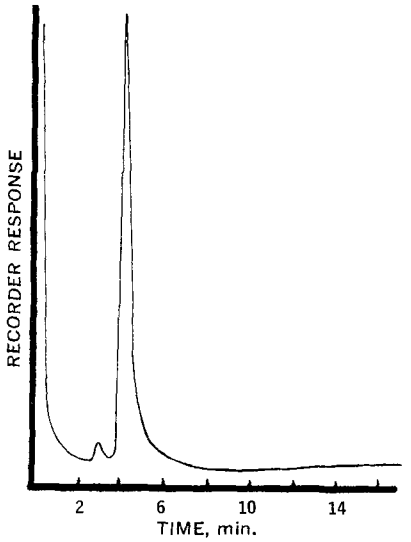

Fig. 1—Gas chromatogram of an extract from combination tablet showing dihydro derivative and anagestone acetate.

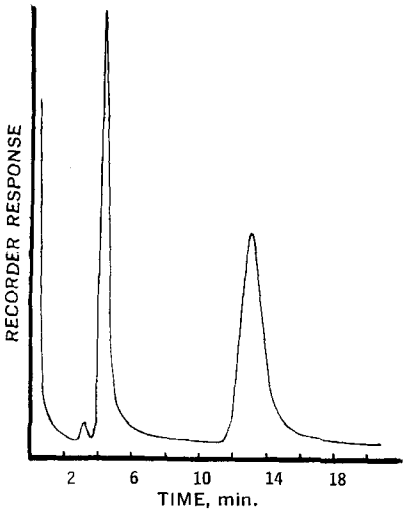

Fig. 2—A typical gas chromatogram of a tablet extract to which internal standard (MEE) has been added.

dard was checked by extracting two tablets with water–cyclohexane and following the procedure outlined in the experimental section but omitting the internal standard. A typical gas chromatogram of an extract from combination tablets is shown in Fig. 1. The small peak preceding the major anagestone acetate peak is attributed to a dihydro derivative of anagestone acetate (a synthetic by-product). The peak response for MEE (see Fig. 2 for retention time) was negligible, if any, with the attenuation used. The gas chromatogram of material extracted from tablets to which the internal standard (MEE) was added is shown in Fig. 2. The internal standard does not interfere with detection of anagestone acetate and the resolution between the peaks is good.

The MEE showed no decomposition to estrone methyl ether on a freshly prepared column. However, if the column packing was not prepared properly, then after a few days and, at times, after conditioning the column decomposition became apparent. The peak for estrone methyl ether appeared between anagestone acetate and MEE (Fig. 3) and it was found that this decomposition did not vary with time. Thus, by preparing a fresh calibration curve the column can be used effectively. Routinely we have found the method to be independent of the volume of the injected sample and independent of small variations in column temperature and gas flow.

The Analgesic, Hypothermic, and Depressant Activities of Some *N*-Substituted α-5,9-Dimethyl-6,7-benzomorphans

By M. MAY, L. CZONCHA, D. R. GARRISON, and D. J. TRIGGLE

A series of *N*-substituted α-5,9-dimethyl-6,7-benzomorphans bearing *N*-2-hydroxyalkyl and *N*-2-bromoalkyl substituents have been synthesized and their analgesic, hypothermic, and depressant activities determined. The analgesic activities were not outstanding but the *N*-2-bromoethyl- and the *N*-2-bromopropyl derivatives produced prolonged hypothermia and depression. Possible mechanisms of these prolonged actions are discussed.

It is generally assumed that narcotic analgesics produce their pharmacological effects by interaction at a specific analgesic receptor (or receptors). Extensive work by Beckett and co-workers (1, 2) has resulted in the publication of a tentative description of the analgesic receptor. This description has recently been critically discussed by Portoghese (3) who points out that the analgesic receptor may be more flexible in its binding capability than Beckett originally assumed. Nevertheless, both Beckett and Portoghese assume that one of the principal binding sites at the analgesic receptor is an anionic grouping which is capable of binding, *via* an ion–ion interaction, a protonated amino group of the analgesic molecule.

An anionic binding site (a carboxylate or phosphate anion) is also assumed to be an important fea-

This work was supported by grants from the United States Health Foundation of Western New York (G-65-UB-3) and the U. S. Public Health Service (GM11603) with supplemental assistance from NASA (grant No. NGR-33-015-016).

ture of the structure and function of the adrenergic and cholinergic receptors (4–6), and since it has proved possible to design antagonists which act at these receptors by forming covalent bonds to these anionic sites (4, 7, 8), it appeared of interest to extend this approach to the design of compounds that might interact irreversibly at the narcotic analgesic receptors. This approach, if successful, would yield information valuable in attempted identification of the receptor site(s) and, additionally, might furnish compounds of considerable therapeutic importance.

In this initial approach, the compounds selected for study were *N*-(2-bromoethyl) derivatives (I*b*–III*b*) of α-5,9-dimethyl-6,7-benzomorphan,

I(*a*) X = OH, R = H, (*b*) X = Br, R = H
II(*a*) X = OH, R = CH_3, (*b*) X = Br, R = CH_3
III(*a*) X = OH, R = Ph, (*b*) X = Br, R = Ph

together with their corresponding nonalkylating parent compounds (I*a*–III*a*). *N*-Methyl-α-5,9-dimethyl-6,7-benzomorphan was employed as an appropriate "standard" analgesic compound (7).

EXPERIMENTAL

Chemistry—Melting points were recorded on a Thomas-Kofler hot stage and are corrected. Analyses are by Dr. A. E. Bernhardt, Mulheim, West Germany.

***N* - Methyl - α - 5,9 - dimethyl - 6,7 - benzomorphan**—This was prepared by the method of May and Fry (9). The hydrochloride salt had m.p. 204° [lit. [9] m.p. 203–204°]. The hydrobromide salt was recrystallized from acetone and had m.p. 188–190°.

Anal.—Calcd. for $C_{15}H_{22}BrN$: C, 60.83; H, 7.48; Br, 26.97. Found: C, 60.91; H, 7.22; Br, 27.11.

***N* - (2 - Hydroxyethyl) - α - 5,9 - dimethyl - 6,7-benzomorphan Hydrobromide (Ia)**—To α-5,9-dimethyl-6,7-benzomorphan (10) (4.1 Gm., 0.02 mole) in methanol (20 ml.) was added ethylene oxide (1.3 Gm., 0.03 mole) and the solution was heated to 100° in a steel bomb for 6 hr. On cooling the solution was saturated with hydrogen bromide gas, evaporated under reduced pressure, and the residue dissolved in dry acetone. On cooling crystals of I*a* (74%) were deposited with m.p. 210–212°.

Anal.—Calcd. for $C_{16}H_{22}BrNO$: C, 58.9; H, 7.42; Br, 24.49; N, 4.29. Found: C, 59.21; H, 7.17; Br, 24.41; N, 4.51.

***N* - (2 - Bromoethyl) - α - 5,9 - dimethyl - 6,7-benzomorphan Hydrobromide (Ib)**—I*a* (3.3 Gm., 0.01 mole) suspended and stirred in chloroform (20 ml.) at 0° was treated dropwise with a solution of phosphorus tribromide (3.0 Gm., 0.011 mole) in chloroform (10 ml.). The mixture was then refluxed for 4 hr., evaporated under reduced pressure, and the orange residue extracted with boiling acetone (3 × 15 ml.) and filtered through diatomaceous earth. On cooling the filtrate yielded crystals of I*b*, (82%) which were recrystallized (acetone) to a constant m.p. of 195°.

Anal.—Calcd. for $C_{16}H_{23}Br_2N$: C, 49.38; H, 5.96; Br, 41.1. Found: C, 49.61; H, 5.71; Br, 40.83.

***N* - (2 - Hydroxypropyl) - α - 5,9 - dimethyl - 6,7-benzomorphan Hydrobromide (IIa)**—This was prepared from α-5,9-dimethyl-6,7-benzomorphan and propylene oxide using the procedure described for I*a*. The product had m.p. 208–215° (82%).

Anal.—Calcd. for $C_{17}H_{26}BrNO$: C, 59.99; H, 7.7; Br, 23.48; N, 4.11. Found: C, 60.15; H, 7.31; Br, 23.52; N, 3.98.

***N* - (2 - Hydroxy - 2 - phenylethyl) - α - 5,9-dimethyl-6,7-benzomorphan Hydrobromide (IIIa)**—This was prepared similarly from α-5,9-dimethyl-6,7-benzomorphan and 1,2-epoxyethylbenzene. The product had m.p. 225–235° (92%).

Anal.—Calcd. for $C_{22}H_{28}BrNO$: C, 65.63; H, 7.02; Br, 19.86. Found: C, 65.82; H, 6.77; Br, 19.76.

***N* - (2 - Bromopropyl) - α - 5,9-dimethyl - 6,7-benzomorphan Hydrobromide (IIb)**—This was prepared from II*a* and phosphorus tribromide using the procedure described under I*b*. The product had m.p. 180–190° (78%).

Anal.—Calcd. for $C_{17}H_{25}Br_2N$; C, 50.61; H, 6.25; Br, 39.64; N, 3.47. Found: C, 50.79; H, 6.51; Br, 39.34; N, 3.50.

***N* - (2 - Bromo - 2 - phenylethyl) - α - 5,9 - dimethyl-6,7-benzomorphan Hydrobromide (IIIb)**—This was prepared similarly from III*a* and phosphorus tribromide. The product had m.p. 168–175° (89%).

Anal.—Calcd. for $C_{22}H_{27}Br_2N$: C, 56.76; H, 5.85; Br, 34.34; N, 3.01. Found: C, 56.41; H, 6.13; Br, 34.33; N, 3.21.

PHARMACOLOGY

Analgesic activity (Table I) was determined using the Eddy-Leimbach modification (11) of the hot-plate method devised by Woolfe and Macdonald (12). Compounds were administered subcutaneously in 0.1 ml. of water. Swiss albino male mice (weight 20–30 Gm.) were employed, 10 animals each dose, and an increase of 10 sec. or more in reaction time from the pretreatment time was taken as an analgesic response (see under *Discussion*).

Spontaneous motor activity (Table II) was mea-

sured using a Lehigh Valley Electronics activity cage (model 1497). The compounds were administered subcutaneously to male mice which were placed immediately in the cage and the locomotor activity determined from the fifteenth to the thirtieth and from the thirtieth to the sixtieth min. Locomotor activity was again determined 24 hr. later. Control animals were treated similarly but received only an equivalent amount of injected water. Locomotor activity of treated mice is expressed as a percentage of the activity of control mice.

Rectal temperatures (Table III) were taken with an Electric Universal thermometer using male mice. Control animals received an equivalent injection of water only. A statistical analysis revealed the significance of the difference in temperature between treated and control mice. In some experiments the effects of prior administration of *N*-methyl-α-5,9-dimethyl-6,7-benzomorphan on the hypothermic and depressant activities of *Ib* and *IIb* were determined. These results are summarized in the bottom columns of Tables II and III.

DISCUSSION

The analgesic activities of compounds I–III listed in Table I are not outstanding, but it is relevant to note that the differences in each pair of compounds (*a* and *b*) are such as to preclude the possibility that hydrolysis of the 2-bromoethylamine to the 2-hydroxyethylamine is a prerequisite for analgesic activity. However, it is not entirely clear to what extent the effects of *Ib* and *IIb* listed in Table I are due to analgesic or to depressant actions since mice receiving these compounds were found to be profoundly depressed. *Ib* and *IIb* were shown to produce a severe reduction in the locomotor activity of mice (Table II) which, in the case of *IIb*, was still pronounced 24 hr. after administration. None of the other compounds listed in Table I produced depression, indeed, *N*-methyl-α-5,9-dimethyl-6,7-benzomorphan (standard) produced an increase in locomotor activity. These results are in general agreement with the data of Table I which show that compounds *Ia*, *IIa*, and *IIIa* are closely similar to *N*-methyl-α-5,9-dimethyl-6,7-benzomorphan with respect to times of onset and duration of action and thus probably are exhibiting a genuine analgesic effect, whereas *Ib* and *IIb* exhibit a delayed onset and prolonged duration of "analgesic action" which may, in fact, be attributed to depression rather than to true analgesia.

The prolonged depressant actions of *Ib* and *IIb* were also accompanied by severe and prolonged decreases in body temperature (Table III). The onset and duration of the hypothermia paralleled approximately the depressant actions. It is particularly interesting to note that only compounds *Ib* and *IIb* produced hypothermia and that the other compounds listed in Table I had no significant effect on body temperature.

The mechanisms by which *Ib* and *IIb* produce their prolonged effects remain to be elucidated. Since the alcohols (*Ia* and *IIa*) corresponding to *Ib* and *IIb* are devoid of both depressant and hypothermic activities, it is possible that the prolonged duration of pharmacological activity of *Ib* and *IIb* is due to alkylation, by the derived ethyleniminium ions, of specific sites in the CNS concerned with motor and temperature regulation. In order for this to occur, these compounds must enter the CNS: it is pertinent in this connection to note that *IIIb*, which will cyclize very rapidly to a quaternary ethyleniminium ion (14) probably incapable of entering the CNS, is devoid of pharmacological activity. Compounds *Ib* and *IIb* will be significantly less reactive (14) and thus may enter the CNS before cyclization to the ethyleniminium ion takes place. Alternatively, *Ib* and *IIb* may be slowly metabolized to an active product which is neither rapidly metabolized nor excreted and hence produce prolonged activity. McMahon *et al.* (15) have demonstrated, for example, that α-(−)-acetylmethadol is slowly metabolized to the active product α-(−)-noracetylmethadol the analgesic effects of which are fairly prolonged. However, the present work does not serve to distinguish either of these possibilities.

The pretreatment studies (Tables II and III, bottom columns) offer some evidence that the spectrum of activities of *N*-methyl-α,5,9-dimethyl-6,7-benzomorphan and *Ib* and *IIb* are different, since the depressant and hypothermic effects were not reduced by prior administration of the standard compound, as might have been expected had all three compounds acted at a common receptor site.

Titration of Residual Moisture in Lyophilized Vials

By EDGAR E. THEIMER and JOSEPH J. PAVELEK

Karl Fischer titration of residual water in lyophilized vials can be performed very simply, without specialized equipment, and gives results which are more reliable than loss-on-drying methods.

IN THE determination of moisture, the Karl Fischer (K.F.) titrimetric method presents many advantages over the weight-loss-on-drying method. The literature abounds with comparative studies, most of which favor the K.F. method. Levy, Murtaugh, and Rosenblatt (1) titrated water in penicillin vials, assuming a zero blank. Wiberley (2) stressed the use of micro-equipment and introduced some improvements intended to broaden the use of the K.F. reagent. Burger and Polderman (3) used similar technique in some precise work on effect of lyophilizing conditions on residual water, using mannitol, *etc.* For lyophilized proteinaceous preparations, Sobel (4) suggested a colorimetric procedure, and Alajos (5) devised a special two-chambered vial for extraction of water and subsequent K.F. titration, to prevent direct contact of K.F. reagent with the protein.

Figure 1 depicts a vial containing a lyophilized mixture of 100 mg. of mannitol and 20 mg. of acetylcholine chloride.[1] It was desired to set up a specification limiting the water content of these vials in production batches. The primary aim of this study was to devise a simple quantitative test for water, of reasonable precision, without the use of specialized apparatus, and as free as possible from sources of error.

The first test method used involved drying in a vacuum oven to constant weight. Since it seemed likely that the rubber center seal might lose some weight during this treatment, similar blank vials were simultaneously treated and a correction applied. After further trials, it became evident that this correction value was variable, sometimes becoming as large as 0.6 mg. Also, it was found difficult to prevent weight gain between drying and weighing. Another difficulty was the need for microweighing technique in handling relatively large vials. In addition, there was some evidence that slight differences in drying temperature gave different results. In order to deal with these difficulties, various rather awkward dodges were devised, including weighing the vials while still hot, withdrawing and discarding the center seal, and pairing of samples with individual blank vials, but eventually a different water determination method was sought.

The technique in the following method is simple and probably free from important sources of error. It does not involve the use of a magnetic stirrer, titrating vessel with special cover, or humidity-controlled work chamber, nor special drying of the diluent, methanol. In the case dealt with here, with the white background afforded by the methanol-insoluble mannitol, the end point can be detected visually when strong K.F. reagent is used and no electrometric equipment is needed. By using the vial as titrating vessel, it is possible to avoid sample transfer and exposure to the atmosphere. Also, the vial being designed to allow penetration of the stopper with a hypodermic needle for withdrawing the contents without exposure to the atmosphere, a hypodermic needle can be similarly used for addition of K.F. reagent. These advantages are important because the amount of water determined is less than 1 mg. and the sample is hygroscopic.

The actual amount of water in the methanol and the "handling blank" involved in the manipulations need not be determined directly, since they cancel out automatically.

TITRIMETRIC DETERMINATION OF WATER IN FREEZE-DRIED ACETYLCHOLINE CHLORIDE-MANNITOL

Reagents—*Methanol*—Rinse adequately an automatic buret equipped with a silica-gel drying tube, with absolute or anhydrous grade methanol; then fill it with methanol. Various brands were used in this work. A.C.S. anhydrous methanol "low in acetone" (Matheson, Coleman, and Bell) was found to give the lowest blank.

Water in Methanol—Rinse adequately a 100-ml. volumetric flask with a needle-penetrable stopper, using methanol from the same container. Add exactly 0.1 ml. water. Add methanol to volume.

Karl Fischer Reagent—Use the stabilized reagent available commercially with each ml. equivalent to approximately 5 mg. water. K.F. Reagent, single solution, stabilized (Fisher Scientific Co.) was used.

Protect all liquids from atmospheric moisture as much as possible.

Procedure—Preparation of vials and stoppers for blanks and standards. Obtain 10–20 vials similar to the sample vials, with siliconed stoppers and center-seals. Remove metal rings. Discard water in the top chambers. Push center seals through, using a metal rod or similar tool. Clean vials and stoppers by rinsing, as necessary, with water, acetone, and an air stream. Place them in a 105–110° oven for 1 hr. Remove the vials and stoppers from the oven, and stopper the vials at once. Store in a desiccator until used.

Preparation of Samples—Remove stoppers and metal rings. Pour water out from top chamber. Dry stoppers and top chambers with acetone and a stream of air. Place vials and stoppers in 105–110° oven for 1 hr. Remove, and at once insert oven-dried stoppers. Store in a desiccator until used.

Titration of Blanks—Remove stopper from vial, quickly add 2.0 ml. of methanol from buret and replace stopper. Release pressure by puncturing stopper with breather needle. Remove needle. Shake well. Titrate with K.F. reagent from a 1-ml. tuberculin syringe and needle. Repeat until precision confidence is established.

Titration of Standards—With a calibrated syringe and needle, withdraw water in methanol through the stopper, first rinsing the syringe several times, then measuring 2.0 ml. Remove stopper from Univial and quickly add the 2.0 ml. water in methanol and replace stopper. Insert breather needle. Shake well. Titrate with K.F. reagent from 1-ml. tuberculin syringe and needle. Repeat until precision confidence is established.

Titration of Samples—Remove stopper, quickly push center seal through, using a suitable instrument, add 2.0 ml. methanol from buret and replace stopper. Release pressure by puncturing stopper with breather needle. Remove needle. Shake well. Titrate with K.F. reagent from 1-ml. tuberculin syringe and needle. Fading of amber color is due to slow extraction of the last bit of water from the crystals by K.F. reagent. The end point should be stable for 15 sec.

Calculation—Sample titration = V_{sam}, blank = V_B, standard = V_{stan}. Then the weight of water in the lower chamber of the sample is:

$$\frac{V_{sam} - V_B}{V_{stan} - V_B} \times 2 \text{ mg.}$$

DISCUSSION AND RESULTS

The blank titer combines K.F. reagent comsumption due to: (*a*) water in the methanol reagent. (*b*) moisture unavoidably introduced in the handling.

Although some attempts were made to use as blanks vials containing oven-dried samples, the values showed unsatisfactory reproducibility. It was felt that any difference in titer between such blanks and the empty-vial blanks eventually adopted was due to the handling errors caused by the extreme hygroscopicity of acetylcholine chloride.

In order to justify the use of empty-vial blanks it was necessary to determine whether completely dry acetylcholine chloride or mannitol consume K.F. reagent. Two-gram samples of each were oven-dried to constant weight in flasks, closed with rubber-stoppers fitted with a short needle-penetrable rubber core, and cooled in a desiccator. Twenty-five milliliters of methanol was added quickly by pipet and the flasks were titrated with K.F. reagent. An empty flask was similarly treated, as a blank.

It was found that mannitol was easily dried at 105° to give zero net titer, and that acetylcholine chloride could be dried to a negligibly small or zero net titer by heating at 110° for 16 hr., although 105° was not hot enough to drive off the last 0.1% moisture in some cases even after 4 days heating.

In order to study the effect of the drying temperature used in preparing blanks, the following experiment was run. Two groups of samples, all from the same batch, were prepared:

(*A*) Top chamber dried with acetone, an air-stream, and 10 min. warming close under an infrared lamp. (Infra-red Economy Heater, Fisher Scientific Co.).

(*B*) Top chamber dried with acetone, an air stream, and heating entire vial at 110° for 3 hr.

The vials were then stoppered with oven-dried stoppers, and titrated in the usual way. The titration values are shown in Table I. The following conclusions may be drawn from this experiment.

(*a*) The brief warming of the top chamber of the Group A vials is sufficient to dry them, even though the center seal has been in contact with water for a

authors found that a lyophilized B complex containing 10 mg. riboflavin could be titrated to an easily identified end point despite the color in the sample. Other types of sample have not been tested but it would seem that the method is applicable to any parenteral-type vial containing lyophilized or powdered sample low in water content, unless it is deeply colored or contains a substance which interferes with the titration, such as ascorbic acid.

Simple vials do not require the preliminary preparation described for the double-chambered vial, but can be titrated directly.

Preliminary Phytochemical Investigation of Wild Rice Ergot

By GREGORY T. SINNER* and LEE C. SCHRAMM†

Ergot parasitizing wild rice was analyzed for moisture, fat, and alkaloid content. Results indicated 4.6 percent moisture, 32 percent fat, and a total alkaloid content of approximately 0.1 mg. percent. The fungus was cultured in a modified *Claviceps* culture medium, but alkaloids could not be detected in culture filtrates.

Species of Claviceps have been found as parasites of nearly all members of the grass family (1).

authors found that a lyophilized B complex containing 10 mg. riboflavin could be titrated to an easily identified end point despite the color in the sample. Other types of sample have not been tested but it would seem that the method is applicable to any parenteral-type vial containing lyophilized or powdered sample low in water content, unless it is deeply colored or contains a substance which interferes with the titration, such as ascorbic acid.

Simple vials do not require the preliminary preparation described for the double-chambered vial, but can be titrated directly.

The authors wish to acknowledge the assistance of Mrs. Doris Severn, Fergus Falls, Minn., and Mr. Harry Wilson, Spooner, Wis., for their collections of wild rice ergot.

The occurrence of this fungus on wild rice (*Zizania aquatica*) was first reported by Dennison in 1900 (2). In 1915, Fyles (3) published a preliminary morphological description of wild rice ergot and noted its host specificity. Although she was able to cause infestation of healthy wild rice by inoculation with conidial suspensions and honey dew from diseased wild rice, she was repeatedly unable to infect other healthy grains (normally susceptible to *Claviceps* infestations) with this organism. Presumably because of this, Fyles later referred to the ergot of wild rice as a distinct species, *Spermoedia zizaniae*, a

name which was never widely accepted. In 1959 Pantidou (4) published a complete description of wild rice ergot and proposed the presently accepted binomial, *Claviceps zizaniae* (Fyles) Pantidou, again as a species distinct from the common rye ergot *C. purpurea* (Fries) Tulasne. The consideration as a separate species results from discrete differences in physical characteristics of the sclerotia, and from the apparent host specificity of *C. zizaniae*.

Wild rice abounds in Minnesota and Wisconsin. Infestation of the natural stands of wild rice with *C. zizaniae* is common. The availability of sclerotia of wild rice ergot from local sources prompted the present phytochemical investigation for moisture, fat, and alkaloid content. An isolate of this fungus was grown in agitated submerged liquid culture, and the culture filtrate was examined for alkaloids.

EXPERIMENTAL

Sclerotia of wild rice ergot were collected from central Minnesota, near Fergus Falls, and from northern Wisconsin, near Spooner. These sclerotia corresponded to the description of Pantidou (4). The average size was 12 mm. in length (4–16 mm.) and 5 mm. in width, externally pink to black in color and having a brilliant purple fracture.

Moisture Determination—The sclerotia were ground in a Wiley Mill to a coarse powder. Moisture content was accomplished by determining weight loss after drying at 108° to constant weight. The average weight loss on drying was 4.6%.

Fat Determination—Samples of powdered wild rice ergot dried at 108° were extracted with petroleum ether by continuous extraction in a Soxhlet apparatus for 12 hr. Fat content was determined by loss of weight during extraction. The average fat content was 32% by weight.

Alkaloid Determination—The methods of Silber and Schulze (5) and Michelon and Kelleher (6) were used for the detection of alkaloids in wild rice ergot and on the filtrates of 7-day-old cultures of *C. zizaniae*.

Colorimetric analysis of the alkaloid content of wild rice ergot indicated the presence of alkaloids, but in a concentration of approximately 0.1 mg. %, the lower limit of detection of the analytical procedure. Water-soluble alkaloids appear to be absent in wild rice ergot, although they may have escaped detection because of a limited quantity of sample available for study. No indication of water-soluble alkaloids was observed chromatographically.

Investigation of Liquid Cultures—Individual sclerotia were sterilized by submersion in the following solutions for 30 sec. each: benzalkonium[1] chloride (1:500); sterile distilled water; 95% alcohol; 70% alcohol; 50% alcohol; sterile distilled water. After sterilization and rinsing, each sclerotium was peeled with a sterile scalpel; a small cubical portion (approximately 3 mm. on a side) was placed on a sterile agar slant of medium prepared according to Brady and Tyler (7). The slants were incubated at 26°; small portions of the mycelium were transferred to new medium monthly. Liquid cultures were prepared from 7-day-old slants by transferring a small portion of mycelium to 100 ml. of a sterile liquid medium modified slightly from Arcamone's "medium A" or preculture medium (8) consisting of 4% mannitol, 1% succinic acid, 0.1% neopeptone, 0.1% KH_2PO_4, 0.03% $MgSO_4$, and tap water, contained in a 500-ml. conical flask. The liquid cultures were incubated in a constant temperature room at 26° on a rotary shaker (300 r.p.m., 2.54-cm. diameter rotation). Filtrates of agitated submerged cultures of *C. zizaniae* were assumed not to contain ergot alkaloids since there was only a very weak reaction of the filtrate with the PDAB reagent. The color developed was not intense enough to be detectable in the analytical procedure.

Chromatographic Examination—Attempted identification of the alkaloids was accomplished on Silica Gel G thin-layer plates using two solvent systems comprised of benzene–ethanol (1:1) and (1:0.6) and on Alumina G thin-layer plates using solvents composed of chloroform, chloroform–*n*-butanol (10:1), and *n*-butanol. Each chromatoplate was examined under ultraviolet light to detect fluorescent substances, then sprayed with 0.2% para-dimethylaminobenzaldehyde in 18% HCl (PDAB) as a detection reagent.

On the silica gel plates, two alkaloid spots were observed. Although both yielded a blue fluorescence in ultraviolet light, they were readily differentiated on the basis of their reaction with the PDAB spray reagent. The alkaloid with the lower R_f value yielded a blue color with PDAB, while the other alkaloid gave a purple color with the reagent. The R_f values in the benzene–ethanol (1:1) system were 0.79 and 0.87; for the benzene–ethanol (1:0.6) system these values were 0.72 and 0.80.

On alumina plates, only one spot was observed. This spot also fluoresced blue and formed a purple or blue color with PDAB. The R_f value in the three solvent systems ranged from 0.93 to 0.96. Although other attempts were made to identify these alkaloids chromatographically, the results were inconclusive.

Interpretation of the Kinetics of Salicylic Acid Elimination

Sir:

Wagner (1) contends that the data relating to the elimination of salicylate can be interpreted on the basis of first-order kinetics. The present communication presents evidence which indicates that the application of Wagner's theoretical considerations to these particular aspects is not acceptable. It also reaffirms the validity and application of certain equations which Wagner (1) has claimed to be erroneous.

It was first suggested by Cummings (2) in 1963 that when the plasma salicylate level exceeds a certain value, the formation of salicyluric acid closely approaches a zero-order process. Evidence has been presented by Cummings and Martin (3–6) to support the view that the elimination of salicylate in man cannot be completely described by first-order kinetics, and that above a certain drug level its elimination can be better described in terms of simultaneous first-order and zero-order processes. It may be pointed out that Wagner makes no reference to the publication of Bedford, Cummings, and Martin (5). A similar interpretation of experimental results has been offered by Levy (7) and Nelson, Hanano, and Levy (8).

The evidence for this interpretation can be considered as follows.

1. The fraction of the dose of aspirin which is eliminated and excreted in the urine at certain specified times shortly after dosage is almost constant for doses of 160, 240, and 320 mg., but at higher dosage the fraction of the dose excreted at these times becomes progressively less (5). This is explicable on the basis that the elimination of salicylate is not first order when the dose of aspirin exceeds 320 mg., when it is assumed that the absorption step is not rate limiting.

Furthermore, the percentage of the dose which is eliminated as salicyluric acid is less after the larger doses than after the small doses (5). This suggests that the rate of formation of salicyluric acid is not always proportional to the amount of salicylic acid in the body.

2. When the decline of the serum salicylate concentration and of the rate of excretion of salicyluric acid in urine was followed for about 40 hr. after loading doses of aspirin—1 Gm. every 6 hr. for 36 hr. (5, 6): (*a*) Plots of these values against time could not be described as log-linear for 20 hr. or more after the final dose. (*b*) The rate of excretion of salicyluric acid remained almost constant between the sixth and the 17th hr. after the final dose. (*c*) These plots ultimately tended to become log-linear with a slope similar to that of corresponding plots obtained after a low single dose of aspirin. (*d*) The amount of salicylic acid remaining in the body at a time when elimination approaches a first-order rate was calculated to be 150–300 mg. (5).

If an explanation of these findings based on the continuing absorption and distribution of salicylic acid over a period of 20 hr. is not accepted, the experimental findings provide a strong indication that the formation of salicyluric acid closely approaches a zero-order rate during the period between the sixth and the 17th hr.

Wagner was able to demonstrate in his model (Example 1) that first-order kinetics can give rise to a plateau in the excretion rate plot from the third to the sixth hour. Such an explanation cannot, however, be considered sufficient to account for a plateau extending over a period of 11 hr.

3. The area under the salicylate plasma level *versus* time plot appears to be much larger when aspirin is rapidly absorbed than when the equivalent dose is slowly absorbed (3, 4), although the total urinary recovery of drug after 24 hr. is the same in both instances (9). The maximum plasma salicylate level obtained when aspirin was rapidly absorbed is almost double that obtained when aspirin was slowly absorbed, yet the maximum rates of excretion of total salicylate in urine were almost identical (3, 4). This suggests that the elimination of salicylate is relatively slower at the higher drug level which results when absorption is rapid, assuming that the total amount of aspirin absorbed within the period of the study, *viz.*, 7 hr., is the same in both instances.

4. There is a considerable difference in the maximum plasma salicylate level obtained after a single 1-Gm. dose of aspirin and after multiple 1-Gm. doses of aspirin. Thus, in a group of individuals, a single 1-Gm. dose gave an average maximum observed value of 5.1 mg./100 ml. (10), whereas after seven doses each of 1 Gm. administered six hourly, the average maximum observed value was 18.1 mg./100 ml. (4).

An attempted interpretation of salicylate elim-

ination based on first-order kinetics gives a half-life equal to 2–3 hr., as calculated from the slope of the terminal log-linear section of the plasma level plot or urinary excretion plot after a small (0.3 Gm.) dose of aspirin (5). Wagner (1) makes use of a similar value. On this basis a 6-hr. multiple-dosage schedule corresponds to a dosage interval which is equal to 2–3 half-lives of the drug, and this would give a plasma salicylate level only marginally greater than that obtained with a single dose. The plasma levels obtained, however, are at least three times greater. This suggests that the half-life of salicylate which pertains after multiple 1-Gm. doses is certainly much longer than 2–3 hr. and would appear to be nearer 10 hr.

It is submitted that the cumulative evidence refutes Wagner's (1) contention that the elimination of salicylate can be interpreted solely on the basis of a first-order kinetic model. It is considered that the experimental observations can be better described by a model based on simultaneous first-order and zero-order elimination as postulated by Cummings and Martin (3–6) and by Levy (7, 8).

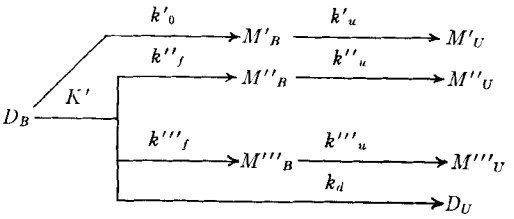
Wagner (1) also states that Cummings and Martin (11) have incorrectly used the Butler equation (12). This is not so. The considerations of Cummings and Martin (11), as those of Butler (12), were stated to apply to a substance, in this instance a metabolite, which was eliminated only by excretion, and in this case the elimination rate constant and the excretion rate constant are one and the same.

Wagner (1) states that the equation presented by Cummings, Martin, and Park (13), with respect to simultaneous first-order and zero-order drug elimination, is erroneous. The equation appears to be perfectly valid and its derivation in a more general form, is given below.

RATE OF EXCRETION OF TOTAL DRUG IN URINE WHEN ONE METABOLITE IS FORMED AT A ZERO-ORDER RATE

The kinetics of the excretion of total drug in urine is considered with respect to a model drug which is entirely eliminated by excretion in the urine and by metabolism to three metabolites (M', M'', M'''); the metabolites are eliminated solely by excretion in the urine. Thus, "total drug in urine" is defined as the sum of the amounts of drug and metabolite excreted and this will ultimately be equivalent to the amount of drug absorbed. One metabolite, M', is formed at a zero-order rate, otherwise all the processes of drug elimination and metabolite excretion are first order.

The processes of drug elimination may be represented as follows:



These processes are described by the following equations in which:

D_0	= The amount of drug in the body at a time when the process of absorption can be considered to be complete, this is designated $t = 0$
D_B	= The amount of drug in the body at time t
M_0	= The amount of metabolite in the body at a time $t = 0$
M_B	= The amount of metabolite in the body at time t
D_U	= The amount of drug excreted in the urine at time t
M_U	= The amount of metabolite excreted in the urine at time t
k'_0	= The zero-order rate constant for the formation of metabolite M'
k''_f, k'''_f	= The first-order rate constants for the formation of the metabolites M'' and M''', respectively
k_d	= The first-order rate constant for the excretion of drug
k'_u, k''_u, k'''_u	= The first-order rate constant for the excretion of the metabolites M', M'', and M''', respectively
K'	= $k_d + k''_f + k'''_f$

Thus,

$$-\frac{dD_B}{dt} = K'D_B + k'_0 \qquad \text{(Eq. 1)}$$

and integration between $t = 0$ and $t = t$ gives:

$$D_B = [D_0 + k'_0/K']e^{-K't} - k'_0/K' \qquad \text{(Eq. 2)}$$

Also,

$$M'_B = \frac{k'_0}{k'_u}[1 - e^{-k'_u t}] + M'_0 e^{-k'_u t} \qquad \text{(Eq. 3)}$$

and

$$M''_B = \frac{k''_f}{k''_u - K'}[D_0 + k'_0/K'][e^{-K't} - e^{-k''_u t}] - \frac{k''_f k'_0}{k''_u K'}[1 - e^{-k''_u t}] + M''_0 e^{-k''_u t} \qquad \text{(Eq. 4)}$$

Substitution of k'''_f and k'''_u for k''_f and k''_u in Eq. 4 gives the corresponding equation for M'''_B.

The rate of excretion of drug and of drug metabolites in urine is given by:

$$\frac{dD_u}{dt} = k_d D_B; \quad \frac{dM'_u}{dt} = k'_u M'_B; \quad \frac{dM''_u}{dt} = k''_u M''_B; \quad \frac{dM'''_u}{dt} = k'''_u M'''_B.$$

The rate of excretion of total drug in urine is ob-

tained by summing the individual rates, so that:

$$\frac{d[D_u + M_u]}{dt} = \frac{dD_u}{dt} + \frac{dM'_u}{dt} + \frac{dM''_u}{dt} + \frac{dM'''_u}{dt}$$

where

$$M_u = M'_u + M''_u + M'''_u$$

Then,

$$\frac{d[D_u + M_u]}{dt} = \left[k_d + \frac{k''_f k''_u}{k''_u - K'} + \frac{k'''_f k'''_u}{k'''_u - K'}\right] \times [D_0 + k'_0/K']e^{-K't} - \left[\frac{k''_f k''_u}{k''_u - K'} e^{-k''_u t} + \frac{k'''_f k'''_u}{k'''_u - K'} e^{-k'''_u t}\right][D_0 + k'_0/K'] + \frac{k'_0}{K'}[k''_f e^{-k''_u t} + k'''_f e^{-k'''_u t} - K'e^{-k'_u t}] - \frac{k'_0}{K'}[k_d + k''_f + k'''_f - K'] + k'_u M'_0 e^{-k'_u t} + k''_u M''_0 e^{-k''_u t} + k'''_u M'''_0 e^{-k'''_u t} \quad \text{(Eq. 5)}$$

The term $[k_d + k''_f + k'''_f - K'] = 0$, since by definition $K' = k_d + k''_f + k'''_f$, therefore only exponential terms remain.

Equation 5 is thus of the form:

$$\frac{d[D_u + M_u]}{dt} = Ae^{-K't} + Be^{-k'_u t} + Ce^{-k''_u t} + De^{-k'''_u t} \quad \text{(Eq. 6)}$$

where A, B, C, and D are constants.

When all k_u are large relative to K' and when t is large, all the $e^{-k_u t}$ terms become very small relative to the $e^{-K't}$ term and so Eq. 6 approaches:

$$\frac{d[D_u + M_u]}{dt} = Ae^{-K't} \quad \text{(Eq. 7)}$$

This equation may then be written:

$$\ln \frac{d[D_u + M_u]}{dt} = \ln [\text{const.}] - K't \quad \text{(Eq. 8)}$$

which is the equation of a straight line having a slope equal to $-K'$.

A plot of the log rate of excretion of total drug against time ultimately exhibits a linear section with a slope equal to the sum of the rate constants which govern the first-order processes of drug elimination when a zero-order process is occurring simultaneously.

Deterioration of Nitroglycerin Tablets

Sir:

The effect of packaging and storage conditions on drug product stability is a subject of growing interest and concern (1). We wish to report here our investigations on the relationship between certain novel packaging materials and the deterioration of nitroglycerin tablets.

FDA recently found that a batch of nitroglycerin tablets sealed in aluminum foil was grossly subpotent. The faulty product had been prepared by individually wrapping 0.43-mg. ($^1/_{150}$-grain) nitroglycerin tablets in strips of aluminum foil to which a thin film of polyethylene had been laminated. Each tablet was placed between the polyethylene surfaces of two strips, and the ends were heat-sealed to provide a 25 × 15 mm. cell.

Assays of individual tablets showed that they contained 0–10% of the declared quantity of nitroglycerin (2). However, when the packaging material in one cell was extracted with isooctane, the extract contained 0.36 mg. of nitroglycerin [determined colorimetrically with phenoldisul-

tained by summing the individual rates, so that:

$$\frac{d[D_u + M_u]}{dt} = \frac{dD_u}{dt} + \frac{dM'_u}{dt} + \frac{dM''_u}{dt} + \frac{dM'''_u}{dt}$$

where

$$M_u = M'_u + M''_u + M'''_u$$

Then,

$$\frac{d[D_u + M_u]}{dt} = \left[k_d + \frac{k''_f k''_u}{k''_u - K'} + \frac{k'''_f k'''_u}{k'''_u - K'}\right] \times [D_0 + k'_0/K']e^{-K't} - \left[\frac{k''_f k''_u}{k''_u - K'} e^{-k''_u t} + \frac{k'''_f k'''_u}{k'''_u - K'} e^{-k'''_u t}\right][D_0 + k'_0/K'] + \frac{k'_0}{K'}[k''_f e^{-k''_u t} + k'''_f e^{-k'''_u t} - K'e^{-k'_u t}] - \frac{k'_0}{K'}[k_d + k''_f + k'''_f - K'] + k'_u M'_0 e^{-k'_u t} + k''_u M''_0 e^{-k''_u t} + k'''_u M'''_0 e^{-k'''_u t} \quad \text{(Eq. 5)}$$

The term $[k_d + k''_f + k'''_f - K'] = 0$, since by definition $K' = k_d + k''_f + k'''_f$, therefore only exponential terms remain.

Equation 5 is thus of the form:

$$\frac{d[D_u + M_u]}{dt} = Ae^{-K't} + Be^{-k'_u t} + Ce^{-k''_u t} + De^{-k'''_u t} \quad \text{(Eq. 6)}$$

where A, B, C, and D are constants.

When all k_u are large relative to K' and when t is large, all the $e^{-k_u t}$ terms become very small relative to the $e^{-K't}$ term and so Eq. 6 approaches:

$$\frac{d[D_u + M_u]}{dt} = Ae^{-K't} \quad \text{(Eq. 7)}$$

This equation may then be written:

$$\ln \frac{d[D_u + M_u]}{dt} = \ln [\text{const.}] - K't \quad \text{(Eq. 8)}$$

which is the equation of a straight line having a slope equal to $-K'$.

A plot of the log rate of excretion of total drug against time ultimately exhibits a linear section with a slope equal to the sum of the rate constants which govern the first-order processes of drug elimination when a zero-order process is occurring simultaneously.

Deterioration of Nitroglycerin Tablets

Sir:

The effect of packaging and storage conditions on drug product stability is a subject of growing interest and concern (1). We wish to report here our investigations on the relationship between certain novel packaging materials and the deterioration of nitroglycerin tablets.

FDA recently found that a batch of nitroglycerin tablets sealed in aluminum foil was grossly subpotent. The faulty product had been prepared by individually wrapping 0.43-mg. ($^1/_{150}$-grain) nitroglycerin tablets in strips of aluminum foil to which a thin film of polyethylene had been laminated. Each tablet was placed between the polyethylene surfaces of two strips, and the ends were heat-sealed to provide a 25 × 15 mm. cell.

Assays of individual tablets showed that they contained 0–10% of the declared quantity of nitroglycerin (2). However, when the packaging material in one cell was extracted with isooctane, the extract contained 0.36 mg. of nitroglycerin [determined colorimetrically with phenoldisul-

fonic acid (3)] or 84% of the declared quantity. The carbon disulfide extract of another cell exhibited the infrared absorption spectrum of nitroglycerin, when compared to a blank consisting of a carbon disulfide solution of extractives from the laminating adhesive.

Our explanation of these findings is based upon three observed facts: the low but appreciable volatility of nitroglycerin at room temperature; the permeability of plastics, such as polyethylene, polypropylene, and polyvinyl chloride to nitroglycerin vapor; and the solubility of nitroglycerin in the adhesive used to bond the polyethylene to the aluminum foil.

When nitroglycerin tablets are placed in an open container, the drug substance evaporates. If the tablets are sealed in an envelope of plastic film, evaporation may be retarded, but it proceeds to eventual depletion if the packet remains exposed in an open vessel. By contrast, our investigations have shown that when nitroglycerin tablets are stored in a tightly stoppered glass container they retain essentially the same concentrations of active ingredient for prolonged periods. Within such a closed system, evaporation away from the dosage form proceeds only until the comparatively low partial pressure of nitroglycerin in the available space is equal to the vapor pressure of the compound in the tablets, and a dynamic equilibrium is achieved. If the bottle is opened intermittently to remove tablets, nitroglycerin vapors escape, but the loss is usually so small that changes in tablet composition are negligible.

Although the sealed aluminum package comprising the deteriorated product under discussion also represents a closed system, an additional operating factor prevents establishment of a stabilizing dynamic equilibrium. Because nitroglycerin is soluble in the laminating adhesive, the vapors that escape from the surface of the tablet and diffuse through the polyethylene are continuously removed from the atmosphere by incorporation into the film of adhesive. Thus the flow of nitroglycerin molecules is unidirectional away from the tablet and all of the drug migrates to the packaging material.

Review Article

The Binding of Drugs by Plasma Proteins

By MARVIN C. MEYER* and DAVID E. GUTTMAN†

GOLDSTEIN'S CLASSIC REVIEW (1) of interactions between drugs and proteins, which was published in 1949, surveyed and summarized a rather large literature and, in addition, clearly and lucidly emphasized the potential importance of protein binding with respect to the behavior of drugs. His review undoubtedly contributed to an increased awareness of the significance of protein binding and stimulated many investigators to study various aspects of the phenomenon. A large number of publications, describing such studies, has appeared in the 18 years since his review. All, either directly or indirectly, resulted from the desire to answer one or more of the five fundamental guideline questions posed by Scatchard *et al.* (2): "How many? How tightly? Where? Why? What of it?" Thus, many of the reported studies were physical-chemical in nature, utilized synthetic *in vitro* systems, and were oriented to the determination of the maximum number of: (*a*) small molecules which could be reversibly bound by a protein molecule, (*b*) the association constant or constants and other thermodynamic parameters which characterized the reversible association, (*c*) the chemical and conformational nature of the binding sites on the protein molecule, and (*d*) the nature of the intermolecular forces which were responsible for interaction. Other studies, by necessity of a more qualitative nature, attempted to experimentally and/or theoretically assess the importance of protein binding as it relates to the actions and uses of specific drugs.

Excellent general discussions of such studies have appeared. For example, principles and concepts fundamental to an understanding of the phenomenon were discussed by Foster (3), Weber (4), Klotz (5), Edsall and Wyman (6). Brodie and Hogben (7), in a review of physicochemical factors in drug action, discussed reversibility of binding, binding forces, and possible therapeutic consequences resulting from drug–protein interactions. Van Os *et al.* (8) briefly considered the influence of protein binding on drug excretion, drug concentration in tissue fluids, therapeutic activity, and toxicity of drugs. Several chapters, which were devoted to this topic, appeared in a book edited by Binns (9). Brodie (10), for example, cited the importance of binding on the kinetics of drug penetration through biological membranes. He also reviewed the concept of protein–drug complexes functioning as "storehouses" for drug in the body, effectively buffering the level of free drug in the biological fluids. Thorp (11) considered some general aspects of the binding phenomenon and noted that the majority of drug interactions with albumin appear to involve a single binding site on the protein. He speculated that rates of association and dissociations of drug–protein complexes are probably sufficiently great so as to not hinder drug transport from the plasma. The proceedings of a symposium entitled "The Transport Function of Proteins" edited by Desgrez and De Traverse (12) contains a number of chapters

Received from the Department of Pharmaceutics, School of Pharmacy, State University of New York at Buffalo, Buffalo, NY 14214

* Predoctoral fellow, U. S. Public Health Service.
† To whom inquiries should be addressed.

which are directly related to important aspects of protein–small molecule interactions. Bennhold (13), for example, summarized studies pertaining to the transport of dyes. Guillot (14) reviewed the nature of intermolecular forces responsible for binding. Presentations by Vannotti *et al.* (15) and by Salvatore *et al.* (16) dealt with the binding of thyroid hormones. Polonovski (17), Desgrez (18), Raoul (19), and Lathe (20) discussed the role of plasma proteins in the transport of lipids, corticosteroids, vitamins, and bilirubin. Brodie (21) reviewed possible therapeutic implications of drug–protein interactions and considered "drug buffering," the absorption, distribution, and excretion of highly bound drugs, saturation of binding sites, and the displacement of drugs and endogenous substances by the concomitant administration of certain drugs. Truhaut (22) contributed a review of the interactions between a variety of toxic compounds and plasma proteins. Serum inactivation of penicillins due to protein binding has been recognized for many years and has been the subject of many investigations. Warren (23) has summarized much of the current literature and has attempted the difficult task of relating and correlating binding behavior with the clinical performances of a number of penicillins.

Scope of the Present Review—It did seem desirable to supplement the works cited above with a current review of drug–plasma protein interactions. Because of the extensiveness of the literature in this field, the objectives of a review required limitations. It was decided, therefore, to briefly summarize, in tabular form similar to that employed by Goldstein, some important observations for many of the studies reported during the past 18 years. Supplemental to this tabulation, this report will attempt to review some of the newer experimental techniques which have been employed to investigate protein–small molecule interactions, and the methods used to present and to treat experimental data. Additional emphasis will be directed, by reference to pertinent and representative studies, to recent advances which have been made in understanding, evaluating, and predicting the extent to which drug–protein interactions can influence the distribution of drug in the body and the removal of drug from the body. Finally, attention will be drawn to the many studies which have been concerned with the use of agents which compete with a particular small molecule for binding sites on the protein and can, thus, cause an inhibition or diminution of binding.

Tabulations—Studies which have been specifically concerned with the binding, by plasma proteins, of therapeutic agents or endogenous substances of physiologic importance are summarized in Table I. The tabulation is self-explanatory and reflects the current and continuing interest in the interactions of drugs, metabolites, and naturally occurring compounds with plasma proteins. Table II refers, without commentary, to a number of studies which have employed dyes as the substrates in binding experiments. This class of compounds will not be considered in detail and the table is merely presented as a reference to current work for those interested in such systems. While the majority of dyes included in Table II are not of therapeutic importance, they serve as useful tools in general studies of the binding process and such studies have provided insights into the mechanisms and sites of interaction.

References to the many studies dealing with the binding of steroids have been omitted from Table I because of the availability of several recent and extensive reviews of this topic (24–34). The binding of steroids by proteins is the subject of considerable current interest which stems from the possible involvement of binding in events which are of physiological and pharmacological importance. For example, the apparent absence of the manifestations of Cushing's syndrome during pregnancy, when the corticosteroid level is elevated, has been attributed to an increase in plasma protein binding (35). Evidence has been presented by a number of groups to support the existence of a specialized plasma protein, transcortin, which has a high affinity but low capacity for corticosteroids. It has been speculated (21) that many of the important nonsteroidal anti-inflammatory agents may function *in vivo* by displacing bound endogenous corticosteroid. It has also been reported (36, 37) that the administration of oral contraceptives can result in a marked increase in the fractions of cortisol and aldosterone which are bound in the plasma.

In addition to the many studies which have been considered by authors of the various review articles, the results of a number of recent investigations have appeared and are of interest. Akasu *et al.* (38) demonstrated that dehydroepiandrosterone is highly bound. Several workers have studied the binding of free (39) and conjugated estrogens (40, 41) to serum proteins. Pearlman and Crepy (42) utilized gel filtration to measure the binding of testosterone. Kroneberg and Stoepel (43), using the isolated frog heart, determined that the presence of protein inhibited the digitalis-like activity of a prednisolone derivative. Davidson *et al.* (44) determined the binding characteristics of aldosterone and spirolactones. Hydrocortisone binding to rat and guinea pig pro-

14 Sulfonamides	S,A	D,U	Discusses types of binding and pharmacodynamic effects.	193
19 Sulfonamides	S(R)	U	Discusses binding, distribution, and excretion.	183
21 Sulfonamides & 6 metabolites	S(H)	U	Binding resulted in decreased glucuronidation, increased acetylation.	364
35 Sulfonamides	S(H)	U	Only unbound drug found to be active.	194
Series of several sulfonamides	S(H)	D	Discusses structure-binding correlation.	365
	A(H)	OR	Tertiary structure of albumin altered by binding.	366
	A,S(H)	D	Determined temperature and concentration effects.	367
	S(H)	U	Correlated binding, ionization, and metabolism.	251
	S,A(H)	UC,GF,D	Good agreement between experimental methods.	368
	S,A,G(γ)(H)	D	Influence of pH and sulfa structure studied.	369
	A(B)	NMR	—	159
	S(B)	U	Ultrafiltration discussed.	370
	S(H)	UC	Compared results with dialysis and ultrafiltration.	371
	S	—	Tripiraphen displaced bound sulfa.	372
Several pyridazine sulfonamides	S(H,M,Rt)	U	B = 60–90%.	373
Series of long-acting sulfonamides	S(H,R,Rt,B,D,M)	D,U,E,	Data fit Freundlich isotherm; determined activity, tissue distribution, and excretion.	182
	S(M,D,B,R,Rt,H)	D	Elimination rate independent of binding, activity, and tissue distribution dependent on binding.	181
	S(H)	U	Noted dependency of kidney elimination on binding.	255
	S	BF	Slow elimination due to protein binding.	254
	S(H)	BF	Factors affecting renal excretion discussed.	374
	S,A,G(γ)(H)	D,U	—	375
	S(M)	D,BF	Determined blood, tissue, and CSF levels.	376
	A(H,B)	—	n's reported.	
	G(γ)(H)	D	—	377
		Barbiturates		
Phenobarbital	A(B,H)	D	B = 0%(4% alb.), pH independent 6.1–8.6.	378
Pentobarbital	S(D)A(H)	(^{14}C)	Studied influence of binding on peritoneal dialysis in dogs.	186
	S(Rt)	B	Radiocontrast media and dextran potentiated barbiturate activity.	212
Thiopental	A(B)	D	n = 5, k = 12,000 (8° C., pH 7.4). EDTA decreased n and k.	379
	S(R)A(H,B)	U	Correlated sleeping time and binding.	380
Thiopentone & buthalitone	S(H)	D,B	Determined binding, partition coefficients, and plasma levels.	381
3 Barbituric acids	S(H)	U	Determined % bound and clearance.	382
4 Barbiturates	S(H)	GF(^{14}C)	Studied effect of urea and SO_4.	145
7 Barbiturates	S(H)	D	B = 46–81%.	383
Series of barbiturates	S(R)A(B)	U	B = 5–65%. Determined effects of pH, salts, and temperature. Reported n and k.	384
		Miscellaneous Drugs		
I. *Anti-inflammatory Agents, Analgesics, and Antipyretics*				
A. Salicylates	S(H)	D,EP	Compared binding behavior *in vitro* and *in vivo*. Studied effects of heparin & thyroid hormone.	237
	A(H)	D	B = 66–82%, n = 2.7–3.4(5°, pH 7.4).	385
	S(H,R)	D,B	Measured febrile response in rabbit.	198
	S,PF(B)	D	—	386
	S(R,B,H)	U	Binding and excretion rate compared.	387
	A(B)	D	Determined structure-binding correlations.	388
	A(B)	D	Measured competition by methyl orange.	389
	S	F	1° binding to albumin.	390
	A(B)	D	Studied 27 benzoate derivatives. Reported n, k, % binding, and pH effects.	211
B. *p*-Aminosalicylic acid	A(B)	D	Varied pH and ionic strength.	391
	S(H)	U	B = 58–73%	392
C. Na salicylate & morphiline sal.	S(H)	BF	Determined blood level and excretion rates with and without PABA.	393
D. Several nonsteroidal drugs	PF(B,H)	ST	Anti-inflammatory activity related to binding.	213

(*Continued on next page.*

TABLE I—(*Continued.*)

Substance	Protein Studied[a]	Method[b]	Remarks[c]	Ref.[d]
E. Other misc. drugs				
Morphine	S(H,D)	U	Suggested tolerance and prolonged blood levels related to binding.	264
Phenylbutazone	S	D	B = 99%.	394
	S(H)	D,U	n = 1.	395
	S		Measured association *in vivo* and *in vitro*.	396
	S(H)	D,SP	Loose binding, not displaced by salicylamide.	397
	S(H)	D		398
p-Hydroxyphenylbutazone	S(H)	D	Binding behavior similar to phenylbutazone.	399
Colchicine	S	SP	—	400
Probenecid	PF(H)	D	Reported % binding and half-lives after oral and i.v. doses.	401
	S(D)	U	Data fit Freundlich isotherm. B = 70–80%. Determined blood levels after injection.	402
Several anti-inflamm. drugs	A(B)	SP	Determined displacement of pyridoxal PO_4 and trinitrobenzaldehyde.	216
	S(B)G(H)	ST	Measured stability of protein to UV, heat, urea, and formalin denaturation.	403
II. *Tranquilizers and Antidepressants*				
A. Phenothiazines				
Chlorpromazine	S(R)	E	1° binding to albumin and globulins.	404
Phenothiazone & thional	A(B)	SP,D	Detn. n's and k's for oxidation products of phenothiazine.	405
Chlorpromazine & imipramine	S(D)	D,E	B = 31–36%, pH 8.6.	406
4 Phenothiazines	A	GF	Correlated antihistaminic activity with degree of binding.	200
B. Dicarbamates				
Meprobamate & 3 other derivatives	S(H)	D(^{14}C)	Correlated % binding with partition coefficients.	407
III. *Diuretics*				
Chlorthiazide	S(H)A(B)	D	Caused increased binding of pempidine.	247
Meralluride Na	S(H)	D	B = 90%(1:1000 concn.) and 50%(1:100 concn.).	408
Sulfamoyl-anthranilic acid derivative	S(E)	D	—	409
Ethacrynic acid	A(B)	D,EP(^{14}C)	n_1 = 4, n_2 = 12 (26°, pH 7.4.).	410
Acetazolamide	S(R)	D	B = 10–35%.	411
IV. *Antimalarials*				
Chloroquine	S(H)	E	1° binding to albumin.	412
	A(B)	SP	B = 33%, determined pH effect.	413
Acridine & quinoline derivative	S(B)	SP	Derived equations for spectral analysis.	414
V. *Antineoplastics*				
Methotrexate	S(H,D,M)	U(^{3}H)	B = 50%, determined excretion rate after i.v. dose.	415
	S,A(B)	U(^{3}H)	B = 50% BSA, displaced by PABA, sulfas, salicylates.	226
Melphalan	S(H)	U,D	B = 50–60%.	416
Pluramycin	PF(H)	C,E,UC	Bound drug less toxic.	202
2 Nitrogen mustards	S(H)	U	Data fit Freundlich isotherm.	417
3 Nitrogen mustards	S(H)	U,ST	Hydrolysis rate decreased in serum. Strong binding of 2 derivatives.	418
VI. *Anticoagulants*				
Heparin	A	E,T,B	Also studied suramin binding.	419
	A(B)	E	Also studied suramin binding.	420
	A(B)	E	1:2 heparin–alb. complex.	421
Bishydroxycoumarin	PF	D	B = 99%, half-life is dose-dependent.	261
Ethyl biscoumacetate	S(H)A(H)	D	B = 90%.	422
Warfarin Na	S,A(H)	B,BF	Displacement by phenylbutazone caused increase in activity.	222
	S(H)	B,BF	Hemorrhagic episodes with co-administration of phenylbutazone.	223
	S(H)		Clotting time increased with co-administration of oxyphenbutazone.	224
	S(H)	E,D	n_1 = 1, $k = 1.54 \times 10^6$, also calculated $\Delta F°$, $\Delta H°$, $\Delta S°$. Bound to albumin.	423
VII. *Hypoglycemic Agents*				
Glycodiazine	S(R,Rt,D)	B,BF(^{3}H)	B = 81–98%.	424
Tolbutamide	S,A(H,B)	U,B	Determined n and k, 5-ethyl sulfadiazine increased activity.	217
	S(H)	D,B,BF	Determined displacement by sulfa and phenylbutazone.	219
Chlorpropamide	S(H)	B	ASA increased hypoglycemic effect.	425
	S(H)	D(^{35}S)	% bound increased with increasing concentration.	426
	S(H)	D	B = 80%.	151
	S(H)	D(^{35}S)	B = 80%.	150
Phenethylbiguanide	A,G(B)	D	No significant interaction.	427
4 Sulfonylureas	A(B,H,D,E,P,R)	D,U	Noted species differences in binding. Salicylate displaced bound drug.	218
VIII. *Cardiovascular Drugs*				
Digitoxin	S(Rt)A(B)	D,U	Also determined binding of metabolites.	428
	S(Rt)	E(^{3}H)	Binding capacity = 0.01 Gm./mg. protein.	148
	PF(H,Rt)	EG(^{14}C)	1° binding to albumin fraction.	149
Several digitalis derivatives	A,G(H)	UC	Determined k and $\Delta F°$. Discussed binding forces.	429
Quinidine	A(H)	D	n = 3 (pH 10); ϵ-amino and carboxyl groups involved. Determined pH effects.	430
	A,G(H)	D	n = 1 (pH 7.4) $k = 7.7 \times 10^3$. Displaced by other quinoline drugs.	431

(*Continued on next page.*)

TABLE I—(*Continued.*)

	Substance	Protein Studied[a]	Method[b]	Remarks[c]	Ref.[d]
		A(H)	D	n = 1, k = 0.2 to 0.8 × 10^4 at pH 5.5–8. n = 3, k = 1.1 × 10^4 at pH 10.	432
	Procainamide	S(D)	D	B = 15%; calculated that most of drug localized in tissue.	433
IX.	*Anesthetics*				
	Procaine	S(D,R)	U	Data fit Freundlich isotherm. Determined effects of citrate, NaF, and PABA.	434
	Procaine & 3 other local anesthetics	A,G(H)	D	n = 2, k varies with drug. 1° binding to albumin.	435
	3 Anesthetic gases	A(H)	S	Albumin increases solubilities of gases.	436
	14 Anesthetic gases	A(B)	OR	Correlated high activity with high degree of binding.	437
X.	*Radiopaque Agents*				
		S(H)	E,A(^{131}I)	Used normal and diseased plasma.	438
		S(Rt)		Studied 4 compounds ranked in order of binding.	439
XI.	*Plasma Extenders*				
	Dextran	A(H)	E	Determined effect on binding of age and mol. wt. of dextran.	440
		PF(H)	E	1° binding to albumin.	441
	PVP	S	E	Mol. wt. 33,000 bound; mol. wt. 12,500 not bound.	442
XII.	*Parasympatholytics*				
	Atropine	S(H)	U,UC	Calcd. 50% of therapeutic dose bound *in vivo*.	443
		S,G(H,R)	EP,D	—	444
		A(B)	B,U,SP	N = 20 (pH 6), n = 100 (pH 8). Albumin decreased anticholinergic activity.	201
		A(B)	U,D	Determined effect of pH and buffers. Displaced by choline and acetylcholine.	248
XIII.	*Anti-infectives*				
	Furazolidone & nitrofurantoin	S(B,H)	E	1° binding to albumin.	445
	5 Nitrofurans	PF(B)	—	—	446
	20 Nitrofurans	S(Rt)	U	No correlation between binding and pharmacological effects.	447
XIV.	*Tuberculostatics*				
	Isoniazid	S(H)	(^{14}C)E	No apparent binding noted.	147
		S	PG	—	448
		PF(B,H)	U,E	PAS, streptomycin bound, but not isoniazid.	449
	Sulzolin	S(H)	U	B = 16%.	450
XV.	*Misc. Studies and Studies with Drugs of Various Classes*				
	Rivanol	A(B)	E,D,P	n = 17, k = 150.	451
	Disulfuram & diethyldithiocarbamate	S(H)	GF	Suggested formation of disulfide bond with disulfuram.	452
	d-Tubocurarine	S(H)	BF,D,E	Used plasma from normal and refractory patients.	199
	Epinephrine & norepinephrine	S(H)	BF	Epinephrine highly bound.	453
	Several basic amines	S	SP	Studied ephedrine, amphetamine, and adrenalin.	454
	Xanthine derivatives	A(B)	D	Determined % bound, n, k, and structural requirements for binding.	455
		A(B,H)	SP	Determined effects of temperatures, pH, and modified protein structure.	456
	Several alkaloids & mercurials	A,G	E	—	457
	3 Drugs	S(Rt)	Dc	37°. Studied thiopental, acetazolamide, and iproniazid.	458
	5 Drugs	S	D	Studied sulfadimethoxine, chlorpropamide, phenbutamide, acepromaxine, and dimethylbebeerine.	459
			Vitamins		
	Vitamin B_{12}	S(H)	E,B	B = 93%, 1° binding to α_1-globulin.	460
		S(H,B)	E	Determined effect of pH. 1° binding to α-globulin.	461, 462
		S(var.)	C(^{60}Co)	Used 11 animal species. 1° binding to albumin.	154
		S(H)	D,C(^{57}Co)	Noted several binding sites.	155
		S(H)	—	Binding by transcobalamin studied.	463
		S(H)	C	Hydroxycobalamin and cyano derivative bound by transcobalamin.	464
		S(H)	C	Normal serum saturated *in vivo*.	465
		S(H)	Ad	Bound vitamin resists charcoal adsorption.	466
		S(H,D,R,F,C)	D	n = greater than one.	467
		S(var.)	U,E	Studied binding in 7 animal species.	468
		S(H)	C	Noted two classes of binding sites.	469
	Vitamin B_{12}	S(H)	EP,C	Studied normal and leukemic serum.	470
		S(H)	Dc	Endogenous B_{12} bound greater than exogenous B_{12}.	471
		S(H)	E	1° binding to α-globulin.	472
		S(H)	B	Noted a limited binding capacity.	473
		S(H)	D	Used normal and leukemic serum. 1° binding to β-globulin.	474
		S(H)	EG	Used normal and leukemic serum.	475
		S	E,A	1° binding to γ-globulin.	476
		S(H)	E	1° binding to α-globulin.	477
		S(H)	D	1° binding to γ-globulin, trypsin, and pepsin displaced bound vitamin.	478
		S(H)	EP	1° bound to α_2-globulin.	479
		S(H,C)	E	Measured effect of sialidase on binding.	480
		S(H)	E	*In vivo* 1° binding to α_1-globulin. *In vitro* 1° binding to α_1 and α_2-globulin.	481

(*Continued on next page.*)

TABLE I—(*Continued.*)

Substance	Protein Studied[a]	Method[b]	Remarks[c]	Ref.[d]
	S,CSF	E,A(^{58}Co)	Also measured binding of ^{46}Ca.	153
	S(H)	D(^{60}Co)	Compared normal and leukemic serum.	482
	S(H)	GF	Compared normal and leukemic serum.	483
Hydroxocobalamin	ST	—	Binding to serum protein greater than to liver tissue.	484
Vitamin A	S(R)	BF,E	1° binding to albumin.	485
Vitamin D_2	S(H)	E(^{14}C)	1° binding to α-globulin and albumin.	486
Biotin	S(H)	EP(^{14}C)	1° binding to albumin.	152
Vitamin D_3	S(D)	P,UC,BF(^{3}H)	Noted strong binding *in vivo* and *in vitro*.	487
Tocopherol	A(B)	Pt	—	125
	S	B	Bound vitamin apparently had same activity as unbound.	488
Several fat-soluble vitamins	S(H)	E,D	Vitamin A bound 90%, other vitamins tested bound 10%.	489
13 Vitamins	PF(H)		Determined distribution of vitamins between globulin, albumin, and other proteins.	490
		Endogenous Substances		
Insulin	S(H,Rt,GP)	—	Tolbutamide displaced bound insulin.	246
	S(H)	E(^{131}I)	Binding to a specific insulin antibody reported.	491
	S(H)	E(^{131}I)	Used serum from normal and diseased patients. 1° binding to albumin and globulin.	492
	S(H)	E	Bound insulin found not to be active.	493
	S	Ad	Measured differential adsorption to Cellulose.	494
Glucagon	S(H)	(^{131}I)	Measured effect of pH and growth hormone.	495
Growth hormone	S(H)	E	1° bound to α_2-globulin.	496
Vasopressin	S(H)	B	Pressor activity decreased in presence of protein.	497
Serotonin	S(H)	B	$k = 6.5 \times 10^2$. Activity decreased by albumin. Measured effects of pH, Cu, and Zn.	498
Hyaluronic acid	A(B)	E,UC	—	499
Urate	S(H)	GF	Saturation of protein observed in hyperuricemic patients.	500
	S(H)	GF	Saturation at 10 mg.% urate with 50 mg.% HSA.	138
Bile acids	PF(H)	D	Detn. k and n. Studied effect of pH and structure.	501
Palmitic acid	A(B)	(^{14}C)	Measured uptake of acid by rat epididymal fat pads.	502
Pyridoxal-5-PO_4	A(B)	SP	$n_1 = 1$, $n_2 = 1.9$, $n_3 = 2.5$, $k_1 = 10^6$, $k_2 = 10^5$, $k_3 = 7.8 \times 10^2$.	503
18 Amino acids	S(H)	—	—	504
Indole analogs	A(H)	D	Determined effect of fatty acids, $\Delta F°$, $\Delta H°$, $\Delta S°$.	505
	A(H)	D	Determined effect of pH, salts, and fatty acids.	119
	A(H)	D	Determined effect of pH, salts, and fatty acids.	506
Tryptophan	A(H,B)	D	Reported n and k, effect of pH, fatty acids, and competing compounds.	507
	S(H)	U,UC	$n = 1$, B = 75%, k reported with and without competitors.	508
	S(H)	U,D	Calculated $\Delta F°$, $\Delta H°$, $\Delta S°$.	509
	S(H)	D	Used D and L isomers.	510
Acetyl tryptophan and skatol	A(B)	D	Studied effect of KCl, dioxane, temperature, pH, urea, and glycine.	511
Phosphatidylserine	A(H)	T	$n_1 = 2$, $n_2 = 30$; $k_1 = 2 \times 10^5$, $k_2 = 1.3 \times 10^3$.	512
Bilirubin	A(H)	B	Measured oxidative phosphorylation in brain and liver mitochondria.	513
	S		pH effect determined, 1° association with albumin.	514
	A,G(H)	SP,EP	1° association with albumin, none with globulin.	515
	A(B,H)	SP	Bound to extent of 20 mg./Gm. protein.	516
	PF	E	1° association with albumin. Association with globulins occurred at high concentration.	517
	S(H)	EG	Only albumin binding found in hyperbilirubinemic serum.	518
	A(H)		Studied peritoneal dialysis.	187
	S(H)	D,UC	B = 98%, $n = 10$, also studied metabolites.	519
	S(H)	SP	Displaced by sulfa, salicylates, pH, caffeine Na benzoate.	229
	S(H)A(B)	SP,U,D	Bound form displaced by salicylates and sulfas.	228
	S(H)	BF	Studied 40 infants with neonatal jaundice. Bilirubin displaced by heme, salicylates, and sulfonamides.	227
	S(H)	BF	Compared ability of drug to displace bilirubin in infants.	232
	S(H)	BF	Studied effect of sulfisoxazole on bilirubin level in infants.	230
Bilirubin	A,S(H)	U,GF	$n = 2$ for HSA, displaced by sulfonamides.	231
	S(D,H)	U,D,UC,E	1° bound to albumin, measured excretion rate.	520

[a] Type of protein: A, albumin; CSF, cerebral spinal fluid; G, globulin; L, lymph; PF, plasma fractions; S, serum or whole plasma; T, tissues. Animal species in parentheses: B, bovine; C, chicken; D, dog; E, horse; F, frog; G, goat; GP,

(*Continued on next page.*)

TABLE I—(*Continued.*)

guinea pig; H, human; M, mouse; O, ox; P, pig; R, rabbit; Rt, rat; S, sheep; T, turkey. [b] A, autoradiography; Ad, adsorption; B, assay for biological activity; BF, assay of biological fluids for drug; C, column chromatography; D, dialysis; Dc, continuous flow dialysis; DF, diffusion; E, electrophoresis; EG, gel electrophoresis; EP, paper electrophoresis; F, fluorescence; GF, gel filtration; NMR, nuclear magnetic resonance spectroscopy; OR, optical rotation; P, precipitation; PG, polarography; Pt, partitioning; S, solubility; SP, spectrophotometric; ST, stabilization of protein or drug; T, turbidimetric analysis; U, ultrafiltration; UC, ultracentrifugation. [c] Includes experimental conditions, observations, and conclusions derived from the various studies. B = percentage of drug which was bound; 1° = protein involved in primary interaction; n = number of binding sites on the protein; k = binding association constant; k_{dp} = binding dissociation constant; U = drug concentration in units. [d] Grouped by class of compound investigated.

TABLE II—SUMMARY OF STUDIES INVOLVING PROTEIN BINDING OF VARIOUS DYES

Dyes	Ref.
Azo Dyes	
Methyl orange	(117, 122, 521–534)
Methyl red	(535)
Trypan blue	(536–538)
Trypan red	
Congo red	(534, 539–543)
Evans blue	(124, 544, 545)
Miscellaneous azo dyes	(91, 116, 265, 546–556)
Phthalein Dyes	
Phenol red	(557–562)
Bromophenol blue	(563–567)
Bromocresol green	(565, 568–570)
Bromothymol blue	(571)
Sulfobromophthalein	(137, 572–574)
Fluorescein	(575)
Miscellaneous dyes and studies involving several classes of dyes	(576–595)

tein was measured by several investigators (45, 46). Kripalani and Sorby (47) measured albumin binding of cortisol and its degradation products and have emphasized the necessity of determining the extent of steroid degradation when equilibrium dialysis and other methods requiring extended periods of time are employed to detect and quantitate binding behavior. Blair *et al.* (48) and Beisel *et al.* (49) studied the binding and renal excretion of cortisol and the glucuronides of 17-hydroxy-corticosteroids. A number of other investigations employing electrophoresis (50–52), ultracentrifugation (53), ultrafiltration (54–56), and biochemical assays (54, 57) have dealt with the binding of corticosteroids to plasma proteins of man, rat, cow, and a variety of other animal species.

Similarly, the binding of thyroid hormones by proteins has been the subject of comprehensive reviews (58–66) and references to this topic were also omitted from Table I. Such interactions are thought to be of consequence in the distribution, biotransformation, elimination, and activity of the hormones. Specialized plasma proteins with high affinities for thyroxine have been identified and classified. Of possible therapeutic importance is the observation that 2,4-dinitrophenol, salicylate (58, 59), trypan blue (58), organic dyes, and diphenylhydantoin (67) can inhibit the binding of thyroxine by some proteins. An interesting study (68) showed that ethylchlorophenoxyisobutyrate can apparently increase the binding capacity of serum proteins for triiodothyronine. More recent studies, which were not included in the cited review articles, utilized a variety of techniques including fluorescence (69), dialysis (69, 70), and electrophoresis (71–77) to demonstrate binding. Other studies were concerned with the effect of subject age (78), sex (79), thyroidectomy (80), pH, and buffers (81) on the plasma binding of thyroid hormones.

A number of studies dealt with the interactions of plasma proteins with compounds which are not of therapeutic significance, and illustrate the ability of albumin, in particular, to interact with a seemingly limitless variety of structures. Many surfactants (82–92, 3), for example, have been studied in this respect. Ethanol (93), various polyelectrolytes (94), polymers (95), fatty acids (96–98), buffer components (99–101), thio acids (102), quinone imides (103), acetamide (104, 105), octane and dodecane derivatives (106), *p*-aminobenzene (107), phosphoric esters (108), aromatic acids (109), benzpyrene (110), and a variety of other compounds have been shown to reversibly combine with plasma proteins. In addition, many inorganic anions and cations were observed to interact with albumin (111–113, 2). It has been demonstrated that the presence of inorganic ions can influence drug protein interactions by forming a bridge between protein and small molecule (114, 115), by competing for available binding sites (116–119), by altering the configuration of the macromolecule or inducing changes in ionization characteristics of the protein (2, 120).

New Experimental Methods — Classical methods, employed to detect, determine, and study binding characteristics, such as equilibrium dialysis, ultrafiltration, ultracentrifugation, and electrophoresis have been discussed by a number of authors (1, 6, 121). Although most of the studies tabulated in Tables I and II utilized these methods, modifications and some relatively new approaches were also described. Stein (122) described a rapid, nonequilibrium dialytic method which was shown to yield, for the protein binding of methyl orange, results which were comparable to those obtained by equilibrium methods. Bennett and Kirby (123) developed a vacuum ultrafiltration cell which was used to investigate the

binding of penicillins. Differences in the polarographic behavior of bound and free substrate have been demonstrated and applied to the determination of binding parameters as illustrated by the studies of Markus and Baumberger (124) with Evans blue. The interactions of protein with methyl orange (117), fatty acids (97), tocopherol (125), testosterone (118, 126–128), and other steroids (129) were examined by determining the influence of protein concentration on the apparent partition coefficient of the small molecule. Gel filtration has, in recent years, been extensively used to detect the binding of small molecules. Techniques and theory applicable to this method have been presented by several authors (130–134). Such procedures employ beads of cross-linked polysaccharides which are water insoluble but which undergo extensive swelling when in contact with water. Macromolecules such as proteins and protein complexes are unable, because of size, to penetrate into the internal volume of the gel matrix while small molecules do penetrate. The method is capable of yielding data similar to that obtainable from dialytic techniques without concomitant problems of membrane binding, Donnan effects, and time considerations. However, difficulties can be encountered. For example, many small molecules can interact with the gel material resulting, from mass law considerations, in dissociation of the protein complex (135, 136). In addition, when gel-filtration chromatography is used to demonstrate binding, the elution step results in dilution of the binding system and possible significant dissociation of the complex. The technique has been employed to study the binding by plasma proteins of a variety of compounds such as dyes (137), uric acid (138), antibiotics and sulfonamides (139–141), corticosteroids (142–144), and barbiturates (145).

Improved sensitivities have been realized with many of the classical techniques through the use of isotopically labeled small molecules. The ease of analysis afforded by this approach has permitted *in vitro* studies at concentration levels comparable to those encountered *in vivo*. This subject was recently reviewed by Cohen *et al.* (146). Illustrative of the utility of this approach are studies which employed isoniazid-^{14}C (147), ^{3}H or digitoxin-^{14}C (148, 149), chlorpropamide-^{35}S (150), testosterone-^{14}C (151), biotin-^{14}C (152), vitamin B_{12} ^{57}Co-, ^{58}Co-, ^{60}Co- (153–155), penicillins-^{14}C (156, 157), and progesterone-^{14}C (158).

Recent studies have established the value of nuclear magnetic resonance spectroscopy as a tool for studying protein–small molecule interactions and for assessing the extent to which various functional groups on the small molecule participate in the interaction. Jardetsky and Wade-Jardetsky (159) and Fisher and Jardetzky (160), for example, studied the binding of sulfonamides and penicillins by determining NMR spectra of the compounds in the presence and absence of albumin. They observed that relaxation rates for certain protons changed in the presence of protein and were able to conclude that the *p*-aminobenzene sulfonamide moiety of sulfonamides and the phenyl ring of penicillin were the functional groups which participated in the interaction.

The majority of reported studies were concerned with a characterization of binding behavior at equilibrium. A limited number of studies were also conducted to assess the kinetics of binding. Robbins *et al.* (161) investigated the rate of interaction of thyroxine with serum protein. They employed a rapid dialysis technique which consisted of placing a thin piece of lens paper, which was saturated with a solution of drug or drug and protein, directly on a dialysis membrane. It was shown that the association and dissociation reactions were complete within 2 min. A more sophisticated method was also employed and consisted of determining the rate of quenching of the fluorescence of albumin caused by the interaction with thyroxine. Association was determined to be complete within 150 msec. The dissociation process was resolved into two steps with half-lives of 0.1 sec. and 7 sec. Froese *et al.* (162) employed a temperature-jump technique to investigate the kinetics of interaction between albumin and two azo dyes. The reaction system was perturbed by about 10° within 1 μsec. and the readjustment of the system to equilibrium conditions at the higher temperature was followed spectrophotometrically. Rate constants for association were found to be 0.36×10^{6} and 2.1×10^{6} mole^{-1} sec.$^{-1}$. Rolinson and Sutherland (163) attempted to investigate the kinetics of penicillin binding using dialysis and ultrafiltration. They found that equilibrium was attained rapidly and that the rate of attainment was too fast to investigate by these methods. Although there is general agreement that, in most systems, rates of association and dissociation are very rapid, there is a paucity of quantitative information and a need for additional studies in this area.

Treatment and Presentation of Experimental Data—Most investigators have been concerned with protein–small molecule systems at equilibrium and with the determination of degree of binding as a function of compositional and environmental variables. A number of methods for treating and presenting the results of such investi-

gations are commonly used. The reciprocal plot and the Scatchard plot of experimental data are employed frequently and are directly derived from mass-law considerations. It can be shown (6) from such considerations that reversible binding is described by the familiar equation:

$$r = \sum_{i=1}^{i} \frac{n_i k_i D_f}{1 + k_i D_f} \qquad \text{(Eq. 1)}$$

where

r = moles of small molecule bound to total moles of protein in the system.
n_i = number of binding sites in the i'th class of sites.
k_i = intrinsic association constant for the binding of small molecule by sites in the i'th class.
D_f = concentration of unbound small molecule.

Equation 1 assumes that activities can be represented by concentrations, that all sites within a class are equivalent in binding affinity, and that all sites are mutually independent. For a single class of sites:

$$r = \frac{nkD_f}{1 + kD_f} \qquad \text{(Eq. 2)}$$

Equation 2 can be rearranged to yield:

$$1/r = 1/n + 1/nk\,D_f \qquad \text{(Eq. 3)}$$

which is the basis for the reciprocal plot in which $1/r$ is plotted as a function of $1/D_f$. Estimations of n and k are made from the slope and intercept values of such a plot. The Scatchard plot is based on a different rearrangement of Eq. 2;

$$\frac{r}{D_f} = nk - rk \qquad \text{(Eq. 4)}$$

A plot is made of r/D_f as a function of r; extrapolation to abscissa and ordinate allows estimation of n and nk. Curvature of such plots is usually indicative of the existence of more than one class of sites, *i.e.*,

$$r = \frac{n_1 k_1 D_f}{1 + k_1 D_f} + \frac{n_2 k_2 D_f}{1 + k_2 D_f} + \cdots + \frac{n_i k_i D_f}{1 + k_i D_f} \qquad \text{(Eq. 5)}$$

Graphical treatment of data by means of the reciprocal plot heavily weights those experimental points which are obtained at low D_f and can, therefore, lead to misinterpretations concerning behaviors at high D_f. The Scatchard plot does not suffer from this disadvantage and is the graphical method of choice. Extrapolation of a Scatchard plot curve, obtained when more than one class of sites are responsible for binding, yields $\Sigma n_i k_i$ and Σn_i. Various curve-fitting techniques can be employed to estimate individual n and k values. Hart (164) has recently discussed the analysis of such curves and showed that n and k values for each class of site can be evaluated by solving a set of simultaneous linear equations. For a system containing i classes of sites, $2i$ experimental points are required to generate $2i$ linear equations which can be solved for the i sets of n and k.

Reciprocal and Scatchard plots cannot be constructed if the nature and amount of protein in the experimental system is not known, as would be the case, for example, in determining the binding characteristics of plasma. Many authors have presented the results of such determinations in terms of "percent bound" or "fraction bound." This way of describing binding behavior is so commonly used that it is pertinent to repeat Goldstein's criticism (1): "The statement that a given fraction is bound in plasma is meaningless, unless qualified by an indication of the unbound drug concentration at equilibrium." The relationship between "fraction bound," β, and the fundamental parameters of binding, n and k, for the case of a single class of binding sites, is:

$$\beta = \frac{1}{1 + D_f/n\,P_t + 1/nk\,P_t} \qquad \text{(Eq. 6)}$$

where, P_t = total molar concentration of protein.

It is apparent that "fraction bound" exhibits a dependency on the concentration of free drug and the concentration of protein. Thus, "fraction bound" is a useful characterization of intrinsic binding strength only when D_f/nP_t approaches zero. Under such conditions, β approaches a maximum value and

$$nk\,P_t = \frac{\beta}{1 - \beta} \qquad \text{(Eq. 7)}$$

It should also be noted in this respect that experimental techniques which perturb the protein–small molecule system by dilution prior to the determination of the fraction of drug which is bound can grossly underestimate the true extent of binding. Saris (165) has presented data related to sulfonamide binding which illustrates this potential source of error. Similarly, Oppenheimer and Surks (166) have shown that when the association constant is large, such as in thyroxine-plasma systems, "fraction bound" is unaffected by reasonable dilution.

Krüger-Thiemer *et al.* (167) have discussed mathematical problems associated with studies on the binding of drugs in plasma samples. They showed that plasma binding, if due to a single plasma protein with a single set of sites, can be characterized by two parameters, according to the equation:

$$D_t = D_f\left(w + \frac{\beta' p}{D_f + k_{dp}}\right) \qquad \text{(Eq. 8)}$$

where

D_t = total molar concentration of drug in the plasma
D_f = molar concentration of unbound drug in the plasma
w = volume fraction of water in the plasma
β' = maximum binding capacity of plasma for drug in μmoles/Gm.
k_{dp} = intrinsic dissociation constant for the drug–protein complex
p = protein concentration in Gm./L.

They demonstrated the application of three equations, first published by Woolf (168), for linearizing data and for the graphical determination of β' and k_{dp}:

$$\frac{\beta' p}{D_b} - \frac{k_{dp}}{D_f} = 1, \qquad \text{(Eq. 9)}$$

$$D_b = \beta' p - k_{dp}\frac{D_b}{D_f}, \qquad \text{(Eq. 10)}$$

$$D_f = \beta' p \frac{D_f}{D_b} - k_{dp} \qquad \text{(Eq. 11)}$$

where D_b = concentration of bound drug. They also described the application of a digital computer to the estimation of β' and k_{dp} from experimental data and illustrated their approach with studies on three sulfa drugs. The binding behaviors of two of these could be adequately described by Eq. 8. The third drug exhibited a more complex behavior which could be explained by expanding Eq. 8 to include a term for a second binding process.

Sandberg *et al.* (169) and Rosenthal (170) have also discussed treatment of binding results when the nature and concentration of the protein is not known. They have recommended a Scatchard-type plot based on a rearrangement of Eq. 2:

$$\frac{D_b}{D_f} = nkP_t - kD_b, \qquad \text{(Eq. 12)}$$

which will also be recognized as a slightly modified form of Eq. 10. A plot of D_b/D_f as a function of D_b is independent of protein concentration and allows estimation of nkP_t, nP_t, and k from ordinate intercept, abscissa intercept, and slope. If more than one protein or more than one class of binding site on a single protein are involved in the binding, curvature of the plot results. This plot can also be used to provide a useful display of data from which can be determined the concentrations of all drug-containing species at any total or free drug concentration.

Hansch *et al.* (171) discussed a novel type of data treatment which was designed to provide an insight to the nature of intermolecular forces responsible for binding. They studied the binding by albumin of phenol and 18 substituted phenols and determined in each case the concentration, C, required to yield a 1:1 complex with the protein. They also determined the partition coefficient of each compound between octanol and water and calculated a substituent constant, π, which was defined as:

$$\pi = \log P_X/P_H, \qquad \text{(Eq. 13)}$$

where

P_X = partition coefficient of a phenol derivative
P_H = partition coefficient of phenol.

A semi-log plot of $1/C$, which is proportional to the complex association constant, *versus* π was found to be linear. The authors concluded that, mechanistically, binding closely paralleled the transfer of phenol from water to octanol, that binding was rather nonspecific, and was best described as being due to hydrophobic bonding.

Influence of Protein Binding on Drug Distribution—There is general consensus that, because macromolecules and macromolecular complexes pass across membranes only with difficulty, protein binding in plasma can influence the distributional pattern of a drug in the body. The extent to which this influence is manifest and significant has been the subject of a number of studies. Martin (172) has provided, by means of a simple model, a quantitative visualization of the potential effects of plasma binding on drug distribution. His treatment admirably serves as a basis for a discussion of this topic. His approach to this evaluation was based on the following assumptions: (*a*) drug in the body is distributed into two aqueous compartments—plasma and a compartment composed of the remaining body water, (*b*) unbound drug is in equilibrium in the two compartments, (*c*) binding of drug occurs only in the plasma and results from the formation of 1:1 complexes with albumin, (*d*) for a 70-Kg. man, the plasma volume is 3 L. and the total volume of water is 42 L., (*e*) the molar concentration of albumin in the plasma is 5×10^{-4}. He then conducted calculations related to the binding of four hypothetical drugs whose interactions with albumin could be characterized by association constants (k) of 10^4, 10^5, 10^6, and 10^7 L. mole^{-1}, respectively. For each drug he assumed a concentration of unbound drug, D_f, and calculated, first, the total concentration of drug in plasma, D_t, by an equation directly derivable from Eq. 6:

$$D_t = D_f\left(1 + \frac{P_t}{1/k + D_f}\right) \qquad \text{(Eq. 14)}$$

He then calculated for each value of D_f: (*a*) amount of drug in body $= 39\,D_f + 3\,D_t$; (*b*) percent of drug, free in body $= 42\,D_f \times 100/(39\,D_f + 3\,D_t)$; and (*c*) percent of drug in plasma $= 3\,D_t \times 100/(39\,D_f + 3\,D_t)$.

The results of such calculations were presented in graphical form such as illustrated by Figs. 1 and 2. It is apparent from these representative theoretical curves that binding can influence drug distribution in the body and that the magnitude of the effect will depend both on the strength of association and the dosage of drug. For example, a strongly bound drug such as that with a k of 1×10^7 will, at low dosage levels, be concentrated primarily in the plasma compartment. However, at higher dosage levels, the fraction of drug in the plasma will be markedly reduced. Martin also emphasized another characteristic attributable to the plasma binding of drugs with a high affinity for proteins; that there is a dosage range within which small increases in dose result in relatively large increases in the amount of drug in the body which is not bound. He noted that this behavior can have interesting manifestations on dose-response characteristics and pharmacokinetic properties of such drugs. The treatment additionally emphasizes that binding to the plasma proteins will have an appreciable effect on drug distribution only if the strength of binding is quite large ($k > 10^4$). Martin (172) showed, to illustrate this point, that with a drug having a k of 10^4, the "fraction bound" in plasma can be 83.4% but, nevertheless, 73% of the total dose is present in the body in the unbound form. Martin's model is a highly simplified representation of what might indeed be a highly complex distributional pattern involving binding to tissue proteins, partitioning into fatty compartments, the unavailability of certain aqueous compartments, *etc.* Nevertheless, he clearly demonstrates that plasma-protein binding can be an important determinant in drug distribution for some drugs but that for many others, it might not be of significance in spite of *in vitro* demonstrations that interaction occurs to produce a seemingly high "fraction bound."

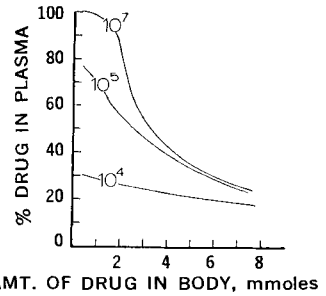

Fig. 1—A plot, based on theoretical considerations, illustrating the potential influence of plasma binding on the distribution of drug between plasma and other aqueous compartments in the body. Each curve represents a different value of k. *After Martin (172).*

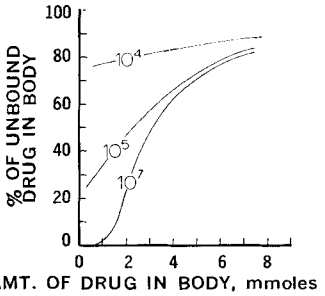

Fig. 2—A plot, based on theoretical considerations, illustrating the potential influence of plasma binding on the distribution of drug between bound and unbound forms in the body. Each curve represents a different value of k. *After Martin (172).*

A number of recent experimental studies have demonstrated, in a qualitative sense, that plasma binding can influence drug distribution. Verwey and co-workers (173–175) developed a method for sampling lymph by cannulation of the peripheral lymphatics of dogs. They noted that examination of peripheral lymph is useful in drug distribution studies since it is derived directly from interstitial fluid. They studied, in dogs, the distribution of seven penicillins between plasma and lymph and showed that for six of the seven analogs, plasma concentrations were significantly higher than those found in the lymph. The degree of binding in plasma and in lymph was determined and it was demonstrated that unbound drug was in equilibrium between the two fluids. Their results supported the conclusions of Rolinson (176) who considered theoretical aspects of protein binding as it relates to the distribution of penicillins and emphasized that only unbound drug is free to diffuse from plasma. Similar conclusions were made by Kunin (177) who showed with a series of penicillins that as the degree of protein binding decreased, localization of antibiotic in brain, muscle, lung, and heart of rabbits increased. He also showed that the co-administration of an agent capable of displacing protein-bound drug increased the amount of antibiotic which localized in the tissues.

Fishman (178) found that probenicid, when co-administered with penicillin, resulted in a higher level of antibiotic in the cerebral spinal fluid of the dog. He postulated that this effect was due, in part, to the displacement of protein-bound antibiotic by probenicid. Additional studies of this nature will be discussed in a subsequent section. Kharchenko (179, 180) also conducted studies on the distribution of antibiotics in the rabbit. He showed that when human serum was injected into the pleural cavity, distribution into this compartment occurred to a much greater extent than when saline controls were injected. Johnson *et*

al. (150) reported on the distribution of chlorpropamide-^{35}S in a patient with edema. They determined that the plasma concentration of drug was two to six times higher than that in the edematous fluid. Scholtan (181, 182) showed that a relationship existed between the degree of binding of sulfonamides and tissue distribution, in several species of animals. Rieder (183) also found a correlation between binding parameters and sulfonamide distribution in the rabbit and reported that the concentration of unbound drug in the plasma provides a reasonable estimate of the concentration of unbound drug in extravascular fluids. Ruiz-Torres and Meinig (184) reported, however, that no such correlation existed in their studies on the distribution of sulfonamides in the rat.

An interesting application of the influence of drug–protein interactions on drug distribution is illustrated by studies in which albumin was employed as an additive to the fluid used for reducing, by peritoneal dialysis, body levels of toxic substances. Campion and North (185) treated, in this way, dogs that were intoxicated with phenobarbital, amobarbital, and secobarbital and reported that the dialysis fluid containing albumin was more efficient than a control fluid. Bourne *et al.* (186) utilizing pentobarbital-intoxicated dogs, found that only a slightly greater efficiency was achieved with the technique. Grollman and Odell (187) observed that inclusion of albumin in dialysis fluid increased the amount of bilirubin which could be removed by a factor of 25. Other authors have noted enhanced removal, by this method, of salicylates from dogs (188) and barbiturates from humans (189).

Competitive Inhibition of Plasma Binding—A number of investigations have clearly demonstrated that the pharmacological response to a drug can be diminished as a result of interaction to form nondiffusable protein complexes. It is pertinent to briefly review some of these studies and to then examine the possibility of eliciting, either intentionally or unintentionally, a more pronounced response through the administration of agents which competitively inhibit binding.

Antibiotics and anti-infective agents have been intensely investigated in this respect. Plasma inactivation of penicillins, cephalosporins, and other antibiotics is a well-known phenomenon (190–192). Rolinson and Sutherland (163), for example, studied the plasma binding of 17 antibiotics and found that *in vitro* activity was inversely proportional to the observed extent of binding. Evidence supporting the premise that only unbound sulfonamides are antibacterially active was accumulated by Witzgall and Boyens (193) and Krüger-Thiemer *et al.* (194). Other workers (195, 196) failed to observe this effect, but it should be noted that their experimental methods employed rather large dilutions of plasma samples with concomitant pertubation of binding equilibria. Anton (197) also demonstrated an inverse correlation between bacteriostatic activity and extent of binding of sulfonamides.

Reynolds and Cluff (198) have shown that the antipyretic activity of sodium salicylate in rabbits was decreased when albumin was coadministered. Aladjenoff *et al.* (199) observed that plasma levels of *d*-tubocurarine were unusually high in patients who were refractory to the drug. They also found that the drug, when preincubated with albumin, lacked a curarizing effect in dogs. They suggested that the highly bound drug was unable to diffuse from the plasma to the neuromuscular junction. Jindrova *et al.* (200) evaluated four phenothiazine derivatives and determined that those which were least bound exhibited the greatest antihistaminic activity. Oroszlan and Maengwyn-Davies (201) found that the cholinolytic activity of atropine, on the isolated rat colon, was inhibited by the presence of albumin. Ogawara *et al.* (202) showed that a pluromycin A–albumin complex was less toxic than pluromycin A, and that the complex had a greater antitumor activity. Several investigators (54, 57, 203) reported that the presence of protein interfered with the participation of various steroids in biochemical processes.

Reversal of this type of drug "inactivation" by the addition of a competitive inhibitor to the binding system has been considered by a number of workers and attempts to evaluate such a possibility, *in vitro* and *in vivo*, have been reported. The theoretical foundations for this approach can be readily demonstrated. If drug, D, and competitor, C, for example, form 1:1 protein complexes and compete for the same binding site on the macromolecule, it can be shown that:

$$\frac{D_f}{D_t} = \frac{1 + k_D D_f + k_c C_f}{1 + k_D P_t + k_D D_f + k_c C_f}, \quad \text{(Eq. 15)}$$

where

k_D = association constant for the drug–protein complex
k_c = association constant for the competitor–protein complex
C_f = concentration of unbound inhibitor.

It is readily apparent, from Eq. 15, that the effectiveness of an inhibitor in "freeing" drug from combination with protein will depend on its concentration and affinity for the protein. It is il-

lustrative to assess quantitative aspects of such drug "displacement" by the construction of drug distribution curves in the same manner as was previously discussed. The results of such a treatment for a strongly bound drug ($k_D = 10^7$) is shown in Fig. 3. These theoretical curves were generated from Eq. 15 by the calculations and assumptions that were employed by Martin (172) and which were discussed previously. Various values of k_eC_f were assumed in making these calculations. It is obvious from examination of the curves that the influence of a competitive inhibitor on the fraction of drug which is free in the body can be quite pronounced and that this influence will be especially significant at lower dosage levels of the drug. It is also apparent that, in order to displace a strongly bound drug by this mechanism, an inhibitor must be present in the system at a relatively high concentration or have an affinity for the protein which is significantly greater than that exhibited by the drug.

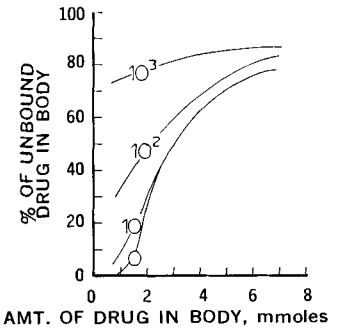

Fig. 3—A plot, derived from theoretical considerations, illustrating the potential influence of competitive inhibitors of plasma binding on the distribution of drug between unbound and bound forms in the body. See text for the assumptions made in deriving the relationship. Each curve represents a different value of k_eC_f.

Anton's studies (197, 204) have been frequently cited as an example of this approach to the possible potentiation of the pharmacological activity of a strongly bound drug. He was concerned with the inhibition, *in vitro* and *in vivo*, of sulfonamide binding. He demonstrated that phenylbutazone, sulfinpyrazine, ethyl biscoumarate, and iophenoxic acid were, among many compounds evaluated, effective in displacing protein-bound sulfonamides and that the antibacterial activity of a sulfonamide in the presence of albumin was markedly increased by the presence of a displacing agent. He showed quite dramatically that administration of sulfinpyrazone to rats which were dosed with sulfaethylthiadiazole or sulfamethoxypyridazine resulted in a precipitous decline in the total plasma concentration of sulfonamide but an increase in the concentration of unbound drug. Concomitant with this was an increase in the concentration of sulfonamide in tissues. Studies with other sulfonamides showed that displacing agents altered tissue and plasma concentrations of only those which were reasonably strongly bound. Genazzani *et al.* (205) determined that various tetracycline derivatives competed with sulfaethylthiazole for binding sites on albumin. Bahal (206) found that the binding of sulfaethylthiazole was modified by the presence of salicylate. His attempts to evaluate *in vivo* displacement of bound sulfonamide and the resulting effect on excretion rate was complicated by the observation that the agents which were effective in displacing the sulfonamide also retarded tubular secretion of the drug.

Kunin (156, 157, 207, 208) has published the results of exhaustive studies in which over 250 compounds, representing a wide variety of structures, were evaluated for their ability to displace protein-bound penicillin G, penicillin V, and other derivatives. Three compounds—sulfamethoxypyridazine, sulfaethylthiadiazole, and acetylsalicylic acid—were found to be effective and were employed in studies with human volunteers to determine their effects *in vivo*. The results indicated that it was possible to reduce serum binding of penicillins in man by this approach. The administration of binding inhibitors tended to lower the total serum concentration and to increase the concentration of unbound antibiotic in the serum. His results demonstrated that the relative effectiveness of an inhibitor is defined by both the relative concentrations and relative affinities for the protein of drug and inhibitor. Thus, administration of sulfaethylthiadiazole was effective in reducing the binding of the moderately bound penicillin V from approximately 81 to 65%. However, the binding of strongly bound dicloxacillin was reduced only slightly from 98.3 to 97.7%. Kunin discussed the possible clinical implications of reversing, by even a small amount, the binding of a strongly bound drug. He also noted that attainment of enhanced clinical activity by displacement might be realized only with difficulty because of the large doses of inhibitors required and the often limited degree of displacement which may be achieved in man. Rolinson and Sutherland (163), Anderson *et al.* (209), and Fishman (210) have also reported the results of *in vitro* investigations on the competitive inhibition of penicillin binding.

Other studies in this general area include those of Davison and Smith (211) who observed that a variety of benzoates and salicylates are bound to the same sites on albumin. Lasser *et al.* (212) found that the administration of a highly bound radiopaque agent caused potentiation of pento-

barbital hypnosis which they attributed to the displacement of the barbiturate from protein complexes. Brodie (21) reported a correlation between the activity of nonsteroidal anti-inflammatory agents and their ability to displace bound corticosterone. Mizushima and Suzuki (213) similarly noted some correlation between the antirheumatic activity of nonsteroidal drugs and their ability to interact with various serum protein fractions. Florini and Buyske (214), however, concluded from their investigations that such compounds did not appear to function *via* displacement of bound hydrocortisone. Other studies have been concerned with the displacement of aldosterone by spirolactones and other steroids (44), and the mutual competition between cortisol, corticosterone, and progesterone (55), as well as estrone (215) for plasma protein binding sites. Skidmore and Whitehouse (216) have suggested that displacement of protein-bound pyridoxal phosphate or 2,4,6,-trinitrobenzaldehyde might be useful as an approach to the screening of anti-inflammatory activity. Buttner and Portwich (217) observed that 5-ethylsulfadiazine and tolbutamide mutually displaced each other from albumin binding sites. Concomitant administration of the two drugs resulted in enhanced clinical activity. Wishinsky *et al.* (218) measured the binding of four sulfonylurea drugs and found that addition of salicylate to the binding system resulted in a substantial increase of unbound drug. The occurrence of hypoglycemic episodes was reported with a patient who was receiving both tolbutamide and sulfaphenazole (219). It was explained, however, as resulting not from drug displacement but rather from an increased half-life for tolbutamide due to inhibition of a carboxylation process.

A general discussion of possible therapeutic difficulties which might be encountered in the concomitant administration of drugs has been presented by MacGregor (220) and Brodie (221). Several reports have been concerned with possible hazards resulting from the displacement of bound anticoagulants. Aggeler *et al.* (222) observed that phenylbutazone can decrease warfarin plasma concentrations 35 to 60%, decrease biological half-time 20 to 60%, and increase anticoagulant effects 40 to 80% in normal patients and 250% in warfarin-resistant patients. Other clinical reports (223, 224) noted a marked increase in prothrombin time as a result of the co-administration of sodium warfarin and phenylbutazone or oxyphenbutazone. Solomon and Schrogie (225) demonstrated by *in vitro* studies that a variety of agents were capable of displacing protein-bound warfarin. Reference has been made to the fact that methotrexate (226), which is administered in near toxic doses, can be displaced by salicylates and certain sulfonamides.

Consequences resulting from the displacement by drugs of protein-bound endogenous compounds have also been considered and studied. Bilirubin is an important example since its displacement can result in toxic manifestations in infants and in individuals with impaired bilirubin conjugating mechanisms. Odell (227, 228) showed that salicylates and sulfonamides, in concentrations which are encountered clinically, could displace bilirubin. He reviewed (229) the clinical implications of such an event. Kantor *et al.* (230) and Josephson and Furst (231) also considered displacement of this compound by the administration of sulfonamides to premature infants with kernicterus or to mothers before and during labor. Silverman *et al.* (232) compared the mortality rate of premature infants who received either penicillin and sulfisoxazole, or tetracycline. Their data suggested that kernicterus was more prevalent in the population which received the sulfonamide.

Christensen (233) has studied the effect of several benzoates and salicylates on thyroxine binding and has attempted to relate physiological and toxicological effects to the displacement of bound hormone. Yamada *et al.* (234) have concluded that a prime effect of diazo dyes, such as trypan blue, on the thyroid occurs due to displacement of thyroxine from plasma proteins and subsequent inhibition of TSH release. Numerous studies have shown that salicylate (235–237), hydantoin derivatives (238, 239), penicillins (239, 240), thyroxine analogs (241), dinitrophenol (242–244), and novobiocin (245) were capable of displacing bound thyroxine. In addition, studies on the binding of insulin (246) indicate that tolbutamide was able to liberate protein-bound insulin in guinea pig serum.

Of interest are two studies which indicate binding enhancement induced by the presence of a second compound. Thus, Dollery *et al.* (247) noted that pempidine, a ganglionic blocking agent, did not interact with bovine serum albumin. However, when chlorothiazide was added to the system, considerable binding was apparent. It was speculated that chlorothiazide induced a structural alteration in the protein which resulted in a configuration capable of binding pempidine. Similarly, acetylcholine was found to increase binding of atropine to albumin in systems buffered at pH values from 5 to 6 (248).

Protein Binding and Pharmacokinetic Behavior—The influence of protein binding on the time course of drug in the body has been con-

sidered by a number of authors. Many qualitative and semiquantitative observations have indicated that binding can be an important parameter in the pharmacokinetic characterization of a drug. *In vitro* studies have, for example, established that the addition of protein to isolated biochemical and physiological preparations can result in a decreased rate of substrate disappearance. Thus, Newbould and Kilpatrick (249) showed that the rate of acetylation of two long-acting sulfonamides in a perfused rabbit liver preparation was decreased when plasma was added to the perfusion fluid. They determined that the observed rate depended on the concentration of unbound drug. Similarly, Anton and Boyle (250) showed that, in an *in vitro* enzyme system, albumin interfered with the acetylation of sulfamethoxypyridazine. Wiseman and Nelson (251) reported a rank-order correlation between the rates of *in vivo* metabolism of a number of sulfonamides and their degree of protein binding. A number of other studies (252–256) have suggested that an interdependence does exist between the rates of elimination of sulfonamides and degree of plasma binding. Rieder (183), however, did not observe a correlation between binding parameters and rate of disappearance from plasma or rate of renal excretion for the various sulfonamides which he studied. Similar results were obtained by Scholtan (181, 182) and by others (257–259). Rieder, in his discussion, points out that only when elimination proceeds primarily *via* glomerular filtration and without significant tubular secretion and reabsorption should binding be anticipated to exert an appreciable effect on the rate of elimination of a drug.

Other observations pertinent to this topic include those of Bennhold (260). He noted that the rate of elimination of congo red from patients with depressed albumin blood levels (0.1 to 0.2% of normal) was approximately 60% more rapid than with normal subjects. Upon infusion of human albumin, the elimination rate of the dye was depressed to near normal levels. Weiner *et al.* (261) have suggested that the slow biotransformation and negligible kidney elimination of dicoumarol is a result of the high degree of protein binding of this drug. The prolonged blood levels of chlortetracycline[1] were explained by Sirota and Saltzman (262) as being due to protein binding since the renal excretion of the drug was found to be solely a process of glomerular filtration. Kunin (263) has similarly related the prolonged plasma levels, slow kidney clearance, and low apparent volume of distribution of methacycline to its degree of binding. Nadeau and Subolewski (264) have suggested that extended blood levels and tolerance to morphine in dogs may be related to binding. Priestly and O'Reilly (265) reported a qualitative correlation between the biliary excretion rates of four azo dyes and their relative degrees of binding to liver homogenates and blood proteins. Beisel *et al.* (266), from their studies on cortisol elimination, concluded that plasma binding provides a reservoir of readily available steroid which is protected from excretion and metabolism. Other workers (267–269) studying different steroidal compounds have made similar conclusions.

Krüger-Thiemer and his associates, who have made outstanding contributions to the quantitative understanding of the influence of protein binding on the behavior of drugs, recently (270) discussed pharmacokinetic models which focus attention on the involvement of the binding phenomenon. One model, which was discussed in detail, depicted a drug as being distributed and in rapid equilibrium between two compartments, plasma water of volume V_1, and residual body water of volume V_3. Protein binding occurred only in the plasma compartment and the rate of renal excretion or elimination, characterized by the rate constant k', was proportional to the concentration of unbound drug in the plasma water. A rate equation analogous to the following was derived:

$$-\frac{d \ln Dt}{dt} = \frac{k'}{\left(1 + \frac{nP_t}{k_{dp} + D_f}\right)\left(V_1 + \frac{V_3}{1 + \frac{k_{dp} n P_t}{(k_{dp} + D_f)^2}}\right)} \quad \text{(Eq. 16)}$$

It should be noted that for the purposes of consistency in this paper, Eq. 16 was derived on the assumption that drug binding resulted from the interaction of drug with a specific plasma protein having n equivalent sites, and is, therefore, slightly different from that presented by Krüger-Thiemer *et al.* (270). Examination of the equation leads to the conclusion that, in such a case, a semi-log plot of D_t (plasma concentration, determined as the sum of bound and unbound drug) *versus* time will not be linear but will be characterized by a diminishing steepness of slope as time proceeds. They similarly showed that:

$$-\frac{d \ln D_f}{dt} = \frac{k'}{V_3 + V_1\left(1 + \frac{k_{dp} n P_t}{(k_{dp} + D_f)^2}\right)} \quad \text{(Eq. 17)}$$

Equation 17 predicts nonlinearity of a semi-log

[1] Trademarked as Aureomycin, Lederle Labs., Pearl River, N. Y.

plot of D_f (the concentration of unbound drug in the plasma) as a function of time. Moreover, the slope of such a curve will be initially greater than the corresponding D_t curve and will change more rapidly with time.

The model was examined by Krüger-Thiemer *et al.* (270) using computer generated data for various values of k_{dp}. In addition, blood level data obtained from a patient who was administered a long-acting sulfonamide, sulfaorthodimethoxine, were evaluated and found to be consistent with the behavior predicted by the model.

Martin (271) also considered theoretical aspects of the kinetics of elimination of drugs possessing high affinities for plasma proteins. He discussed a model in which drug was distributed between residual water and plasma. Binding occurred to form a 1:1 complex and drug disappearance proceeded at a rate which was directly proportional to the concentration of free drug. He did not present a rigorous mathematical analysis of the model but by approximate graphical methods was able to show that the rate of decline of drug concentration in the plasma underestimates the rate of drug elimination from the body. His calculations led to a conclusion that, because of protein binding, it could be possible to obtain a nonlinear semi-logarithmic plot of plasma concentration *versus* time in which slope values increase as time proceeds. It would seem, however, that this could not be the case and that this result was artifactually generated by his method of estimating plasma levels of drug. This model is similar to that discussed by Krüger-Thiemer *et al.* (270) and should exhibit the same type of behavior as they described.

Conclusions—The binding of drugs by plasma proteins continues to be a subject of active research interest and has attracted the attention of investigators from diverse disciplines. Research in this field is dipolar in character, consisting of, on the one hand, studies oriented to a fundamental physical-chemical understanding of the phenomenon and, on the other, investigations directed toward evaluation and quantitation of possible clinical manifestations and implications. Substantial progress has been made in both general areas.

While the majority of the reported *in vitro* studies have been semi-quantitative in nature, in recent years an increasing number have been conducted to yield a quantitative characterization of fundamental binding parameters. Analytically, the newer techniques of gel filtration, nuclear magnetic resonance spectroscopy, and fluorescence quenching provide the means of rapidly detecting binding, elucidating active sites involved in binding, and estimating the rates of interaction.

Considerable *in vitro* and *in vivo* evidence has been accumulated to demonstrate that plasma-protein binding can influence the distributional, pharmacological, and pharmacokinetic properties of certain drugs. In addition, theoretical contributions have been made which are of value in assessing the possible magnitudes of such influences. An impression, gained from the literature, is that there appears to be a tendency to overemphasize the general importance of the binding phenomenon in the behavior of drugs in the body. Evidence exists that only in the case of highly bound agents will binding be important in a practical sense. Many workers, in attempting to extrapolate *in vitro* data to *in vivo* expectations, tend to lose sight of the fact that the plasma comprises a relatively small fraction of the total volume available for drug distribution and that protein–drug complexes of rather extraordinary stability must be formed to substantially reduce the amount of drug that exists in the body in the active, diffusible, unbound form. A number of important drugs do, however, fall in the category of "strongly bound" and these serve as examples which emphasize the need to at least consider protein binding as a necessary parameter in the characterization of drug behavior.

New Method for Calculating the Intrinsic Absorption Rate of Drugs

By J. C. K. LOO and S. RIEGELMAN

If conceiving the body to be a single compartment is correct, calculations based on this presumption should result in an exact estimate of the rate of appearance of a drug into the blood when administered intravenously at a precisely known rate. In order to test this hypothesis selected drugs were administered intravenously at known logarithmic and linear rates of infusion, thereby mimicking first- and zero-order absorption conditions. It is shown that methods based on the single-compartment concept do not result in acceptable estimates of the absorption rates. Not only do these methods lead to an incorrect rate constant but occasionally allow incorrect assignment of the order of the process. A new equation is presented, presuming the drug distributes between a central and one peripheral compartment, which allows one to calculate the rate of absorption. The equation results in an accurate estimate of the known rates of infusion (absorption) for the drugs studied to date.

PROBABLY THE oldest published method for estimation of the rate of absorption of a drug into the blood was published by Dominguez and Pomerene (1). Their method was based on a presumption that the body may be treated as a single-compartmental reservoir from which the drug is eliminated by first-order processes. The calculation of the absorption by their method required estimation of the apparent volume of distribution of the drug in this single-compart-

Received December 4, 1967, from the Departments of Pharmacy and Pharmaceutical Chemistry, School of Pharmacy, University of California, San Francisco Medical Center, San Francisco, CA 94122
Accepted for publication January 23, 1968.
Presented to the Basic Pharmaceutics Section, APhA Academy of Pharmaceutical Sciences, Las Vegas meeting, April 1967.
This research was supported in part by a grant-in-aid from the research funds of the Academic Senate, San Francisco Division, University of California.

New Method for Calculating the Intrinsic Absorption Rate of Drugs

By J. C. K. LOO and S. RIEGELMAN

If conceiving the body to be a single compartment is correct, calculations based on this presumption should result in an exact estimate of the rate of appearance of a drug into the blood when administered intravenously at a precisely known rate. In order to test this hypothesis selected drugs were administered intravenously at known logarithmic and linear rates of infusion, thereby mimicking first- and zero-order absorption conditions. It is shown that methods based on the single-compartment concept do not result in acceptable estimates of the absorption rates. Not only do these methods lead to an incorrect rate constant but occasionally allow incorrect assignment of the order of the process. A new equation is presented, presuming the drug distributes between a central and one peripheral compartment, which allows one to calculate the rate of absorption. The equation results in an accurate estimate of the known rates of infusion (absorption) for the drugs studied to date.

PROBABLY THE oldest published method for estimation of the rate of absorption of a drug into the blood was published by Dominguez and Pomerene (1). Their method was based on a presumption that the body may be treated as a single-compartmental reservoir from which the drug is eliminated by first-order processes. The calculation of the absorption by their method required estimation of the apparent volume of distribution of the drug in this single-compart-

This research was supported in part by a grant-in-aid from the research funds of the Academic Senate, San Francisco Division, University of California.

ment, the slope of the blood level time curve at time, t, and the apparent elimination rate constant of the drug from the volume of distribution which is assumed to be constant and independent of time and dose administered. A number of other methods based on the same model have been proposed. These include the blood level maximum and time of maximum methods of Dost (2), and the ordinate intercept and total area methods of Krüger-Thiemer and Diller (3). Each of these methods requires one to make a basic presumption that the drug is being absorbed by a first-order process starting immediately after the drug is administered.

In 1960 Nelson (4) proposed a method utilizing the first and second derivatives of the urinary excretion data as a function of time. Later, in 1963, Wagner and Nelson (5) published what has become the most commonly used methods for estimating the apparent absorption rate of drugs utilizing either urinary or blood data. These methods have gained wide acceptance since they do not require prior estimate of the volume of distribution and they place no limitations on the order of the absorption rate process.

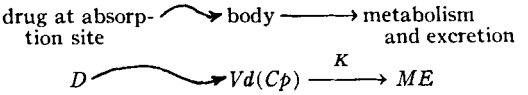
Several methods have been proposed by different workers which utilize the complete i.v. curve in conjunction with the oral absorption curve. The method of Scholer and Code (6) published in 1954 is an involved and extensive numerical estimation. The method of Silverman and Burgen published in 1961 (7) involves a curve follower and analog computer to deconvolute the blood data relative to a known i.v. curve. Recently Rescigno and Segre (8) have published a numerical rather than a computer method of deconvoluting the blood data. In 1965 Stelmach *et al.* (9) proposed an analog computer program which included the release of the drug from a dosage form prior to the absorption step. Their program initially was presented on a single-compartmental model. Their procedure was based on the presumption that one had previously defined the elimination rate constant, and the absorption rate constant of the drug administrated orally in solution.

In spite of all the available methods and the large number of estimates of the apparent absorption rate of different drugs by a variety of available methods, the literature[1] apparently contains no comparisons of these estimates with known input rates obtained from individual test subjects or animals.

The purpose of this paper is to present some experimental blood level data following infusion at known input rates. It will then be shown that the methods based on the single-compartmental model result in grossly inaccurate estimates of the known input rates and can lead to error and occasionally false interpretations of the results. Further, a new equation will be derived which allows one to use rather simple numerical procedures to estimate the true input rates.

THEORY

The Single-Compartmental Model—The single-compartmental model is based on the assumption that the dose absorbed is distributed into what is conceived to be a single compartment and is eliminated from it by first-order processes of metabolism and excretion. This is represented schematically below:



D is the amount of the original dose remaining at the absorption site, Cp is the concentration of the drug in the blood, Vd is the apparent volume of distribution[2] based on the presumption that the body behaves as a single compartment, ME represents the combined amount of drug metabolized and excreted by simultaneous first-order processes, K is the first-order rate constant for the elimination of the drug from the body and is equal to the sum of the individual rates of metabolism and excretion. On the basis of material balance, the amount of the intact drug reaching the fluids of distribution is taken to be the amount of drug absorbed at any time $(A)_t$. This is in effect the *net* influx of intact drug which has transferred into the blood stream. This is set equal to the amount of the drug in the body compartment plus the amount eliminated by all processes. Wagner and Nelson derived their absorption equations on the basis of this material balance. Since the rates of metabolism and excretion are often found to be directly proportional to the blood level, they proposed that the amount of the drug eliminated up to time t_n could be evaluated by $KV\int_{t_0}^{t_n} Cpdt$. Therefore, integration of the differential mass balance equation between the limits of t_0 and t_n, resulted in what has become known as the Wagner-Nelson (W-N) absorption equation for blood data:

$$(A/Vd)_{t_n} = Cp_{t_n} + K\int_{t_0}^{t_n} Cpdt \quad \text{(Eq. 1)}$$

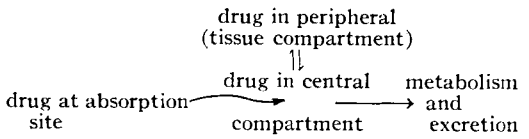
With Eq. 1, one attempts to evaluate the amount absorbed (expressed in concentration units) as being the sum of the concentration in the body as represented by the plasma concentration plus the second terms which is equal to the amount eliminated (expressed in concentration units). When all of the drug is absorbed, the value of $(A/Vd)_\infty$ will approach

[1] Wagner (10) utilized averaged data for 24 subjects obtained from Fig. 1 of Jopikii and Turpeinen's (11) data on the administration of i.v. infusions of glucose. Although a good fit was apparently obtained, the original data of Jopikii from these 24 subjects had been corrected for a varying basal glucose level. Further, the postinfusion elimination constant was different from the elimination constant during the infusion.

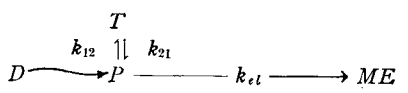
[2] In the nomenclature of the earlier papers of this series, this apparent volume of distribution is more correctly specified as Vd_{area}(11).

an asymptotic value representing the estimated total amount of the drug absorbed. Since the apparent volume of distribution may not be known, it is necessary to express the data in terms of the percent remaining to be absorbed. These data are frequently interpreted in terms of pseudo-zero and pseudo-first-order rates. Occasionally more complicated interpretation of the results is attempted (10).

The Two-Compartmental Open-System Model—Riegelman, Loo, and Rowland have recently proposed that it is mathematically and physiologically more acceptable to conceive the body to be a two-compartmental open system (12). Such a model is shown in the following schematic:



or in appropriate symbols:



P is the amount of the intact drug in the central compartment, which includes the blood, fluids, and tissues which, in effect, spontaneously equilibrate with the blood; T is the amount of intact drug in the peripheral (tissue) compartment; Vp is the volume of the central compartment; k_{12} and k_{21} are the first-order distribution rate constants out of and back into the central compartment from the peripheral compartment, and k_{el} is the sum of the (presumed) first-order rate constants for the simultaneous processes of metabolism and excretion. The above two-compartmental model results in the following general equation describing the blood level time curve after a single i.v. injection:

$$Cp = Ae^{-\alpha t} + Be^{-\beta t} \qquad \text{(Eq. 2)}$$

where at $t = 0$, $Cp^{\circ} = A + B$, and α and β are hybrid rate constants each influenced by *all* the individual rate processes. Because of this, Riegelman *et al.* (12) proposed that α and β be called the *fast and slow disposition* rate constants, respectively. The relationships between these disposition rate constants and the individual rate constants of this model have been presented in earlier publications. (12, 13). In the following presentation, it will be presumed that the accurate data have been obtained at appropriat : times and analyzed for the rate constants, k_{12}, k_{21}, and k_{el}.

It is convenient to convert all of the drug amounts represented in the model to concentration terms by dividing by Vp, whereupon they become Cp, Ct, and Cme, respectively. The amount metabolized and excreted up to time t_n, expressed in concentration units becomes:

$$(Cme)_{t_n} = k_{el} \int_{t_0}^{t_n} Cpdt \qquad \text{(Eq. 3)}$$

Integration of the differential mass balance equation between the limits of t_0 and t_n results in:

$$(A/Vp)_{t_n} = Cp_{t_n} + k_{el} \int_{t_0}^{t_n} Cpdt + Ct_{t_n} \qquad \text{(Eq. 4)}$$

This is in effect a modified Wagner-Nelson equation for the two-compartmental model; however, before Eq. 4 can be used to estimate the absorption rate of a drug, it is necessary for the tissue compartment concentration term to be expressed in measurable quantities. The differential equation representing the rate of change of this compartment with time is:

$$dCt/dt = -k_{21}Ct + k_{12}Cp \qquad \text{(Eq. 5)}$$

Since k_{12} and k_{21} can be estimated from the blood data, if Cp could be expressed as a function of time, the solution of Eq. 5 would be feasible. If one assumes that between the two data point times t_n and t_{n-1} the blood level data can be approximated by a straight-line segment, it is possible to substitute for Cp_{t_n} on the basis of the equation for a straight line:

$$Cp_{t_n} = Cp_{t_{n-1}} + M \cdot \Delta t \qquad \text{(Eq. 6)}$$

where

$$\Delta t = t_n - t_{n-1}\,; \quad \Delta Cp = Cp_{t_n} - Cp_{t_{n-1}}$$

and

$$M = \Delta Cp/\Delta t$$

whereupon we may substitute for Cp_{t_n} in Eq. 5 the equation can be integrated by Laplace transforms and the second term simplified by a two-term Taylor approximation:[3]

$$Ct_{t_n} = \frac{k_{12}}{k_{21}} Cp_{t_{n-1}}[1 - e^{-k_{21}\Delta t}] + k_{12}\frac{\Delta Cp\ \Delta t}{2} + Ct_{t_{n-1}}e^{-k_{21}\Delta t} \qquad \text{(Eq. 7)}$$

The total absorption equation based on the two-compartmental model can be obtained by substituting for $(Ct)_{t_n}$ in Eq. 4.

$$(A/Vp)_{t_n} = Cp_{t_n} + k_{el} \int_{t_0}^{t_n} Cpdt + \frac{k_{12}}{k_{21}} Cp_{t_{n-1}}[1 - e^{-k_{21}\Delta t}] + \frac{k_{12}\Delta Cp\Delta t}{2} + Ct_{t_{n-1}}\, e^{-k_{21}\Delta t} \qquad \text{(Eq. 8)}$$

As with the W-N equation, Eq. 1, the second term including the integral is evaluated by progressive summing of the area under the plasma concentration time curve from t_0 to t_n, usually using the trapezoidal rule for estimating the areas. Since the concentration of drug in the tissues is usually zero at the start of the study, when evaluating the tissue concentration at t_1 it is appropriate to set the last term in Eq. 8 equal to zero.[4] At each subsequent time, t_n, the tissue term must be solved by a method of successive substitution of the tissue concentration from the previous time interval.[5]

EXPERIMENTAL

The *N*-methylglucamine salt of acetylsalicylic acid (ASA) was prepared by mixing equimolar amounts of the base and acid. A 650-mg. dose of ASA was prepared in 10 ml. of solution. The solution was bacteriologically filtered and injected into

[3] A detailed derivation of Eq. 7 is given in the appendix.
[4] As with the use of Eq. 1, it may be necessary to make a time shift to correct for a delay in absorption.
[5] In order to facilitate the use of this complete absorption equation, a detailed analysis of sample data is included in Tables I and II under *Appendix*.

the antecubital vein by rapid i.v. injection. Blood samples were taken from the opposite arm at 1, 2, 4, 6, 8, 10, 15, 20, 25, 30, 45, 60, 75, 90, 120, 150, 180 min., and at hourly time periods for 8 hr. The samples were assayed for ASA by the specific gas chromatographic method of Rowland and Riegelman (13). Several weeks later the experiment was repeated using a Harvard infusion pump (model 975). Since this pump has a series of gears at constant ratio to one another, it was possible to establish a logarithmic rate of infusion by shifting the gears at constant time intervals. *In vitro* experiments showed the pump to produce logarithmic results through 97% of the injection, whereupon the final 3% were injected without further gear change. Different rates of infusion could be generated by merely modifying the time intervals for the gear changes. In order to keep the sampling as near as possible to the true log curve, the blood samples were taken at or near to the time of the gear changes. All experiments reported herein were done on male tests subjects.

Griseofulvin was injected into adult male volunteers in a specially prepared solution of griseofulvin dissolved in polyethylene glycol 300. The solution was not injected directly but by diluting it into a rapidly flowing normal saline solution, which was being administered by intravenous drip over a 3-min. period. Several weeks later the drug was administered over a 2-hr. constant infusion into the same test subject. The plasma samples were assayed for intact drug by a modification of the method of Bedford *et al.* (14).

An AEI model TR48 analog computer and a Varian Associates 11 × 17-in. X-Y recorder was used to study the models.

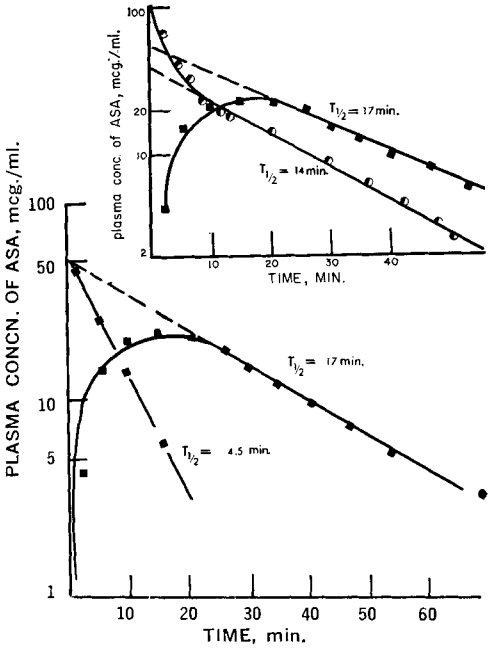


Fig. 1—Blood level of ASA after logarithmic infusion of 650 mg. into subject S at first-order rate of 0.0693 min.$^{-1}$ ($t_{1/2}$ = 10.0 min.) Infusion ceased at 64 min. Insert (Fig. 1a)—The superimposed blood curves after log infusion (■) and single i.v. injection (◐) of 650 mg. ASA.

RESULTS AND DISCUSSION

Figure 1 represents the data obtained when ASA was administered intravenously under logarithmic infusion conditions to a test subject. The data appear to be completely compatible with the concept of the body exhibiting the properties of a single compartment since the up curve could be said to represent the infusion period while the down curve then could represent the disappearance of the drug from the body by a single rate constant process. Indeed, a theoretical curve could be drawn through all the data points, except the 1-min. point, using the following equation where the rate constants were obtained by graphical estimation:

$$Cp = 0.53(e^{-0.041t} - e^{-0.15t})$$

The insert curves show the logarithmic infusion data superimposed on the rapid (10-sec.) i.v. injection data. The logarithmic infusion was continued for 64 min. Therefore, not only is absorption taking place at the same time as the drug is distributing into the peripheral tissue compartment, but it continues well beyond the peak in the blood curve. Due to the relative rates of drug infusion and loss from the body, the apparent disappearance curve changes. The observed disposition half life, $0.693/\beta$, for the i.v. curve is 14 min., while due to the continued influence of the infusion (absorption) process, the disposition half-life from the simulated logarithmic absorption data becomes 17 min. Changes in half-life such as these have been occasionally proposed to be due to changes in the elimination rate during the test period. Wagner (11) has also emphasized that the absorption process continues far beyond $t_{max.}$, the time of the maximum blood level.

Figure 2*a* represents the amount absorbed, divided by the appropriate volume constants *versus* time plots for Eqs. 1 and 8. The convergence on a false early asymptote with Eq. 1 is illustrated. Figure 2*b* includes plot of the log percent remaining to be absorbed *versus* time plot of the same data. The ASA was infused at a rate such that the half-life was precisely 10.0 min. Analysis of the data using Eq. 1 results in an estimate of the half-life for absorption in error by several orders of magnitude. In contrast, calculations based on Eq. 8 almost exactly duplicate the known infusion data. When 3% or less remains to be infused, the infusion pump no longer produces a log infusion. It is in this region that the calculated data diverges from the theoretical curve.

Figure 3 contains data for a second test subject administered ASA by a rapid i.v. and log infusion at a precise rate equal to a half-life of 6.0 min. The i.v. data are for a 650-mg. and a 325-mg. dose of the drug. While there is some small amount of experimental error, if the two curves are normalized, they are superimposable and therefore result in identical distribution and elimination rate constants and volume of distribution. Again there is a slight increase in disposition half-life in the log infusion (absorption curve). Additional assay data beyond the time indicated were obtained out to the limit of the assay method (0.4 mcg./ml.) and all three curves show mono-exponential decay. Figure 4 includes semilog and linear plots of the percent remaining to be absorbed plots. Once again the complete absorp-

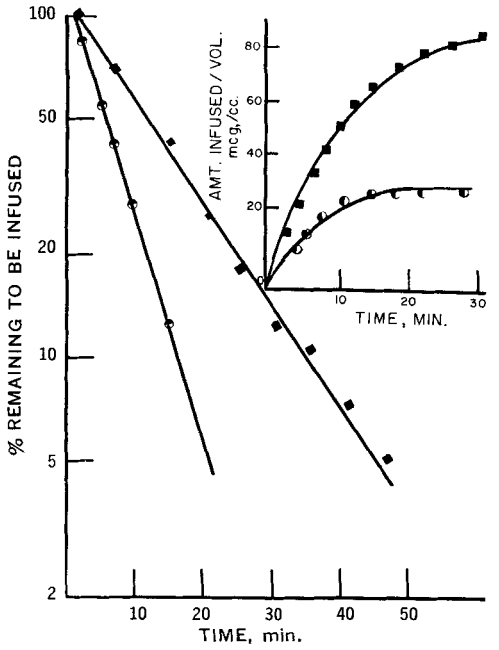

Fig. 2—The percent ASA remaining to be infused as determined by Eq. 1 (◐) and Eq. 8 (■). The latter data exactly coincide with the actual infusion rate ($t_{1/2}$ = 10.0 min.). Insert (Fig. 2a)—Corresponding amount infused divided by the volume constant intrinsic to the model, Eq. 1 (◐) and Eq. 8 (■).

tion equation predicts the known infusion rate, while it is difficult to draw a good curve through the W-N plot. When comparing Figs. 2, 4, and 6 it may appear that the magnitude of error in the Wagner-Nelson method is large only because of the infusion rates used and the selection of a rapidly metabolized drug such as ASA. That this is not so is seen where a PACE TR48 analog computer was programmed for distribution and elimination of griseofulvin found in the test subject reported in Figs. 5 and 6. Figure 7 includes curves illustrating the W-N plots which would have been found for this compound at selected first-order absorption rates. The disposition half-life was set at 9.5 hr. while the half-lives of the absorption processes were adjusted from 1.8 to 7 hr. When the input rates are large relative to the disposition rate constants, then the W-N calculation may result in an apparent first-order plot. However, the relative error in the estimated half-life varies with each experimental situation. The intermediate input rates result in concave descending-type curves to which it is difficult to assign a half-life. Usually the initial data points are emphasized in these analyses. However, it is important to note that the curves approach the theoretical half-lives near the end of the absorption process. Unfortunately, this is the portion of the data where the experimental error would be the largest. It would appear that if a given drug were made up as different formulations resulting in different rates of absorption, analysis of the blood data by Eq. 1 would apparently result in a varying error of estimation of their true absorption rates. The data for the theoretical input with a half-life of 3.8 hr. are replotted in Fig. 8 where the method of residuals is utilized to separate out the fast absorption component from the slower step. The appropriate bi-exponential equation for such a plot is:

$$\text{percent unabsorbed} = 0.45e^{-0.77t} + 0.55e^{0.183t}$$

It can be interpreted to indicate 45% of the drug was

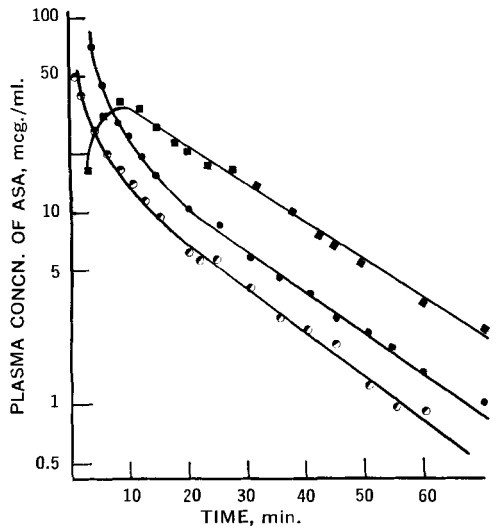

Fig. 3—Blood levels of ASA of subject P after single i.v. injection of 325 mg. (◐) and 650 mg. (●), and after a logarithmic infusion of 650 mg. ASA (■) at 0.115 min.$^{-1}$ ($t^1/_2$ = 6.0 min.).

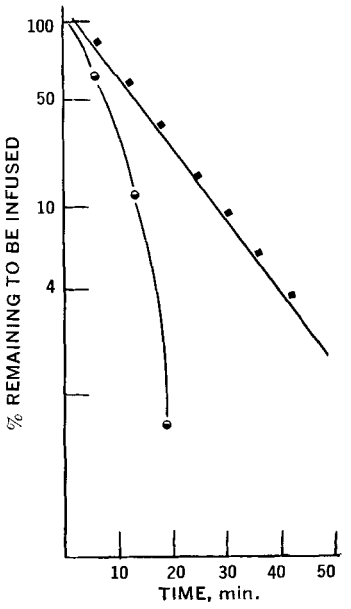

Fig. 4—The calculated percent ASA remaining to be infused as estimated by Eq. 1 (◐) and Eq. 8 (■). The latter is a good estimate of the actual infusion rate ($t_{1/2}$ = 6.0 min.).

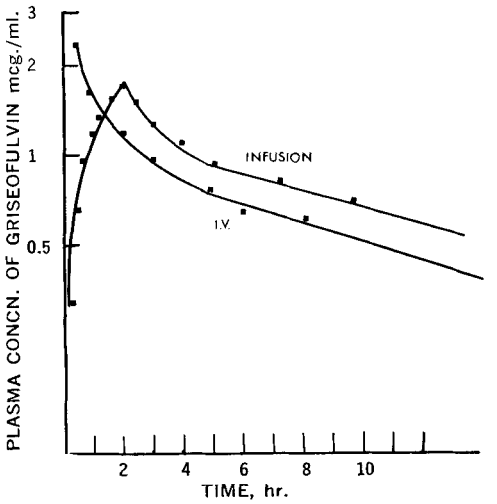

Fig. 5—The blood level of griseofulvin after a 2-hr. constant infusion at a rate of 12.8 mg./min. and after a single intravenous injection of 142 mg.

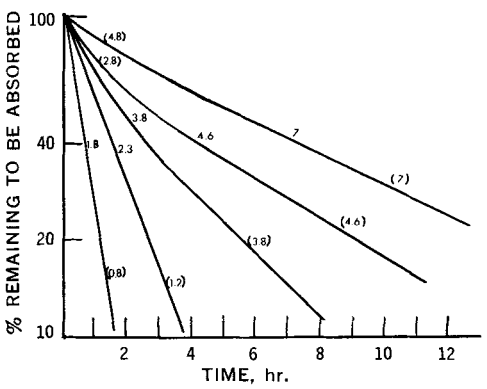

Fig. 7—Analog computer simulated plots of the percent remaining to be absorbed computed in accordance with Eq. 1. The values for the rate constants of the two-compartmental model are: $k_{12} = 0.29$ hr.$^{-1}$; $k_{21} = 0.31$ hr.$^{-1}$; $k_{el} = 0.16$ hr.$^{-1}$. The absorption half-life was changed for each plot and is indicated on each curve. The half-life values in parentheses are those which may be estimated from each appropriate linear segment.

absorbed at a half-life of 0.9 hr. while 55% was absorbed at a half-life of 3.8 hr. These are, of course, figments of the numerical method.

Using other appropriate distribution and elimination constants, the A/V *versus* time curves for the W-N method were obtained. It was noted that when the absorption rate is large relative to the rate of disappearance from the body that some of these curves exhibit a pronounced maxima. In their original publication Wagner and Nelson allude to this problem by indicating that the A/V value may reach a maximum. It appears that both the bi-exponential and the occasional appearance of maxima are artifacts of the numerical method. In Figs. 2*b* and 4, it can be seen from the percent unabsorbed plots that the use of Eq. 1 results in an underestimation of the time at which absorption ceases. This may cause difficulty in defining the release characteristics of prolonged-action dosage forms. It would appear virtually impossible to separate the perturbation of the absorption data caused by the use of the W-N equation from the complexities introduced by the two different absorption rates.

The absorption process of a drug is undoubtedly

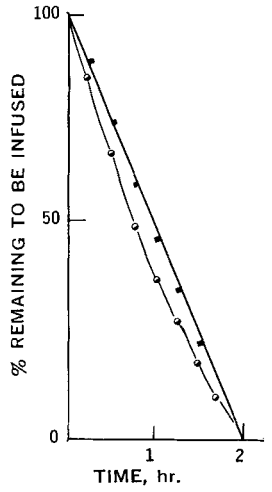

Fig. 6—The calculated percent griseofulvin remaining to be infused after a 2-hr. constant infusion. The curves are based on calculation using Eq. 1 (◐) and Eq. 8 (■); the latter is an excellent fit of the actual infusion rate curve.

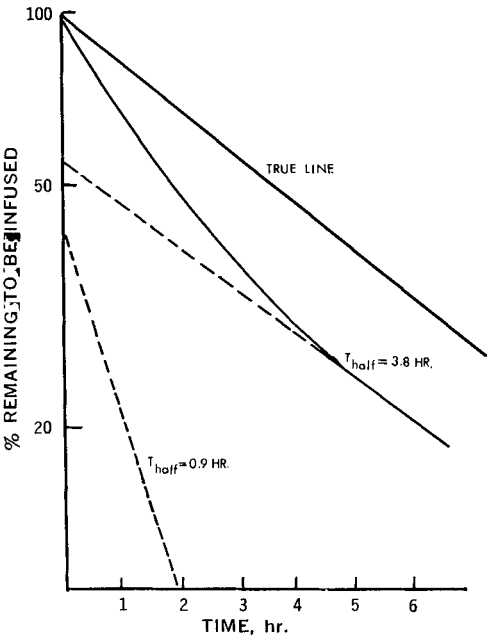

Fig. 8—An enlargement of the data given in Fig. 7 in which the input absorption half-life was set at 3.8 hr. The middle curve represents the data that would be obtained from Eq. 1. The lower curve is obtained from the middle curve by the method of residuals

highly complex. It is probable that each dose differs in its rate of passage down the gastrointestinal tract as well as in the rate at which the drug is released from its dosage form. If the new equation allows us to obtain valid data on such absorption rate processes, as it now appears, then it may allow some interpretation of the influence of the site of absorption on the rate process. This has been proposed as a significant contributing factor to the results obtained from the oral administration of griseofulvin to man. It appears that a significant fraction of the total griseofulvin is absorbed in a short interval of time which may coincide with the transfer of the drug through the duodenum. This is followed by a prolonged slow absorption for many additional hours (15). This small amount of secondary absorption causes a profound change in the apparent rate of disappearance of the drug from the blood. It would have been impossible to make any quantitative analysis of the absorption process of griseofulvin without the availability of i.v. data on this drug (15) along with this new method of analysis. The present authors have emphasized in earlier publications of this series (12, 13) that the plasma concentration time curves for virtually all drugs require utilization of a multi-exponential equation such as represented by Eq. 2. This is well recognized by many workers. However, until an i.v. dose is administered, with blood taken at proper sampling intervals, it is impossible to assess the contribution of the first term, Ae^{-at}, to the early phase of the drug disposition. The W-N equation is derived on the presumption that this first term is negligible. The modified absorption equation does not make this presumption. It is based only on the following two assumptions: (*a*) that the i.v. blood curve can be defined by a set of first-order differential equations, and (*b*) that the values of the rate constants are independent of dosage level and time. The data presented in this study have been shown to comply with those restrictions within the dosage ranges studied.

The two-compartmental model derivation has resulted in three important changes in the W-N equation. First, the very important peripheral tissue compartmental term Ct has been included. Second, the model forces one to distinguish between the rate constant for the disappearance of the compound from the body and the specific elimination rate constant, k_{el}. The former constant is a hybrid constant and is a complex function of the distribution rate constants k_{12} and k_{21} as well as the elimination rate constant, k_{el}. In most drugs the elimination rate constant, k_{el}, calculated on the multicompartmental model is two to fivefold larger than the slowest disposition rate constant. However, with drugs such as digitoxin, it may be as much as 40 times larger than the slowest disposition rate constant. Third, the volume constant used to convert the amounts into concentrations is found to be the volume of the central compartment, Vp, rather than the apparent total volume of distribution Vd_{area} (11). The effect of the first two modifications influences the shape of the A/V *versus* time plot, and results in evidence for a longer period for the absorption before the asymptotic value is reached. The third term merely changes the absolute value of the A/V.

It should be noted that the new absorption equation, derived on a two-compartmental open-system model, can be expanded to include additional peripheral compartments when necessary. For example, if the i.v. data indicates that a tri-exponential equation is required to describe the total curve, it would be necessary to expand the mammillary model to two peripheral compartments. One would then estimate the distribution rate constants for each compartment (13, 16). Finally, during an absorption study of such a drug one would have to estimate the tissue concentration in each peripheral compartment at each data point time by using Eq. 7 written to include the unique distribution rate constants of each compartment.

One criticism which might be made against the new equation is the dependency it places upon the evaluation of the distribution and elimination rate constants from previously administered i.v. dose. Undoubtedly there will be instances when these constants will change with continued use of the drug and the absorption test should be conducted as soon as possible after the i.v. experiment. Further, the effect of possible changes in the elimination rates, such as might be caused by induction of drug metabolizing enzymes can best be evaluated on the basis of the multicompartmental model. It is believed, however, that some of the variation in the disposition rate constant reported by some observers is due to the variable influence of the absorption rate process on the disposition rate constant. This can be seen in Fig. 9 by comparing the i.v. and oral curves which have been generated on theoretical data derived in the appendix and in experimental data shown in Figs. 3 and 4.

Absorption Analysis Based on Urinary Excretion Data—A relatively large number of the analyses of absorption rates published to date have been made using the W-N equation derived for the analysis of urinary data, which is:

$$f(A)_{t_n} = \frac{1}{k}\left(\frac{d\,Ae}{dt}\right)_{t_n} + (Ae)_{t_n} \qquad \text{(Eq. 9)}$$

$(Ae)_{t_n}$ is the cumulative amount excreted up to time t_n and $(dAe/dt)_{t_n}$ is the rate of excretion estimated from the differential data from t_{n-1} to t_n, and f is the fraction of the administered drug excreted intact. The first term on the right-hand side represents the amount of the absorbed dose remaining in the body and the second term is to represent the amount eliminated by all processes.

Application of the two-compartmental open-system model to urinary data requires insertion of a term for the tissue compartment. The resultant equation is:

$$f(A)_{t_n} = k_{el}\left[\left(\frac{dAe}{dt}\right) + Ae\right]_{t_n} + T_n \qquad \text{(Eq. 10)}$$

where

$$T_n = \frac{1}{k_{el}}\left[\left(\frac{dAe}{dt}\right)_{t_{n-1}} \cdot \frac{k_{12}}{k_{21}}\left(1 - e^{-k_{21}\Delta t}\right)\right] + \frac{1}{k_{el}}\left[\left(\frac{dAe}{dt}\right)_{t_n} - \left(\frac{dAe}{dt}\right)_{t_{n-1}}\right]\frac{k_{12}\Delta t}{2} + T_{n-1}e^{-k_{21}\Delta t}$$

It is immediately apparent that the application of this equation to urinary excretion data will be difficult. With some drugs, such as amines, it is extremely difficult to detect the level of these com-

pounds in the blood without recourse to radioactive tracers while they may be conveniently and more simply followed by urinary excretion methods. Nevertheless, to apply Eq. 10, it will be necessary to define the distribution and elimination rate constants from the urinary data after an i.v. injection. This will require urine samples at short intervals in the first few hours or may at times necessitate collection of the samples by catheterization. If urine samples are taken at sufficiently frequent intervals, under conditions of controlled pH, the urinary excretion data should also result in a bi-exponential curve, which upon being normalized may be analyzed for the appropriate distribution and elimination rate constants.

Alternate Methods for Analyzing Blood Data—The alternative analytical methods for estimating absorption rates utilizing both i.v. and oral data published by earlier authors have not been utilized in pharmacokinetic literature on drug absorption. The method of Scholer and Code was utilized by these authors in studying the oral absorption of D_2O (6) and later by Graham *et al.* (17) in their study of the absorption of ^{28}Mg. This method is a valid, but extremely tedious method of analyzing for the absorption rate of the compound. The method utilizes the multi-exponential equation representing the fate of the compound in the body (obtained in a prior i.v. experiment) to estimate numerically the fate of each increment of dose at each data point. This method, therefore, necessitates a large number of repetitive calculations, *i.e.*, N^2, where N is the number of data points during the interval where absorption is taking place. In contrast, Eq. 9 requires one calculation per data point.

The method of Silverman and Burgen and the method of Recigno and Segre each directly utilize the multi-exponential equation representing the fate of the drug in the body after an i.v. dose. In these methods the absorption data are compared to the curve of the i.v. dose and an amount remaining to be absorbed is obtained by a mathematical procedure of deconvolution of the oral absorption data. The method of Silverman and Burgen utilizes an analog computer while the latter method is a numerical procedure, which also may be carried out by utilizing a digital computer (18).

The method proposed in this paper utilizing Eq. 8 differs in an important characteristic from these alternative methods. While requiring prior information as to the multi-exponential fate of the drug in the body, a two- or three-compartmental open-system model is defined and the distribution and elimination constants are evaluated. The method does not require comparison with the i.v. curve itself but utilizes the distribution and elimination rate constants in the equation. It therefore allows one to carry out this calculation using a simple desk calculator. It also affords an excellent picture of the fate of the drug within the body at all times.

APPENDIX

A Derivation of Eq. 7—As noted in the text, Eq. 6 is the differential equation representing the rate of change of the tissue concentration in terms of the two variables, Ct and Cp. It is necessary to substitute for the Cp at time t_n in terms of the prior blood value Cp at time t_{n-1}. This can be done if we presume that the plasma concentration time curve is linear over this short interval so that the equation for the straight line applies. This is represented as Eq. 6 in the text. Equation 5 can be written as:

$$\frac{dCt}{d\tau} = -k_{21}Ct + k_{12}Cp + k_{12}M\tau \quad \text{(Eq. 1}a\text{)}$$

where $\tau = t_n - t_{n-1}$.

In order to integrate Eq. 1a, we convert to Laplace notation, with $\overline{Ct}$ referring to the Laplace transform of Ct, with the initial conditions set at $(Ct)_{t_{n-1}}$ and S is the Laplace operator notation:

$$\overline{Ct}S - Ct_{t_{n-1}} = -k_{21}\,\overline{Ct} + \frac{k_{12}\,Cp}{S}\,t_{n-1} + \frac{k_{12}M}{S^2} \quad \text{(Eq. 2}a\text{)}$$

Rearranging we have:

$$\overline{Ct}(S + k_{21}) = Ct_{t_{n-1}} + \frac{k_{12}Cp}{S}\,t_{n-1} + \frac{k_{12}M}{S^2} \quad \text{(Eq. 3}a\text{)}$$

or

$$\overline{Ct} = \frac{Ct}{S + k_{21}}\,t_{n-1} + \frac{k_{12}Cp}{S(S + k_{21})}\,t_{n-1} + \frac{k_{21}M}{S^2(S + k_{21})} \quad \text{(Eq. 4}a\text{)}$$

The inverse transform of Eq. 4a is

$$Ct_{t_n} = Ct_{t_{n-1}}e^{-k_{21}\Delta t} + \frac{k_{12}}{k_{21}}\,Cpt_{n-1}(1 - 3^{-k_{21}\Delta t}) + \frac{k_{12}}{(k_{21})^2}\,\frac{\Delta Cp}{\Delta t}\,(e^{-k_{21}\Delta t} + k_{21}\Delta t - 1) \quad \text{(Eq. 5}a\text{)}$$

where Δt is substituted for τ and $\Delta Cp/\Delta t$ for M. The third term of Eq. 5a can be reduced by substituting for the exponential component in terms of a two-term Taylor expansion, namely, $e^{-x} = 1 - x + x^2/2$, or

$$\frac{k_{12}}{(k_{21})^2}\,\frac{\Delta Cp}{\Delta t}\,(e^{-k_{21}\Delta t} + k_{21}\Delta t - 1) = \frac{k_{12}}{k_{21}}\,2\,\frac{\Delta Cp}{\Delta t}\left(1 - k_{21}\Delta t + \frac{(k_{21})^2(\Delta t)^2}{2} + k_{21}\Delta t - 1\right) \quad \text{(Eq. 6}a\text{)}$$

which reduces to $k_{12}\Delta Cp\Delta t/2$.

Substituting into Eq. 5a we arrive at the form given as Eq. 7 in the above text:

$$Ct_{t_n} = Ct_{t_{n-1}}e^{-k_{21}\Delta t} + \frac{k_{21}}{k_{12}}\,Cpt_{n-1}\,(1 - e^{-k_{21}\Delta t}) + \frac{k_{12}\Delta Cp\Delta t}{2} \quad \text{(Eq. 7)}$$

Sample Calculation Using Eq. 7—The following model will be utilized:

$$D \xrightarrow[k_a = 0.41\ \text{hr.}^{-1}]{} P \xrightarrow[k_{el} = 0.16\ \text{hr.}^{-1}]{} ME$$

$$P \underset{k_{21} = 0.31\ \text{hr.}^{-1}}{\overset{k_{12} = 0.29\ \text{hr.}^{-1}}{\rightleftarrows}} T$$

This results in a disposition rate constant, β, of 0.0725 hr.$^{-1}$ ($t_{1/2}$ = 9.5 hr.) after sufficient time for the absorption process to be complete. However, Table I includes data points for Cp at various times up to 15 hr., generated with the use of the TR-48 analog computer. These data are plotted in Fig. 9.

TABLE I—CALCULATIONS OF *Ct* VALUES[a]

[a] Calculated using the following rate constants: $k_{12} = 0.29$ hr.$^{-1}$; $k_{21} = 0.31$ hr.$^{-1}$; $k_{el} = 0.16$ hr.$^{-1}$; $\beta = .0725$ hr.$^{-1}$; $Ct_n = k_{12}\Delta Cp\,\Delta t/2 + k_{12}/k_{21}Cp_{t_{n-1}}(1-e^{-k_{21}\Delta t}) + Ct_{t_{n-1}}e^{-k_{21}\Delta t}$.

Fig. 9—Simulated data for a theoretical drug with distribution and elimination characteristics given in Fig. 7 and used in calculation for Tables I and II. Note the slight divergence of the slopes of the i.v. and the oral curves. The straight line indicates the log percent remaining to be absorbed ($t_{1/2}$ = *1.8 hr.*).

It is to be noted that the data points beyond the fourth hour appear to lie on a straight line even though 20% of the drug remains to be absorbed ($t_{1/2}$ for the absorption = 1.8 hr.). One would usually define this slope as the elimination rate constant; more appropriately in the context of the nomenclature of this paper it is called the "apparent" disposition rate constant with a half-life of 8.9 hr. (β = 0.078 hr.$^{-1}$). It is to be noted that the value is not identical with the half-life for the true disposition rate process, *i.e.*, 9.5 hr. since the absorption and the fast disposition component, α, are still contributing to the observed value. Columns 3 through 12 include the steps required in the numerical calculation of the values for Ct_{t_n} utilizing Eq. 7. The accuracy of the estimates of *Ct* can be checked in this instance since the analog computer can generate the tissue concentration curve. The solid line in Fig. 10 increases the computer generated curve and the superimposed open circles indicate the calculated values as listed in Table I, Column 12. The excellent fit is readily apparent.

The estimation of the absorption rate constant from the data utilizing Eq. 7 is given in Table II. The appropriate steps are those used in the original W-N equation, in which the area under the blood curve between each set of data points is estimated by the trapezoidal rule. These are listed in Column 3. These values are progressively summed from t_o to t_n in Column 4, and the cumulative sum of these estimates are multiplied by the known elimination rate constant k_{el}. The A/Vp values are then calculated from the sum of Columns 2 + 5 + 6. These data can be converted into the percent unabsorbed as indicated.

Table II also includes the calculation of the

[a] Columns 1-9: $A/Vp = Cp_{t_n} + k_{el}\int_0^{t_n} Cpdt + Clt_n$; $Clt_n = k_{12}\Delta Cp\Delta t/2 + k_{12}/k_{21}\, Cp_{t_{n-1}}(1 - e^{-k_{21}\Delta t}) + Clt_{n-1}e^{-k_{21}\Delta t}$. Columns 10-13: $A/Vd = Cp_{t_n} + \beta\int_0^{t_n} Cpdt$.

Fig. 10—Simulated plots of data taken from Table II simulating the blood level (Column 2; ●), tissue level (Column 6; ○), and drug elimination (Column 5; ■). The solid lines are the computer simulated curves. The insert includes the percent remaining to be absorbed plots (Column 9; ●) calculated using Eq. 8 and Eq. 1 (Column 13; □).

"apparent" percent unabsorbed according to the W-N equation. This is listed in Columns 10 through 13. Figure 10 includes the semilog plots of the percent unabsorbed, according to the two methods of calculation, *i.e.*, Columns 9 *versus* 13. It is noted that the calculations based on Eq. 8 (Column 9) result in an exact prediction of the known absorption half-life of 1.8 hr. while the W-N equation (Column 13) leads to a prediction that the half-life for the absorption process is approximately 0.8 hr.

Effect of Topical Vehicle Composition on the *In Vitro* Release of Fluocinolone Acetonide and its Acetate Ester

By B. J. POULSEN, E. YOUNG, V. COQUILLA, and M. KATZ

A model was developed to test certain concepts regarding the *in vitro* release of steroids from topical vehicles. The steroids studied were fluocinolone acetonide and fluocinolone acetonide acetate. The vehicles selected for the study were propylene glycol–water mixtures gelled with Carbopol 934. Isopropyl myristate was used as the receptor phase for the diffusing steroids. Assay of the quantity of the steroids in the receptor phase was simplified by the use of radioactive compounds. The study indicated that the important factors influencing the release of steroid into the receptor phase were the solubility in the vehicle and the partition coefficient of the steroid between the vehicle and the receptor phase. Maximum release was achieved by altering the propylene glycol content of the vehicles.

OCCLUSIVE DRESSINGS have been successfully used to extend the therapeutic effectiveness of topical corticosteroids (1–3). This enhanced activity has been attributed to improved penetration of the skin by the drug (1). This indicates that, in certain instances, the development of formulations that increase drug penetration would be desirable.

There are two general approaches to the problem. One is to include in the vehicle agents which affect the barrier function of the epidermis so as to promote penetration of the therapeutic compound (4–7). The other approach is to alter the physical characteristics of the vehicle and thus affect the diffusion of the drug from the vehicle into the skin. As a preliminary to evaluating this latter effect of vehicles on skin penetration, the *in vitro* release of steroids from model vehicles was studied.

Higuchi (8) suggested the following equivalent relationships could be used to approximate the penetration of the barrier phase of the skin by a drug dissolved in a topical vehicle.

$$\frac{dQ}{dt} = (P.C.)C_v\frac{DA}{L} \qquad \text{(Eq. 1)}$$

$$\frac{dQ}{dt} = \frac{a_v}{\gamma_s}\frac{DA}{L} \qquad \text{(Eq. 2)}$$

The terms in these equations are defined as follows:

dQ/dt = steady rate of penetration
$(P.C.)$ = the effective partition coefficient of drug between skin barrier and vehicle
C_v = concentration of drug in the vehicle
D = the effective average diffusivity of the drug in the skin barrier
A = cross-sectional area of the application site
L = effective thickness of the skin barrier
a_v = thermodynamic activity of the drug in the vehicle

γ_s = effective activity coefficient of the drug in the skin barrier

If Eqs. 1 and 2 are considered with the objective of altering the penetration of a topically applied drug, it becomes apparent that only certain terms are readily susceptible to manipulation by the formulator. These are the partition coefficient (*P.C.*) and drug concentration (C_v) terms of Eq. 1 and, equivalently, the activity term (a_v) of Eq. 2.

Relationships between partition coefficients of various compounds and skin penetration have been reported (9–13). For our purposes, the partition coefficient can be defined as

$$P.C. = \frac{\gamma_v}{\gamma_s} \qquad \text{(Eq. 3)}$$

where γ_v and γ_s are the activity coefficients of the drug in the vehicle and skin, respectively. While it may be necessary to regard the activity coefficient of the drug in the skin barrier phase as an unknown and unalterable value, γ_v can be modified simply by altering the composition of the vehicle. Higuchi (8) has reported, for instance, that the activity coefficient of Sarin is approximately 1,500 times greater in perfluorotributylamine than in *m*-cresol. Katz and Shaikh (9) have previously reported the correlation of solubility and partition coefficient to topical corticosteroid therapeutic activity as measured by the Stoughton-McKenzie vasoconstrictor test.

It is evident that increasing the thermodynamic activity of a topically applied drug by altering vehicle composition might be expected to enhance its rate of penetration. It is, however, also necessary to consider what can be accomplished with a specific drug relative to the concentrations actually required in therapy. In practical terms, the saturation solubility in the vehicle places an upper limit on the activity that can be achieved for the penetrant (8). In this study, a simple model system was devised to test the effect of vehicle composition on the release of therapeutic concentrations of two topically active corticosteroids.

EXPERIMENTAL

Materials—Carbopol 934,[1] diisopropanolamine,[2] isopropyl myristate,[3] propylene glycol,[4] toluene (scintillation grade),[5] PPO,[6] POPOP,[6] fluocinolone acetonide,[7] and fluocinolone acetonide acetate[8] were used as received. In the release experiments, ^{14}C-labeled (acetonide label) fluocinolone acetonide and fluocinolone acetonide acetate were used as provided by the Institute of Steroid Chemistry, Syntex Research, Palo Alto, California.

Preparation of Vehicles—The propylene glycol and propylene glycol–water mixtures used as the donor phase were gelled by the addition of 1% w/w Carbopol 934 resin. The Carbopol was neutralized by the addition of an equal weight of diisopropanolamine. The steroids were incorporated into the vehicles by dissolving the steroid in the propylene glycol portion of the vehicle. The Carbopol resin was dispersed in water or a portion of the propylene glycol with the aid of an Eppenbach Homo-Mixer and added to the steroid solution. Diisopropanolamine was then added to gel the mixture. The final pH of the preparations ranged from 6–7. Freshly prepared formulations were used in the release studies.

Since viscosity of a preparation could be a factor affecting release, viscosity determinations were made on gels containing from 1 to 100% propylene glycol. The measurements were made with a Brookfield model RVT viscometer using the Helipath stand. Determinations made at room temperature, using the TC spindle at 5 r.p.m., indicated that a slight decrease in viscosity occurred as the propylene glycol content of the gels was increased. This decrease amounted to approximately a 20% reduction in viscosity over the propylene glycol concentration range from 1 to 100%.

Determination of Release Rates—The containers used to support the gels in this study were Petri dishes 100 mm. in diameter and 5 mm. deep. The dish was completely filled with the vehicle and the excess removed with the edge of a spatula to produce an even, uniform surface of constant dimensions. The weight of vehicle required to fill the dish was approximately 30 Gm. The dish containing the vehicle was placed in the bottom of a 1,000-ml. beaker, and the beaker was partially immersed in a large water bath at 37°. Two-hundred milliliters of isopropyl myristate previously equilibrated to 37° was carefully layered over the vehicle to begin the experiment. A large stirring blade of a width approximately equal to the diameter of the Petri dish was employed to produce agitation. The bottom edge of the stirring blade was positioned just above the surface of the gel. Six experiments could be run simultaneously in the same water bath by the use of a multiple-blade Phipps-Bird laboratory stirrer. It was determined experimentally that the release rates were sensitive to the rate of stirring up to approximately 30 r.p.m. Accordingly, the stirring rate was maintained at 40 r.p.m. Samples of isopropyl myristate were withdrawn for assay at intervals over a 24-hr. period.

Solubility Determinations—The solubilities of fluocinolone acetonide and fluocinolone acetonide acetate in propylene glycol–water mixtures were determined by two methods. In the first, excess steroid was rotated in sealed 10-ml. ampuls in a constant-temperature bath at 25°. Samples were withdrawn for chemical analysis after 2 weeks. In the second method, excess steroid was heated to 80°,

with rapid stirring for a few minutes, and the resulting mixture sealed into 10-ml. ampuls and rotated in the constant-temperature bath at 25° for 24 hr. prior to analysis. Equivalent results were obtained by the two methods.

The samples were assayed by withdrawing 5 ml. of solution, filtering through a Millipore filter (type GS, mean pore diameter 0.22 ± 0.02 μ), diluting with water, extracting the steroid with chloroform, evaporating the chloroform extract to dryness, taking up the steroid with ethanol, and assaying a suitable dilution of the alcoholic solution by the blue tetrazolium colorimetric assay.

Partition Coefficient Determinations—One-tenth milligram of steroid per ml. was dissolved in isopropyl myristate. Twenty-five milliliters of this solution was added to an equal volume of the various propylene glycol–water mixtures and equilibrated at 37°. After equilibrium, the phases were separated and assayed individually for steroid content. Partition coefficients were calculated as the ratio of the steroid concentration in the isopropyl myristate to that in the glycol–water phase.

Radiochemical Assays—The specific activities of the radiochemicals used in the study were 0.20 μc./mg. for fluocinolone acetonide-^{14}C and 0.10 μc./mg. for fluocinolone acetonide acetate-^{14}C. Samples of the isopropyl myristate receptor phase were assayed for steroid by counting in a Packard Tri-Carb liquid scintillation counter. Two-milliliter samples were mixed directly with 15 ml. of scintillation fluid consisting of 5 Gm. of PPO (2,5-diphenyloxazol), and 0.1 Gm. of POPOP (1,4-bis-2-[4-methyl-5-phenyloxazolyl]benzene) diluted to 1 L. with scintillation grade toluene. Internal standardizations were used to evaluate quenching of the samples. Ordinarily, quenching was found to be negligible and no quenching correction was required. Since steroids of low specific activity were used in the study, samples were counted for a total of 10 min. Total steroid release was calculated from the specific activities of the isotopes.

Confirmation that the radioactive assay measured only intact steroid was accomplished as follows: Samples of isopropyl myristate were withdrawn following release experiments of 24-hr. duration. The steroid was extracted from the isopropyl myristate and spotted from chloroform solution on silica gel TLC plates. The plates were developed in chloroform–butyl acetate–acetone (2:2:1) and dried. The plates were then scanned for radioactivity in a Vanguard model 880 dual-channel autoscanner equipped for thin-layer plates. It was found that essentially all the radioactivity was concentrated in a plate region corresponding to the correct R_f value for the steroid in question.

RESULTS

The solubilities of fluocinolone acetonide and the 21-acetate ester in propylene glycol–water mixtures at 25° are shown in Fig. 1. Partition coefficients for the two steroids between isopropyl myristate and various propylene glycol–water mixtures were determined at 37° and are shown in Fig. 2. Since the composition of the isopropyl myristate remained essentially unchanged during the release experiments, the partition coefficients are a reasonable approximation of the relative activity coefficients for the drug in the vehicles.

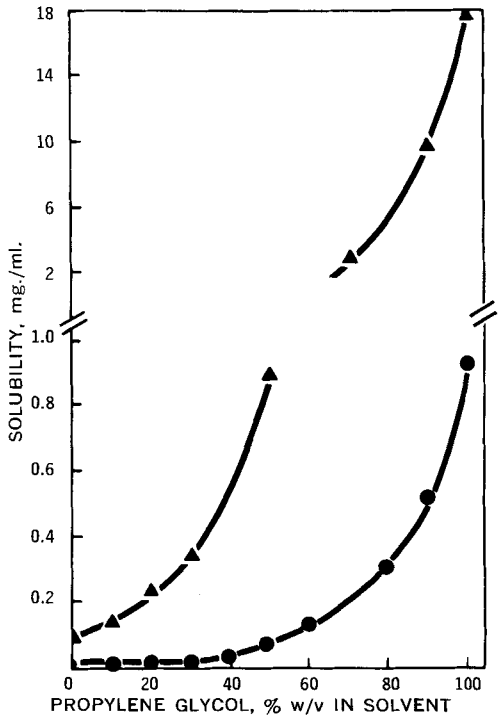

Fig. 1—Solubility of fluocinolone acetonide and its acetate ester in propylene glycol–water mixtures at 25°. Key: ▲, fluocinolone acetonide; ●, fluocinolone acetonide acetate.

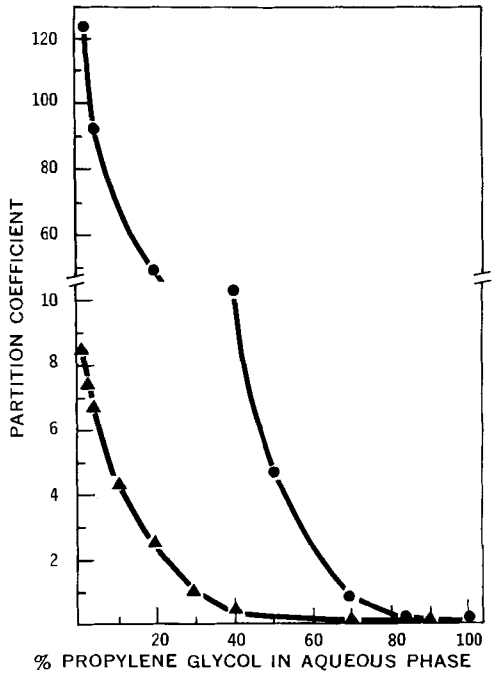

Fig. 2—Partition coefficients for fluocinolone acetonide and its acetate ester between propylene glycol–water mixtures and isopropyl myristate at 37°. Key: ▲, fluocinolone acetonide; ●, fluocinolone acetonide acetate.

Figure 3 is a plot of the total release of fluocinolone acetonide after 2, 6, and 12 hr. at 37° from gels containing various concentrations of propylene glycol. Optimal release for 0.025% fluocinolone acetonide preparations occurred with gels containing approximately 20% propylene glycol. As seen in Fig. 1 this concentration of propylene glycol is only slightly less than the minimum amount estimated to be required to completely solubilize 0.025% fluocinolone acetonide in the vehicle. At lower concentrations of propylene glycol, precipitated steroid appeared in the gel. Although reduced release rates were observed with gels containing mostly undissolved steroid, the poorest release was actually obtained with gels containing very high concentrations of propylene glycol.

Somewhat different results were found for the less soluble fluocinolone acetonide acetate (Fig. 4). The solubility data obtained for the acetate ester (Fig. 1) indicated that about 75% propylene glycol would be required to solubilize this compound at a concentration of 0.025%. Maximum release at 37° occurred from vehicles containing approximately 70% propylene glycol. In contrast to fluocinolone acetonide, the poorest release occurred from gels containing low propylene glycol concentrations in which a relatively large proportion of the steroid was present as undissolved material.

Figure 5 compares the release of the two steroids from several of the vehicles tested over a 24-hr. period. Figure 6 gives a comparison of percent steroid released after 6 hr. from vehicles containing 0.01, 0.025, and 0.1% fluocinolone acetonide.

These data are reasonably consistent with the observation that maximum release for various steroid concentrations in the vehicles studied occurred from gels containing the minimal amount of propylene glycol required to dissolve the compound. Figure 6 also shows the result of the increase in the activity

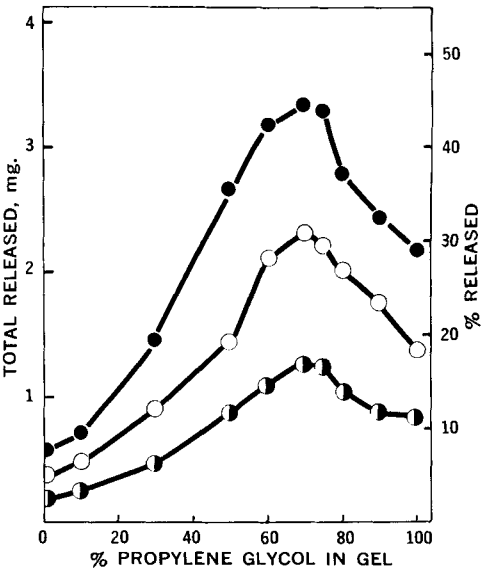

Fig. 4—Effect of propylene glycol concentration on the release of 0.025% fluocinolone acetonide acetate from propylene glycol–water gels at 37°. Key: release after— ◑, 2 hr.; ○, 6 hr.; ●, 12 hr.

coefficient that could be achieved at the lower (0.01 and 0.025%) fluocinolone acetonide concentrations. While total release was greater for the higher concentrations, the percent released over a 6-hr. time period was much greater for the 0.01% steroid concentration.

DISCUSSION

A number of studies describing the release of drugs from topical vehicles are reported in the literature. When the vehicle and receptor phase are mutually

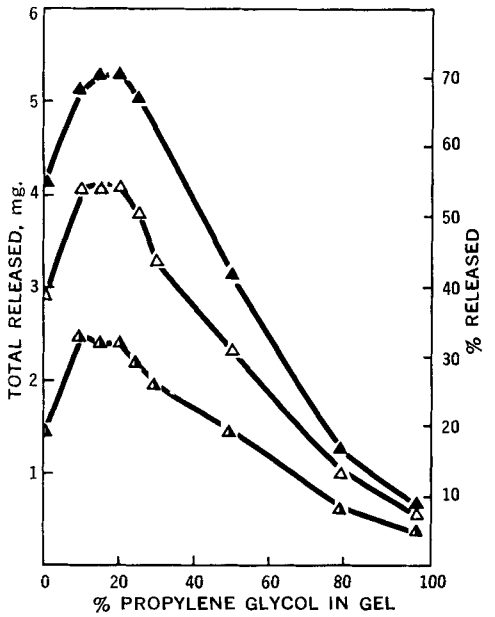

Fig. 3—Effect of propylene glycol concentration on the release of 0.025% fluocinolone acetonide from propylene glycol–water gels at 37°. Key: release after— △, 2 hr.; △, 6 hr.; ▲, 12 hr.

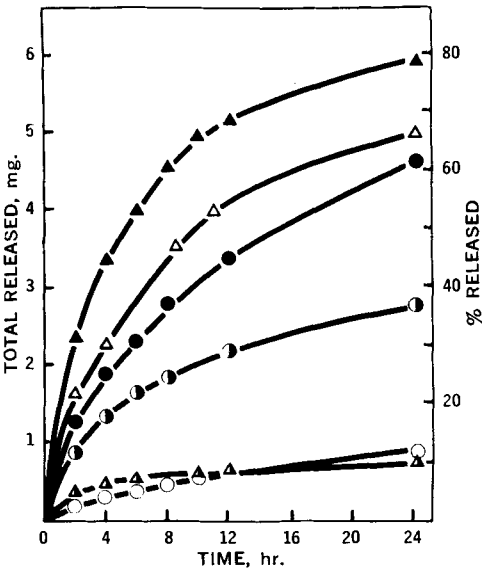

Fig. 5—Effect of propylene glycol concentration on the release of 0.025% steroid from Carbopol gels. Key: concentration of propylene glycol in fluocinolone acetonide gels—△, 1%; ▲, 20%; ◭, 100%; concentration in fluocinolone acetonide acetate gels—○, 1%; ●, 70%; ◑, 100%.

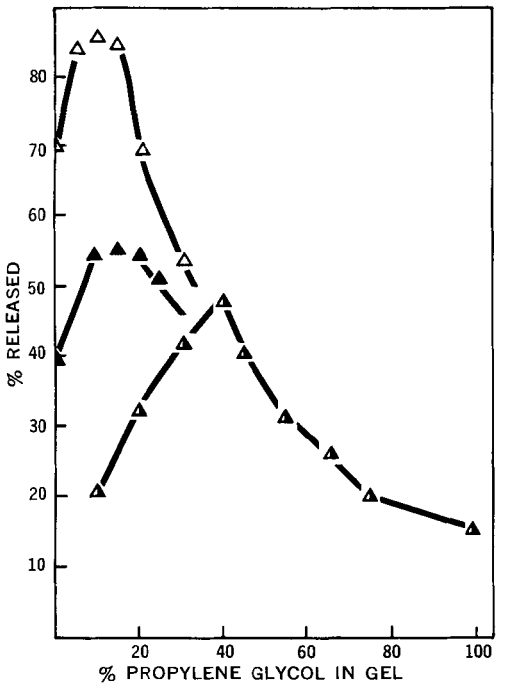

Fig. 6—Comparison of release of 0.01%, 0.025%, and 0.1% fluocinolone acetonide from propylene glycol–water gels after 6 hr. at 37°. Key: % steroid—△, 0.01%; ▲, 0.025%; ◭, 0.1%.

miscible, physical separation of the two phases is necessary. A dialysis membrane has frequently been used for this purpose (14–18). In this study, isopropyl myristate was employed instead of water as the receptor phase to more closely simulate skin lipids or skin itself. Since isopropyl myristate is immiscible with water and propylene glycol, it was not necessary to introduce an artificial membrane to separate it from the vehicles used in this study. The solubilities of fluocinolone acetonide (0.9 mg./ml.) and fluocinolone acetonide acetate (0.2 mg./ml.). at 37° were adequate for this lipid-like material to be used as the receptor phase.

Propylene glycol–water mixtures gelled with Carbopol 934 were selected as vehicles because steroid solubility could be readily altered by varying the concentration of propylene glycol. Solubility data for the two steroids in propylene glycol–water mixtures were determined at 25° (Fig. 1) and used to estimate the solubility in these same mixtures gelled with Carbopol. Microscopic examination of the vehicles indicated that addition of the gelling agent resulted in negligible changes in the solubility of the steroids in the glycol–water mixtures.

Partition coefficients were determined between glycol–water mixtures and isopropyl myristate (Fig. 2) and, as indicated by Eq. 3, were useful as an index of the relative activity coefficients for the steroids in these vehicles. This information was particularly valuable in estimating the potential effect of changes in the steroid concentrations in these vehicles on the release rate.

The possibility exists that molecular interactions between the steroids and the carboxyvinyl polymer gelling agent were a factor affecting the release rates. In addition, the solubility data for the steroids in glycol–water mixtures were obtained at room temperature (25°), whereas the release experiments were conducted at 37°. Consequently, steroid solubility in the gels under the conditions of the experiments was probably slightly greater than shown in Fig. 1. This may account in part for the observation that maximum release of 0.1% fluocinolone acetonide (Fig. 6) occurred from vehicles containing somewhat less propylene glycol than required to completely dissolve the steroid at room temperature. For these reasons, the solubility and partition coefficient data developed with the glycol–water mixtures were used only as an aid in interpreting the release data.

Maximum release for a given concentration of either fluocinolone acetonide or fluocinolone acetonide acetate was obtained from vehicles containing approximately the minimum amount of propylene glycol necessary to dissolve the steroid completely. Excess propylene glycol increased the affinity of the vehicle for the steroid and resulted in a decrease in steroid release. When insufficient propylene glycol was present to dissolve all the steroid, then diffusion into the receptor phase became dissolution rate limited and the release rate was reduced. As might be expected, the latter effect was much more pronounced with the less soluble compound, fluocinolone acetonide acetate.

The results obtained in this study clearly demonstrate the dependence of steroid release on the physical properties of both steroid and vehicle. For steroid concentrations of 0.025%, a vehicle containing 20% propylene glycol releases approximately 70% of available fluocinolone acetonide but only 15% of the acetate ester after 12 hr. Likewise, a vehicle containing 70% propylene glycol releases 45% of the acetate ester and only 25% of fluocinolone acetonide. Clearly, a vehicle that provides good release of one drug may be a poor vehicle for another closely related compound. The results obtained with different concentrations of the same steroid are of particular interest (Fig. 6). A much higher percent release over a given time interval could be obtained from 0.01% fluocinolone acetonide gels than from vehicles containing higher concentrations of steroid. In this case, higher partition coefficients were obtained with the lower steroid concentration while completely solubilizing the steroid. The obvious implication is that vehicle composition can be varied not only to improve release of different steroids but also specific concentrations of a given steroid.

Release studies have long been used as one criterion for judging the possible effect of vehicle on drug availability from topical formulations. There are obvious limitations of such methods, and conclusions must be drawn with great caution. Certainly the partition coefficient for a steroid between vehicle and isopropyl myristate will not duplicate that between vehicle and human skin. But, regardless of the actual value of the partition coefficient for a penetrant present on the surface of the skin, it must be subject to its environment. If that environment is a pharmaceutical vehicle, the composition of that vehicle should affect the passage of penetrant into an adjacent phase whether that phase is sebum or skin tissue. The degree to which this is actually true, and its clinical implications, must ultimately be established by correlation to *in vivo* studies using the same topical formulations.

SUMMARY

Isopropyl myristate was used as the receptor phase to evaluate the release of fluocinolone acetonide and its acetate ester from gelled propylene glycol–water vehicles. Steroid release was found to be a function of its (*a*) concentration, (*b*) solubility in the vehicles, and (*c*) partition coefficient between vehicles and receptor phase. Release was reduced if a vehicle contained cosolvent in excess of that required to dissolve the steroid. Release could be improved not only for the different steroids, but also for different concentrations of the same steroid, by use of the proper vehicle.

Euphorbia esula L. (*Euphorbiaceae*) I

Preliminary Phytochemical and Biological Evaluation

By N. R. FARNSWORTH*, H. WAGNER, L. HÖRHAMMER, H. P. HÖRHAMMER, and H. H. S. FONG

The aerial parts of *Euphorbia esula* were subjected to a fractionation scheme which resulted, after several chromatographic separations, in the isolation of β-sitosterol, 24-methylenecycloartanol, hexacosanol-(1), *n*-nonacosane, and *n*-hentriacontane. The presence of *n*-pentacosane, *n*-hexacosane, *n*-heptacosane, *n*-octacosane, *n*-triacontane, *n*-dotriacontane, and *n*-tritriacontane was demonstrated by means of gas chromatography. None of these compounds had previously been reported as isolated from *Euphorbia esula*. The presence of flavonoids and alkaloids was demonstrated, a finding that is contrary to literature reports. A defatted ethanol extract elicited no antimicrobial activity against several test organisms and was found to induce only weak central nervous system depression in mice. Seven tumor systems were not inhibited by the extract, and it was not cytotoxic in cell culture.

LIMITED phytochemical investigations on *Euphorbia esula* L. have shown only the presence of L-inositol (1), gallic acid (2), rubber (2), and a number of common amino acids (3). Conversely, phytochemical screening of this plant has indicated the absence of hemolytic saponins, flavonoids, alkaloids, and tannins (4). Peroxidase and polyphenoloxidase activity has been reported for rootbud extracts (3), and an inhibitor of indole-3-acetic acid has been shown to be present in whole plant extracts (5).

Folkloric usage for the treatment of cancer has been recorded for several species of *Euphorbia*

Euphorbia esula L. (*Euphorbiaceae*) I

Preliminary Phytochemical and Biological Evaluation

By N. R. FARNSWORTH*, H. WAGNER, L. HÖRHAMMER, H. P. HÖRHAMMER, and H. H. S. FONG

The aerial parts of *Euphorbia esula* were subjected to a fractionation scheme which resulted, after several chromatographic separations, in the isolation of β-sitosterol, 24-methylenecycloartanol, hexacosanol-(1), *n*-nonacosane, and *n*-hentriacontane. The presence of *n*-pentacosane, *n*-hexacosane, *n*-heptacosane, *n*-octacosane, *n*-triacontane, *n*-dotriacontane, and *n*-tritriacontane was demonstrated by means of gas chromatography. None of these compounds had previously been reported as isolated from *Euphorbia esula*. The presence of flavonoids and alkaloids was demonstrated, a finding that is contrary to literature reports. A defatted ethanol extract elicited no antimicrobial activity against several test organisms and was found to induce only weak central nervous system depression in mice. Seven tumor systems were not inhibited by the extract, and it was not cytotoxic in cell culture.

LIMITED phytochemical investigations on *Euphorbia esula* L. have shown only the presence of L-inositol (1), gallic acid (2), rubber (2), and a number of common amino acids (3). Conversely, phytochemical screening of this plant has indicated the absence of hemolytic saponins, flavonoids, alkaloids, and tannins (4). Peroxidase and polyphenoloxidase activity has been reported for rootbud extracts (3), and an inhibitor of indole-3-acetic acid has been shown to be present in whole plant extracts (5).

Folkloric usage for the treatment of cancer has been recorded for several species of *Euphorbia*

Received December 12, 1967, from the Institut für Pharmazeutische Arzneimittellehre der Universität München, Munich, Germany, and the Department of Pharmacognosy, School of Pharmacy, University of Pittsburgh, Pittsburgh, PA 15213

Accepted for publication February 13, 1968.

This investigation was supported, in part, by a research grant from the Jane Olmstead Thaw Fund, University of Pittsburgh, Pa.

The authors acknowledge the technical assistance of Mr. O. Seligmann and Misses E. Sedlaczek, M. Schellhammer, and C. Schmid.

* Recipient of an Alexander von Humboldt Stiftung research fellowship.

(*E. ingens*, *E. bupleurifolia*, *E. clavarioides*, *E. gorgonis*) (6), and experimentally, extracts of *Euphorbia amygdaloides* (7), *E. drummondii* (8), *E. marginata* (9), *E. pilulifera* (8), and *E. resinifera* (8) have been reported to induce tumor remissions in laboratory animals.

Interest was piqued by the limited phytochemical reports on *Euphorbia esula*, and by the interesting biological activity reported for this and related species of this genus; therefore, an investigation of this plant was initiated.

EXPERIMENTAL

Plant Material—Plant material used in this investigation was collected in Greensburg, Pa., during May and August 1964. Whole, flowering plants were uprooted, air-dried, separated into roots and aerial parts, and milled to a coarse powder. Voucher specimens were prepared and authenticated as *Euphorbia esula* L. (*Euphorbiaceae*).[1] Specimens representing the collections have been deposited in the herbaria of Carnegie Museum, and in the Department of Pharmacognosy, University of Pittsburgh, Pittsburgh, Pa.

Extraction and Fractionation—Only the aerial parts were used in this study. A total of 27.57 Kg. of plant material was extracted continuously with skellysolve B (*n*-hexane) for 72 hr. in a Lloyd extractor. Concentration of this extract *in vacuo* to about 4 L. yielded, on standing overnight, 116 Gm. of a gray powder (Fraction *A*). The mother liquor remaining from the removal of Fraction *A* was reduced to dryness to yield 410 Gm. of residue (Fraction *B*).

The skellysolve B-exhausted plant material was again continuously extracted with methanol for 72 hr. in a Lloyd extractor. This extract was concentrated to about 4 L., 4 L. of distilled water was added, and the mixture concentrated *in vacuo* until all traces of methanol were removed. Lyophilization of the methanol-free mixture yielded 1,688 Gm. of dark-green, dry powder (Fraction *C*) (Scheme I).

Isolation of Hexacosanol-(1) from Fraction A—Thin-layer chromatography of Fraction *A* on Silica Gel G plates, using a developing solvent composed of *n*-hexane–ethyl acetate (75:25), revealed that the fraction consisted mainly of a single spot at R_f 0.56, with small amounts of a substance traveling at or near the solvent front. The detecting reagent was 70% sulfuric acid, applied as a thin spray, followed by heating the treated plates at 120° for 10–15 min.

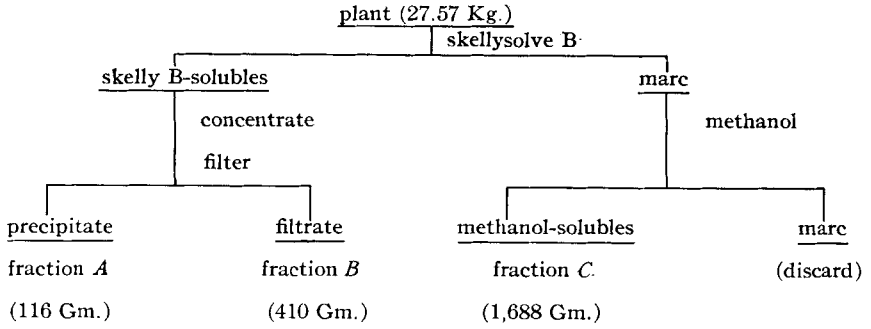
A small amount of Fraction *A* was purified by boiling it with acetone, filtering, and cooling the filtrate to room temperature. An amorphous precipitate formed which was removed, dissolved in hot chloroform, boiled for several minutes with decolorizing charcoal, and the mixture filtered. This filtrate, on standing at room temperature, produced a copious white precipitate which was removed and dried in a desiccator at room temperature *in vacuo* for 48 hr. Thin-layer chromatography of this material, as previously described, indicated a homogeneous one-spot material. The sample was identified as hexacosanol-(1) on the basis of its having melting point 76.5–77° (cap., uncorr.) [lit. m.p. 79.5–79.8° (10)], and a specific rotation $[\alpha]_D^{23}$ + 0° (c 1.0, $CHCl_3$).

Anal.—Calcd. for $C_{26}H_{54}O$: C, 81.60; H, 14.22. Found: C, 81.86; H, 14.00.

An infrared spectrum (KBr) was identical with that of an authentic sample of hexacosanol-(1), and a mixed melting point of the isolated material and the authentic sample was not depressed.

Saponification and Separation of Fraction B—An aliquot (195 Gm.) of Fraction *B* was dissolved in about 1 L. of 95% ethanol, 30 Gm. of KOH added, and the mixture refluxed for 1.5 hr. Removal of the ethanol was accomplished by means of a flash evaporator and the residue remaining was mixed with 1 L. of distilled water. This mixture was then extracted several times with petroleum ether (b.p. 30–60°), the combined petroleum ether extracts (about 3 L.) washed with distilled water, and the aqueous phase discarded. Attempts to reduce the petroleum ether extract to dryness, *in vacuo*, yielded a thick oil. This oil was mixed with about 1 L. of acetone, heated on a steam bath, and filtered while hot to remove 11 Gm. of a black tar (Fraction *B*-1). Cooling the filtrate to room temperature resulted in the deposition of a gray, amorphous precipitate, which was removed by filtration, air-dried, and labeled Fraction *B*-2 (4 Gm.). The Fraction *B*-2 mother liquor was concentrated to about 500 ml. and formed, on standing at room temperature, a copious precipitate which weighed 30 Gm. (Fraction *B*-3). Concentration of the mother liquor remaining from the isolation of

[1] Dr. Leroy K. Henry, Carnegie Museum Herbarium, Pittsburgh, Pa.



Fractionation Scheme for Euphorbia esula aerial parts
Scheme I

Fraction *B*-3, to about 250 ml. yielded 27 Gm. of an additional precipitate (Fraction *B*-4). This mother liquor was reduced to dryness, about 1 L. of *n*-hexane was added, the mixture heated to boiling, and then filtered while still hot. Concentration of the filtrate (*n*-hexane-solubles) to dryness yielded 32 Gm. of Fraction *B*-5. The filtration residue (*n*-hexane-insoluble material), which represented a considerable weight of material, was mixed with about 1 L. of acetone, the mixture heated to boiling, and filtered while hot. Evaporation of the filtrate to dryness yielded 55 Gm. of acetone soluble material (Fraction *B*-6). The acetone-insoluble residue (Fraction *B*-7). weighed 3 Gm.

Thin-layer chromatography of Fractions *B*-1 to *B*-7 was accomplished on silica gel G plates, utilizing a solvent system of *n*-heptane–benzene–ethanol (50:50:0.5), and revelation of spots was effected by spraying each plate with 70% sulfuric acid, followed by heating at 120° for 15 min. Fractions *B*-1, *B*-2, and *B*-3 were found to exhibit identical chromatographic patterns. Each exhibited a major spot at R_f 0.11 and trace amounts of *n*-alkanes migrating at or near the solvent front. The R_f 0.11 spot in each fraction corresponded to hexacosanol-(1) in this and in several other solvent systems; therefore, no further studies were made on these fractions.

Fractions *B*-4 and *B*-5, however, showed the presence of several spots, giving characteristic color reactions suggestive of the presence of triterpenes and/or sterols (11), in addition to hexacosanol-(1) and *n*-alkanes. Since these two fractions were almost identical in migration patterns and chromogenic response of the resolved components to the spray reagent, they were combined and marked as Fraction *B*-8 (59 Gm.). Fractions *B*-6 and *B*-7 exhibited dissimilar chromatographic patterns and therefore were not combined (Scheme II).

Investigation of Fraction B-8—The fraction (59 Gm.) was dissolved in a minimum volume of hot petroleum ether (b.p. 30–60°) and this solution held overnight at room temperature. Crystals which formed were removed and recrystallized from petroleum ether in a similar manner yielding 0.194 Gm. of material having a melting point of 75–77° (cap., uncorr.). Comparison of this isolate with hexacosanol-(1) by means of mixture melting point, optical rotation, infrared absorption spectrum, and thin-layer chromatography, showed them to be identical.

After removal of the hexacosanol-(1), the fraction was taken to dryness, dissolved in a minimum volume of *n*-hexane, and added to the top of a column (5.5 × 55 cm.) of Woelm, neutral, activity grade I alumina, packed as an *n*-hexane slurry. Elution was initiated with *n*-hexane, followed by *n*-hexane–benzene (1:1), benzene, ether, and methanol. One hundred-milliliter fractions were collected, reduced to about 10 ml., and subjected to thin-layer chromatography as previously described, using a solvent system of *n*-heptane–benzene–ethanol (50:50:0.5). Fractions were grouped according to the eluting solvent used, taken to dryness, and crystallizing attempts initiated with the usual solvents. These data are presented in Table I.

Isolation of *n*-Nonacosane and *n*-Hentriacontane—Fractions 1–41 were combined, taken to dryness, and dissolved in a minimum volume of *n*-hexane. Chilling produced a material which deposited as shiny plates when dried *in vacuo* at room temperature for 24 hr. This isolate was weighed (0.685 Gm.) and found to have a m.p. of 67–68° (cap., uncorr.). The sample exhibited no ultraviolet absorption spectrum and had optical rotation $[\alpha]_D^{24} \pm 0°$ (c, 1.25, $CHCl_3$). An infrared absorption spectrum (KBr) showed typical absorption peaks suggestive only of *n*-alkanes, with an absence of OH absorption. The

[a] On Woelm, neutral, activity grade I alumina. [b] Each fraction was 100 ml.

sample was analyzed by gas chromatography, using the conditions described in an earlier work (12), and was found to be composed of the following *n*-alkanes: *n*-pentacosane (<1%), *n*-hexacosane (<1.0%), *n*-heptacosane (<1%), *n*-octacosane (<1%), *n*-nonacosane (31%), *n*-triacontane (2%), *n*-hentriacontane (53%), *n*-dotriacontane (2%), and *n*-tritriacontane (7%). An additional sample of this *n*-alkane mixture was subjected to a preparative gas chromatographic separation and the major peaks, corresponding to the C_{29} and C_{31} *n*-alkanes, were collected. Melting point determinations (cap., uncorr.) on the two isolates showed m.p. 63.0–63.5° for the C_{29} peak isolate, and 67.5–68.0° for the C_{31} peak isolate, which corresponded to m.p. 63.4–63.7° and 67.5–68.5° reported in the literature for *n*-nonacosane and *n*-hentriacontane, respectively (10).

Direct crystallization procedures performed on the other column chromatographic fractions yielded only hexacosanol-(1) (Table I).

Separation of Fraction B-8 (58-152)—After removal of the hexacosanol-(1), obtained by direct crystallization procedures, the material eluted by benzene during the column chromatography of Fraction *B*-8 (column Fractions 58–152) was dried, dissolved in a minimum volume of benzene, and rechromatographed on this column with benzene as the initial eluent. Again, 100-ml. fractions were collected, each fraction concentrated to about 10 ml., and monitored by means of TLC using *n*-heptane–benzene–ethanol (50:50:0.5) as previously described. Based on changes in the TLC patterns, eluents were increased in polarity and fractions were pooled as indicated in Table II. Combined Fractions 69–83 were taken to dryness, dissolved in hot methanol, and the resulting solution chilled. After 24 hr. crystals formed which, after they were harvested and dried *in vacuo* in an Abderholden pistol over boiling methanol for 24 hr., weighed 0.247 Gm., and melted at 112–113.5° (Kofler, uncorr.). Thin-layer chromatography of the sample, as previously described, utilizing *n*-heptane–benzene–ethanol (50:50:2.0) as the developing solvent, showed it to be a homogeneous one-spot material, exhibiting an R_f of 0.19, which was identical to the R_f of a reference sample of 24-methylenecycloartanol.[2]

Identification of 24-Methylenecycloartanol—The isolate having m.p. 112–113.5° [lit. m.p. 118–119° (13)] exhibited an optical rotation of $[\alpha]_D^{24}$ + 47.9° (c 1.087, $CHCl_3$) [lit. $[\alpha]_D^{14.5}$ + 48.8° (c 0.26, $CHCl_3$) (13)], and an infrared absorption spectrum (KBr) that was identical with that of reference 24-methylenecycloartanol[2] (Fig. 1).

Anal.—Calcd. for $C_{31}H_{52}O$: C, 84.48; H, 11.89. Found: C, 84.03; H, 11.86.

Acetylation of the isolate was accomplished with acetic anhydride in pyridine in the usual manner, and the acetate crystallized from ethanol to give needles having m.p. 105–106° [lit. m.p. 110–111° (13)], and optical rotation $[\alpha]_D^{24}$ + 56.8° (c 1.467, $CHCl_3$), lit. $[\alpha]_D^{18.5}$ + 56.6° (c 0.49, $CHCl_3$) (13).

Anal.—Calcd. for $C_{33}H_{54}O_2$: C, 82.10; H, 11.27; $OCOCH_3$, 10.96. Found: C, 81.60, 81.68; H, 11.20, 11.42; $OCOCH_3$, 10.95.

Isolation of β-Sitosterol—Fractions 84-128 (12.7 Gm.) (Table II) from the column chromatographic separation of the combined Fractions 58–152 obtained from the column chromatography of Fraction *B*-8 would not yield crystals on direct crystallization attempts from the usual solvents. Therefore, 9.5 Gm. of the fraction was dried, dissolved in 40 ml. of *n*-hexane, applied to the top of a glass chromatographic column (5.5 × 49 cm.) containing an *n*-hexane slurry of silicic acid (Kieselgel-Merck, 0.05–0.20 mm.), which had previously been activated by

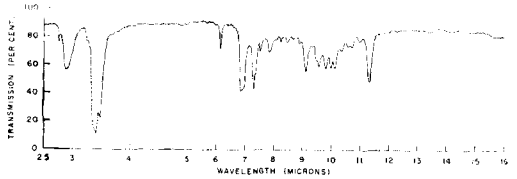

Fig. 1—Infrared absorption spectrum of 24-methylenecycloartanol (KBr).

[2] Reference samples of 24-methylenecycloartanol were supplied through the courtesy of Drs. Wesley Cocker, A. N. Starratt, and G. Ponsinet.

heating at 110° for 24 hr., and elution was initiated with *n*-hexane. Fractions (100 ml.) were collected, grouped on the basis of TLC behavior as previously described, and on the basis of shifts in TLC patterns, eluents were changed as indicated in Table III. Fractions 17–22 were combined, taken to dryness, and the residue dissolved in a minimum volume of hot methanol. A small amount of decolorizing charcoal was added, the mixture boiled for a few minutes, filtered until clear, and refrigerated for 24 hr. Crystals that formed were removed and, after drying *in vacuo* over boiling methanol for 24 hr., were shown to be one-spot material (R_f 0.09) on TLC as previously described, using the solvent system *n*-heptane–benzene–ethanol (50:50:2.0). This isolate was found identical in its chromatographic behavior, in several solvent systems, with β-sitosterol. The yield was 0.319 Gm. and the crystals had m.p. 133–135° [lit. m.p. for β-sitosterol 137–138° (14, 15)]. Optical rotation $[\alpha]_D^{22}$ −22.58° (c 0.80, $CHCl_3$), lit. $[\alpha]_D$ −37.8° (c 1.2, $CHCl_3$) (16).

Anal.—Calcd. for $C_{29}H_{50}O$: C, 83.99; H, 12.15. Found: C, 84.02, 83.92; H, 12.14, 11.75.

The infrared absorption spectrum was identical in all respects with that of a reference sample of β-sitosterol.[3] Acetylation of a small sample of the isolated product with acetic anhydride in pyridine in the usual manner produced an acetate which, after crystallization from ethanol, gave needles having m.p. 124–125° [lit. m.p. for β-sitosterol acetate 126–128° (17)].

Anal.—Calcd. for $C_{31}H_{52}O_2$: C, 81.52; H, 11.48; $OCOCH_3$, 11.48. Found: C, 81.25, 81.14; H, 11.28, 11.36; $OCOCH_3$, 10.62.

An infrared spectrum of this acetate was identical with that of an acetate prepared as described above from authentic β-sitosterol.

Fractions 23–26 yielded 0.125 Gm. of crystals from chloroform–methanol that were identical in all respects with the β-sitosterol isolated from Fractions 17–22.

Treatment of Fractions 11–14, in methanol, with decolorizing charcoal, yielded 0.065 Gm. of crystals that were identical with the 24-methylenecycloartanol previously isolated from Fractions 69–83 from the column chromatographic separation of Fraction *B*-8 (58–152). Crystals could not be induced to form from the remaining fractions, either before or after acetylation.

Separation of Flavonoids—Fraction C (500 Gm.) was dissolved in about 2 L. of distilled water with the aid of heat, the resulting solution concentrated on a steam bath to about 1 L., and then refrigerated for 24 hr. During this time a green scum separated, which was removed by filtration, to give a clear brown solution. This solution was extracted several times with chloroform, which on drying yielded Fraction *C*-1 (6.78 Gm.). The aqueous phase remaining from the chloroform extraction was then extracted several times with diethyl ether, which, following evaporation of the ether and drying, yielded 2.97 Gm. of Fraction *C*-2. Fractions *C*-3 (19.50 Gm.) was obtained by extracting the aqueous phase several times with ethyl acetate. Finally, the aqueous phase was extracted several times with ethyl acetate–methanol (9:1) to yield 5.93 Gm. of Fraction *C*-4. Thin-layer chromatography of Fractions *C*-1, *C*-2, *C*-3, and *C*-4 on polyamide plates, using methanol as the developing solvent, and followed by spraying each plate with an aqueous saturated solution of lead subacetate, revealed the presence of several fluorescent and visible spots in each fraction that were suggestive of the presence of flavonoids (18). Work is now in progress toward the isolation and identification of the flavonoid constituents in each of these fractions.

Detection of Alkaloids—A 20-Gm. sample of Fraction *C* was dissolved in methanol, mixed with 250 ml. of 5% hydrochloric acid, and the mixture was steam distilled *in vacuo* to remove the methanol and convert any alkaloids present to hydrochloride salts. This mixture was then filtered, and the filtrate was made basic to litmus with 28% ammonium hydroxide solution. Three 500-ml. and six 250-ml. chloroform extractions of the basic solution were pooled, dried over anhydrous sodium sulfate, and filtered. This filtrate was then taken to dryness to yield 300 mg. of residue, which was designated as the tertiary alkaloid fraction.

The alkaline mother liquor was acidified with 1.0 *N* hydrochloric acid, refrigerated overnight, and then filtered. This solution was next concentrated by the addition of methanol and evaporation *in vacuo* using a flash evaporator. During the concentration procedure, copious amounts of a white crystalline material separated (about 18 Gm. was collected), which was shown to be ammonium chloride. The extract was then taken to dryness, treated with hot acetone, and filtered to remove the quaternary bases. This treatment failed to remove a large quantity of residual crystalline material, which was presumed to be ammonium chloride. The acetone solution was designated as the quaternary alkaloid fraction.

TABLE III—COLUMN CHROMATOGRAPHIC SEPARATION OF FRACTIONS 84–128 (9.5 Gm.)[a]

Fraction,[b] No.	Eluent	Fraction Wt., Gm.	Isolated Compd.	Yield, Gm.

[a] On silicic acid (Kieselgel-Merck, activated, 0.05–0.20 mm.). [b] Each fraction was 200 ml.

The tertiary alkaloid fraction (300 mg.) was dissolved in 15 ml. of chloroform. Ten milliliters of this solution was mixed with 10 ml. of 5% hydrochloric acid solution, the mixture was shaken, and the acidic portions removed. Two-milliliter aliquots of this acidic extract were placed in each of four test tubes, and three drops of the following reagents were added

[3] A reference sample of β-sitosterol was supplied by Dr. G. H. Constantine, Jr.

TABLE IV—THIN-LAYER CHROMATOGRAPHY OF *E. esula* ALKALOID FRACTIONS[a]

Solvent System	R_f Values of Resolved Alkaloids: Tertiary Fraction	Quaternary Fraction	Control[b]
n-Propanol–NH_4OH–water (2:1:1)	0.87	0.95, 0.88, 0.73	0.88
Ethyl methyl ketone–methanol–10% NH_4OH (6:3:1)	0.27, 0.17	0.85, 0.15	0.22
Methanol–NH_4OH(99:1)	0.85, 0.05	...	0.25

[a] On Silica Gel G plates (250 μ). [b] *l*-Hyoscyamine.

separately to the contents of each tube: Valser's reagent, Mayer's reagent, phosphotungstic acid, Bouchardat's reagent. A moderate precipitate was observed in each of the four tubes after addition of the reagents, indicative of the presence of tertiary alkaloids.

Twenty milliliters of 5% hydrochloric acid solution was added to about one-half of the quaternary alkaloid fraction in acetone, and the acetone removed by means of a flash evaporator. The resulting solution was divided equally between four test tubes and the alkaloid test reagents indicated above were added. A moderate precipitate was observed in each of the tubes, indicative of the presence of quaternary alkaloids.

In order to confirm these initial qualitative tests for alkaloids, both the tertiary and quaternary alkaloid fractions were subjected to thin-layer chromatography on Silica Gel G plates (250 μ) and several different solvent systems.

Because of the reported presence of tropane alkaloids in *Euphorbia* species (19), hyoscyamine was used as a control. The dried chromatograms were sprayed with modified Dragendorff's reagent as a means of detecting the alkaloid components. These results are presented in Table IV.

Biological Activity Screening—A defatted ethanol extract was prepared from *Euphorbia esula* aerial parts as previously described (20). This extract was evaluated for antitumor, antibiotic, and mouse behavior activity, using the protocols described in an earlier work (20).[4] The extract tested by these methods had no antitumor activity at the doses indicated in each of the following tumor systems: adenocarcinoma 755 (30 mg./Kg.), mecca lymphosarcoma (30 mg./Kg.), myeloma X-5563 (30 mg./Kg.), C-1498 leukemia (30 mg./Kg.), and the P-1534 leukemia (7.5 and 15 mg./Kg.). Using different tumors and methods (21),[5] the extract was inactive against the P-1798 lymphosarcoma (31.3–250 mg./Kg.), the Lewis lung carcinoma (31.3–250 mg./Kg.), and the sarcoma 180 (250 mg./Kg.), and had an $ED_{50} > 1.0 \times 10^2$ mcg./ml. (inactive) against Eagle's 9 KB human epidermoid carcinoma of the nasopharynx in cell culture.

The extract was devoid of antibiotic activity against the bacterial and fungal pathogens and saprophytes, the plant pathogens and material-degrading organisms, and the algae and protozoa employed as test organisms in the evaluation (20).[4] At doses ranging from 5–400 mg./Kg., i.p., the extract produced only a weak central nervous system depressant effect in mice (20).[4]

[4] Extracts were evaluated through the courtesy of Eli Lilly and Company, Indianapolis, Ind.

[5] Extracts were evaluated for antitumor activity through the Cancer Chemotherapy National Service Center (CCNSC), National Cancer Institute, National Institutes of Health, Bethesda, MD 20014. The procedures were those described in *Cancer Chemotherapy Rept.*, **25**, 1 (1962).

DISCUSSION

Whole plant extracts of *Euphorbia esula* L. were previously reported to be devoid of hemolytic saponins, flavonoids, alkaloids, and tannins (4). However, this investigation has shown that several flavonoids are present in the aerial parts of this plant, and at least two tertiary and three quaternary alkaloids have been shown to be present by means of thin-layer chromatography. It is interesting to note that at least 50 species of the genus *Euphorbia* have been tested for the presence of alkaloids, and 25 of them have been recorded as alkaloid-positive. However, it has only been recently that Hart *et al.* succeeded in isolating the first crystalline alkaloid, (+)-9-aza-1-methylbicyclo[3.3.1]nonan-3-one, from the genus *Euphorbia* (*E. atoto*) (19).

Details for the extraction and fractionation of *E. esula* aerial parts have been presented, together with the first report on the isolation of 24-methylenecycloartanol, β-sitosterol, hexacosanol-(1), *n*-nonacosane, and *n*-hentriacontane from this plant.

Hexacosanol-(1) was previously reported isolated from *E. pilulifera* (22), and *E. cyparissias* (14, 23), but not from closely related *E. esula* or any other *Euphorbia* species. The *n*-alkanol, octocosanol-(1), was reported isolated from *E. jolkini* (24) and from *E. regis-jubae* (25); tetracosanol-(1) from *E. watanabei* (15); triacontanol-(1) from *E. hirta* (26), and docosanol-(1) from *E. calculata* (27), but none of these later *n*-alkanols were encountered in the present investigation.

β-Sitosterol has been isolated for the first time from *E. esula*, but it is known to occur in *E. adenochlora* (16), *E. cyparissias* (14), *E. hirta* (26), *E. hirta* var. *procumbens* (28), *E. lathyris* (29), *E. maculata* (25), *E. watanabei* (15), and *E. pulcherrima* (30).

The tetracyclic triterpene, 24-methylenecycloartanol, which is a probable intermediate in the biosynthesis of phytosterols (31), was also isolated for the first time from *E. esula*, as the major constituent of the triterpene fraction. Its presence in other *Euphorbia* species appears to be restricted to *E. cyparissias* (14). On the basis of interpretation of thin-layer chromatograms of the several *E. esula* nonsaponifiable fractions separated in this investigation, it is evident that several triterpenes are present in this plant. However, all attempts to crystallize them from several column chromatographic separations, either before or after acetylation, were unsuccessful.

The finding of the *n*-alkanes having composition C_{25} to C_{33} in *E. esula*, with *n*-nonacosane and *n*-hentriacontane being present in the highest concentrations, is consistent with the studies of Eglinton *et al.* (32) who investigated the *n*-alkanes of *E. peplus*, *E. balsamifera*, *E. atropurpura*, *E. regis-jubae*, *E. aphylla*, and *E. bourgaeana*, and studied their distribution in this and in other genera.

To date, *n*-nonacosane has been reported isolated from *E. adenochlora* (16) and *E. watanabei* (15, 33); *n*-triacontane from *E. pilulifera* (34), and *E. antisiphilitica* (34); *n*-hentriacontane from *E. pilulifera* (22), *E. lathyris* (29, 33), *E. antisiphilitica* (35), *E. candelilla* var. *luxurians* (36), *E. hirta* (26), *E. hirta* var. *procumbens* (28), *E. humifosa* (22) and *E. thymifolia* (35), and *n*-dotriacontane from *E. antisiphilitica* (35). However, these identifications must all be considered as equivocal, since it has been shown that most reports on the isolation of *n*-alkanes from plants have been erroneous (37, 38). Indeed, in most cases an investigator bases his identity of an *n*-alkane almost completely on melting point, elemental analysis and/or solubility characteristics. It has been shown recently that the substance reported as *n*-nonacosane from *E. watanabei* (15) was, in effect, a complex *n*-alkane mixture having *n*-hentriacontane as the major component (33). Similarly, the *n*-hentriacontane isolated from *E. lathyris* (29) was shown to be a mixture containing only about 53% of this compound, together with varying amounts of six other *n*-alkanes (33).

SUMMARY

(*a*) β-Sitosterol, 24-methylenecycloartanol, hexacosanol-(1) (ceryl alcohol), *n*-nonacosane, and *n*-hentriacontane have been isolated and are reported for the first time from the aerial parts of *Euphorbia esula*.

(*b*) The *n*-alkanes having constitution C_{25} to C_{33} were shown by means of gas chromatography.

(*c*) In addition to flavonoids, small amounts of tertiary, as well as quaternary alkaloids, were shown to be present in the aerial parts of *E. esula*.

Opium Alkaloids VII

Isolation of a New Benzylisoquinoline Alkaloid. Synthesis and NMR Studies of Papaveroline Trimethyl Ethers

By EINAR BROCHMANN-HANSSEN and KENTARO HIRAI*

A new phenolic alkaloid was isolated from opium and named palaudine. It was characterized spectroscopically as 1-(3′-hydroxy-4′-methoxybenzyl)-6,7-dimethoxyisoquinoline and the structure confirmed by synthesis. The other three papaveroline trimethyl ethers were also synthesized and their NMR spectra investigated.

1-BENZYLISOQUINOLINE ALKALOIDS containing a hydrogenated heterocyclic ring (1,2,3,4-tetrahydro) are widely distributed in several plant families. On the other hand, very few fully aromatic benzylisoquinolines have been isolated from natural sources, the best known being the opium alkaloid papaverine (I). Investigation of the minor alkaloids of opium has now revealed a new alkaloid of this type. It was isolated from the phenolic alkaloid fraction of powdered opium and purified by preparative thin-layer chromatography on silica gel and by column chromatography on alumina and crystallized from ethanol, m.p. 175–176°. The mass spectrum showed a molecular ion with mass *m/e* 325. The M-1 peak (*m/e* 324) was of greater intensity than the peak of the parent ion. The M-15 peak (*m/e* 310) was also quite pronounced, while the M-31 peak (*m/e* 294) was small. The UV spectrum (in methanol) had maxima at 239, 280, 313.5, and 326.5 mμ and minima at 262, 306.5, and 320 mμ, and was very similar to that of papaverine (1). The NMR spectrum in deuteriochloroform revealed three methoxyl groups resonating at τ 6.01, 612, and 6.19, corresponding to three of the four methoxyl group signals of papaverine. A 2-proton signal at τ 5.51 corresponded to the methylene group signal of papaverine. These spectroscopic data suggested that the new alkaloid had the aromatic benzylisoquinoline structure and a substitution pattern similar to papaverine, *i.e.*, *O*-desmethylpapaverine = papaveroline trimethyl ether. The alkaloid gave a positive test with Gibb's reagent, indicating that it might be unsubstituted in the *para* position to the phenolic hydroxyl group (II). This structure was confirmed by unambiguous synthesis as outlined in Scheme I.

β - Methoxy - β - (3,4 - dimethoxyphenyl)-ethylamine (III) was prepared according to Rosenmund *et al.* (2) by reduction of 1-methoxy-1-(3,4-dimethoxyphenyl)-2-nitroethane with lithium aluminum hydride. The acid chloride (IV) was synthesized from 3-benzyloxy-4-methoxybenzaldehyde *via* the azlactone as described by Robinson and Sugasawa (3). Schotten-Baumann reaction gave the amide (V) which lost methanol and water by treatment with phosphorus oxychloride in toluene.

Acid hydrolysis of VI gave the phenolic base II, which was crystallized from ethanol, m.p. 176°. No melting point depression was observed when mixed with the natural alkaloid. The natural and the synthetic compounds had the same R_f values on silica gel in two different solvent systems (4), and had identical NMR, UV, and IR spectra. Since the new opium alkaloid is closely related to papaverine and has the same pattern of oxygenated substituents as laudanidine, the authors propose to name it palaudine.

Pohl and Wiegrabe (5) have reported the NMR spectrum of papaverine, but the chemical shifts of the individual methoxyl groups have not been established. In order to make these assignments, the three remaining papaveroline trimethyl ethers were synthesized by the same route described for II and illustrated in Scheme I. In this way were obtained 1-(3′,4′-dimethoxybenzyl)-6-methoxy-7-hydroxyisoquinoline (VII), m.p. 163–165°, 1-(3′-methoxy - 4′ - hydroxybenzyl) - 6,7- dimethoxyisoquinoline (VIII), m.p. 165°, and 1 (3′-4′-dimethoxybenzyl) - 6- hydroxy - 7 - methoxyisoquinoline (IX), m.p. 165–167°. Billek (6) has previously synthesized VII and IX by catalytic dehydrogenation of the corresponding 1,2,3,4-tetrahydro derivative. These melting points are in good agreement with his. Boucherle and Alary

Scheme I

(7) have reported obtaining IX by heating of papaverine hydrochloride. However, their product decomposed without melting at 245°, thus leaving some uncertainty as to its identity.

The NMR spectrum of papaverine in deuteriochloroform showed methoxyl groups resonating at τ 6.01, 6.10, 6.18, and 6.23. The methoxyl signal at τ 6.23 was absent from II and could, therefore, be assigned to the 3′-position. Similarly, by comparing the methoxyl signals of papaverine with those of the other papaveroline trimethyl ethers, the chemical shift assignment could be made as shown in Table I.

TABLE I—CHEMICAL SHIFTS (τ) IN DEUTERIOCHLOROFORM

Compd.	6-OMe	7-OMe	4′-OMe	3′-OMe	—CH₂—
I (papaverine)	6.01	6.10	6.18	6.23	5.47
II (palaudine)	6.01	6.12	6.19	...	5.51
VII	5.98	...	6.23	6.28	5.55
VIII	6.00	6.09	...	6.24	5.47
IX	...	6.08	6.18	6.24	5.44

EXPERIMENTAL

The melting points were measured with a Kofler hot-stage micro melting point apparatus and are uncorrected. Ultraviolet spectra were obtained in ethanol solutions with a Cary model 11 spectrophotometer. Infrared spectra were determined in potassium bromide with a Beckman IR-9 spectrophotometer. Nuclear magnetic resonance spectra were measured in deuteriochloroform with a Varian Associates model A-60A nuclear magnetic resonance spectrometer. Tetramethylsilane was used as the internal standard. The mass spectrum was obtained with a Varian M-66 mass spectrometer. The elemental analyses were performed by the Microanalytical Laboratory, Department of Chemistry, University of California, Berkeley, California.

Isolation of Palaudine from Opium—Powdered opium of Indian origin was extracted and the major alkaloid groups separated by liquid–liquid extraction as described in a previous communication (8). The phenolic alkaloid fraction was subjected to preparative thin-layer chromatography on silica gel (9). A broad band having a high R_f value in chloroform–methanol (9:1) consisted of a mixture which was chromatographed on a column of neutral alumina, Merck (activity 4) with chloroform. Twenty-milliliter fractions were collected with an automatic fraction collector. One of the fractions obtained in this way was again subjected to preparative thin-layer chromatography on silica gel with chloroform–methanol (9:1) and gave an alkaloid (7 mg.) which was purified by crystallization from ethanol, m.p. 175–176°. It produced a single spot by thin-layer chromatography in two different solvent systems (4) and gave a single peak by gas chromatography on a polyester column (3% HIEFF 8B, 4 ft., 220°) with a retention time of 162 min. A grayish blue spot was produced on the TLC plate with Gibb's reagent. UV spectrum: $\lambda_{max.}$ at 239, 280, 313.5, and 326.5 mμ (log ϵ, 4.78, 3.89, 3.70, 3.73, respectively); $\lambda_{min.}$ at 262, 306.5, and 319 mμ (log ϵ, 3.81, 3.59, 3.65, respectively). IR spectrum: $\nu_{max.}$ at 3430, 3000, 2868, 2817, 1620, 1589, 1569, 1513, 1478, 1463, 1450, 1432, 1420, 1385, 1350, 1323, 1273, 1235, 1203, 1160, 1130, 1080, 1050, 1030, 988, 961, 921, 894, 860, 823, 810, 788, 761, 652, 600, 565, 560, 500 and 400 cm.$^{-1}$ Mass spectrum: peaks at *m/e* 325 (M), 324 (M-1), 310 (M-15).

Syntheses of—N-(3′-benzyloxy-4′-methoxyphenylacetyl)-β-methoxy-β-(3,4-dimethoxyphenyl)ethylamine(V)—3-Benzyloxy-4-methoxyphenylacetic acid (0.45 Gm.) (3) was refluxed with

0.8 ml. of thionyl chloride in 8 ml. of chloroform for 2 hr. The reaction mixture was concentrated *in vacuo*. Excess of thionyl chloride was removed by repeated addition and evaporation of anhydrous toluene. The oily residue of acid chloride (IV) was dissolved in 10 ml. of anhydrous ether and added dropwise, with stirring and cooling in an ice bath, to a mixture of 10 ml. sodium hydroxide (10%) and 10 ml. of an ether solution of β-methoxy-β-(3,4-dimethoxyphenyl)-ethylamine (III) (2) prepared from 0.52 Gm. of the oxalate. After the addition was completed, stirring was continued for 1 hr. at 0°. The amide crystallized, was filtered off, washed with cold water, and dried. Yield 0.90 Gm. Recrystallization from ethanol gave colorless needles, m.p. 115–116°. The NMR spectrum showed the following proton resonances: Singlet at τ 6.82 for β-methoxyl group, singlet at τ 6.13 for two aromatic methoxyl groups, singlet at τ 6.52 for —CH_2—CO—, and singlet at τ 4.85 for the benzyloxy methylene protons.

Anal.—Calcd. for $C_{27}H_{31}NO_6$: C, 69.66; H, 6.71; N, 3.01. Found: C, 69.45; H, 6.75; N, 2.92.

1 - (3' - Hydroxy - 4' - methoxybenzyl) - 6,7 - dimethoxyisoquinoline (II)—A mixture of 0.436 Gm. of V, 1.2 ml. of phosphorus oxychloride, and 6 ml. of toluene was heated under reflux for 1.5 hr. The reaction mixture was concentrated *in vacuo* to give an oil of 1-(3'-benzyloxy-4'-methoxybenzyl)-6,7-dimethoxyisoquinoline (VI) hydrochloride. The crude product was refluxed with a mixture of 4 ml. of 18% hydrochloric acid and 2 ml. of ethanol for 2 hr. The solution was concentrated *in vacuo*, made strongly alkaline with 10% sodium hydroxide solution, and washed once with chloroform. Ammonium chloride was added to a pH of about 10 and the liberated phenol extracted with chloroform. The chloroform extract was dried over anhydrous magnesium sulfate and evaporated to dryness *in vacuo* to a brown oil (0.1 Gm.), which crystallized on addition of a small amount of ethanol. Recrystallization from ethanol gave colorless prisms, m.p. 176°. The sample gave no melting point depression in mixture with palaudine isolated from opium. The UV, IR and NMR spectra corresponded to those described for palaudine.

Anal.—Calcd. for $C_{19}H_{19}NO_4$: C, 70.14; H, 5.89; N, 4.31. Found: C, 69.91; H, 5.89; N, 4.19.

N - (3',4' - Dimethoxyphenylacetyl) - β - methoxy-β - (3 - methoxy - 4 - benzyloxyphenyl)ethylamine (XII)—The acid chloride (XI) was prepared from 0.25 Gm. of 3,4-dimethoxyphenylacetic acid as described for IV. It was dissolved in 10 ml. of benzene and added dropwise and with stirring and cooling to a mixture of 10 ml. of 1 *N* sodium hydroxide and 10 ml. of a benzene solution of β-methoxy-β-(3-methoxy-4-benzyloxyphenyl)-ethylamine (X) (10) obtained from 0.5 Gm. of the hydrochloride. After 2 hr. of stirring, the benzene layer was separated and washed with water, then with dilute hydrochloric acid and again with water. The benzene layer was dried with anhydrous magnesium sulfate and evaporated *in vacuo* to give the amide (XII) as a brown oil (0.7 Gm.). It was purified by chromatography on a column of neutral alumina, Merck (activity 4) with chloroform. The colorless syrup obtained after evaporation of the solvent gave a single spot by thin-layer chromatography on silica gel with chloroform–methanol (9:1). The NMR spectrum showed the following signals: singlet at τ 6.13 for two aromatic methoxyl groups, singlet at τ 6.52 for —CH_2—CO— and singlet at τ 4.87 for the benzyloxy methylene protons.

1 - (3',4' - Dimethoxybenzyl) - 6 - methoxy - 7-benzyloxyisoquinoline (XIII)—A mixture of 0.5 Gm. of the amide (XII), 1.5 ml. of phosphorus oxychloride, and 6 ml. of toluene was refluxed for 1.5 hr. After cooling, petroleum ether was added, and a dark brown oil separated. The petroleum ether layer was decanted off, and the residual oil dissolved in methanolic hydrochloric acid and poured into cold 1 *N* sodium hydroxide solution. The mixture was extracted with chloroform, the extract dried over anhydrous magnesium sulfate, and the chloroform removed under reduced pressure. The brown, oily residue was purified by preparative thin-layer chromatography on silica gel with chloroform–methanol (9:1) to give a colorless oil. NMR spectrum: singlets at τ 6.23, 6.18, and 6.01 for three aromatic methoxyl groups, singlet at τ 5.55 for the methylene substituent in position-1, singlet at τ 4.82 for the benzyloxy methylene and doublet at τ 1.65 for the C-3 proton (J = 6 c.p.s.).

1 - (3',4' - Dimethoxybenzyl) - 6 - methoxy - 7-hydroxyisoquinoline (VII)—A solution of XIII (0.095 Gm.) in 2 ml. of ethanol was mixed with 1.5 ml. of hydrochloric acid (38%) and refluxed for 3 hr. The reaction mixture was evaporated to dryness *in vacuo*, the residue dissolved in water, and the solution washed once with chloroform. After addition of sodium hydroxide and ammonium chloride to pH about 10, the solution was extracted with chloroform, the extracts dried over anhydrous magnesium sulfate, and evaporated under reduced pressure. The residual oil crystallized on treatment with ethanol. Recrystallization from ethanol gave pale brown prisms, m.p. 163–165° [lit. 165–167° (6)]. The substance gave a single spot by thin-layer chromatography on silica gel with chloroform–methanol (9:1).

Anal.—Calcd. for $C_{19}H_{19}NO_4$: C, 70.14; H, 5.89; N, 4.31. Found: C, 70.06; H, 5.97; N, 4.45. The NMR signals are given in Table I.

N - (3' - Methoxy - 4' - benzyloxyphenylacetyl)-β - methoxy - β - (3,4-dimethoxyphenyl)ethylamine (XV)—The acid chloride (XIV) was prepared from 0.7 Gm. of 3-methoxy-4-benzyloxyphenylacetic acid (11) and reacted with β-methoxy-β-(3,4-dimethoxyphenyl)ethylamine (III) (from 0.8 Gm. of oxalate) as described for the synthesis of V. The amide which separated (1.3 Gm.) was recrystallized from ethanol to give colorless needles, m.p. 117–118°.

Anal.—Calcd. for $C_{27}H_{31}NO_6$: C, 69.66; H, 6.71; N, 3.01. Found: C, 69.54; H, 6.60; N, 3.15. The NMR spectrum gave the following proton resonances: singlet at τ 6.83 for the β-methoxyl group, singlet at τ 6.12 for two aromatic methoxyl groups, singlet at τ 6.50 for —CH_2—CO— and a singlet at τ 4.83 for the benzyloxy methylene protons.

1 - (3' - Methoxy - 4' - benzyloxy) - 6,7 - dimethoxyisoquinoline (XVI)—Cyclization of XV (0.6 Gm.) was carried out with phosphorus oxychloride in toluene as described above. The reaction mixture was concentrated *in vacuo*, made alkaline with sodium hydroxide solution, and extracted with chloroform. The chloroform extract was dried and evaporated to a brown oil (0.48 Gm.). The NMR

spectrum showed the following signals: singlets at τ 7.27, 6.12, 5.98 corresponding to three aromatic methoxyl groups, singlet at τ 4.89 for the benzyloxy methylene protons and doublets at τ 1.60 and 2.52 (J = 5.5 c.p.s.) for the C-3 and C-4 protons.

1 - (3' - Methoxy - 4' - hydroxybenzyl) - 6,7 - dimethoxyisoquinoline (VIII)—Hydrolysis of XVI (0.4 Gm.) with ethanolic hydrochloric acid was carried out as described for VII, and the isolated oil (0.1 Gm.) crystallized on standing. Recrystallization from ethanol gave pale tan-colored prisms, m.p. 165° [lit. 165° (6)]. The substance gave a single spot by thin-layer chromatography on silica gel with chloroform–methanol (9:1). The NMR signals are recorded in Table I.

Anal.—Calcd. for $C_{19}H_{19}NO_4$: C, 70.14; H, 5.89; N, 4.31. Found: C, 69.87; H, 5.87; N, 4.62.

N-(3',4'-Dimethoxyphenylacetyl)-β-methoxy-β-benzyloxy-4-methoxyphenyl)ethylamine (XVIII)—A benzene solution of the acid chloride (XI), prepared from 0.35 Gm. of acid, was added dropwise with stirring and cooling to a flask containing 10 ml. of sodium hydroxide solution (10%) and 10 ml. of a benzene solution of β-methoxy-β-(3-benzyloxy-4-methoxyphenyl)ethylamine (XVII), prepared from 0.6 Gm. of oxalate. After 2 hr. in an ice bath, the benzene layer was separated, washed with water, then with dilute hydrochloric acid and again with water, dried and evaporated *in vacuo*. The residual oil (0.7 Gm.) showed the following NMR signals: singlet at τ 6.90 for the β-methoxyl group, singlet at τ 6.12 for three aromatic methoxyl groups, singlets at τ 6.52 for the —CH_2CO— group, and at τ 4.87 for the benzyloxy methylene protons.

1 - (3',4' - Dimethoxybenzyl) - 6 - benzyloxy - 7-methoxyisoquinoline (XIX)—Cyclization of XVIII (0.6 Gm.) was carried out as described for XIII. The product was a brown oil (0.45 Gm.) which gave only a single spot by thin-layer chromatography on silica gel with chloroform–methanol (9:1). The NMR spectrum gave the following signals: singlets at τ 6.23, 6.18, and 6.10 corresponding to three aromatic methoxyl groups, singlet at τ 5.47 for the methylene substituent in position 1, and a singlet at τ 4.72 for the benzyloxy methylene protons.

1 - (3',4' - Dimethoxybenzyl) - 6 - hydroxy - 7-methoxyisoquinoline (IX)—The hydrolysis of XIX (0.45 Gm.) was carried out as described above, and the isolated oily compound (0.3 Gm.) purified by preparative thin-layer chromatography on silica gel with chloroform–methanol (9:1). This gave a crystalline substance which was recrystallized from ethanol as prisms having a light tan color, m.p. 165–167° [lit. 165° (6)]. The substance produced a single spot by thin-layer chromatography on silica gel. The NMR data are recorded in Table I.

Anal.—Calcd. for $C_{19}H_{19}NO_4$: C, 70.14; H, 5.89; N, 4.31. Found: C, 69.96; H, 5.93; N, 4.35.

Evaluation, Control, and Prediction of Drug Diffusion Through Polymeric Membranes I

Methods and Reproducibility of Steady-State Diffusion Studies

By EDWARD R. GARRETT and PRAMOD B. CHEMBURKAR

The equipment and methods for the study of drug diffusion through polymeric membranes are described. Among studies conducted on a given day, diffusion rates were reproducible within a coefficient of variation of 3.2 percent. Variation in ionic strength from 0.1–0.4 and the variations in hydrostatic head studied had no significant effect on the rates of diffusion of 4′-aminopropiophenone from 6.8 phosphate buffer through silastic membrane into 0.12 *N* HCl. Silastic membrane is shown to be impermeable to phosphate buffer and hydrogen and chloride ions.

THE POSSIBLE mechanisms for the passage of nutrients and drugs across a succession of membranes in the living organism have been explained on their postulated similarity to the transport or diffusion processes in artificial membranes (1–5).

Diffusion is characterized by the tendency of molecules to migrate from a region of high concentration to a region of lower concentration, but is more rigorously stated with respect to chemical potentials or activities rather than concentrations. The membrane is an imperfect barrier separating two fluids and hinders free diffusion of a substance in an isotropic medium.

Dialysis is due to sieve action and is largely dependent on the molecular weight of the diffusate and the viscosity of the solvent in accordance with the Sutherland and Einstein equation (6). Dialysis membranes may be considered as heterogeneous barriers in the sense that they possess pores. The ease of transport is generally a measure of the probability of a solvated molecule entering and diffusing through these pores. There is little selectivity in the separation of two closely related molecules except when their size is approximately that of the size of the pore (7). In general, the solvent as well as the solute is transported; membranes which allow salt transport are permeable to water (8).

Many polymeric membranes, such as copolymers based on polyoxyethylene glycols and polyethylene terephthalate, act as homogeneous barriers to free diffusion (7). Transport may be generally dependent on the relative adsorption of the molecules diffusing to the face of the membrane and solubility of these molecules in the membrane. Lyman and co-workers (7, 9, 10) have prepared synthetic membranes with the express intent of endowing them with specific characteristics which would transfer substances by an adsorption and solubility mechanism and not by sieve action. Variation in copolymer ratios of the synthetic membranes variably affected the transfer rates of glucose and urea. These observations were consistent with postulates of different degrees of association or partitioning with the membranes (11).

Studies on the diffusion of drugs from solution through polymeric substances that cannot be considered as dialysis have been limited. Johnson (12) has studied the diffusion of drugs in cross-linked thiolated gelatin and has observed that both ionic and nonionic drugs diffuse in accordance with Fick's law, which implies dialysis. No rigorous dependence of diffusivity on molecular weight can be concluded among the compounds studied.

The extensive use of polymeric materials for packaging purposes in the pharmaceutical industry has led to the investigation of polymer-drug interactions (13–18). It has been concluded from pH-sorption studies that undissociated acids interact with the basic amide groups of the polyamide nylon through hydrogen bonding. The rate-determining step was stated to be the diffusion of the solute within the polymer. The number of binding sites are finite and Langmuir or Freundlich adsorption models are applicable. Decreased solvent polarity decreased the extent of sorption.

Model systems for the kinetics of drug transport through lipoidal barriers have been studied recently. A series of nonpolar liquids have been selected as models of living membranes between aqueous phases (19–22). The purpose was to obtain values which could be employed to cor-

Presented in part to the Basic Pharmaceutics Section, APhA Academy of Pharmaceutical Sciences, Las Vegas meeting, April 1967.

Abstracted in part from a thesis submitted by P. B. Chemburkar to the University of Florida, in partial fulfillment of Doctor of Philosophy degree requirements.

The authors are grateful to the Dow Corning Center for Aid to Medical Research, Midland, Mich., for their supplies of the polymeric membranes.

relate the structures, solubilities, and partition coefficients of drug molecules with their ability to pass through different membranes.

The studies reported in this series on the diffusion and permeation of drugs through polymeric membranes from various solvent systems were initiated to establish and test model systems with solid membranes as homogeneous barriers. These may be considered a more realistic simulation of drug transport through solid lipoidal barriers. The purpose was also to quantify those parameters necessary for the evaluation, control, and prediction of drug diffusion through polymeric membranes. This is of practical importance in the light of recent pharmaceutical interest in the applications of such phenomena to the design of new dosage forms (7, 9, 10), particularly with reference to silicone rubber or silastic membranes (23, 24).

This first paper of the series describes the apparatus and techniques used to study steady-state and quasi-steady-state diffusion through such a lipid-like polymeric membrane and statistically evaluates the reproducibility of the former.

EXPERIMENTAL

Materials—The silastic medical grade sheeting (H-0169, H-0293), a dimethyl-siloxane polymer (25) was obtained from the Dow Corning Center for aid to Medical Research, Midland, Michigan. They were available in labeled thicknesses of 3, 5,10, and 20 mil. The actual thickness was obtained from the difference of measurements between two sheets of hard-surfaced paper and of the thickness of the two sheets alone. A micrometer screw with an accuracy of 0.1 mil was used at 10 equally spaced sites on seven different 2.54 cm. × 2.54 cm. square patches.

The 4′-aminopropiophenone, m.p. 139–140.5°, lit. value 140° (26), was purchased from Eastman Organic Chemicals, Rochester, New York. All other materials were of analytical reagent grade.

Analytical Methods—The absorbance of 4′-aminopropiophenone, 307 mμ, ϵ = 16,016 was measured in pH 6.8 phosphate buffer solutions against an appropriate blank with a Beckman model DU spectrophotometer in standard 10-mm. light path silica cells at 24.0 ± 1.0°.

Steady-State Diffusion Cells, Assembly, and Procedure—The steady-state diffusion cell designed was a modification of the cell used by Lyman *et al.* (10). An exploded schematic view of the diffusion cell is shown in Fig. 1. It consisted of two stainless steel plates (6.35 cm. × 5.1 cm. × 3.8 mm.), a glass T joint, two silicone rubber gaskets (2.57 cm. i.d. × 2.95 cm. o.d. × 0.16 cm. thick), and a set of four stainless steel nuts and bolts.

Each of the stainless steel plates had a hole in the center, 2.57 cm. in diameter. Around this hole there was a border 0.43 cm. in width from the perimeter of the hole and recessed 2 mm. into one face of the stainless steel plate. The silicone gaskets fitted into the recessed borders around the holes. The two plates had four holes in four corners for the stainless steel bolts.

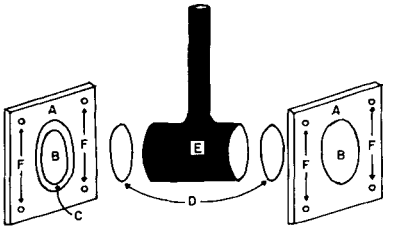

Fig. 1—Diffusion cell used for steady-state diffusion. Key: A, stainless steel plates (6.35 cm. × 5.1 cm. × 3.2 mm.), B, hole in stainless steel plate (2.57 cm. in diameter); C, recessed border around hole B (0.43 cm. in width from the perimeter of the hole and recessed 2 mm. into the stainless steel plate); D, silicone rubber gaskets (2.57 cm. i.d.; 2.95 cm. o.d.; 0.16 cm. thick); E, glass T joint with horizontal glass cylinder (2.6 cm. in diameter, 3 cm. long) and vertical stem (0.8 cm. in diameter and 11 cm. long); F, holes for stainless steel bolts.

The glass T joint consisted of a 3 cm. long hollow glass cylinder 2.60 cm. in diameter joined in its center at right angles on one side to an 11 cm. long glass tube 0.8 cm. in diameter to form a hollow T-shaped device. The two annular edges of the glass cylinder fitted into the recessed borders against the gaskets in the plates.

A 5.1 cm. × 5.1 cm. square of membrane under study (after washing with distilled water and drying in air) was positioned between the recessed border of each of the plates and a silicone rubber gasket. The open ends of the glass cylinder were then fitted into the recessed borders on the face of the silicone rubber gaskets. The whole assembly was held in position by a set of four nuts and bolts passing through the holes in the corners of the plates. The volume of the assembled cell was approximately 22 ml. and the total area of the two membranes available for diffusion was 10.4 cm.^{2}.

The diffusion cell was filled with 20 ml. of the buffered solution of the drug under study and was placed in either a 200 (or 400) ml. beaker which contained either 120 (or 200) ml. of solution into which the drug was to diffuse. The level in the cell was maintained about 3.88 cm. above the horizontal portion of the inverted T joint. This was effected by pumping the drug solution from a 2-L. reservoir through one channel of a Durrum 12-channel Dial-A-Pump (Durrum Instrument Corp., Palo Alto, California) at a rate of 25–30 ml./min. to a tube opening at the diametric center of the horizontal portion of the inverted glass T joint of the assembled diffusion cell. Another pump channel removed the solution back to the reservoir at a rate of 35–40 ml./min. through a tube whose opening was positioned in the stem of the cell at the level of the solution in the beaker (Fig. 2). The net results were to provide excellent agitation of the solution in the cell, maintain a constant level at the positioning of the opening of the effluent tube, renew the cell's contents every few min., and maintain a constant concentration therein (Fig. 2).

The beaker was covered with a Parafilm membrane (American Can Company, Neenah, Wisconsin) taped to the sides of the beaker with a hole in it

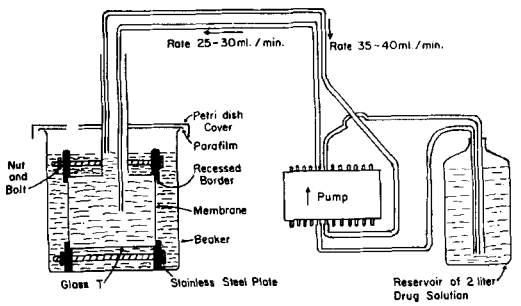

Fig. 2—Diffusion apparatus and pump assembly for steady-state diffusion studies.

for the stem of the diffusion cell. Over this was placed a plastic Petri dish with one hole for the stem and another for sample removal. This construction immobilized the diffusion cell in the beaker and minimized evaporation or contamination of the solution in the beaker (Fig. 2). The beakers with their respective diffusion cells were fitted rigidly in a metal rack inserted in the water contained in the thermostatted shaker bath (American Instrument Co., Silver Spring, Maryland) which was operated at 108 strokes per min. of 3.8 cm.

Prior to initiating any study, the beaker and its contents and the reservoir and its contents were equilibrated at the temperature of the study for about 10 hr.

At the end of each experiment, the volume and pH of the solutions in the beakers and the diffusion cells were measured. The pH values did not change throughout the course of an experiment for all studies.

Reproducibility of Steady-State Diffusion Studies—The reproducibility of diffusion studies was tested by studying the diffusion of 4′-aminopropiophenone, PAPP, from 22.0 ml. of its saturated solution in pH 6.53 ± 0.02 phosphate buffer through 3 mil silastic membrane into 184 ml. of 0.12 *N* HCl at 37.3° ± 0.1°. The cell solution contained excess undissolved PAPP and additional agitation was afforded by bubbling nitrogen through the cell. Samples (1.00 ml.) of the beaker solution of phosphate buffer were removed every hr. for 8–10 hr. Each sample, diluted with 4.00 ml. of pH 6.8 phosphate buffer (μ = 0.3) was measured at 307 mμ. Five separate experiments were performed on each of 5 days. Typical data for one such day are given in Table I.

Effect of Hydrostatic Pressure on Steady-State Diffusion—Solutions of PAPP ($1.70 \times 10^{-3} M$) in pH 6.8 phosphate buffer were circulated into four diffusion cells. The suction tubes of the channels returning the solutions from the diffusion cells to the reservoir were adjusted at four different levels (see Fig. 3) in the stem of the diffusion cell. The levels of the tubes were 0, 1.3 cm., 2.54 cm., and 7.62 cm. above the level of the solution in the beaker. The higher rate of pumping the solution from the cell to the reservoir over that of pumping the solution from the reservoir to the cell, kept the level in the cell constant at the level of the suction tube orifice. The rate of diffusion was monitored by spectrophotometric analysis of the samples from the beaker.

Effect of Ionic Strength on Steady-State Diffusion—A 100-ml. solution of 0.4 *N* HCl containing 2.5 Gm. of PAPP was prepared. Twenty-milliliter aliquots of this solution were added to 170, 330, 500, and 670 ml. of pH 6.8 phosphate buffer with an ionic strength of μ = 1.2. The solutions were then diluted with distilled water to 2 L. to obtain solutions of PAPP of the same concentrations in phosphate buffer but with ionic strengths of 0.102, 0.198, 0.300, and 0.402, respectively. The pH values of these solutions were 6.69, 6.73, 6.75, and 6.78, respectively. These solutions were then circulated in four diffusion cells to study the diffusion of PAPP through silastic membrane into 200 ml. of 0.12 *N* HCl at 23.0°.

TABLE I—STEADY-STATE DIFFUSION OF 4′-AMINOPROPIOPHENONE FROM 22.0 ML. SATURATED SOLUTION ($2.36 \times 10^{-3} M$) IN pH 6.5 PHOSPHATE BUFFER THROUGH 3-MIL SILASTIC MEMBRANE INTO 184 ML. OF 0.12 *N* HCl AT 37.3°[a]

[a] The desorbing sample solutions surrounding the cell were diluted 1:5 with pH 6.5 phosphate buffer before measurement of absorbance at 307 mμ.

Permeability of Silastic Membrane to Phosphate Buffer Salts and Hydrochloric Acid—A steady-state diffusion cell was assembled with 5-mil thick silastic membrane in position. It was filled with about 20 ml. of distilled water. The cell was kept in a 400-ml. beaker containing about 250 ml. of pH 6.5 phosphate buffer (μ = 1.2). A sample of distilled water from the cell was tested after 15 hr. for the presence of PO_4^{3-} by the ammonium molybdate test (27).

Another diffusion cell filled with 20 ml. distilled water was kept in a beaker containing 250 ml. of 0.1 *N* HCl solution. The distilled water inside the cell was tested for the presence of chloride ions after 11 hr. by the silver nitrate test (27). The pH of the distilled water was also measured.

Quasi-Steady-State Diffusion Cell, Assembly, and

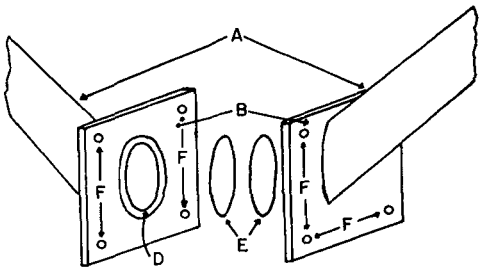

Fig. 3—Diffusion cell used for quasi-steady-state diffusion. Key: A, stainless steel cylinders (3.81 cm. in diameter, 17.8 cm. long); B, stainless steel plates (6.35 cm. × 6.35 cm. × 3.2 mm.); C, hole in stainless steel plate (3.1 cm. in diameter); D, recessed border around hole C (0.8 cm. in width from perimeter of the hole and recessed 2 mm. into the stainless steel plate); E, silicone rubber gaskets (3.1 cm. i.d.; 3.8 cm. o.d.; 3 mm. thick); F, holes for stainless steel bolts.

Procedures—The quasi-steady-state diffusion cell (Fig. 3) consisted of two stainless steel plates (6.35 cm. × 6.35 cm. × 3.2 mm.). Each of these plates was welded to one end of a stainless steel tube (3.81 cm. in diameter and 17.8 cm. long) at an angle of 45°. Each plate had a hole in the center (3.1 cm. in diameter) with a circular border 0.8 cm. in width from the perimeter of the hole and recessed 2 mm. into the face of the plate. The plates had four holes in the four corners for the stainless steel bolts. Two silicone rubber gaskets (3.1 cm. i.d. × 3.8 cm. o.d. × 3 mm. thick) fitted into the recessed border around the holes in the plates. A square of the membrane under study after washing with distilled water and drying in air was clamped between the two silicone rubber gaskets placed in the recessed borders in the plates. The plates were then clamped together with four stainless steel nuts and bolts. The diffusion cell when assembled formed a V-shaped device and held 150 ml. of solution in each of the tubes. The area of the membrane available for the diffusion was 7.55 cm.^{2}.

The solutions in the arms of the quasi-steady-state diffusion cell were agitated by the thermostated shaker bath in which the cell was immersed and wired to the shaker tray.

The cell was initially equilibrated in the thermostated shaker bath for about 8–10 hr. with 100 ml. of the appropriate buffer solution in both arms. Subsequently these solutions were removed by suction and a previously thermally equilibrated 50 ml. or 100 ml. solution of fresh appropriate buffer was added to one arm and an equal volume of thermally equilibrated solution of the drug in the buffer was added to the other arm. The open ends of the arms were covered with Parafilm. At regular intervals, samples from both arms of the diffusion cell were removed and spectrophotometrically analyzed for drug against the appropriate blanks until the differences in absorbances became small. The volume and pH of the solutions in both arms were measured at the end of the experiment.

RESULTS AND DISCUSSION

Impermeability of Silastic Membranes to Salts and Acid—The ammonium molybdate reagent solution (28) gave a yellow colored solution when mixed with an equal volume of 4.8×10^{-4} *M* solution of phosphate buffer. A faintly yellow colored solution was obtained with 9.60×10^{-6} *M* phosphate buffer solution. The sample from the diffusion cell kept for 15 hr. in a beaker containing phosphate buffer did not yield a precipitate or a colored solution with this reagent. It was therefore concluded that phosphate buffer salts do not diffuse significantly through silastic membrane.

A white turbid solution was obtained when 4×10^{-5} *M* solution of HCl was acidified with nitric acid and an equal volume of 10% silver nitrate solution was added. A sample from the diffusion cell kept for 11 hr. in a beaker containing 0.1 *N* HCl did not yield a turbid solution when treated similarly. Also, the 6.45 pH of the solution in the cell was constant for the time interval. It was therefore concluded that HCl does not diffuse significantly through silastic membrane.

Reproducibility of Steady-State Diffusion Studies—An example of the typical data obtained from a steady-state diffusion study of saturated solutions of PAPP in 6.5 phosphate buffer through a 3-mil silastic membrane into 200 ml. of 0.12 *N* HCl (where the concentration of the diffusing species, uncharged PAPP, is effectively zero) is given in Table I for five different cells run simultaneously on 1 day at 37.5°. The absorbances at 307 mμ of PAPP in the desorbing solution were monitored as a function of time, and when plotted against time are straight lines that appear to have zero intercepts.

The data of Table I were statistically analyzed (28–30) to determine linear regression against time, and it was concluded that the hypothesis that the intercepts were zero could not be rejected at the 5% level. The coefficient of variation for values among the slopes of the 5 replicate studies (Table I) conducted on 1 day was 7.0%.

Studies of five replicate diffusion experiments that resulted in data similar to Table I were repeated on each of 5 days. The slopes of the linear plots of concentration of the desorbing solution *versus* time and the analysis of variance (28–30) of these slopes are given in Table II. There was no significant difference between the slopes on the same day and between the slopes on different days. The estimates of variances were: for error, $\sigma_{E^2} = 0.0029$; for replicates, $\sigma_{R^2} = 0.000609$; and for days, $\sigma_{D^2} = 0.0042$. The coefficient of variation for all slopes was 12% and for the means of the slopes on differ-

[a] Steady-state diffusion of 4′-aminopropiophenone from saturated solution (2.35×10^{-3}*M*) in phosphate buffer through 3-mil silastic membrane into 200 ml. of 0.12 *N* HCl at 37.5° where in the latter solution the PAPP is fully protonated. [b] Moles of PAPP diffused per hr. would be 0.200 time these slope values which are in moles/L./hr. [c] N.S.—not significant.

ent days was 5.3%. This would include the inherent errors of the measurements and the variations among the membranes.

In subsequent experiments where nitrogen purging was not used, the variability among repetitive experiments was even less. For example, in a similar steady-state diffusion experiment at 23.0° through 3-mil silastic membrane where the PAPP concentration was 1.79×10^{-3} moles/L., the ionic strengths and the slopes of plots of concentration in desorbing solution *versus* time in 10^5 moles/L./hr. were: 0.102; 1.25; 0.198; 1.24; 0.300; 1.30; 0.402; 1.31. The coefficient of variation of the slopes was 3.2%, well within the 7.0% calculated for the variation in slopes of the five replicated nitrogen purged diffusion studies conducted in 1 day. These data showed that ionic strength had no significant effect on steady-state diffusion of PAPP through silastic membranes.

Another example is a similar steady-state diffusion experiment at 25.0° through 3-mil silastic membrane where the PAPP concentration was 1.70×10^{-3} moles/L. The number of inches the level of the solution in the cell was above that of the desorbing solution in the beaker (Fig. 3) and the slopes of the plots of concentration in desorbing solution *versus* time in 10^5 moles/L./hr. were: 0.00 in.; 1.42; 0.50 in.; 1.46; 1.00 in.; 1.39; 3.00 in.; 1.45. The coefficient of variation of the slopes was 1.5%. These data showed that hydrostatic pressure exerted by variation of the levels in the diffusion cell within the limits studied had no significant effect on the rate of diffusion of PAPP through silastic membrane.

Evaluation, Control, and Prediction of Drug Diffusion Through Polymeric Membranes II

Diffusion of Aminophenones Through Silastic Membranes: A Test of the pH-Partition Hypothesis

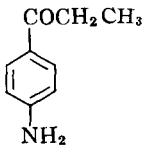
By EDWARD R. GARRETT and PRAMOD B. CHEMBURKAR

The steady-state and quasi-steady-state diffusions of 4′-aminopropiophenone, 4′-aminoacetophenone, and 3′-aminoacetophenone through various thicknesses of silastic membrane have been studied as functions of temperature, concentration, pH, and various ethanol–water compositions of diffusing and desorbing solutions. The membranes are impermeable to the protonated compounds, and the pKa values can be obtained from the pH profile of the apparent diffusion constants. The applicability of Fick's law was confirmed and the saturation of the membrane and/or limitations of numbers of binding sites are not rate determining. The transport of drug across the membrane is consistent with the partitioning from the diffusing solution into the membrane, diffusion within the membrane, and subsequent partitioning in the desorbing solution. Equations have been established on the basis of an assumed constancy of an intrinsic diffusion constant within the membrane to predict the transport of drugs through membranes separating different solvents where the drug would have different activities and have been experimentally verified. Satisfactory correlation between the apparent diffusion constants from steady-state diffusion studies and the partition coefficient in chloroform–water solutions has been observed for the several compounds. The apparent diffusion constant of 4′-aminopropiophenone from various ethanol–water solutions is linearly related to the reciprocal of its solubility in these solutions.

THE STUDIES reported here on the diffusion and permeation of drugs through polymeric membranes from various solvent systems were initiated to establish and test model systems with solid membranes as homogeneous barriers (1). These may be considered a more realistic simulation of drug transport through solid lipoidal barriers. The purpose was also to quantify those parameters necessary for the evaluation, control, and prediction of drug diffusion through polymeric membranes.

It has been implied that adsorption on surfaces of such polymeric membranes may be rate determining (2–4), that the number of surface binding sites may be finite, that the capacity of the membrane is related to its total number of internal binding sites (5–10), and that diffusion through aqueous diffusion layers on each side of the lipoidal membrane may be rate determining (11). If any but the last of these are so, the diffusion of drugs should not be linearly dependent on the concentration of the diffusing solution. As this concentration is increased, the rates of diffusion should approach a maximum value when adsorption or binding sites are limited. If desorption is rate determining, the rate of diffusion should become independent of membrane thickness as the concentration of the diffusing solutions is increased. These implications demand experimental evaluation to rigorously test the applicability of Fick's laws to diffusion through homogeneous polymer membranes.

This paper (part II of this series) considers the detailed study of the diffusion and permeation of the aminophenones, with specific reference to the antiradiation drug 4′-aminopropiophenone (PAPP), through silastic (silicone rubber) membranes.



4′-aminopropiophenone (PAPP)

EXPERIMENTAL

Materials—The silastic medical grade sheeting (H-0169, H-0293), a dimethyl-siloxane polymer (12), was obtained from the Dow Corning Center for aid to Medical Research, Midland, Mich. It was available in labeled thicknesses of 3, 5, 10, and 20 mil and the actual thicknesses were measured (1).

The following compounds were purchased from

Received January 12, 1968, from the College of Pharmacy, University of Florida, Gainesville, FL 32601

Accepted for publication February 14, 1968.

Presented in part to the Basic Pharmaceutics Section, APhA Academy of Pharmaceutical Sciences, Las Vegas meeting, April 1967.

Abstracted in part from a thesis submitted by P. B. Chemburkar to the University of Florida in partial fulfillment of Doctor of Philosophy degree requirements.

The authors are grateful to the Dow Corning Center for Aid to Medical Research, Midland, Michigan, for their supplies of the polymeric membranes.

Eastman Organic Chemicals, Rochester, N.Y.: 4′-aminopropiophenone, m.p. 139–140.5° [lit. value 140° (13)]; 4′-aminoacetophenone, m.p. 105–106° [lit. value 106° (13)]; 3′-aminoacetophenone, m.p. 97–99° [lit. value 99° (13)]. All other materials were of analytical reagent grade.

Analytical Methods—The absorbances of the aminophenones were measured in pH 6.8 phosphate buffer solutions against appropriate blanks with a Beckman model DU spectrophotometer in standard 10 mm. light path silica cells at 24 ± 1°. The compound, wavelength used, and molar absorptivity were, respectively: 4′-aminopropiophenone, 307 mμ, ϵ = 16,016; 4′-aminoacetophenone, 312 mμ, ϵ = 13,700; 3′-aminoacetophenone, 327 mμ, ϵ = 1,840. Adherence to Beer's law was confirmed by readings of diluted solutions of a known molarity.

The pKa′ of 100 ml. of 8.56×10^{-5} *M* 4′-aminopropiophenone was determined spectrophotometrically. The pH of the solution was measured on the Beckman expanded scale pH meter standardized with pH 4.0 and 7.0 standard Beckman buffer solutions. An ultraviolet spectrum of this solution was obtained against a distilled water blank on the Cary recording spectrophotometer, model 15. The sample solution in the cell was returned to the bulk solution, and a drop of concentrated HCl was added and the solution stirred. The pH of the solution was measured and the spectra determined again. This procedure was repeated and the absorbances at 307 mμ were plotted against the pH of the solutions. The pH value corresponding to the midpoint of the resultant sigmoidal curve was the half neutralization point taken as the pKa′ of 4′-aminopropiophenone and was 2.42.

Ethanol in aqueous solutions was quantitatively determined with an F & M model 700 gas chromatograph equipped with a flame-ionization detector. The column was a 3.05 cm. (1.2 in.) × 6.4 mm. o.d. stainless steel column packed with 20% Carbowax 20 M on 60–80 mesh Chromosorb W maintained isothermally at 50°. The temperature of the detector was 250° and that of the injection port was 150°. The helium carrier gas was used at a pressure of 30 psig. while hydrogen and air for the flame were used at 10 and 40 psig., respectively. Samples of 5 μl. of aqueous ethanol were injected without any prior treatment. The peak heights were measured and the concentration of the ethanol in the sample was obtained from a calibration curve prepared from ethanol solutions of known concentrations.

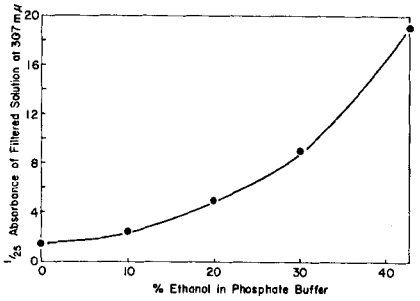


Fig. 1—Solubility of 4′-aminopropiophenone in 6.8 phosphate buffer at 25.0° plotted as absorbance of filtered saturated solutions at 307 mμ, ϵ = 16,016, against the percentage of ethanol in the phosphate buffer.

Solubility Studies—Saturated solutions of the compounds were prepared in pH 6.8 phosphate buffer (ionic strength of 0.3) at 50° and equilibrated at 37.5° in a thermostated shaker bath. The saturated solutions of 4′-aminopropiophenone in pH 6.8 phosphate buffer containing 0, 10, 20, 30, and 40% ethanol by volume were prepared by vigorously shaking the solutions at room temperature in the presence of excess solids and allowed to equilibrate at 25° in the thermostated shaker bath for 48 hr.

The solutions were filtered by suction through electrode isolation tubes which are fitted with a finely porous fritted-glass membrane (E. H. Sargent & Co., Chicago, Ill.). Aliquots of the filtered solution were appropriately diluted with pH 6.8 phosphate buffer and spectrophotometrically analyzed against appropriate blanks. The solubility of 4′-aminopropiophenone in phosphate buffer is shown as a function of ethanol concentration in Fig. 1.

Partition Coefficients—Aqueous pH 6.8 phosphate buffer and chloroform were saturated with respect to each other. The mixtures were separated by a separator and subsequent centrifugation at 3,200 r.p.m. for 5 min. An approximately 5×10^{-4} *M* solution of the compound was prepared in the phosphate buffer presaturated with chloroform. One milliliter of this solution was diluted appropriately with phosphate buffer and spectrophotometrically analyzed (at an absorbance 0.5–0.7) against a blank treated similarly. Five milliliters of the phosphate solution and 5.0 ml. of the chloroform presaturated with aqueous phosphate buffer in a capped stoppered vial were mixed on a Vortex Jr. mixer for 3 min., centrifuged for 3 min. at 3,200 r.p.m., and 1.00 ml. of the aqueous phase was removed, diluted, and spectrophotometrically analyzed. The ratio of the differences in absorbances of the aqueous layer before and after partitioning to the absorbance of the aqueous layer after partitioning was taken as the partition coefficient of the drug in the $CHCl_3$–phosphate buffer system.

Steady-State Diffusion Studies—The equipment and methods used have been described in detail in the prior paper of this series (1).

Effect of Thickness of Membrane on Steady-State Diffusion—Silastic membrane was available in four different thicknesses of 3, 5, 10, and 20 mil. The diffusion of a 1.517×10^{-3} *M* PAPP through these four thicknesses into 200 ml. of 0.12 *N* HCl was studied at 24.9°. A solution of PAPP in pH 6.8 phosphate buffer from one reservoir containing about 8 L of the solution was circulated through four cells, each one fitted with a silastic membrane of different thickness. The samples of 0.12 *N* HCl from the beakers were analyzed as a function of time to monitor the rates of diffusion of PAPP (Fig. 2).

Effect of Temperature on Steady-State Diffusion—The diffusion of PAPP from its solution in pH 6.8 phosphate buffer through 3-mil thick silastic membrane into 200 ml. of 0.12 *N* HCl was studied at seven different temperatures: 24.75°, 24.90°, 30.40°, 31.25°, 33.60°, 37.50°, and 41.0° ± 0.25°. At each temperature the diffusion was studied at four or more concentrations of PAPP in the phosphate buffer solutions. The same diffusion cells were used without changing the membranes to avoid any variation in membrane thickness and in area of the membrane available for diffusion.

Effect of pH on Steady-State Diffusion of PAPP—

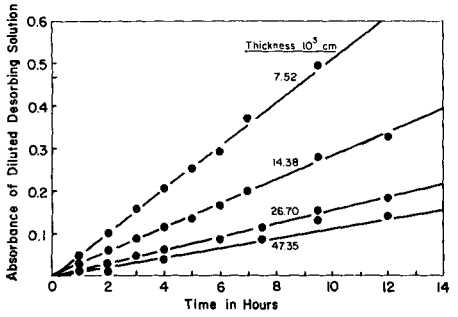

Fig. 2—Diffusion of 4′-aminopropiophenone (C_2 = 1.52×10^{-3} M) *from pH 6.8 phosphate buffer through silastic membranes of different thicknesses at 24.9°. The absorbance at 307 mμ of the desorbing 200 ml. of 0.12* M *HCl solution was monitored as a function of time after a 1:5 dilution with pH 6.8 phosphate buffer.*

The solutions of PAPP were prepared in 0.001 *N*, 0.01 *N*, and 0.1 *N* HCl and pH 3.48, 4.38, and 5.47 acetate buffer and pH 6.70 phosphate buffer. The steady-state diffusion of PAPP from these solutions through 3-mil thick silastic membrane into 200 ml. of 0.12 *N* HCl was studied at 25.0°. The pH values of the solutions were noted before and after the diffusion experiments and were observed to be unchanged. The absorbance of PAPP in the HCl solution in the beaker was measured as a function of time after 1:5 dilution with phosphate buffer. The absorbances of the solutions in the reservoirs, used for the circulation into the diffusion cells, were measured after appropriate dilutions with phosphate buffer.

Steady-State Diffusion of 4′-Aminoacetophenone and 3′-Aminoacetophenone—The diffusion of these two drugs through a 3-mil silastic membrane from their solutions in pH 6.8 phosphate buffer into 120 ml. of 0.12 *N* HCl was studied at 25.0° and 37.5°. The concentrations of the drugs diffusing into HCl were measured spectophotometrically after 1:5 dilutions with pH 6.8 phosphate buffer.

Effect of Alcohols on Steady-State Diffusion of PAPP—The effect of ethanol on the steady-state diffusion of PAPP through 3-mil silastic membrane at 25° was studied by varying the percentages of ethanol in the phosphate buffer (pH 6.8, aqueous) diffusion cell and in the outside desorbing solutions (0.12 *N* HCl). The percentage v/v of ethanol in both solutions and the concentrations of PAPP diffused are given in Table I.

The diffusion of PAPP from its saturated solutions in 0, 10, 20, and 30% v/v ethanol–water through 3-mil silastic membrane into 0.1 *N* HCl containing equivalent percentages of ethanol was studied at 24.3° (Table I). The same diffusion apparatus (Figs. 1 and 2 of *Reference 1*) was also used in the quasi-steady-state diffusion studies of PAPP from 0, 10, 20, and 30% ethanol–water solutions of phosphate buffer into 0, 10, 20, and 30% ethanol–water solutions of phosphate buffer in various combinations. The volume of the diffusing solution in the cell was 0.500 L. and that of the desorbing solution 0.120 L. The concentrations of the desorbing solution were spectrophotometrically monitored as a function of time.

Phosphate buffer (pH 6.8) solutions were prepared 2.0 *M* in ethyl, propyl, isopropyl, and *tert*-butyl alcohol and each contained 0.25 mg./ml. of PAPP. The steady-state diffusion of PAPP from each solution through 3-mil silastic membrane into 200 ml. of 0.12 *N* HCl was measured as a function of time.

[a] The apparent diffusion constant was obtained from steady-state diffusion studies from ethanol–water phosphate buffer (6.8 pH aqueous) diffusing solutions of constant concentration C_2 through a silastic membrane of thickness X = 7.52×10^{-3} cm. or 3.0 mil and available surface area S = 10.4 cm.² into a desorbing ethanol–water 0.12 *M* HCl solution of a volume V = 0.200 L. The concentrations, C_1, of the desorbing solution where the diffusing species was entirely protonated were monitored spectrophotometrically as a function of time, t, and the obtained slope C_1/t of the plotted data which passed through the origin was used to obtain the apparent diffusion constant, $D = (C_1/t)(XV_1)/SC_2$. [b] The solubility of PAPP in ethanol–water phosphate buffer interpolated from a plot of solubilities *versus* % ethanol were: 10^3 *M*, % ethanol; 2.33, 0.0; 3.15, 7.5; 5.63, 15.0; 9.30, 22.5; 14.43, 30.0; 25.20, 37.5.

Effect of Ethanol on Silastic Membrane—Three steady-state diffusion cells were filled with 0, 10, and 30% ethanolic phosphate buffer solutions and kept in 0.12 *N* HCl solutions containing the same concentrations of ethanol. After 15 hr. the cells were emptied and washed with water, and the steady-state diffusion of PAPP from one solution of PAPP in phosphate buffer circulated in all three cells was studied in the absence of ethanol, inside or outside the cell.

Diffusion of Ethanol Through Silastic Membrane—The steady-state diffusion of ethanol through 3-mil silastic membrane into 200 ml. of 0.12 *N* HCl was studied at 24.6° from absolute ethanol, from phosphate buffer solutions of 0.0, 1.90, 3.01, and 5.06 $\times 10^{-3}$ *M* PAPP containing 18% ethanol, and from phosphate buffer solutions containing 10, 20, 30, 40, and 50% ethanol.

Absolute ethanol was circulated into a diffusion

[a] The apparent diffusion constant, D, was obtained from steady-state diffusion studies from pH 6.5 phosphate buffer diffusing solutions of constant concentrations, C_2, through silastic membrane of thickness, $X = 7.52 \times 10^{-3}$ cm. or 3.0 mil and available surface area, $S = 10.4$ cm.^{2}, into a desorbing 0.12 M HCl solution of a volume $V_1 = 0.200$ L. so that D(L./cm.-sec.) = $(C_1/C_2t)\ (XV_1)/S$, where C_1/t and C_1/C_2t values are obtained as given in the subsequent footnotes. [b] The concentrations C_1 of the desorbing solution, where the diffusing species was entirely protonated, were monitored spectrophotometrically as a function of time, t, in hr., and these values are the obtained slopes, C_1/t in moles/L. of desorbing solution per hr., of the plotted data which passed through the origin. These values represent the slopes of C_1/t *vs.* C_2, where C_2 is the concentration of PAPP in the phosphate buffer diffusing solutions and the slopes of these plots are C_1/tC_2 in hr.$^{-1}$, the rate of increase in concentration of the desorbing solution per unit concentration of diffusing solution per hr.

cell fitted with a 3-mil silastic membrane. About 0.5-ml. samples of 0.12 N HCl were removed at hourly intervals, and 5 μl. of each of these samples was injected into a gas chromatograph for vapor phase analysis of ethanol. The percent ethanol present in the samples was calculated from a calibration curve.

Quasi-Steady-State Diffusion Studies—The quasi-steady-state diffusion cell and the methods previously described (1) were used to study the diffusion of PAPP from 50 and 100 ml. of pH 6.8 phosphate buffer through 5-mil silastic membrane into equal volumes of the same buffer at 25°.

RESULTS

Effect of Drug Concentration on Rate of Diffusion—The slopes, C_1/t, of the plots of concentration of PAPP in the 200 ml. of 0.12 M HCl desorbing solution after steady-state diffusion through 3-mil silastic membrane *versus* time are listed in Table II with the temperatures and the appropriate concentrations, C_2 of PAPP in the pH 6.5 phosphate buffer diffusing solution. Typical plots of these slopes, C_1/t in moles/L./hr., against the respective concentrations, C_2 in moles/L., of the diffusing solutions are shown in Fig. 3. The slopes of these plots, C_1/tC_2 in hr.$^{-1}$, are the specific rates of concentration increase in the desorbing solution per unit concentration of diffusing solution through 3-mil silastic membranes and are also given in Table II. The linear dependence of these diffusion rates, C_1/t, for the same membrane area, thickness, and volumes of diffusing and desorbing solutions on concentration of PAPP in the diffusing solution unequivocally demonstrates that the rate of diffusion through silastic membrane is directly proportional to the concentration of the diffusing drug.

Effect of Membrane Thickness on Rate of Diffusion—The plots of absorbance, $A = \epsilon C_1$ of PAPP in 1:5 diluted samples of the 200 ml. of 0.12 M HCl of the desorbing solution after steady-state diffusion *versus* time, t, for various thicknesses of silastic membrane are given in Fig. 2. The concentration increases with time, C_1/t, derived from the slopes of these plots are listed in Table III as well as the derived specific rates of diffusion (the rates of diffusion in moles of PAPP per cm.^{2} of membrane per sec. per mole/L., C_2, of diffusing solution). When these derived specific rates of diffusion, D/X, are plotted against the reciprocal of the thickness of the membranes, a linear relation is obtained (Fig. 4) with a slope of $3.76 \pm 0.19 \times 10^{-10}$ L./sec.-cm., the apparent diffusion constant D for the diffusion of PAPP through silastic membrane at 24.9°.

Effect of Temperature on Rate of Diffusion—The rates of steady-state diffusion of constant concentrations, C_2 of PAPP decrease with decreasing temperature (Fig. 3) through 3-mil silastic membrane and all are linearly dependent on the concentration, C_2, of the diffusing solution. The slopes, C_1/t, of the PAPP concentrations, C_1, of 200 ml. of 0.12 M HCl desorbing solution as a function of time, t, are given for the various studied temperatures in Table II. The derived specific rates, C_1/tC_2, of concentration increase of desorbing solution, per mole/L., C_2, of diffusing solution as well as the apparent diffusion constants, D, at the various tem-

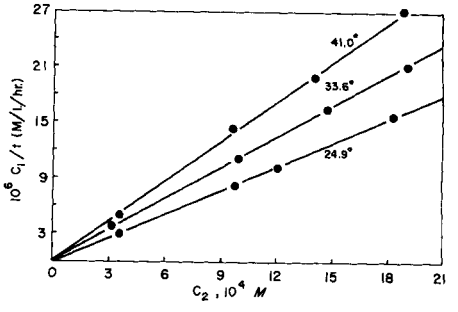

Fig. 3—Rates, C_1/t, of concentration increase in 200 ml. of 0.12 M HCl desorbing solution as a function of concentrations of 4′-aminopropiophenone in pH 6.5 phosphate buffer solution diffusing through 3.0-mil silastic membrane at several temperatures.

[a]Mean thickness and 95% confidence limits of the mean. [b]Standard deviation divided by the mean value. [c]The concentration, C_1, of the 0.200 L., V_1, of 0.12 *M* HCl desorbing solution was spectrophotometrically monitored as a function of time in hr. and these values are the slopes C_1/t of these linear plots with zero intercepts. [d]The specific rates of diffusion are the rates of diffusion in moles of PAPP per cm.^{2} of membrane, S = 10.40 cm.^{2}, per sec. per mole/L. of diffusing solution, C_2. The conditions were steady-state and the concentration of the diffusing solution was maintained constant, $C_2 = 1.517 \times 10^{-3}$ *M*, and the concentration of the diffusing unprotonated species in the acid desorbing solution was effectively zero. Thus, specific diffusion rate = $D/X = (C_1/t)(V_1/C_2S)$.

peratures are also listed in Table II. The logarithm of the apparent diffusion constants, D, are plotted against the reciprocal of the absolute temperatures, T, in Fig. 5 in accordance with the expression

$$\log D = \log (D)_0 - (\Delta E_a/2.303)(1/T) \quad \text{(Eq. 1)}$$

The estimated activation energies of diffusion through silastic membrane, ΔE_a, as obtained from the slope of these plots, are listed in Table IV for the various compounds. In addition, the determined partition coefficients and solubilities are also given.

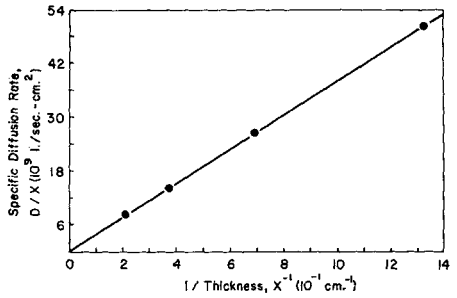

Fig. 4—Effect of thickness, X, of silastic membrane on the specific rates of diffusion, D/X, in moles of PAPP per cm.^{2} of membrane per sec. per mole/L. of phosphate buffer diffusing solution, $C_2 = 1.517 \times 10^{-3}$ M, into 0.12 M HCl desorbing solution at 24.9°.

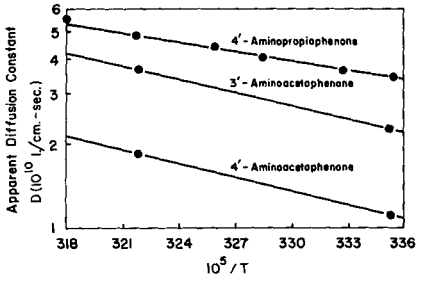

Fig. 5—Arrhenius plots of the logarithm of the apparent diffusion constants, log D, against the reciprocal of the absolute temperature, 1/T, for the diffusion of aminophenones through 3-mil silastic membranes from phosphate buffer solution.

Effect of pH on Rate of Diffusion—The apparent diffusion constants for the steady-state diffusion of PAPP through 2.43-mil silastic membrane into 0.12 *M* HCl from buffered solutions of various pH values with maintained concentrations, C_2, are listed in Table V and are plotted against pH in Fig. 6. The apparent diffusion constant, D, approaches an asymptotic value of 3.66×10^{-10} L./cm./sec. at high pH values and approaches zero at pH values less than one. The pH value corresponding to half the asymptotic value of 1.83×10^{-10} is 2.45, consistent with the experimentally determined spectrophotometric pKa′ of 2.41.

Effect of Alcohols on the Steady-State Diffusion of 4′-Aminopropiophenone (PAPP)—The plots of absorbance, $A = \epsilon C_1$, of PAPP in 1:5 diluted samples of the 200 ml. of 0.12 *M* HCl of the desorbing

2.45[b]	1.639	1.88
3.48[c]	1.592	2.71
4.38[c]	1.59	3.25
5.47[c]	1.670	3.61
6.70[d]	3.310	3.66

[a] The linear concentration, C_1, increases of the V_1 = 0.200 L. of 0.12 M HCl desorbing solution were spectrally monitored as a function of time, t, and the C/t values obtained from the slope. The diffusion was studied from maintained concentrations, C_2, of the specified buffer solutions through X = 6.09 × 10^{-3} cm. or 2.43-mil silastic membrane with available surface area S = 10.4 cm.^{2}. The apparent diffusion constant was calculated from D(L./cm.-sec.) = $(C_1/t)(XV_1/C_2S)$. [b] HCl. [c] Acetate buffer. [d] Phosphate buffer.

solution after steady-state diffusions through silastic membrane *versus* time, t, for various percentages of ethanol in the diffusing solutions are given in Fig. 7. The derived apparent diffusion constant, D, from the slopes of such plots are given in Table I for various concentrations of ethanol of the diffusing solution and the desorbing solution.

The apparent diffusion constants for PAPP decreased with increasing ethanol concentrations of the phosphate buffered diffusing solution when the PAPP concentrations remained constant (Set A, Table I). Variation in the ethanol concentration of the 0.12 N HCl desorbing solution, where the concentration of the uncharged PAPP was effectively zero and where the diffusing solution had no ethanol, had no significant effect on the apparent diffusion constant (Set B, Table I). Variation in PAPP concentration of an 18% ethanol-containing diffusing solution showed that steady-state diffusion was a linear function of this concentration, and that the apparent diffusion constant (per unit of concentration of the diffusing solution) was truly constant (Set C, Table I).

The steady-state diffusion rates at 24.25° of saturated solutions of PAPP from aqueous saturated solutions with 0, 10, 20, and 30% ethanol through 3-mil silastic membrane into 0.1 N HCl with the same ethanolic concentration are given in Table I, Set D. The increased solubility of PAPP gave a decided increase in the overall rates of diffusion.

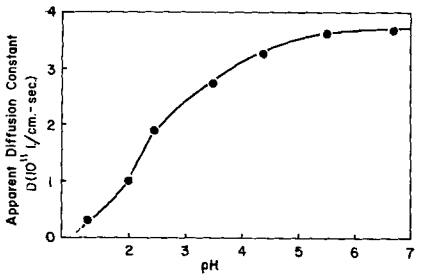

Fig. 6—Apparent diffusion constants for 4′-aminopropiophenone through silastic membrane into 0.12 M HCl desorbing solution at 25.0° against the pH of the diffusing PAPP solutions.

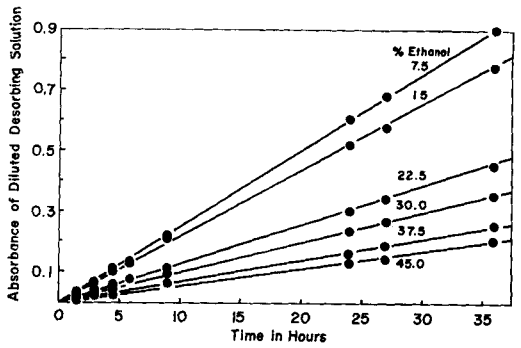

Fig. 7—Diffusion of 4′-aminopropiophenone (C_2 = 1.4 × 10^{-3} M) from various percentages of ethanol–water phosphate buffer (pH 6.8, aqueous) through 3.0-mil silastic membrane at 24.6°. The absorbance at 307 mμ of the desorbing 200 ml. of 0.12 M HCl solution of the same ethanol–water composition was monitored as a function of time after a 1:5 dilution with pH 6.8 phosphate buffer.

However, the apparent diffusion constants decreased with decreasing ethanol concentrations on both sides of the membrane.

The steady-state diffusion rates of PAPP concentrations increase in 200 ml. of 0.12 N HCl desorbing solution per unit concentration of PAPP in alcohol–water phosphate buffer diffusing solution (pH 6.8, aqueous) containing 2.0 M ethyl, propyl, isopropyl, and *tert*-butyl alcohol were 5.1, 6.0, 6.4, and 5.1 × 10^{-3} hr.$^{-1}$, respectively. It could not be concluded that the rates of diffusion of PAPP were significantly modified by variation among these alcohols.

The specific rates of steady-state diffusion of ethanol from phosphate buffer containing 18% ethanol were found to be independent of the PAPP concentration for concentrations up to 5 × 10^{-3} M (Table VI). The specific rates of diffusion of ethanol from phosphate buffer, *i.e.*, per unit of concentration in the diffusing solution, were independent of the concentration of ethanol (10–50%) in the diffusing solution (Table VI). The specific rates of diffusion of PAPP from phosphate buffer through silastic membrane pretreated with ethanol solutions of

[a] Calculated for diffusion of ethanol through 3-mil silastic membrane by dividing slope or the plot of the percent ethanol in 200 ml. of 0.12 M HCl desorbing solution in ethanol–water phosphate buffer solution (pH 6.8, aqueous), where area of membrane, S = 10.4 cm.^{2} and thickness of membrane, X = 7.52 × 10^{-3} cm.

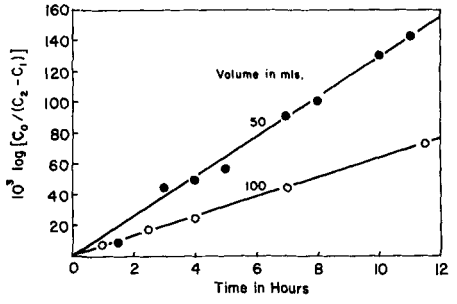

Fig. 8—Plots of log $[C_0/(C_2 - C_1)]$ *against time for quasi-steady-state diffusion of 4'-aminopropiophenone through 5-mil silastic membrane at 25.0°. The* C_2 *and* C_1 *are the concentrations of PAPP in equal volumes of the phosphate buffers of the diffusing solution and the desorbing solution, respectively, where* $C_2 = C_0$ *and* $C_1 = 0$ *at zero time.*

different concentrations were invariant. This indicated that the diffusing properties of these membranes are not altered by ethanol or that any alteration was reversible.

Quasi-Steady-State Diffusion Studies—Quasi-steady-state diffusion differs from steady-state diffusion in that (*a*) the concentrations of the diffusing and desorbing solutions are not held constant; (*b*) the concentration C_2 of the diffusing solution, initially C_0, decreases as the concentration C_1 of the desorbing solution increases; (*c*) as the values of both solutions approach the same equilibrium value with time. The plots of $\log[C_0/(C_2 - C_1)]$ *versus* time are linear for the quasi-steady-state diffusion of PAPP through 5-mil silastic membrane from and to pH 6.8 phosphate buffer at 25° (Fig. 8). The apparent diffusion constants were calculated from the slopes of these plots and were 3.93×10^{-10} and 3.94×10^{-10} L./cm.-sec. for 50-ml. and 100-ml. volumes of the solutions in the arms of the diffusion cell at 25°. These values agree with the estimated diffusion constant obtained from the various steady-state diffusion experiments, *i.e.*, $3.76 \pm 0.19 \times 10^{-10}$ L./cm.-sec. (Tables I, II, IV, V).

DISCUSSION

Fick's Law and Steady-State Diffusion—Fick's first law of diffusion (14–16) states that the rate, dA/dt, of diffusion of moles, A, per unit of time is proportional to the surface area of diffusion, S in cm.^{2}, and the concentration gradient (the rate of change of concentration C' with distance x in cm., dC'/dx) in an isotropic medium:

$$dA/dt = D'SdC'/dx \qquad \text{(Eq. 2)}$$

The experimental steady-state conditions specify that the concentration gradient, dC'/dx, is constant so that at any two planes in the isotropic medium where $x = 0$ at C_2' and $x = X$ at C_1'

$$dA/dt = D'S(C_2' - C_1')/X \qquad \text{(Eq. 3)}$$

In the specific case of diffusion through a membrane of thickness X cm. and surface area S cm.^{2} the steady-state Eq. 3 states that the rate is constant with time for constant concentrations C_2' and C_1', in the first and last monolayers, respectively. If the solutions of concentrations C_2'' and C_1'' of the diffusing species on the diffusion and desorption sides of the membrane, respectively, are in instantaneous equilibrium with their adjacent monolayers in the manner of a partition coefficient, *i.e.*,

$$C_2' = K_2C_2'' \qquad \text{(Eq. 4}a\text{)}$$

$$C_1' = K_1C_1'' \qquad \text{(Eq. 4}b\text{)}$$

the Eq. 3 can be rewritten as

$$dA/dt = D'S(K_2C_2'' - K_1C_1'')/X \qquad \text{(Eq. 5)}$$

Silastic membrane is impermeable to chloride, phosphate, and hydrogen ions (1). The additional fact that the estimated apparent diffusivities of PAPP decreased with increases in the fraction of the concentration that is charged (Fig. 6) confirms that this membrane acts as a lipid-like barrier, permeable only to uncharged species.

Thus the C_i'' terms in the diffusion Eq. 5 refer only to the concentrations of the unionized or uncharged drug in the solutions and are related to total concentrations, C_i by

$$C_i'' = f_iC_i \qquad \text{(Eq. 6)}$$

where f_i is the fraction of the drug that is unionized or uncharged and

$$f_i = K_a/([H^+] + K_a) \qquad \text{(Eq. 7}a\text{)}$$

for an amine such as PAPP whose conjugate acid has a dissociation constant K_a and

$$f_i = [H^+]/([H^+] + K_a) \qquad \text{(Eq. 7}b\text{)}$$

for an uncharged acid of dissociation constant K_a where $[H^+]$ is the hydrogen ion concentration.

The Eq. 5 can be rewritten as

$$dA/dt = D'S(K_2f_2C_2 - K_1f_1C_1)/X \qquad \text{(Eq. 8)}$$

For the special case where $K_1 = K_2 = K$,

$$dA/dt = D'KS(f_2C_2 - f_1C_1)/X = DS(f_2C_2 - f_1C_1)/X \qquad \text{(Eq. 9)}$$

where $D = D'K$ is the apparent diffusion constant or permeability constant for the system of transfer from a diffusing solution through a membrane of X cm. thickness and S cm.^{2} area into a desorbing solution.

In the steady-state diffusion studies of this investigation, the effective concentration $C_1'' = f_1C_1$ of the uncharged diffusing species of PAPP and its analogs was zero at the high acidities of the desorbing HCl solution since $f_1 = 0$ (Eqs. 6 and 7*a*). The concentration C_2'' of the uncharged species was maintained constant in the diffusing solution. The applicable Eq. 9 reduces in this special case to

$$dA/dt = DSf_2C_2/X \qquad \text{(Eq. 10)}$$

which integrates between the limits of zero time and time t to

$$A = C_1V_1 = DSf_2C_2t/X \qquad \text{(Eq. 11)}$$

where A is the amount permeating the membrane in time t. The desorbing solution of volume V_1 was analyzed for its total concentration of the drug, C_1, in moles/L., as a function of time so that plots of the concentration, C_1, *versus* time in seconds provide slopes proportional to the apparent diffusing constant, D, where

$$\text{Slope} = DSf_2C_2/V_1X \quad \text{(Eq. 12)}$$

$$D \text{ (L./cm.-sec.)} = D'K_2 = \text{slope} \cdot (XV_1)/(Sf_2C_2) \quad \text{(Eq. 13)}$$

The validities of Eqs. 11 and 12 have been experimentally verified. The stated conditions of steady-state diffusion give constant rates of diffusion with time (Figs. 2 and 7). The rate of steady-state diffusion of drug through silastic membrane is directly proportional to the concentration of drugs in the diffusing solution, C_2 (Table II, Fig. 3), and this rate is inversely proportional to the thickness of the membrane (Table III, Figs. 2 and 4).

The Eqs. 11 and 12 state that the rates of steady-state diffusion will be directly proportional to the fraction of unionized diffusing drugs and predict that these rates will be lowered to one-half their maxima when $[H^+] = K_a$ or pH = pKa (Eqs. 7, 11–13). This is confirmed by the data of Fig. 6 for PAPP, pKa = 2.42, where the apparent diffusion constants, D (Eq. 13) (actually f_2D) on the assumptions of $C_2'' = C_2$, $f_2 = 1$ are plotted against pH.

The Eqs. 9 and 13 assume that the apparent diffusion constant, D, for steady-state diffusion when $C_1'' = f_1C_1 = 0$ is directly proportional to the partition coefficient, K, of the drug between the diffusing solvent and the membrane. The partition coefficient is a ratio of the activities and/or solubilities (17) so that it may be postulated that

$$D = D'K = D'C_m/C_i = D'S_m\,(1/S_i) \quad \text{(Eq. 14)}$$

where C_m and C_i are the effective concentrations (or activities) of a compound in a membrane and its equilibrated solution, respectively; S_m and S_i are the solubilities in the membrane and its equilibrated solution, respectively.

If it is assumed that drugs in a homologous series have similar intrinsic diffusion constants, D', in the membrane and that the partition coefficients in a chloroform–water system, K_p, are proportional to those in the membrane–water system, K, *i.e.*, $K_p = \alpha K$ where α is a proportionality constant, the apparent diffusion constants, D, should increase with increases in K_p in accordance with Eq. 14. An approximately linear relationship does exist between the apparent diffusion constant, D, and the chloroform–phosphate buffer partition coefficient of the several compounds studied (Table IV).

$$D = 2.3 \times 10^{-12}\,K_p + 0.75 \times 10^{-10} \quad \text{(Eq. 15)}$$

A necessary condition for the plot of D *versus* $1/S_i$ to be linear is that the solubility in the membrane (S_m) is invariant with structural modification of the drug. The data of Table IV confirm the expectation that this is not necessarily so among several drugs.

However, when only the solvent is varied and the diffusion of one drug alone is studied, this necessary condition may be met. Experimental confirmation of Eq. 14 is obtained from the linearity of the plot (Fig. 9) of the apparent diffusion constants of PAPP, D (Table I) obtained from steady-state diffusion studies from ethanolic phosphate buffer solutions through silastic membrane into 0.12 *M* HCl desorbing solution against the reciprocal of the solubilities (Fig. 1) of PAPP, $1/S_i$, in these solutions. Regression analysis showed that the intercept is not significantly different from zero at the 5% level of significance. The slope of the plot of Fig. 9 implies

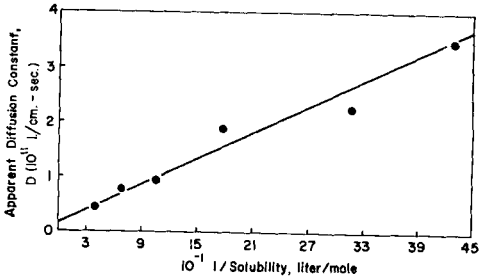

Fig. 9—Plots of apparent diffusion constant D *for the diffusion of 1.5 × 10⁻³M PAPP from various ethanol–water solutions of phosphate buffer (pH 6.8 aqueous) through 3.0-mil silastic membrane into 200 ml. of 0.12* M *HCl desorbing solution against the reciprocal of the solubility in these ethanol–water solutions.*

that the product of the intrinsic diffusion constant and the solubility in the membrane, $D'S_m$, is 8.35×10^{-13} moles/cm.-sec.

Quasi-Steady-State Diffusion—When the concentrations on both sides of a membrane are allowed to equilibrate with time and are monitored by the change of their concentrations with time, these rates can be expressed as (see Eq. 8)

$$dC_1/dt = D'S\,(K_2f_2C_2 - K_1f_1C_1)/XV_1 \quad \text{(Eq. 16}a\text{)}$$

$$dC_2/dt = -D'S\,(K_2f_2C_2 - K_1f_1C_1)/XV_2 \quad \text{(Eq. 16}b\text{)}$$

where V_1 and V_2 are the volumes of the desorbing and diffusing solutions, respectively. When the amounts entering and leaving the membrane are equal for all analytical purposes even though the rate of permeation changes with time as a function of the concentration gradient, this transport is termed "quasi-steady-state diffusion."

The stoichiometry of quasi-steady-state diffusion can be represented by

$$V_1C_1 + V_2C_2 = V_2C_0 \quad \text{(Eq. 17)}$$

and when the value of C_2 from Eq. 17 is substituted into Eq. 16*a* and the resultant expression integrated between the limits of $C_1 = 0$ at $t = 0$ and $C_1 = C_1$ at $t = t$,

$$\log\left\{\frac{K_2f_2C_0 - (K_2f_2V_1 + K_1f_1V_2)\,C_1/V_2}{K_2f_2C_0}\right\} = \frac{-(K_2f_2V_1 + K_1f_1V_2)D'S}{2.303X\,V_1V_2}\,t \quad \text{(Eq. 18)}$$

When both numerator and denominator within the logarithmic term is multiplied by D'.

$$\log\left\{\frac{D'K_2f_2C_0 - (D'K_2f_2V_1 + D'K_1f_1V_2)C_1/V_2}{D'K_2f_2C_0}\right\} = \frac{-(K_2D'V_1f_2 + K_1D'V_2f_1)S}{2.303X\,V_1V_2}\,t \quad \text{(Eq. 19)}$$

A similar expression in terms of C_0 and C_2 results when the value of C_1 from Eq. 12 is substituted in Eq. 16*b*.

If the thermodynamic activities of the drug in the diffusing and desorbing solutions are equal for the same solutions on both sides of the membrane, *i.e.*, $K_1 = K_2 = K$, and when the value of C_0 from Eq. 17 is considered, Eq. 19 reduces to

$$\log \left\{\frac{f_2C_0 - (f_2V_1 + f_1V_2)C_1/V_2}{f_2C_0}\right\} = \log \left\{\frac{f_2C_2 - f_1C_1}{f_2C_2}\right\} = \frac{-(f_2V_1 + f_1V_2)KD'S}{2.303\,XV_1V_2}\,t \quad \text{(Eq. 20)}$$

If $V_1 = V_2 = V$ and $f_2 = f_1 = f$, Eq. 20 reduces to

$$\log \left\{\frac{C_0 - 2C_1}{C_0}\right\} = \log \left\{\frac{C_2 - C_1}{C_1}\right\} = \frac{-2KD'fS}{2.303\,XV}\,t = \frac{-0.869DfS}{XV}\,t \quad \text{(Eq. 21)}$$

where $D = D'K$ is the apparent diffusion constant. This D value can be obtained from the slopes of linear plots of log $(C_2 - C_1)/C_0$ *versus* time for equal volumes of the same phosphate buffer solution in both arms of the quasi-steady-state apparatus (1) (Fig. 8). The linearity is consistent with the expectations of Eq. 21 for quasi-steady-state diffusion. The apparent diffusion constant, $D = 3.94 \times 10^{-10}$ L./cm.-sec., calculated from the slope of such plots, ($f = 1$) was consistent with the highly reproducible apparent diffusion constants 3.66×10^{-10} cm.^{2}/sec. (Table V) for uncharged PAPP obtained from steady-state diffusion data from phosphate buffer into HCl solution at the same temperature for the same silastic membrane.

Quasi-steady-state diffusion (Eq. 20) studies also produced estimates of the apparent diffusion constants $D = KD'$ for PAPP in various percent ethanol–water solutions of phosphate buffer, $f = 1$, diffusing into similar solutions when the volumes were unequal in both arms of the apparatus, $V_2 = 0.500$ L. and $V_1 = 0.120$ L. The obtained values as calculated from the slopes of plots in accordance with Eq. 20 are listed in Set A of Table VII. A new lot of silastic membrane was used in these studies.

Effects of Ethanol on PAPP Diffusion—The rates of steady-state diffusion of PAPP and thus the apparent diffusion constants through silastic membrane decrease with increased concentrations of ethanol in the diffusing solution (Set A, Table I) but are independent of ethanol concentration in the desorbing solution when the effective concentration of the transported drug is essentially zero (Set B, Table I). The specific rates of diffusion (with respect to unit concentrations) or the apparent diffusion constants of PAPP and ethanol from solutions of varying concentrations of PAPP in ethanolic phosphate buffer show negligible variation (Set C, Table I and Table VI). Thus, the diffusions of PAPP and ethanol through silastic appear to be independent processes. Those compounds do not compete or interact within the membrane or on the surfaces for sites. Apparently, the diffusion of the one does not significantly modify the intrinsic diffusivity constant, D', of the other within the membrane.

However, the apparent diffusivity constant of PAPP, $D = D'K$, is modified (Sets A and D, Table I) by varying ethanol concentrations in the diffusing solution. Its independence of the ethanol concentration of the desorbing solution (Set B, Table I), where the effective concentration of PAPP therein is zero ($f_1C_1 = 0, f_1 = 0$) in steady-state diffusion, is consistent with Eqs. 10–13 where the nature of the desorbing solution is not pertinent to the rates of transfer through the membrane. This phenomenon can be assigned to the change in the partition constant, K.

When the diffusing and desorbing solutions are of the same ethanolic concentrations ($K_1 = K_2 = K$) and pH values, ($f_1 = f_2 = f$) in quasi-steady-state diffusion, Eq. 20 is applicable. Thus, when the concentration data is appropriately plotted (Fig. 10) $D'K_i$ values can be obtained from the slope (Set A, Table VII where $f_1 = f_2 = 1$). In these cases the

[a] In this case $D'K_1 = D'K_2 = D$ which are apparent diffusion constants obtained from the slope of the left-hand side of the following equation *vs.* time t, *i.e.*, $\ln C_0V_2/[C_0V_2 - C_1(V_1 + V_2)] = DSt(V_1 + V_2)/XV_1V_2$ where $V_2 = 0.500$ L., $V_1 = 0.120$ L., $S = 10.4$ cm.^{2}, the labeled thickness was 3 mil. [b] In these cases the $D'K_1$ values listed are the apparent diffusion constants DK' of Set A for diffusion from diffusing to desorbing solutions of the same ethanol–water composition of the desorbing solutions in these studies. The $D'K_2$ values listed are the apparent diffusion constants $D'K$ of Set A for diffusion from diffusing to desorbing solutions of the same ethanol–water composition of the diffusing solutions of these studies. [c] The $D'K_2V_1 + D'K_1V_2$ values are obtained from the slopes of the plots of left-hand term of the following equation *vs.* time, t, *i.e.*, $\ln [D'K_2C_0V_2/(D'K_2C_0V_2 - C_1(D'K_2V_1 + D'K_1V_2))] = (DK_2V_1 + D'K_1V_2)St/XV_1V_2$ where C_0, V_1, V_2, S, X are known values, the $D'K_1$ and $D'K_2$ values in logarithmic term are obtained from Set A, and C_1 is experimentally obtained. [d] The $D'K_2V_1 + D'K_1V_2$ values are calculated from the known V_1 and V_2 values and $D'K_2$ and $D'K_1$ values obtained from Set A.

ethanolic water membrane partitioning at the diffusing and desorbing surfaces would be equivalent and $K_1 = K_2 = K$.

If the partition hypothesis (Eq. 4) is correct, these $D'K_i$ values can be used to predict the quasi-steady-state diffusion when the solvents on both sides of the membranes are different and the $D'K_1$ and $D'K_2$ values are not equivalent. The appropriate $D'K_i$ values obtained (Set A, Table VII) for a given ethanol–water mixture can be used to construct the plots of log $[D'K_2C_0 - (D'K_2V_1 + D'K_1V_2)C_1/V_2]/D'K_2C_0$ *versus* time t in accordance with Eq. 19 where $f_1 = f_2 = 1$. The $D'K_2$ values are the apparent diffusion constants for quasi-steady-state diffusion when both solutions (Set A, Table VII) were of the same ethanol–water composition as the diffusing solution (Sets B–E, Table VII). The $D'K_1$ values are the apparent diffusion constants when both solutions (Set A, Table VII) were of the same ethanol–water composition as the desorbing solution (Sets B-E, Table VII). The C_0 (initial concentration of diffusing solution) and C_1 (concentration of desorbing solution at any time) values are experimentally known. The values of $(K_2D'V_1 + K_1D'V_2)$ can be obtained from the slopes of these plots (Fig. 10) in accordance with Eq. 19. These values are given in Sets B–E, Table VII where $V_2 = 0.500$ L. and $V_1 = 0.120$ L. and are in excellent agreement with those calculated from the K_2D' and K_1D' values obtained from the studies with the same ethanol–water composition in both solutions (Set A, Table VII).

Temperature Dependence of Diffusion Through Silastic Membrane—Estimates of the apparent activation energy of diffusion for the several drugs studied (Table IV) were made in accordance with

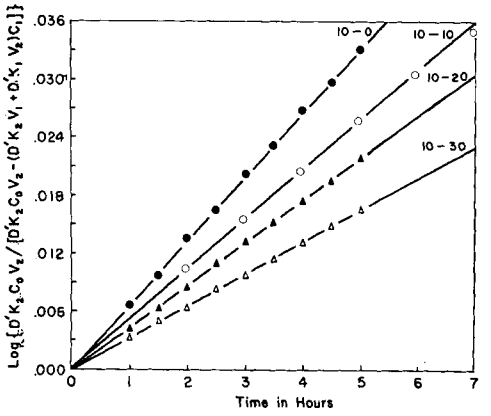

Fig. 10—Examples of plots of a logarithmic function of values against time, t, in accordance with Eq. 19 where $f_1 = f_2 = 1$ *for the diffusion of 4′-aminopropiophenone through silastic membrane from various % ethanol–water diffusing solutions into various % ethanol–water desorbing solutions. The representative plots are labeled accordingly. The slopes of these plots give the* $(K_2D'V_1 + K_1D'V_2)S/2.303XV_1V_2$ *values where* K_2 *and* K_1 *are the partition coefficients between the membrane and the diffusing and desorbing solutions, respectively, where* V_2 *and* V_1 *are the respective volumes, S is the area, X is the thickness of the membrane,* C_0 *is the initial concentration in the diffusing solution, and* C_1 *is the concentration in the desorbing solution as a function of time.*

Eq. 1 from the slopes of the plots of Fig. 5. Since the apparent diffusion constant, D, is a product of the intrinsic diffusion constant D' in the membrane and the partition constant, K in the steady-state diffusion system, it follows from Eq. 14 that

$$\log D' = \log P_D' - \Delta E_D'/2.303RT \quad \text{(Eq. 22)}$$

$$\log S_M = \log P_{S_M} - \Delta E_{S_M}/2.303RT \quad \text{(Eq. 23)}$$

$$\log S_i = \log P_{S_i} - \Delta E_{S_i}/2.303RT \quad \text{(Eq. 24)}$$

see that Eq. 1 may be reinterpreted as

$$\log D = (\log P_D' + \log P_{S_M} - \log P_{S_i}) - (\Delta E_D' + \Delta E_{S_M} - \Delta E_{S_i})/2.303RT \quad \text{(Eq. 25)}$$

and,

$$\Delta E_T = \Delta E_D' + (\Delta E_{S_M} - \Delta E_{S_i}) \quad \text{(Eq. 26)}$$

The apparent energy of diffusion is the sum of the true energy of diffusion inside the membrane and the differences between the heats of solution of the diffusing species in the membrane and the solvent phases. In general the values are approximately double the usual energies of diffusion in solution which are in the range of 3–5 Kcal./mole (18). However, these values are generally obtained for diffusion of large molecules through small molecule liquid solvents. Since the apparent energy of diffusion is perturbed by the heats of solution, changing the diffusing solvent and thus the accompanying heat of solution could increase or decrease the temperature coefficient of apparent diffusion.

Nonsteady-State Diffusion—The rate-determining factor in nonsteady-state transport through a membrane is the rate of diffusion in the membrane. In steady-state transport it is the constant concentration gradient alone and in quasi-steady-state transport both the concentration gradient and the rates of approach to equilibrium of both extramembrane phases are rate determining.

When a membrane is interposed between a solution of the penetrant and the solvent, the transportation of the penetrant is initially a nonsteady-state process and a "time lag" in transport results until the amount leaving the membrane equals the amount entering. This time lag has been used extensively (19–21) for the calculation of the diffusion constant in the nonsteady-state on the premise that a finite amount of time will be needed for a penetrant to traverse the thickness of the membrane before the attainment of a steady state (21). After this initial lag period, when the concentrations on both sides of the membrane are constant, the plot of the amount diffused *versus* time will be a straight line (Eq. 11) which when extrapolated will give an intercept θ on the time axis of

$$\theta = X^2/6D' \quad \text{(Eq. 27)}$$

Use of the authors' apparent diffusion constant, $D = 3.7 \times 10^{-10}$ L./cm.-sec., for the intrinsic diffusion constant D' in Eq. 27 for a membrane thickness $X = 7.52 \times 10^{-3}$ cm. would imply that the intercept of amounts diffused *versus* time would be 7 hr., whereas it is not statistically different from zero. This is consistent with our definition of D as $D'K$. If we assume an excessive error in the zero intercept of as much as 5 min., this would imply that the value of D' is greater than 10^{-8} L./cm.-sec. and that K is less than 10^{-2}.

Mechanistic Study of the Influence of Micelle Solubilization and Hydrodynamic Factors on the Dissolution Rate of Solid Drugs

By P. SINGH*, S. J. DESAI*, D. R. FLANAGAN, A. P. SIMONELLI, and W. I. HIGUCHI

The influence of micelle-drug solubilization on the dissolution rate has been investigated. The dissolution rates predicted by the diffusion layer model, the Danckwerts theory, and by the rotating disk theory were calculated and compared with experimental data obtained for the benzocaine–polysorbate 80 system. All the parameters involved were independently determined. The different conditions under which each of these theories is applicable have been discussed. Different kinds of dissolution experiments were designed to produce the conditions under which each theory would apply. The theoretical and experimental procedures involved in these studies provide a unique method for distinguishing mechanisms and should be useful in future studies, *e.g.*, in studies of the effects of agitation on mechanisms of interphase transport.

As PART of the authors' program on drug release rates it was decided to conduct experiments on the influence of micelle-drug solubilization on the dissolution rate behavior. There were two reasons for carrying out these studies. First, there has been relatively little work reported in the literature on the effects of solubilization by colloids upon the dissolution rate. Therefore, establishing a relationship between solubilization and dissolution rate appeared to be a worthwhile endeavor. Secondly, as will be seen, the different theories for dissolution rates based upon different hydrodynamic models predict significantly different rate relationships when a solubilizing agent is present. Experimental tests of such theories by other methods (1, 2) are extremely difficult, and, in the authors' opinion, past attempts have not led to convincing results. Thus meaningful information on the hydrodynamical aspects of the dissolution rate process might be obtained by the proposed method of study involving colloidal solubilizing agents.

Mechanistic Study of the Influence of Micelle Solubilization and Hydrodynamic Factors on the Dissolution Rate of Solid Drugs

By P. SINGH*, S. J. DESAI*, D. R. FLANAGAN, A. P. SIMONELLI, and W. I. HIGUCHI

The influence of micelle-drug solubilization on the dissolution rate has been investigated. The dissolution rates predicted by the diffusion layer model, the Danckwerts theory, and by the rotating disk theory were calculated and compared with experimental data obtained for the benzocaine–polysorbate 80 system. All the parameters involved were independently determined. The different conditions under which each of these theories is applicable have been discussed. Different kinds of dissolution experiments were designed to produce the conditions under which each theory would apply. The theoretical and experimental procedures involved in these studies provide a unique method for distinguishing mechanisms and should be useful in future studies, *e.g.*, in studies of the effects of agitation on mechanisms of interphase transport.

As PART of the authors' program on drug release rates it was decided to conduct experiments on the influence of micelle-drug solubilization on the dissolution rate behavior. There were two reasons for carrying out these studies. First, there has been relatively little work reported in the literature on the effects of solubilization by colloids upon the dissolution rate. Therefore, establishing a relationship between solubilization and dissolution rate appeared to be a worthwhile endeavor. Secondly, as will be seen, the different theories for dissolution rates based upon different hydrodynamic models predict significantly different rate relationships when a solubilizing agent is present. Experimental tests of such theories by other methods (1, 2) are extremely difficult, and, in the authors' opinion, past attempts have not led to convincing results. Thus meaningful information on the hydrodynamical aspects of the dissolution rate process might be obtained by the proposed method of study involving colloidal solubilizing agents.

THEORETICAL

Diffusion Layer Theory—Recently (3) Higuchi discussed the one-dimensional diffusion layer model for the dissolution rate of a pure solid in a stirred medium containing a colloidal solubilizing agent. The model assumes that equilibrium exists between the solid and the solution at the solid-solution interface, and that therefore the rate is controlled by the diffusion of the free and solubilized solute across an effectively stagnant liquid diffusion layer of thickness, h. Equilibrium between the free and the solubilized solute is assumed at every point in the diffusion layer.

These assumptions lead to the following equation for this model:

$$G = \frac{1}{h}\left(D_1C_1 + \sum_i D_iC_i\right) \qquad \text{(Eq. 1)}$$

Here G is the initial dissolution rate per cm.^{2} for the solid in the medium containing the solubilizing agent, D_1 is the diffusion coefficient of the free molecule in solution, C_1 is the contribution to the total solubility by the free solute, D_1 is the diffusion coefficient of the solubilized species, i, and S_i is the contribution of species, i, to the total solubility. Equation 1 reduces to

$$G = \frac{1}{h}(D_1C_1 + D_MC_M) \qquad \text{(Eq. 2)}$$

where the solubilization involves only a single solubilized species.

The Danckwerts Theory—The eddy diffusion model proposed by Danckwerts (4) assumes that fresh elements of liquid continually replace the aged ones at the solid-liquid interface. While at the interface, the elements absorb solute according to nonsteady-state diffusion laws. Thus the rate of dissolution may be visualized as being a function of the surface renewal rate and the diffusion rate.

When a colloidal solubilizing agent is present, the Danckwerts model gives

$$G = s^{1/2}\sqrt{(D_1C_1 + D_MC_M)(C_1 + C_M)} \qquad \text{(Eq. 3)}$$

Here s is the surface renewal rate constant, which is a function of the agitation rate, the viscosity and density of the medium, and the dimensions of the system. The derivation of Eq. 3 assumes that equilibrium between the free drug and the solubilized drug exists everywhere, and that the ratio of the free to solubilized drug is constant at all drug concentrations for a given concentration of the solubilizing agent.[1] Olander (5) has given the derivation for Eq. 3 although he presented it for the general situation that can be characterized by any equilibrium of the type, reactant $\overset{K}{\rightleftarrows}$ product.

It can be seen that Eq. 3 differs from Eq. 2 in the dependence of G upon the diffusion coefficients. The former predicts a square root dependence upon the effective diffusion coefficient, while the latter depends upon the first power of the effective diffusion coefficient. The effective diffusion coefficient can be written as:

$$D_{eff} = \frac{D_1C_1 + D_MC_M}{C_1 + C_M} \qquad \text{(Eq. 4)}$$

The Rotating Disk Theory—Levich (6) has provided a convective diffusion theory for the rate of mass transport to or from the face of a rotating disk. The equations are based upon Cochran's (7) exact solution to the hydrodynamic problem. As a result this situation represents one of the few instances where a physically well-defined picture can be presented mathematically.

The appropriate rotating disk equation for the dissolution rate of a solid in a medium containing a solubilizing agent is

$$G = 0.62(D_1C_1 + D_MC_M)^{2/3}\nu^{-1/6}\omega^{1/2}(C_1 + C_M)^{1/3} \qquad \text{(Eq. 5)}$$

where ν and ω are the viscosity of the medium and the angular velocity of the rotating disk, respectively. It is assumed, as was done in Eqs. 2 and 3, that equilibrium exists between the free and the solubilized drug and that the ratio of the two species is constant for all drug concentrations. Equation 5 differs from Eqs. 2 and 3 in that a two-thirds power dependence upon the effective diffusion coefficient is predicted.

The Noyes-Whitney Theory—This empirical theory simply predicts that the dissolution rate would be proportional to the total solubility. As the differences between the free drug and the solubilized drug diffusion coefficients are ignored, these parameters do not enter into this theory.

GENERAL CONSIDERATIONS IN THE DESIGN OF EXPERIMENTS

As mentioned earlier the object of these studies was twofold: first, to establish the role of colloid solubilization in dissolution rate processes and, secondly, to study the various theories that differ primarily in the assumptions regarding the interaction between hydrodynamics and molecular diffusion. In order to achieve these goals it was necessary to select a system that would provide a sufficiently large solubility increase and a sufficiently small D_M while not increasing the solvent viscosity and density appreciably with increasing solubilizing agent concentration. As will be seen, the system, benzocaine (ethyl *p*-aminobenzoate) in aqueous polysorbate 80,[2] generally satisfied these requirements and was therefore selected for this work.

Several hydrodynamic situations were selected. A tablet mounted in a beaker with a propeller stirrer, a rotating tablet in a disk mount, and a tablet mounted with no agitation were the three selections employed in the present study.

In addition to the dissolution rate experiments additional independent data were necessary for examining Eqs. 2, 3, and 5. Thus suitable solubility, diffusion coefficient, viscosity, and density experiments were considered and carried out.

EXPERIMENTAL

Dissolution Rates—Dissolution rates were carried out in both a propeller-driven stirrer apparatus and a rotating disk apparatus.

[1] Other experiments indicate that this assumption is approximately valid. In order to vigorously account for any deviations due to nonconstancy, more complex equations must be used, but should not otherwise affect our present interpretation.

[2] Marketed as Tween 80 by Atlas Chemical Industries, Wilmington, Delaware.

Propeller-Driven Stirrer Apparatus—The drug powder (<70 mesh) was compressed into a tablet in a 9.5-mm. ($^3/_8$-in.) die at 2,400 lb. using a Carver press[3] so that the tablet surface was flush with the die surface. The back of the die was then sealed with a cork stopper. The die was mounted directly in a Plexiglas holder in a water-jacketed beaker containing 400 ml. of solvent at 30°. Stirring was achieved by a Teflon-coated stirrer attached to a Hurst synchronous motor[4] mounted on the beaker cover. The stirrer was positioned so that the blade in its closest proximity to the tablet surface was 6 mm. away. The Plexiglas sample holder was also mounted on the cover so that (*a*) all components could be simultaneously introduced into the solvent as an entire unit, and (*b*) the hydrodynamics could be reproduced and maintained constant. Samples were withdrawn at known time intervals and spectrophotometrically assayed on the Perkin-Elmer Hitachi spectrophotometer at 286 mμ. These studies were conducted under stirring speeds of 50 r.p.m. and 150 r.p.m.

Rotating Disk Apparatus—The dissolution studies with the rotating disk were carried out by using an aluminum assembly similar to the one previously reported by Wood *et al.* (8). The powder was compressed in a 1.1-cm. ($^7/_{64}$-in.) die using a Carver press in the same manner as described before. The apparatus was attached to a Bodine motor[5] and started before immersion into the solvent. A 3-L. beaker, containing 950 ml. of solvent was immersed in a water bath maintained at 30°. The rotating disk and the Bodine motor were mounted on a beaker cover as before.

The diameter of the rotating disk was 4.5 cm. and that of the beaker was 15.5 cm.; the apparatus was maintained 5 cm. above the bottom of the beaker. The dissolution runs were conducted over a period of 30 min. at 60 and 300 r.p.m.

For the runs at 0 r.p.m. a different method was employed. The tablet was compressed in the die and the apparatus immersed in the solvent for a known period of time. Sampling was accomplished by removing the apparatus entirely from the solvent, stirring the solution, and removing a known volume for assay. The surface of the tablet was lightly dabbed with tissue to remove adhering solvent and the rest of the apparatus was also quickly dried. The entire apparatus was then immersed in fresh solvent with as little agitation as possible and timing started from zero. Essentially, each time the apparatus was immersed, the tablet was considered to be a new one. The release rate as a function of time was obtained by successively immersing the tablet for proportionally longer periods of time. The validity of this technique was proven by the reproducibility of the dissolution rates for the same solvent system using different tablets with different immersion times, showing that the release rate was independent of the past history of the tablet.

Diffusion Coefficient[6]—The method employed to determine the diffusion coefficients is essentially similar to the one reported earlier (9). The diffusion cell was modified by using a Gelman Versapor[7] filter in place of the porous sintered-glass disk. Also, the apparatus was not water-jacketed so that the two halves could be separated and the filter mounted between them. One Teflon gasket was placed on either side of the filter and the joints were clamped together. A step, 0.6 mm. deep, was made in one of the Teflon gaskets so that the filter could be fitted into it. Once the apparatus was assembled, this procedure insured that leakage from the filter was completely prevented. The filter had a diameter of 37 mm., pore size of 0.9 μ, and a thickness of 0.635 mm.

The filter was initially soaked in a 50:50 ethanol–distilled water solution for 1 day and then in distilled water for 2 days, to remove all soluble components present. Diffusion experiments were then carried out by a similar procedure to that described in *Ref.* 9. Since the diffusion cell was not water-jacketed, it was immersed in a water bath maintained at 30°. Into one compartment of the diffusion cell the aqueous solution of benzocaine in polysorbate 80 was added and the rate of diffusion into the other compartment containing the same polysorbate 80 concentration was determined.

The Versapor filter is made of glass fibers reinforced with epoxy, and its inherent strength enabled it to be used repeatedly without any change in surface area (not true of several other filters tried). In order to check possible changes that might occur in the filter, a benzoic acid standard was run between every two diffusion coefficient determinations.

Other Parameters—Solubility measurements were made as reported earlier (9). The viscosities of all solutions used in this study were measured at 30° using the Ostwald viscometer. The densities of these solutions were measured using a pycnometer.

RESULTS

Dissolution rates of benzocaine were determined in water and five concentrations of polysorbate 80 using both the propeller-driven stirrer and the rotating disk methods. The dissolution rate data obtained from the propeller-driven stirrer apparatus at 50 r.p.m. and 150 r.p.m. and that obtained from the rotating disk apparatus at 60 r.p.m. and 300 r.p.m. were highly reproducible, as can be seen by a typical set of data obtained at 150 r.p.m., shown in Fig. 1. These dissolution rates are tabulated in Column 3 of Table I. Figure 2, illustrating the dissolution rates obtained without stirring, shows, as expected, a larger experimental fluctuation between the data points of each curve. The resulting slopes, however, were in good agreement with theory. The rotating disk dissolution rates are tabulated in Table II.

The data from the diffusion rate experiments are plotted in Fig. 3. It should be pointed out here that each diffusion experiment had a positive intercept (since sampling was started only after steady-state had been reached) which has been subtracted in order to pass all lines through the origin, permitting better comparison. This procedure does not alter the slope of the line, and only the desired steady-state slope is needed in the calculations (9). These diffusion coefficients, along with the respective solubilities and relative viscosities, are presented in Table III.

[5] Type KYC-23RB, Bodine Electric Co., Chicago, Illinois.
[6] In diffusion coefficient determination experiments of this type, there is some uncertainty arising from the assumption that there is an effective diffusion layer adjacent to the membrane. Thus it is assumed that through this apparent stagnant film only molecular diffusion is important. It is estimated from calculations that the effect of some corrective transport should be small compared to the uncertainty in the overall experiment.

Figure 4 illustrates the solubilization curve for benzocaine in polysorbate 80 solutions. The linearity obtained by plotting the amount solubilized against the concentration of polysorbate 80 suggests that the apparent individual micellar participation remains relatively constant over the entire range of surfactant concentrations.

Analysis of Data Obtained with Propeller-Driven Stirrer Apparatus—By using the definition for the effective diffusion coefficient, as given by Eq. 4, Eq. 2 can now be rewritten as

$$G = \frac{1}{h} D_{eff} C_T \qquad \text{(Eq. 6)}$$

where C_T is the total solubility. Similarly, Eq. 3 may be expressed as:

$$G = s^{1/2} D_{eff}^{1/2} C_T \qquad \text{(Eq. 7)}$$

The independently determined parameters listed in Table III can now be used to calculate the dissolution rates predicted by Eqs. 6 and 7 to test the diffusion layer and Danckwerts models, respectively. In order to eliminate the constants present in the two equations, the data were compared to the theories by taking the ratio of the dissolution rate in the surfactant solution to that in water.

Consequent to the above discussion, the final equation used to test the diffusion layer model is:

$$\frac{G'}{G_{H_2O}} = \frac{D_{eff} C_T}{D_1 C_1} \qquad \text{(Eq. 8)}$$

Similarly, for the Danckwerts model:

TABLE I—DISSOLUTION RATES (mg./min./cm.²) FOR THE BENZOCAINE–POLYSORBATE 80 SYSTEM USING THE PROPELLER-DRIVEN STIRRER APPARATUS

Polysorbate 80, % w/v	Stirrer Speed, r.p.m. 50	150
0	0.145	0.199
0.5	0.163	0.236
1.0	0.180	0.270
2.0	0.211	0.306
4.0	0.254	0.379
6.0	0.278	0.402

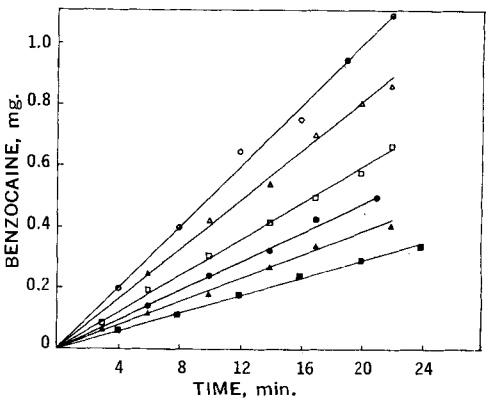

Fig. 2—Dissolution data for benzocaine in different concentrations of polysorbate 80 under nonstirring conditions. Key: polysorbate concn.—○, 6%; △, 4%; □, 2%; ●, 1%; ▲, 0.5%; ■, 0%.

TABLE II—DISSOLUTION RATES (mg./min./cm.²) FOR THE BENZOCAINE–POLYSORBATE 80 SYSTEM USING THE ROTATING DISK APPARATUS

Polysorbate 80, % w/v	Rotation Speed, r.p.m. 0	60	300	300/60
0	0.0151	0.105	0.223	2.12
0.5	0.0201	0.125	0.272	2.18
1.0	0.0242	0.145	0.312	2.14
2.0	0.0299	0.169	0.362	2.14
4.0	0.0415	0.199	0.415	2.08
6.0	0.0495	0.219	0.465	2.13

$$\frac{G'}{G_{H_2O}} = \left(\frac{D_{eff}}{D_1}\right)^{1/2} \frac{C_T}{C_1} \qquad \text{(Eq. 9)}$$

Here G' is the dissolution rate in the surfactant solution.

The theoretical ratio of rates predicted by Eqs. 8 and 9 have been drawn as smooth curves in Fig. 5. The graphical points illustrate the experimental ratio at both 50 r.p.m. and 150 r.p.m., as obtained from Table I. It can be readily seen that the diffusion layer theory gives a much closer fit than the Danckwerts model. Further examination of Fig. 5 reveals that the fit between the experimental data and the diffusion layer prediction is extremely good

4.0	0.580	1.20	3.15 ± 0.39
6.0	0.810	1.35	2.31 ± 0.20

[a] The standard deviation was estimated to be 0.30, determined by considering all 48 experimental values.

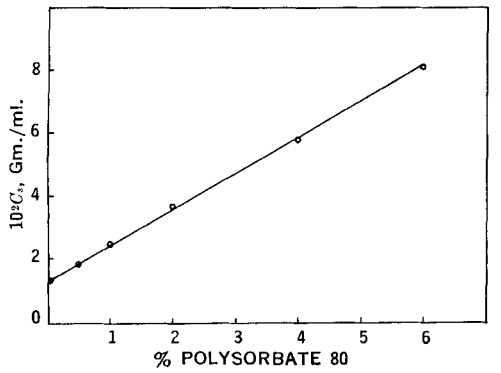

Fig. 4—Solubilization data for benzocaine in different concentrations of polysorbate 80.

at the lower concentrations of polysorbate 80. It was felt that the deviations of the data from the theory at the higher concentrations of polysorbate 80 may be due to some nonlaminar hydrodynamic condition near the tablet surface. In order to test this, a Plexiglas plate was attached to the front of the tablet surface at a distance of about 2 mm. This would ensure laminar solvent flow past the tablet surface. However, the dissolution rate ratios under these conditions were not significantly changed from those without the plate

Analysis of Data Obtained with No Agitation—In Fig. 6, a comparison of the theoretical curves has been made with the experimental dissolution rate data obtained by the rotating disk assembly un-

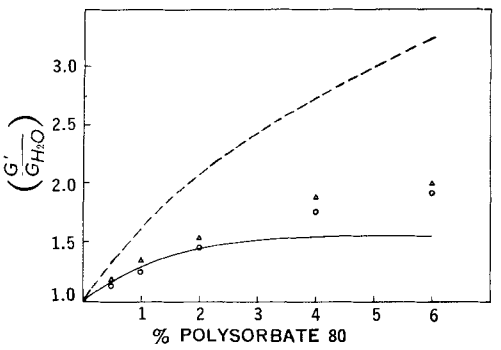

Fig. 5—Comparison of the theoretical ratio of dissolution rates as predicted by Eqs. 8 and 9 (smooth curves) and the experimental ratios obtained from the propeller-driven stirrer apparatus. Key: 0, 50 r.p.m.; △, 150 r.p.m.; – – –, Danckwerts model; —, diffusion layer model.

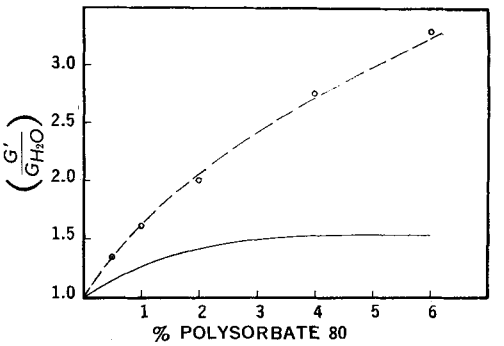

Fig. 6—Comparison of the theoretical ratio of dissolution rates as predicted by Eqs. 8 and 9 (smooth curves) and the experimental ratio obtained under nonstirring conditions. Key: – – –, Danckwerts model; ——, diffusion layer model.

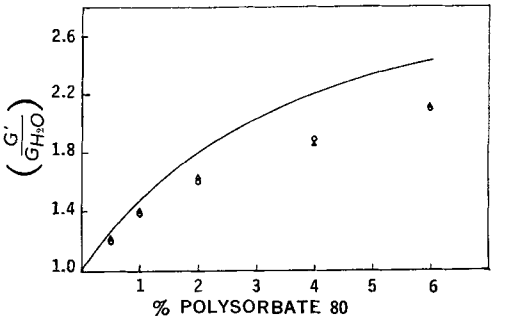

Fig. 7—Comparison of the theoretical ratio of dissolution rates as predicted by Eq. 10 (smooth curve) and the experimental ratios obtained from the rotating disk apparatus. Key: 0, 60 r.p.m.; △, 300 r.p.m.

der nonstirring conditions (see Column 2 of Table II). Here it is evident that the experimental data no longer fit the diffusion layer model but show excellent agreement with the Danckwerts model. It is of interest to point out that Gibaldi *et al.* (10) in their studies of the dissolution rates of benzoic acid in polyoxyethylene ether[8] solution have shown that under no forced convection conditions their data fit the Danckwerts predictions more closely than under stirring conditions.

Analysis of the Rotating Disk Data—Following the same general procedure as before, the fit of the rotating disk theory with the experimental dissolution data can be made by taking ratios of the dissolution rates. Then, under identical conditions of agitation, Eq. 5 becomes

$$\frac{G'}{G_{H_2O}} = \left(\frac{D_{eff}}{D_{H_2O}}\right)^{2/3} \frac{C_T}{C_1} \frac{1}{\nu_{rel}^{1/6}} \qquad \text{(Eq. 10)}$$

The theoretically predicted ratios of rates from Eq. 10 have been drawn as a smooth curve in Fig. 7. While it can be seen that the data are in approximate agreement with theory, the deviations observed may be significant.

DISCUSSION OF THE RESULTS

A further examination of the data with the theories can be made in the following manner. Since the

[8] Marketed as Brij, Atlas Chemical Industries, Wilmington, Del.

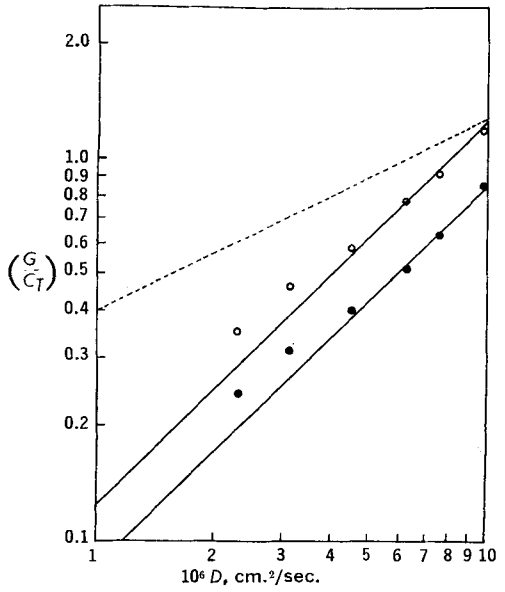

Fig. 8—Comparison of the theoretical slopes of 1.0 as predicted by Eq. 6 and the theoretical slope of 0.5 as predicted by Eq. 7 with experimental data. Key: - - -, 0.5; —, 1.0; ○, 150 r.p.m.; ●, 50 r.p.m.

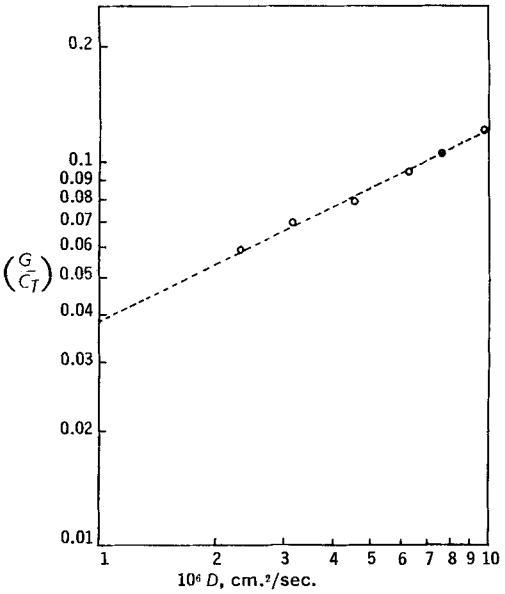

Fig. 9—Comparison of the theoretical slope of 0.5, 0 r.p.m., as predicted by Eq. 7 with experimental data.

main point of difference between these theories is in the exponent of the diffusion coefficient, a more stringent test can be made by plotting log (G/C_T) against log D_{eff}. By this means, the slope of the line in each case would be equal to the critical exponent, and would be a direct indication of the validity of the theory.

In Fig. 8, a theoretical line of slope = 0.5 (as predicted by the Danckwerts theory), and two theoretical lines of slope = 1.0 (as predicted by the diffusion layer model) have been drawn. The experimental data points for surfactant concentrations up to 2% (from Tables I and III) appear to fit a slope of one, which is in good agreement with the diffusion layer theory. The 4.0 and 6.0% polysorbate 80 points deviate from theory. Further studies are needed before an unambiguous reason for the deviations can be presented. However, it can be seen from Table III that the viscosities of the polysorbate 80 solutions begin to increase appreciably at 4.0%. As it has been assumed that viscosity changes are unimportant in comparing Eqs. 8 and 9 with data, the deviations of the 4.0 and 6.0% data from the diffusion layer theory may reside here.

Despite the deviations exhibited by the 4.0 and 6.0% polysorbate 80 data, the plot clearly shows the diffusion layer model best describing the situation with the propeller-driven stirrer apparatus. A least squares analysis was done on the data for both sets of experimental points. For the 50 r.p.m. data, by considering only the data up to 2.0% polysorbate 80, the slope of the line was calculated to be 0.965, whereas for the 150 r.p.m. data, the corresponding slope was 0.890. However, by considering all the data (up to 6.0% polysorbate 80), the slopes were 0.838 and 0.811, respectively.

A similar plot (Fig. 9) for the nonstirring dissolution rate experiment (from Tables II and III) shows that the experimental data give a slope of 0.5. This shows that the Danckwerts predicted dependence on the square root of the diffusion coefficient is applicable under conditions of no agitation.

Finally, a plot of log $G_\nu^{1/6}/C_T$ against log D_{eff} can be made for a test of the rotating disk theory (from Tables II and III). Figure 10 shows that the data for the 60 r.p.m. and 300 r.p.m. are in fair agreement with the predicted slope of 0.667, although somewhat higher—0.722 and 0.736, respectively. More work is needed to establish whether or not this

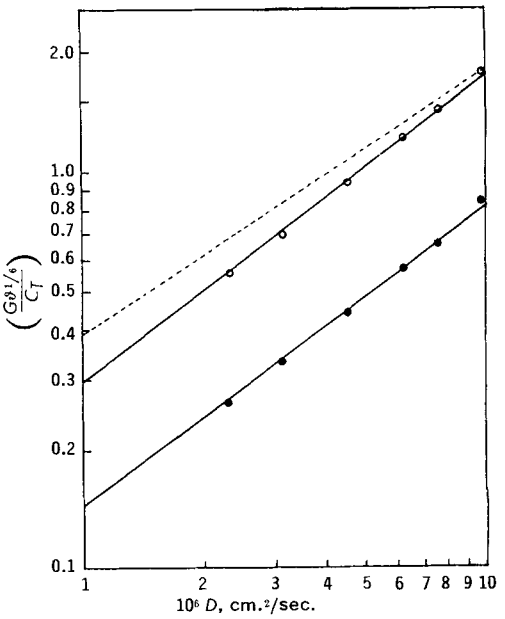

Fig. 10—Comparison of the theoretical slope of 0.667 as predicted by Eq. 5 with experimental data: Key: - - -, slope = 0.667; —○, slope = 0.736, 300 r.p.m.; —●, slope = 0.722, 60 r.p.m.

difference is really a breakdown of the theory. It is noteworthy that the stirring rate dependence obtained with the rotating disk apparatus (Column 5 of Table II) is very close to the theoretical square root prediction of 2.23.

PHARMACEUTICAL SIGNIFICANCE

These studies provide a firm quantitative basis for studying and establishing the particular mechanism of mass transport which is controlling a given dissolution experiment. The need for explicitly describing the hydrodynamics, under which such dissolution takes place also has been shown to be of prime importance. Although a limited number of examples were utilized, it is apparant that large differences in mechanisms may exist among different dissolution processes.

In view of the widespread interest in the use of dissolution studies as a basis for comparison of release profiles of different dosage forms and the resultant need for meaningful comparison of dissolution studies of independent workers, it becomes increasingly apparent that experimental conditions must be ei her standardized or taken into consideration. In addition the results of this study clearly indicate that the use of *in vitro* dissolution rates as a basis of drug availability must consider and account for the differences in the environmental conditions which exist in the respective *in vitro* and *in vivo* systems. As an example, it is very possible that an *in vitro* test in which the diffusion layer model may be operative could be used to draw conclusions regarding an *in vivo* system in which the Danckwerts model may be functioning. Such a possible system may be drug absorption when the rate of diffusion in the intestinal lumen is rate controlling.

These results also demonstrated that the effective diffusion coefficient can be radically altered with changes in components of the transport medium. Depending upon the kind and the intensity of the agitation, the dependence upon the effective diffusion coefficient may range from a one-half power to a first power. The conception of increased apparent solubility leading to an increased dissolution rate can be thus seen to be faulty if overextended. As a matter of fact, recent dissolution studies by Parrott (11) showed that dissolution rates did not increase linearly with an increased solubility and may be explained on the basis of a reduced effective diffusion coefficient.

Various biopharmaceutical transport systems which have been studied involve species of widely differing sizes, *viz.* molecules, micelles, colloidal particles, emulsion droplets, *etc.* In such situations the effective diffusion coefficient may range over several orders of magnitude and the importance of understanding the predominant transport mechanism becomes apparent.

Quantitative Determination of Volatile Components in Pressurized Aerosols by Gas Chromatography

By SHELDON COHEN

Gas chromatography has been used for analysis of aerosol propellants and active ingredients. The propellant analysis generally involved introduction of a previously vaporized sample into the gas chromatograph. Such methods become impractical when dealing with small aerosol packages such as those used for inhalation therapy. The purpose of this work was to develop methods for the accurate sampling and analysis of the propellants and cosolvents of such packages. These methods may also be extended to other volatile components of aerosol packages. Two sampling techniques were developed. These include the use of gas-tight sampling devices to either prepare solutions of the aerosol contents or to load a small-volume, high-pressure, liquid syringe. The volatile components were separated on a porous polystyrene bead column and the composition was calculated from peak areas.

PRESSURIZED AEROSOLS used for inhalation therapy generally are packaged in small containers fitted with metered valves. Accurate sampling of such packages and analysis of the volatile constituents, contained therein, are difficult, since the composition of a small volume of such mixtures in the liquid phase can change considerably by fractionating as it volatilizes. The aerosols may contain a wide boiling range of solvents, from propellant 12, b.p. −29.8°, to some of the glycols with boiling points in excess of 200°. To further complicate matters, the metered valve does not provide a convenient access to sample for such analyses.

Prior to the development of gas chromatography, aerosol propellants were analyzed by several methods such as mass spectrometry, infrared spectrophotometry, liquid density measurements, and vapor pressure determinations (1). Gas chromatography has been utilized for the past decade for the analysis of halogenated hydrocarbons such as used in aerosols (1, 2, 4, 7) and for the analysis of other ingredients in pharmaceutical aerosols (3, 6).

Percival (1) and Thonet (7) used variations of gas sampling systems to obtain samples of aerosol propellants in the vapor state prior to introduction into the gas chromatograph. The components were subsequently separated on di-*n*-octyl phthalate or alumina columns in the former work and on a di-*n*-butyl maleate column in the latter. The use of metered valves makes these methods impractical. There is also the possibility of condensation of the higher boiling constituents in the vapor sampling system and absorption of propellants by rubber "o" rings normally found in gas sampling valves.

Lysyj (4) used a parallel dual column system to analyze a mixture of air, carbon dioxide, propellant 11, propellant 12, and ethylene oxide used in a sterilizing process. The high boiling constituents were separated on a polyglycol column and the low boiling constituents on a dibenzyl ether column. Separate detectors were used to monitor each column simultaneously. The system was intended primarily as a rapid in-process control of a mixture in the gas phase.

Jenkins and Amburgey (2) chilled aerosol samples and dissolved them in large volumes of solvent. They used 0.5–0.8 Gm. of aerosol in 10 ml. of cyclohexane. The components were then separated on a decyl phthalate column. Such a system runs the risk of sample evaporation and fractionation during handling. If water is to be determined there is also the possibility of atmospheric water vapor condensing in the sample.

The methods, to be described here, were developed for the accurate sampling and analysis of the volatile constituents of small pressurized packages used in inhalation therapy. These methods take advantage of some of the newer hardware for handling samples and of porous polystyrene beads as column packing (5) for improved separations of aerosol components.

EXPERIMENTAL

Equipment—An F&M model 810-12 gas chromatograph using a thermal conductivity detector was used. The columns used were Porapak types Q, N, R, and S, 80/100 mesh packed in 2.5 m. (8 ft.) long, 5 mm. ($^3/_{16}$-in.) stainless steel columns. The column temperature was programmed starting at 120° and holding for 1 min. and then heating at 15°/min. to 240°, and holding as needed. The injection block temperature was 210°, and the de-

Accepted for publication March 19, 1968.

Presented at the Third Annual Western Regional Meeting of the Industrial Pharmaceutical Technology Section, APhA Academy of Pharmaceutical Sciences, Los Angeles, Calif., October 1967.

The author wishes to thank Mr. T. H. Graves for his able assistance in preparing this manuscript.

tector temperature was 190°. The carrier gas used was helium at a flow rate of 65 ml./min. A 1-mv. Servo recorder equipped with a disk integrator was used.

Hamilton type 701N 10-μl. syringes were used to inject samples into the gas chromatograph in the solution method. A Pressure-Flo high-pressure liquid syringe (Precision Sampling Corp.) of 10 μl. capacity was used to inject samples in the direct method. The gas-tight syringes were Pressure-Lok (Precision Sampling Corp.). These come equipped with valves for containing pressurized samples and were used to prepare sample and standard solutions, and for loading the Pressure-Flo syringe. Sizes convenient for the amount of material being transferred should be used. (High-pressure materials are more easily handled in smaller syringes.) Plastic-coated aerosol bottles that could be fitted with crimp-on type multiple-dose stoppers were used as sample and standard solution containers.

Sampling—A commercial sampling system (Alltek Associates) was used for samples in metal containers. In this system a threaded plate is affixed to the metal container with hose clamps. Smaller hose clamps were substituted for those supplied with the system in order to accommodate the smaller containers. A threaded fitting, closed at one end with a replaceable rubber septum is engaged in the plate threads. The end of the fitting towards the container had a sharpened tube capable of puncturing the container and a rubber gasket around this tube to prevent leakage from the container after puncture. The fitting is twisted into the threads, thus puncturing the can and affixing to it the penetrable rubber septum, through which samples may be withdrawn with gas-tight syringes. In order to prevent septum rupture, it was found advisable to use a septum-retaining nut with an aperture smaller than that of the retaining nut supplied with the system.

For samples in glass containers, a sampling system (Fig. 1) was constructed that enabled the cap to be punctured with an 18-gauge hypodermic needle (C). Leakage at the puncture is prevented by a rubber washer (D). The hub of the needle is fitted with a small rubber septum (B) held in place by a male Luer-Lok plug (A) through which a 1.6 mm. ($^1/_{16}$-in.) hole has been drilled. The sample may then be withdrawn through this septum with a gas-tight syringe.

Samples that do not lend themselves to the use of these devices may be cooled to a temperature sufficiently low to minimize loss and then opened and transferred to a plastic-coated aerosol bottle cooled to the temperature of the sample. The bottle is immediately sealed with a multiple-dose cap through which a sample may be withdrawn with a gas-tight syringe. This operation is conveniently carried out inside an open chest-type freezer to minimize sample loss and moisture condensation. This last method runs a greater risk of sample change than the previous two.

Care must be taken to assure that a minimum change in composition is caused by the sampling procedure. Since the composition of the aerosol will change as it volatilizes, the system must be leak proof, a minimum volume of space should be added by the sampling system to the container, and the volume of space left by withdrawn samples must be considered.

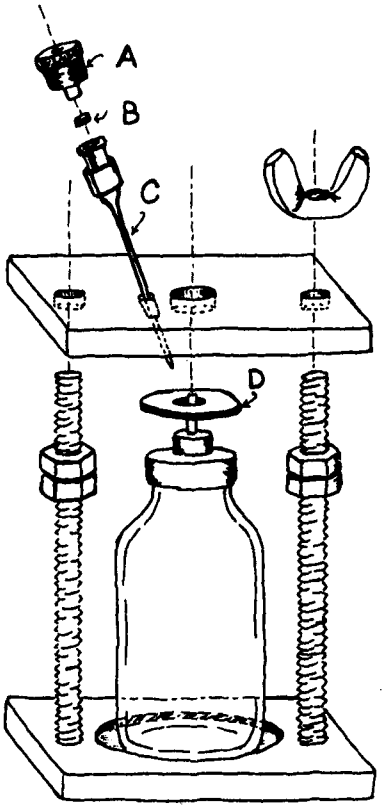

Fig. 1—Sampling system for glass containers.

Solution Method of Analysis—Ethylene glycol monomethyl ether, chloroform, or methylene chloride are suitable solvents for most samples. The choice may be determined by considering the retention time of the solvent relative to those of the aerosol components and by considering the other materials present in the solvent. For example, chloroform normally contains ethanol as a preservative and ethylene glycol monomethyl ether normally contains some water. Ethylene glycol monomethyl ether was found most convenient to use.

Twenty-five milliliters of the solvent is pipeted into a 60-ml. plastic-coated aerosol bottle. A multiple-dose cap is crimped in place and its safety seal removed. The 60-ml. bottle and its contents are weighed; 1.25–2.50 Gm. of the aerosol sample is drawn into a 2-ml. gas-tight syringe from the sample container, which has been prepared by one of the methods described under *Sampling*, and the syringe valve is shut. The sample is transferred from the gas-tight syringe, through the septum, into the tared 60-ml. bottle, the gross weight of the bottle is determined, and the weight of sample taken is calculated.

The standards are prepared in the same manner as the sample. All standard materials that boil near or below room temperature are handled in gas-tight syringes. Less volatile materials can be handled in ordinary syringes. Propellants for the standard solution may be stored in pressurized cylinders and transferred from an inverted cylinder to a gas-tight syringe through a rubber septum

fitted to the cylinder outlet. A 9.6 mm. (3/8 in.) diameter rubber septum can be fitted to 6.4 mm. (1/4-in.) flared tube fitting such as normally found on such cylinders. Alternately the propellants may be stored in the plastic-coated aerosol bottles sealed with multiple-dose caps. One solution may contain several standard components of known amounts. When preparing such a solution the least volatile materials should be added first. It is important that the standard solution contains the identical volume of solvent as the sample solution contains.

The sample solution, the standard solution, and several Hamilton syringes are placed in a freezer at −20°. Just prior to use, a solution and syringe are removed from the freezer, 5–8 μl. of the solution is immediately loaded into the syringe and injected into the gas chromatograph. The recorder chart drive is turned on and the temperature program is initiated simultaneously with the injection. The chromatograph is attenuated for maximum response on scale for each peak. Each component in the sample solution is run at the same attenuation as in the standard solution. A chromatogram of the solvent is run in the same manner as the other solutions. Care should be exercised to avoid bubbling the solutions in the Hamilton syringes. The injections should be made in a reproducible manner. Figure 2 illustrates a chromatogram obtained by this method.

From the integrator record the areas of each component of the sample solution and the standard solution are determined. The attenuation factor can be ignored for any component as long as it is the same in each chromatogram. The areas are corrected geometrically for any base line or integrator drift. The ratios of the area of each component to that of the solvent are calculated. These ratios are corrected if necessary for the blank solvent. For each individual component in the sample:

$$\% \text{ component (w/w)} = \frac{100\ (R_A)(W_S)}{(R_S)(SW)}$$

where, R_A = ratio of the area of the component peak to that of the solvent peak in the sample solution, R_S = above ratio in the standard solution, W_S = grams of component in the standard solution, SW = sample weight (Gm.) of the aerosol in the sample solution.

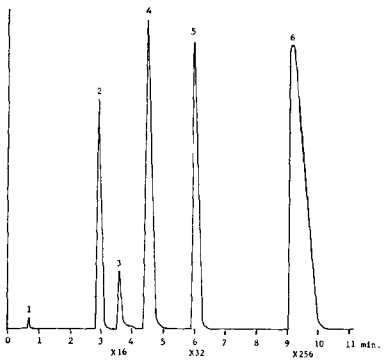

Fig. 2—Chromatogram of aerosol components on a Porapak R column. 1, air; 2, propellant 12; 3, water; 4, propellant 114; 5, ethanol; 6, ethylene glycol monomethyl ether.

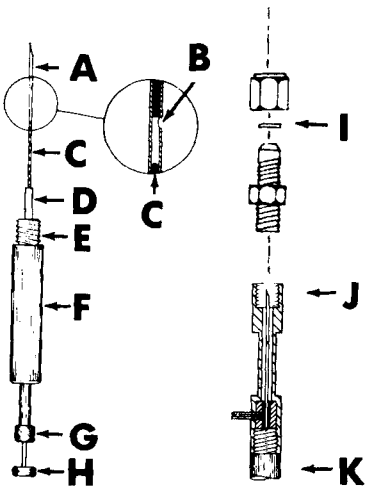

Fig. 3—Pressure-Flo syringe system.

Direct Method of Analysis—Samples analyzed by this method should be limited to those that will not impair the performance of the Pressure-Flo syringe with any residue. Using a 6.4-mm. flared tube to 3.2-mm. (1/8-in.)M.P.T. adapter (Fig. 3) a 6.9-mm. diameter rubber septum (I) is fitted to the sampling end (J) of the filling adapter supplied with the syringe. The retaining nut holding the septum in place should have a reduced aperture to prevent septum rupture. The Pressure-Flo syringe is fitted to the other end (K) of the adapter. The sample is injected through the rubber septum, into the adapter with a gas-tight syringe, preferably of 1.0 ml. capacity, Manual pressure is maintained on the plunger of the gas-tight syringe throughout the filling operation. The manufacturer recommends 25 p.s.i. pressure in excess of the sample vapor pressure to assure a reproducible sample. Unless elaborate equipment is available for determining this, the best approach is a few trial runs to develop an operator feel for the amount of pressure necessary.

The plunger handle (H) of the Pressure-Flo syringe is slowly pumped several times and left in the withdrawn position. This retracts the plunger (C) and allows the sample to enter the hollow needle through the port (B). If a volume of less than 10 μl. is desired using the 10-μl. syringe, a shim can be made so that the plunger is left in a reproducible partially withdrawn position. The needle handle (G) is now withdrawn, drawing the needle (A) into the sealing tube (D), thus entrapping the sample. The Pressure-Flo syringe is then removed from the adapter and a small Teflon sleeve is slipped over the sealing tube (D). The sleeve prevents the sealing tube from puncturing the injector septum of the chromatograph. The sealing tube should protrude slightly beyond the Teflon sleeve, enabling it to slightly penetrate the injector septum. The sealing tube is firmly butted against the injector septum and the needle handle (G) is rapidly depressed, driving the needle through the injector septum and allowing the sample to vaporize in the injection port. The plunger handle (H) is immediately depressed, pumped several times, and left in the depressed position to remove any residual vapor from the hollow needle. The needle handle (G) is with-

drawn, disengaging the syringe from the septum. The recorder chart drive is turned on and the temperature program is initiated simultaneously with the injection. The chromatogram is attenuated for maximum response, on scale, for each peak.

A mixture of the components found in the sample is accurately prepared. The composition should approximate that of the sample. This is done by weighing the components, in order of increasing volatility, into an evacuated plastic-coated aerosol bottle sealed with a multiple-dose cap. Gas-tight syringes are used where needed. To prevent composition changes in the standard mixture, the head space in the container should initially be limited to less than 10% of the liquid volume and should not exceed 40% as the standard mixture is used. This should prevent changes in composition from exceeding 0.5% relative. The standard mixture is treated in the same manner as the sample. The chromatogram is run at the same attenuations used for each component in the sample. Figure 4 illustrates a chromatogram obtained by this method.

From the chromatogram of the standard mixture, the relative detector response for each component is determined as compared to one arbitrarily selected for reference (that is, relative detector response = unity).

$$R = \frac{A/C}{A_r/C_r}$$

where, R = relative detector response for a given component, A = peak area for the component in the standard, C = percent composition of the component in the standard, A_r = peak area of the reference component in the standard, C_r = percent composition of the reference component in the standard. Then for each component in the sample:

$$\% \text{ composition} = 100\,\frac{A/R}{S}$$

where, S = sum of the ratios, A/R, for all the components in the sample. This calculation provides the composition in terms of the percent of the volatile portion of the sample.

DISCUSSION

Because of limitations of the Pressure-Flo syringe, only highly volatile systems could presently be analyzed by the direct method. The direct method offers applicability for rapid analysis and process control of systems which contain components of known identity. Samples containing suspended solids may be analyzed by the direct method if they can be filtered through a Swiney adapter from a gas-tight syringe. If extensive pretreatment is required, it may be better to use the solution method. The solution method offers general applicability for analysis of systems of unknown components having a wide boiling range. Nonvolatile solids in the sample would not be expected to interfere with the solution method, however, these would accumulate in the injection block of the gas chromatograph. This should be cleaned out at intervals, frequent enough to prevent interferences with the gas chromatograms due to adsorption and decomposition. The experience in this laboratory with ingredients such as epinephrine, isoproterenol, and phenylephrine has shown no complications with these when the injection block was cleaned at intervals of several days.

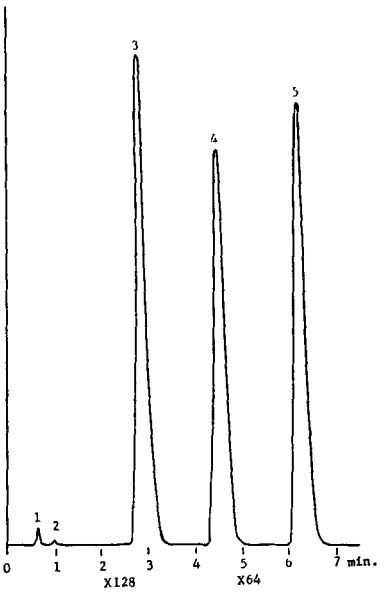

Fig. 4—Chromatogram of aerosol components on a Porapak Q column. 1, air; 2, water; 3–5 propellants 12, 114, and 11, respectively.

Both methods give results of comparable accuracy ±0.5% for most components in a multicomponent analysis. The results for several accurately prepared samples are given in Table I. Ethanol was found to give slightly higher errors up to +0.9%. When greater accuracy is desired for a selected component, it may be obtained by altering the system

TABLE I—ANALYSIS OF AEROSOL COMPONENTS

Components	% Composition (w/w) Taken	Found	Discrepancy
Solution Method			
Propellant 12	48.6 (50.6)	48.3	−0.3
Propellant 114	24.9 (24.1)	25.3	+0.4
Propellant 11	26.5 (25.2)	26.6	+0.1
Total	100.0	100.2	+0.2
Propellant 12	50.4	49.9	−0.5
Propellant 114	24.5	24.9	+0.4
Propellant 11	25.1	25.3	+0.2
Total	100.0	100.1	+0.1
Propellant 12	20.6	20.1	−0.5
Propellant 114	44.8	45.4	+0.6
Ethanol	32.6	33.5	+0.9
Water	2.0	2.1	+0.1
Total	100.0	101.1	+1.1
Propellant 12	20.6	20.1	−0.5
Propellant 114	44.9	44.9	0.0
Ethanol	32.5	33.2	+0.7
Water	2.0	2.1	+0.1
Total	100.0	100.3	+0.3
Direct Method			
Propellant 12	50.3	50.7	+0.4
Propellant 114	24.3	24.0	−0.3

of analysis to obtain greater response and resolution for the selected component. The conditions for analysis of multicomponent systems are often necessarily compromises.

The parenthetical values given for the composition of the first example represent the actual amounts taken. Twenty grams of this solution was in a container that had 61 ml. of head space. The actual composition of the solution then in the container was calculated from physical data of the components.

The relative retention times (to that of propellant 11) for some of the components studied are given in Table II for several Porapak columns. The dimensions of the columns, temperature program, and other parameters are those described in the experimental portion. The values for the propellants are essentially the same for all columns. The values for the other components, which are more polar, vary with the columns. A column can be selected that will completely resolve most systems encountered. With a completely unknown system, the Type S column is useful, the only difficulty encountered being a very slight overlap of the propellant 12 and the water peaks. Type Q columns will not resolve propellant 114 and ethanol. Type R columns will only partially resolve propellant 11 and ethanol; type N columns will only barely resolve propellant 11 and ethanol and will also have a very slight overlap of the water and the propellant 114 peaks.

Other overlaps may be encountered if the column is overloaded causing broadening of a peak. The Porapak columns have very limited capacity and will display overloading by a lessening of the peak retention time and increased band width.

Table II—Relative Retention Times of Aerosol Components

Porapak Type	Q	R	S	N
Propellant 12	0.44	0.41	0.46	0.47
Propellant 114	0.74	0.69	0.74	0.74
Propellant 11	1.00	1.00	1.00	1.00
Propellant 113	1.25	1.26	1.25	1.21
Ethanol	0.74	0.96	0.89	1.03
Water	0.18	0.52	0.34	0.60
Ethylene glycol monomethyl ether	1.35	1.54	1.43	1.61

SUMMARY

Gas chromatography has been the method of choice in recent years for the analysis of aerosol propellants. The advent of the porous polystyrene beads has improved the separation and accuracy of these analyses. The methods presented here provide accurate and convenient sampling and analysis of small aerosol packaged pharmaceuticals. These methods may be extended to other sizes and products.

Bronchodilatory and Cardiovascular Effects of Metaproterenol

By L. DIAMOND*

Until recently, the methods which were available for evaluating bronchodilator drugs in the intact animal did not yield quantitative data which were primarily related to the smooth muscle tone of the airways. In the present study a technique was employed which yielded direct measurements of the total lung resistance to airflow. Since pulmonary resistance values depend directly on the dimensions of the airways, their magnitude is very sensitive to changes in the smooth muscle tone of the tracheobronchial tree. Metaproterenol [1-(3,5-dihydroxyphenyl)-2-isopropyl-aminoethanol sulfate], a new beta-adrenergic stimulant, inhibited the increase in total lung resistance evoked by histamine aerosol. The drug was effective in anesthetized, spontaneously breathing dogs when administered as a 2 percent aerosolized solution. A series of experiments was designed to compare the cardiovascular effects which followed inhalation of a therapeutic dose of metaproterenol with those which occurred following a similar dose of isoproterenol in anesthetized dogs. The positive chronotropic effect and the increase in pulse pressure were more pronounced after metaproterenol inhalation than after isoproterenol inhalation. However, the hypotensive effect of isoproterenol was somewhat greater than that of metaproterenol.

DRUGS CAPABLE of dilating the smooth musculature of the tracheobronchial tree have been employed extensively in the symptomatic treatment of obstructive diseases of the lungs. In recent years, oral inhalation has become a preferred means of administering bronchodilator drugs. Bronchospasmolytic agents administered *via* this route can provide rapid relief from acute episodes of bronchospasm.

The sympathomimetic amine, isoproterenol, is probably the most popular drug in use today for the management of asthma, emphysema, and related conditions. However, whether inhaled or given by some other route, isoproterenol has a limited duration of action and with repeated administration various undesirable systemic effects may develop, such as palpitations, tachycardia, hypotension, and central nervous system stimulation.

A new compound, purported to be as potent a bronchodilator as isoproterenol, but possessing a longer duration of action and producing fewer and milder side effects, has recently been made available. The new compound, metaproterenol,[1] differs chemically from isoproterenol by having the hydroxyl groups on the phenyl nucleus in the *meta* position. The general pharmacodynamic properties of metaproterenol were first studied by Engelhardt *et al.* (1) in 1961.

The method used by the latter workers, as well as many other investigators to assess the bronchodilatory activity of a compound in the intact animal, measures changes in the capacity of the respiratory tract as expressed by an increase or decrease in the volume of air taken up by the lungs under constant pressure inflation (2). This technique provides only a qualitative indication of the bronchiolar resistance. Moreover, it has been shown that at the usual frequencies of respiration this method is sensitive to changes in lung compliance but relatively less sensitive to changes in lung resistance (3).

The purpose of the present study was to obtain quantitative data relating to the bronchodilating efficacy of metaproterenol by utilizing direct determinations of the total lung resistance to airflow. A method similar to the one employed in this study has been previously used for the pharmacological evaluation of bronchodilator drugs by Familiar *et al.* (4). Since pulmonary resistance values depend directly on the caliber of the airways, their magnitude is very sensitive to changes in the smooth muscle tone of the tracheobronchial tree. The cardiovascular side effects which followed inhalation of a therapeutic dose of metaproterenol were also studied and compared with those which occurred after inhalation of a similar dose of isoproterenol.

EXPERIMENTAL

Ten mongrel dogs of either sex were anesthetized with an intraperitoneal injection of a solution containing 100 mg. of allobarbital, 400 mg. of urethan, and 400 mg. of monoethylurea in each ml. (0.6 ml./Kg.). The dogs were suitably restrained upon a surgical table and allowed to breathe spontaneously. A Murphy endotracheal tube was inserted into the trachea and secured there by inflation of its cuff. A

cannula, consisting of an 18-gauge (3.8 cm., 1.5 in.) hypodermic needle attached to a length of polyethylene tubing, was introduced through one of the intercostal spaces into the intrapleural space. The intrapleural cannula was connected to one port of a Sanborn differential pressure transducer. A polyethylene tube leading from the endotracheal tube was connected to the other port of the transducer. This procedure permitted the pressure at the mouth to be subtracted from the intrapleural pressure to provide values for the transpulmonary pressure. A Sanborn pneumotachograph and differential strain gauge were used to measure the flow of air into and out of the lungs. A volume signal was obtained by electrical integration of the flow signal. The three parameters of pressure, flow, and volume were simultaneously recorded on a Sanborn direct-writing oscillograph.

Pulmonary Mechanics—The total lung resistance to airflow was calculated by selecting points along the ascending and descending limbs of the tidal volume record which represented points of equal inflation and deflation. Vertical lines were then drawn from these points through the pressure and flow curves. The difference in pressure and flow between the two points provided the data for the equation: pulmonary resistance = pressure difference in cm. H_2O/flow difference in L./sec. This method provides values which represent the average inspiratory and expiratory resistance near peak inspiratory and expiratory flows. Although the values thus obtained do not express the change of resistance with flow rate, they do closely approximate the average resistance during the respiratory cycle (5).

The compliance of the lungs was calculated from the following formula: pulmonary compliance = volume change in ml./pressure change in cm. H_2O. The necessary data were obtained by measuring volume and pressure changes at corresponding points of no airflow (beginning and end of inspiration) as seen from the flow-rate curve. The details of these methods have been described in an earlier report from this laboratory (6).

Evaluation of Bronchodilating Activity of Metaproterenol—Approximately 1 ml. of a 2% solution of histamine base was placed in a DeVilbiss No. 42 nebulizer which was modified with connectors and placed between the endotracheal tube and the pneumotachograph screen (Fig. 1). Control conditions were recorded and then histamine was administered by squeezing the hand bulb of the nebulizer at the outset of five consecutive inspirations. Immediately thereafter data for pulmonary mechanics calculations were recorded at 30-sec. to 2-min. intervals for a period of 5 min.

After allowing adequate time for the animals to recover from the bronchoconstricting effects of histamine, 10 inhalations of a 2% metaproterenol sulfate solution were administered. Two minutes were allowed for the drug to exert its activity after which time the respiratory patterns of the animals were again recorded. Histamine inhalation was then repeated, and the protection afforded by metaproterenol was evaluated by again measuring changes in pulmonary mechanical values over a 5-min. period.

Comparison of Cardiovascular Side Effects of Isoproterenol and Metaproterenol—A test group of 10 dogs was used to study and compare the cardiovascular side effects produced by inhalation of either isoproterenol or metaproterenol. Systemic blood

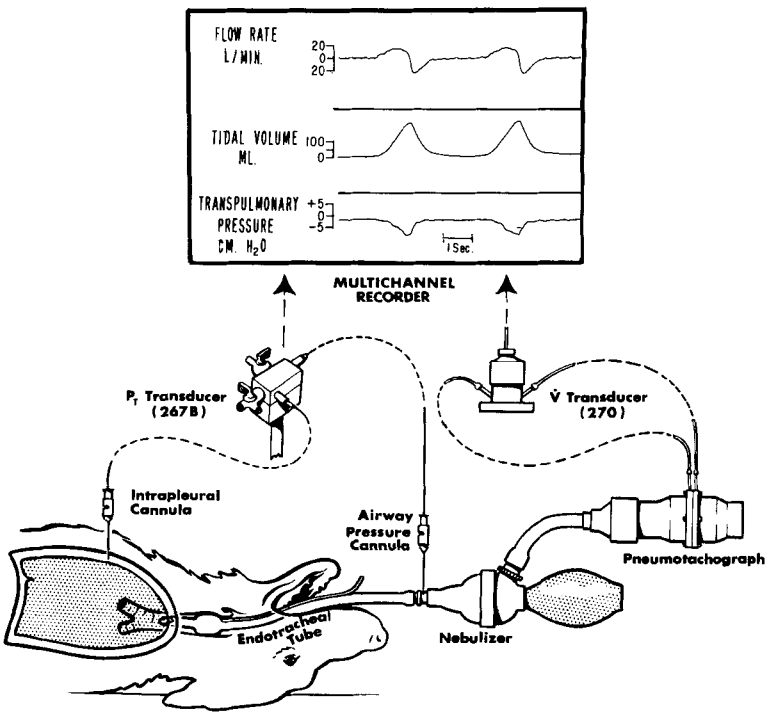

Fig. 1—Apparatus for administration of drug solutions and measurement of pulmonary mechanics.

pressure was measured from the abdominal aorta *via* the left femoral artery using a polyethylene catheter attached to a Sanborn pressure transducer. Pulse pressure was determined by subtracting the diastolic from the systolic pressure. Mean pressure was obtained by switching the pressure preamplifier to a filter circuit having a 1-sec. time constant. This procedure allowed the average value of the load on the transducer to be displayed on the oscillograph. A Sanborn high-gain preamplifier was used to record lead I of the electrocardiogram. Since the chart speed of the recorder was known, the heart rate was easily calculated.

Sufficient time was allowed for the animals' blood pressures to stabilize before control conditions were recorded. Each dog then received 10 inhalations of a 0.5% aqueous solution of isoproterenol hydrochloride. Drug-induced changes in the cardiovascular status of the animals were recorded at 1–3 min. intervals for a period of 15 min. After the isoproterenol effects had subsided, 10 inhalations of a 2% aqueous solution of metaproterenol sulfate were administered and the same data recording procedure repeated.

RESULTS AND DISCUSSION

The results of the first series of experiments, designed to evaluate the bronchodilator potential of metaproterenol, are presented in Tables I and II. The control value of the mean pulmonary resistance was 8.0 ± 0.4 (Table I). Following inhalation of histamine the mean pulmonary resistance increased sharply. The peak of the reaction usually occurred within 1 min. after administration of the spasmogen. Bronchoconstriction subsided in all of the test subjects within 20 min. at which time metaproterenol was administered. Two minutes thereafter the pulmonary resistance was again measured and the mean value found to be 9.4 ± 0.7. The latter value did not differ significantly from the initial control value ($p > 0.2$).

In each of the 10 experimental animals, metaproterenol afforded various degrees of protection

TABLE I—EFFECT OF HISTAMINE INHALATIONS ON PULMONARY RESISTANCE OF ANESTHETIZED, SPONTANEOUSLY BREATHING DOGS BEFORE AND AFTER TREATMENT WITH METAPROTERENOL

Dog	Sex	Wt., Kg.	Pulmonary Resistance (cm. H_2O/L./sec.)[a]

[a] The tabulated values were obtained 2 min. after metaproterenol had been administered.

against subsequent challenging doses of histamine. The percent protection at each of the measurement intervals was computed utilizing the following formula: $P = (I_c/R_c - I_t/R_t)/I_c/R_c \times 100$ where P is the percent protection, I_c is the increase in mean pulmonary resistance after histamine administration, R_c is the control mean pulmonary resistance before histamine had been given, I_t is the increase in mean pulmonary resistance after histamine administration to the metaproterenol treated dogs, and R_t is the mean pulmonary resistance 2 min. after the administration of metaproterenol. The percent protection values 30 sec., 1, 2, 3, and 5 min. after the second series of histamine inhalations were 89.2, 90.6, 89.2, 92.7, and 93.3%, respectively.

The effects of histamine inhalations on tidal volume, respiratory rate, minute volume, and pulmonary compliance, before and after treatment with metaproterenol, are summarized in Table II. The untreated animals experienced a decrease in tidal volume and pulmonary compliance and an increase in respiratory rate and minute volume following histamine. When the histamine inhalations were repeated in the metaproterenol-treated animals, the parameters again changed in the same direction but the magnitude of the changes differed. For instance, the maximum decrease in mean tidal volume of the unprotected animals was 88 ml., whereas the treated animals showed a maximum decrease of 17 ml. The mean respiratory rate of the unprotected animals increased from 25/min. to a maximum of 78/min., while the animals which had received metaproterenol experienced an increase of from 33/min. to a maximum of 57/min. The increase in minute volume of the untreated animals was only slightly less than the increase observed in the treated animals. The mean pulmonary compliance of the unprotected animals fell from the control value of 38 ml./cm. H_2O to a low of 9 ml./cm. H_2O while that of the treated animals fell from the control value of 35 ml./cm. H_2O to a low of 25 ml./cm. H_2O.

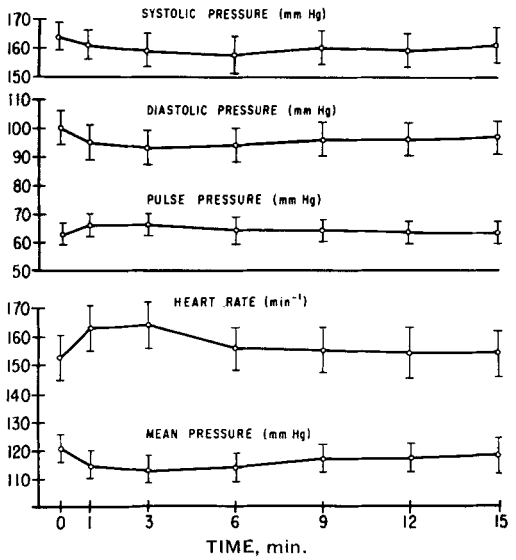

Fig. 2—Cardiovascular effects following 10 inhalations of isoproterenol hydrochloride (0.5%). The standard error is represented by vertical lines.

There are several possible explanations for the increase in respiratory frequency which was observed in both the unprotected and protected animals. Inhalation of histamine has been shown to reduce the systemic blood pressure of anesthetized dogs (7). The latter observation was confirmed by the present investigation. It is possible then that the respiratory stimulation was compensatory in nature and mediated by a reflex response evoked from baroreceptors in the carotid sinus and/or the aortic arch. In this connection it should be noted that in order for an inhaled drug to produce systemic effects it must first undergo transpulmonary absorption. Lovejoy and his co-workers (8) presented evidence to show that systemic effects frequently result after administering drugs from standard commercial nebulizers (such as the one used in this study) owing to their inherent property of delivering particles which are not exclusively submicronic. Robillard *et al.* (9) reported observing tachypnea and hypotension in human patients receiving carbachol from a commercial nebulizer. An increase in the respiratory rate of rabbits following carbachol inhalation was also observed by Karczewski and Dautrebande (10). These authors attributed the increase to the inhibiting effect of increased activity of pulmonary stretch receptors on the inspiratory center.

It is doubtful that the decrease in pulmonary compliance which followed histamine inhalation was caused by an actual lessening of the elastic qualities of the lungs. The changes in lung compliance followed the same time course and were proportional to the changes in total lung resistance. It is likely that histamine caused a marked constriction of several pulmonary units and as a consequence some alveoli collapsed due to surface forces. If such did occur, the decrease in compliance could be accounted for by atelectasis secondary to airway constriction.

The results of the experiments designed to compare the cardiovascular effects produced by inhalation of therapeutic doses of isoproterenol or metaproterenol are presented graphically in Figs. 2 and 3. Statistical analysis of the data was performed by using paired samples and the results were subjected to Student's analysis. A measured difference between control and postdrug values was considered to be significant and used to form conclusions only if $p < 0.05$.

Isoproterenol produced a significant drop in systolic blood pressure and a significant elevation of the heart rate at the 3-min. and 6-min. observation points. The diastolic and mean pressures were significantly depressed 1–6 min. after the drug had been administered. Isoproterenol had no significant effect upon pulse pressure. None of the cardiovascular responses to isoproterenol inhalation persisted for more than 6–9 min.

Metaproterenol produced a slight, insignificant increase in systolic blood pressure. The diastolic and mean pressures fell somewhat, but the decreases were significant only at the 9-min. postdrug administration time. The slight rise in systolic pressure coupled with the small decrease in diastolic pressure was sufficient to produce a significant increase in pulse pressure at each of the measurement intervals. The most pronounced cardiovascular effect of meta-

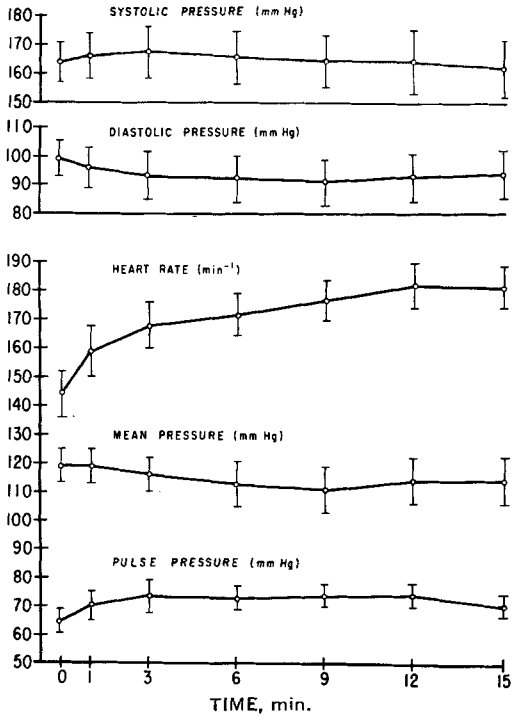

Fig. 3—Cardiovascular effects following 10 inhalations of metaproterenol sulfate (2%). The standard error is represented by vertical lines.

proterenol was observed on the heart rate which showed significant elevation at every observation time. Whereas the maximum increase in heart rate after isoproterenol inhalation was 7% and occurred 1 min. after the drug had been administered, the maximum increase following metaproterenol inhalation was 26% and occurred 12 min. after the drug had been administered.

Effect of Deuterium Oxide on the Culturing of *Penicillium janczewskii* II

Isolation of Fully Deuterated Griseofulvin

By D. A. NONA, M. I. BLAKE, H. L. CRESPI, and J. J. KATZ

Fully deuterated griseofulvin was isolated in pure form from *P. janczewskii* grown in a completely deuterated medium. Direct fermentation and a replacement culture technique were used. The isolated antibiotic was purified by thin-layer chromatography and characterized by ultraviolet, infrared, and nuclear magnetic resonance spectra. The extent of incorporation of deuterium during biosynthesis at the various proton sites in the molecule was determined.

In a previous paper (1) the effect of heavy water both on the growth of the mold *Penicillium janczewskii* and on its production of antibiotic was reported. Nutritional requirements for optimal growth in D_2O and the general culture techniques were described in detail. Griseofulvin production was severely impaired when the organism was grown in pure D_2O media by the usual surface culture method, but the griseofulvin titer was improved when the D_2O culture medium was supplemented with vitamin B complex. In the present study a replacement culture method was employed to produce deuterated griseoful-

vin. Deuterated antibiotic biosynthesized by the organism in replacement culture was isolated, purified, and characterized by chemical means.

EXPERIMENTAL

Replacement Culture Method—The griseofulvin-producing strain *Penicillium janczewskii* (NRRL 2301) was used throughout this study. Mycelial contents of shake cultures grown in an H_2O medium were used as starting tissue for preparative replacement cultures. After 7 days' growth the vegetative tissue from 60 ml. of an H_2O medium culture contained in a 250-ml. conical flask was separated from the medium by filtration. The tissue retained by the filter was resuspended in 75 ml. of sterile D_2O and the suspension was again filtered. This process was repeated twice. Then the mycelium was dispersed in 60 ml. of deuterated medium. The composition and preparation of the nutrient medium have been described previously (1). Fermentation was allowed to take place in 250-ml. conical flasks stoppered with cotton and sealed with aluminum foil. Cultures were returned to the shaker and incubation resumed for a period of 4–6 weeks. All manipulations involving exposed cultures were performed in a bacteriologic hood.

Surface cultures were prepared by inoculating 500 ml. of H_2O medium contained in 3-L. conical flasks with a spore suspension of the organism. Replacement was effected after a 7-day growth period. The water medium was removed from beneath the floating mat by introducing the tip of a sterile 2-ml. pipet below the mat. A section of Tygon tubing was attached to the other end of the pipet, and the medium was carefully siphoned away. The underside of the mat was washed with 100 ml. of sterile D_2O added by slow infusion through a reservoir joined to the pipet by Tygon tubing. After swirling several times, the D_2O wash was siphoned away and fresh sterile heavy water was added. This procedure was repeated twice. After the third washing, 500 ml. of deuterated replacement medium was slowly introduced under the mycelial mat with the aid of a pipet. The fluid flow rate was carefully controlled by adjustment of the reservoir height. For successful preparation of a replacement culture it was essential that the mycelial mat remain floating and that there be no liquid on the upper surface of the mat. In surface culture antibiotic production does not occur when the mat sinks into the medium.

Analysis for deuterium content was performed periodically throughout the fermentation period by the technique of Crespi and Katz (2). At no time was the final deuterium oxide concentration observed to be more than 2% below the initial concentration, indicating that little isotopic dilution had occurred.

Extraction Procedure—At harvest, the mycelium was separated from the fermentor broth by filtration, and both the mycelium and filtrate were extracted for griseofulvin. The filtrate was extracted with chloroform in a 1-L. liquid–liquid extractor for 76 hr. Preliminary studies indicated that this length of time was required for complete extraction of the antibiotic. The chloroform extract was reduced in volume to about 10 ml. on a flash evaporator. Antibiotic was recovered from the concentrate in pure form by preparative thin-layer chromatography.

The mycelium was treated according to the procedure of Oxford *et al.* (3). After drying in an oven at 100° for 24 hr., the mycelium was reduced to a fine powder in a mortar and transferred to an extraction thimble. The thimble was placed in the extractor of a Soxhlet continuous extraction apparatus. The powdered mycelium was extracted with ether for 76 hr. The ether extract was evaporated to dryness in a flash evaporator, the residue redissolved in chloroform, and products separated by preparative thin-layer chromatography.

Preparative Thin-Layer Chromatography—Silica Gel G preparative thin-layer plates, 500 μ in thickness, were prepared with a Desaga variable gauge applicator. Concentrated chloroform extracts were streaked across the plate at the origin (a line parallel to one side of the plate and 3.5 cm. from the edge) with an automatic applicator and streaker (Rodder Instruments, Los Altos, Calif.). All chromatograms were spotted with a chloroform solution of reference standard griseofulvin to serve as a control. Plates were placed in a standard developing tank which was lined with filter paper to ensure saturation of the chamber. The developing solvent consisted of ether–acetone, 3:2. The development time was about 25 min., which was the time required for the solvent front to reach the end of the plate. Since griseofulvin fluoresces strongly, its location on the plate was readily detected by scanning with an ultraviolet lamp. The fluorescent band having an R_f value of 0.62 was scraped from the chromatographic plate with a razor blade. Griseofulvin adsorbed to the Silica Gel G was isolated by shaking at 200 r.p.m. for 30 min., with a mixture of ether–acetone, 1:3; the extract was recovered by centrifugation. The extract after filtration was evaporated to dryness under a stream of nitrogen gas. The residue was dissolved in chloroform and rechromatogramed on a preparative thin-layer plate using as the developing solvent, ether–acetone, 4:1. Griseofulvin was removed from the plate as described previously. A cream-colored powder of purified griseofulvin was obtained.

Silica Gel Chromatopile Technique—As an alternate procedure for obtaining purified griseofulvin from the fermentor broth and mycelium, a preparative chromatopile technique was also employed. A cylindrical form was shaped by rolling a section of chromatography paper to a dimension of 14 cm. in length and 3 cm. in diameter at the base. The paper form was covered with aluminum foil and placed on end. A thick suspension of Silica Gel G (75 Gm. of gel in 35 ml. of water) was poured into the cylindrical mold. After 3 hr. the aluminum foil was removed and the chromatopile was allowed to air dry overnight. Finally, the paper mold was peeled away exposing a cylindrical bar of Silica Gel G.

A concentrated solution of griseofulvin in chloroform was placed in a 50-ml. evaporating dish. The base of the chromatopile was dipped into the solution. When the solvent front reached a height of about 1.5 cm., the chromatopile was removed, air dried, and returned to the evaporating dish. This process was continued until the entire chloroform concentrate had been adsorbed on the lower 1.5 cm. of the chromatopile. The band of sample at

the origin was developed by dipping into a solvent mixture of ether–acetone (3:2) contained in a 50-ml. evaporating dish. Development was continued until the griseofulvin band reached a height of about 4 cm. as determined by fluorescence under ultraviolet light. The chromatopile was then placed into the TLC developing tank containing developing solvent, and development was continued for approximately 25 min., after which it was removed and air dried. The band containing the griseofulvin was sliced from the column with a razor blade, reduced to a powder, and extracted as described previously.

Infrared Spectrum—A 0.5% solution of griseofulvin in chloroform was examined over the 4,000 to 650 cm.$^{-1}$ spectral region in a Beckman spectrophotometer, model IR 7, equipped with a 0.1-mm. ultramicro cavity cell.

Ultraviolet Absorption Spectrum—The ultraviolet absorption spectrum of a solution of griseofulvin in ethyl acetate was obtained with a Beckman DG-B grating spectrophotometer provided with a Sargent recorder (model SR).

Nuclear Magnetic Resonance Spectroscopy—NMR spectra of the griseofulvin samples prepared as 5% solutions in Silanar-C (deuteriochloroform with 1% TMS as internal standard; Merck Sharp and Dohme, Canada, Ltd.) were obtained on a Varian A-60 NMR spectrometer and a Varian HA-100 NMR spectrometer, equipped with a Varian C-1024 computer of average transients.

RESULTS AND DISCUSSION

Good growth does not necessarily imply good antibiotic production. It was noted, however, that good antibiotic production was always associated with good growth. The decreasing griseofulvin titers observed with increasing D_2O solvent concentrations were, for the most part, accompanied by inferior mycelial felts. A replacement culture method allows for the separate analysis of the effects of deuterium isotope replacement on vegetative growth and on griseofulvin production, and it provides a high degree of control over each phase. When the replacement medium consisted of pure D_2O and deuterio sugars, a fully deuterated antibiotic was obtained, and when pure D_2O and protio sugars were employed, the isolated griseofulvin was partially deuterated. Milligram amounts of fully deuterated griseofulvins were obtained from 500-ml. preparative replacement cultures. A comparison of antibiotic yields from varying culture conditions is listed in Table I. After the nutrient was replaced, the cultures were allowed to ferment for an additional 28 days. Both mycelium and fermentor broth were then extracted for antibiotic. Protio griseofulvin was not found to accumulate in mycelium grown in a protioculture before the fifteenth day of incubation. Therefore, if the protio medium is replaced with a deuterated medium before such a time, the mycelium originating from H_2O cultures may be extracted for deuterio griseofulvin at the conclusion of the fermentation period free of contamination with protio griseofulvin. The 50–60 days for maximum antibiotic production by direct fermentation can thereby be reduced to about 30 days by the replacement technique.

Since laboratory scale antibiotic production under the described conditions involves the isolation of small amounts of griseofulvin, the usual preparative procedures cited in the scientific and patent literature were not applicable in this study. A thin-layer chromatographic procedure was developed which served effectively to identify and separate the griseofulvin from its fermentation congeners. The method not only enabled the isolation of small quantities of pure griseofulvin, but was less tedious than solvent extraction and recrystallization techniques, and the small quantitites of griseofulvin produced were obtained in a chromatographically pure state. Purification of the extracts obtained from larger batches of mycelium and fermentor broth required at least five or six TLC plates. The large number of plates is needed because a good separation cannot be effected if the sample is very concentrated and the plates overloaded. The use of a chromatopile thus provided a second method for purification and had the advantage of adsorbing larger amounts of material without impairing separation.

TABLE I—GRISEOFULVIN PRODUCTION IN SURFACE CULTURE BY *P. janczewskii*

Medium	Growth Conditions	Fermentor Broth Titer, mcg./ml.	Recovery, mg./500 ml.
0% D_2O, protio sugars	Direct fermentation	110–120	13.0
99.6% D_2O, protio sugars and vitamins	Direct fermentation	40–50	4–6
99.6% D_2O, protio sugars	Replacement culture	45–50	4–6
99.6% D_2O, deuterio sugars and vitamins	Direct fermentation	45–50	5.2
99.6% D_2O, deuterio sugars	Replacement culture	45–50	4.6

Chloroform solutions of ordinary, partially deuterated, and fully deuterated griseofulvin prepared in this laboratory were characterized by infrared spectrometry. The fully deuterated griseofulvin samples were obtained by both direct fermentation and replacement culture with fully deuterated media. Partially deuterated griseofulvin was obtained from replacement cultures using pure D_2O and protio sugars. The spectra were compared with those obtained with chloroform solutions of authentic griseofulvin and spectral assignments were made according to the interpretation of Page and Staniforth (4).

Infrared spectra of protio griseofulvin isolated in this laboratory from H_2O cultures were identical to that of reference standard griseofulvin. The infrared spectra of chloroform solutions of fully deuterated griseofulvin were found to be identical to that of ordinary griseofulvin with one striking exception, namely, the replacement of the C—H absorption at 2,850 cm.$^{-1}$ by a C—D absorption at 2,120 cm.$^{-1}$. This is the usual isotope effect on the C—H stretch vibration, and the isotope shift confirms the incorporation of deuterium.

The NMR spectra of deuteriochloroform solutions of griseofulvin and selected analogs have been

examined and interpreted independently by Green *et al.* (5) and Arison *et al.* (6). These workers were able to assign each spectral line or group of lines to a particular proton or group of protons, and conversely, to correlate each proton with a particular line or group of lines. The spectra of partially deuterated compounds may be compared directly with the spectrum of the compound which contains only ordinary hydrogen, and in this way information can be obtained about the amount of deuterium present at each molecular site. The effects of the deuterons on the proton resonances may be observed indirectly, but the deuterons themselves will not contribute any signals to the recorded spectrum. Therefore, the situation that is created when the proton magnetic resonance bands are observed for partially deuterated griseofulvin is no different from that which is observed in the fully protiated griseofulvin. Since the NMR signal is proportional to the number of protons contributing to the resonance line in partially deuterated griseofulvin, the proton integral for a particular molecular position will be diminished by a factor which is proportional to the extent of proton replacement by deuterium. If all of the molecules in the collection that forms the sample are fully deuterated at a given position, no signal would be observed and the proton integral for the proton resonances of the position would be zero.

Fully Deuterated Griseofulvin—NMR spectra of griseofulvin samples obtained by direct fermentation and replacement cultures employing fully deuterated media showed a complete absence of resonance peaks at 6.15, 5.53, 4.04, 4.00, 3.63, 2.70, and 0.98 δ.[1] The only absorption peaks in the spectra were the TMS (standard reference signal) peak at 0, and a peak at 7.39 δ due to protons in the deuteriochloroform solvent. When the amplitude was adjusted to the upper limits of the Varian A-60, the noise level was understandably increased, but even so no absorption peaks were observed. These results indicate that the griseofulvin isolated under these fermentation conditions contains essentially no protons, and that there is complete isotopic replacement of hydrogen with deuterium.

High resolution spectra of the fully deuterated griseofulvin samples were then obtained on a Varian HA-100 spectrometer. The spectra obtained exhibited a complete absence of absorption peaks, confirming the spectral results obtained with the Varian A-60. Spectra were also obtained with a computer of average transients (C.A.T.). A readout after multiple scans showed only minor absorption in the C—CH_3 and CH_2—CH absorption region, and no other absorption peaks were observed. The proton resonance observed indicated the presence of some hydrogen in the molecule, but the amount was clearly very small. The origin of these protons is probably due to residual H_2O in the 99.6% D_2O used. From these NMR results it can be concluded that the griseofulvin produced is essentially fully deuterated.

Partially Deuterated Griseofulvin—The extent of deuterium incorporation into griseofulvin isolated from replacement cultures of partially deuterated media, composed of protioglucose (7%) and pure D_2O, was determined by NMR spectroscopy. The spectra obtained were compared directly to that for protio griseofulvin. Examination of the spectrum indicated that no significant chemical shift differences exist between ordinary and partially deuterated griseofulvin. Since the NMR signal integral is proportional to the number of protons contributing to the resonance line, the proton integral for a particular molecular position will be diminished by a factor which is proportional to the total number of nuclei contributing to the signal. By comparing the integrals for these areas to those of a standard signal by a known number of protons, the various regions of the spectrum were calibrated as to the number of protons which were represented.

Sample I was prepared by dissolving an exact amount of partially deuterated griseofulvin, which was obtained from replacement cultures, in exactly 300 μl. of $CDCl_3$ (Silinar-C.). The same quantity (accurately weighed) of ordinary hydrogen griseofulvin, isolated in this laboratory from H_2O cultures, was dissolved in the same volume of Silinar-C and designated as Sample II. The NMR spectra of the two samples were then obtained with a Varian A-60 spectrometer. A spectrum amplitude of 80 was required to obtain a readable spectrum with Sample I, whereas an amplitude of only 40 was needed for Sample II, reflecting the marked difference in proton content of the two samples. The proton content was quantitated by integrating the spectra. Because the volume of deuteriochloroform in each sample was exactly 300 μl., a comparison can be made of the area integrated under the absorption peak of deuteriochloroform arising from the small amount of residual $CHCl_3$ present in the $CDCl_3$. At an amplitude of 80 (Sample I) and 40 (Sample II) the area under the $CHCl_3$ absorption peak was represented by 15 units and 5 units, respectively. Therefore, if the griseofulvin molecule was fully protiated, the expected area under each absorption peak in the spectrum of Sample I (at an amplitude of 80) would be three times that of the spectrum of Sample II (at a spectrum amplitude of 40). Thus the areas under the resonance peaks can be normalized and the relative amounts of hydrogen at the various molecular positions in partially deuterated griseofulvin can be established.

Normalization shows that there is a considerable replacement of hydrogen by deuterium at various

Table II—Isotope Fractionation Factors for Partially Deuterated Griseofulvin Obtained by Biosynthesis in D_2O from Hydrogen Substrates

Resonance	Chemical Shift (δ, p.p.m.)	Partially Deuterated Griseofulvin—Expected Area[a] (Units)	Partially Deuterated Griseofulvin—Observed Area[a] (Units)	Isotope Fractionation Factor K_H/K_D
$CHCl_3$ (present in $CDCl_3$)	7.39	15	15	—
Aromatic *H*	6.15	54	11	0.26
Vinyl *H*	5.53	54	11	0.26
Aromatic OCH_3 (6-methoxyl)	4.04	75	17	0.30
Aromatic OCH_3 (4-methoxyl)	4.00	27	7	0.35
Vinyl OCH_3	3.63	42	10	0.31
CH_2—C*H*	2.70	54	18	0.50
C—CH_3	0.98	48	14	0.41

[1] Chemical shifts are given in parts per million relative to tetramethylsilane (TMS) with downfield shifts positive.

molecular positions in the partially deuterated griseofulvin (Table II), which results from the incorporation of deuterium during biosynthesis at the various proton sites in the molecule. The amount of deuterium incorporated varies with the particular proton site. From Table II it can be seen that replacement of hydrogen by deuterium is maximal at the aromatic and vinyl positions. These molecular sites apparently afford little opportunity for biosynthetic incorporation of proton from the protio substrate, and a maximum of solvent D_2O equilibration occurs at these loci. Decreasing amounts of isotopic substitution occur at the OCH_3, C—CH_3, and CH_2—CH positions, indicating that the protio sugars have a more extensive role in the biosynthetic mechanisms leading to the formation of these moieties. In addition, these sites probably have a decreased capability for equilibration with the solvent. The isotope fractionation factor K_H/K_D calculated as the average of all molecular positions in partially deuterated griseofulvin was found to be 0.36. This indicates a ratio of approximately one hydrogen atom for every three deuterium atoms in the molecule, and an average deuterium isotope replacement of about 75%.

CONCLUSIONS

Griseofulvin extracted from the mycelium and culture filtrates of *P. janczewskii* was purified by preparative thin-layer chromatography and characterized by visible, infrared and nuclear magnetic resonance spectra. Fully deuterated griseofulvin, the first fully deuterated antibiotic so far prepared, was obtained from organisms grown on a fully deuterated medium by direct fermentation. A yield of over 5 mg. was obtained from 500 ml. of culture medium. When a protio medium used for vegetative growth was replaced with a fully deuterated medium, fully deuterated griseofulvin was isolated. Approximately the same amount of antibiotic was obtained from 500 ml. of replacement medium. By this procedure the 50–60 days necessary for maximum deuterio griseofulvin production by direct fermentation could be reduced by about one-half. When the replacement medium was only partially deuterated (protio sugars and pure D_2O), an antibiotic was isolated which was deuterated in part. A yield of 4–6 mg. was obtained from 500 ml. of partially deuterated replacement medium.

Subsequent studies are concerned with the determination of the effect of deuterium on the antibiotic activity. If detoxification of griseofulvin requires rupture of carbon-to-hydrogen bonds it is expected that the deuterio analog should exhibit an enhanced activity since carbon-to-deuterium bonds are generally more stable. A statistical analysis of antifungal activity of deuterio griseofulvin will be the subject of the next report.

Synthesis of 2-(*N*,*N*-Dialkylaminomethyl)-7-phenylthioindoles

By ROBERT L. DUNCAN, JR.* and JOHN ANDRAKO†

A series of 2-(*N*,*N*-dialkylaminomethyl)-7-phenylthioindoles was prepared. The Japp-Klingemann reaction followed by Fisher cyclization with polyphosphoric acid gave 7-phenylthioindole-2-carboxylic acid. The lithium aluminum hydride reduction of amides derived from this acid provided the corresponding aminomethyl indoles. Infrared and NMR data are reported.

As part of a program directed at the synthesis and pharmacological evaluation of dialkylaminoalkyl-7-substituted indoles, the authors wish to report the synthesis of a series of 2-(*N*,*N*-dialkylaminomethyl)-7-phenylthioindoles (VI). Relatively few 7-substituted indoles and indole derivatives have been reported and there is an almost total lack of pharmacological data for compounds of this type. Hiremath and Siddappa (1) reported the synthesis of 5-methoxy-7-

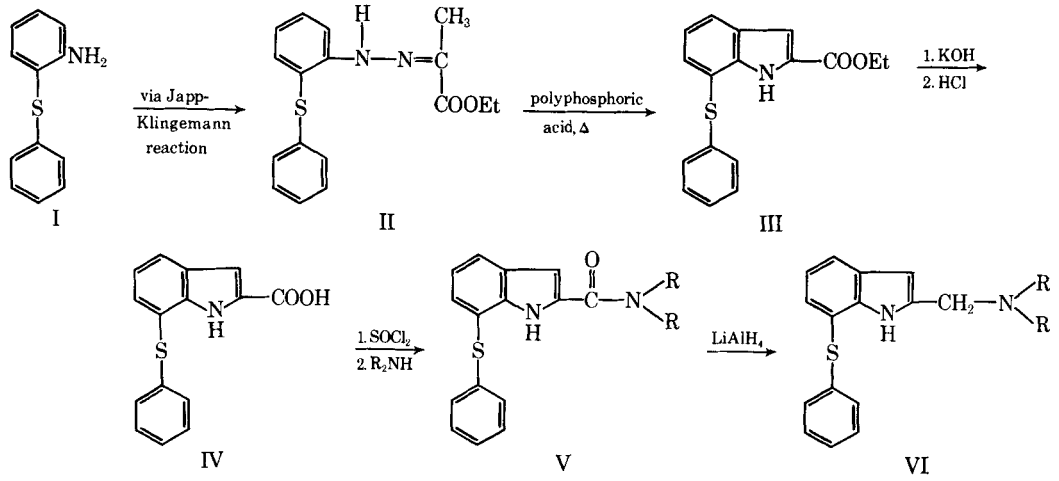
nitroindole, 5-methyl-7-nitroindole, and the corresponding aminoindoles as possible antiserotonin agents, but did not report any biological data for these compounds. The syntheses of a number of 2-dialkylaminomethylindole derivatives have been reported by Kornfeld (2), Yoneda, and co-workers (3) and others (4–6).

The 2-dialkylamino-7-phenylthioindoles are of particular interest since they may be related structurally to "open" phenothiazines.

DISCUSSION

The synthesis of the reported compounds was accomplished by the sequence of reactions outlined in Scheme I.



Scheme I

The *o*-(phenylthio)aniline (I) was obtained in good yield by reduction of *o*-(phenylthio)nitrobenzene which was prepared by treating sodium thiophenoxide with *o*-chloronitrobenzene. Diazotization of I and reaction of the resulting diazonium compound with ethyl 2-methylacetoacetate under Japp-Klingemann conditions yielded the desired ethyl pyruvate *o*-(phenylthio)-phenylhydrazone in about 50% yield. An attempt to obtain *o*-(phenylthio)phenylhydrazine by reduction of the diazonium compound of I with stannous chloride and hydrochloric acid was made. A solid was obtained which on the basis of its infrared absorption at 2260 cm.$^{-1}$ (N ≡ N) (7) appeared to be a stable tin double salt of diazotized II. No further characterization of the solid was made.

The indole ester, III, was prepared by cyclization of II using polyphosphoric acid. When the temperature of the reaction mixture was raised to 90° an exothermic reaction occurred. At this point the reaction was immediately quenched with ice water. If the reaction mixture was maintained at 90° for longer periods of time, extensive tar formation occurred, the yields of indole ester were lower, and it was more difficult to purify the small amounts of product which were isolated. Attempts to bring about the cyclization of II using a saturated ethanolic solution of hydrogen chloride or ethanolic zinc chloride were unsuccessful.

The 7-phenylthioindole-2-carboxylic acid, was obtained by hydrolysis of the ester (III) with potassium hydroxide followed by acidification with hydrochloric acid. The indole acid was converted to the acid chloride using thionyl chloride and was used without prior isolation to prepare the carboxamides, V*a*, *b*, *c*, *d*, described in Table I. Conversions of indole acids to indole acid chlorides have been reported (2, 8, 9).

The carboxamides were reduced with lithium aluminum hydride to the corresponding 2-(*N*,*N*-dialkylaminomethyl)-7-phenylthioindoles, VI*a*, *b*, *c*, *d*, indicated in Table II.

The infrared and NMR spectra are in agreement with the assigned structures at each step indicated in Scheme I.

EXPERIMENTAL[1]

o-(Phenylthio)nitrobenzene—To a sodium ethoxide solution prepared by adding slowly 20.7 Gm. (0.9 mole) of sodium metal to 300 ml. of absolute ethanol there was added in portions over a period of 20 min., 110 Gm. (1.0 mole) of benzenethiol followed by 157.6 Gm. (1.0 mole) of *o*-chloronitrobenzene.

[1] Melting points were obtained with a Thomas-Hoover capillary melting point apparatus and are uncorrected. All analyses were performed at the Medical College of Virginia unless otherwise indicated. Infrared spectra were obtained with a Beckman IR-8 spectrophotometer. NMR data were obtained with a Varian Associates model A60 NMR spectrometer through the courtesy of the A. H. Robins Co., Richmond, Va.

[a] Recrystallized from 2-butanone. [b] Hydrochlorides.

The mixture was allowed to reflux for 3.5 hr. After the addition of 500 ml. of water, the mixture was extracted with ether. The combined ethereal extracts were dried (anhydrous sodium sulfate) and concentrated. The solid residue thus obtained weighed 154.4 Gm. (74.2%) and after recrystalliza-

tion from ligroin melted at 77–79° [lit. 77° (10); 78–80° (11)].

o-(Phenylthio)aniline (I)—A solution of 43.1 Gm. (0.23 mole) of stannous chloride in 106 ml. of concentrated hydrochloric acid was added slowly to a stirred solution of 11.6 Gm. (0.05 mole) of *o*-(phenylthio)nitrobenzene. The solution was heated on a steam bath until the yellow color disappeared (2–3 hr.). The solution was cooled, carefully made basic with sodium hydroxide, and extracted with ether. The ethereal extracts were combined, dried (anhydrous sodium sulfate), and concentrated. The residual oil, upon standing in the freezer, crystallized and 7.1 Gm. (70%) of pale yellow crystals was obtained which melted at 34–36° [lit. 33° (11)]. The acetyl derivative melted at 84–86° [lit. 86° (10)].

Ethyl Pyruvate o-(Phenylthio)phenylhydrazone (II)—A solution of 60.4 Gm. (0.3 mole) of *o*-(phenylthio)aniline in 270 ml. of 6 *N* hydrochloric acid contained in a three-necked flask was cooled in an ice-salt bath and stirred. While maintaining the temperature of the reaction mixture at 0–5°, 22.1 Gm. (0.32 mole) of sodium nitrite in 60 ml. of water was added dropwise. The solution of the diazonium salt was maintained at 0° until it was used later. A solution of 44.6 Gm. (0.31 mole) of ethyl 2-methylacetoacetate in 300 ml. of ethanol was stirred and cooled to 0°, and 108 ml. of a 50% solution of potassium hydroxide was added with vigorous stirring. About 400 ml. of an ice–water mixture was added to the reaction mixture, and the previously prepared cold solution of the diazonium salt was introduced immediately. The red mixture was stirred for 16 hr. during which time it was allowed to come to room temperature. The aqueous reaction mixture was extracted with ether. The ethereal extracts were combined, and the ether was evaporated leaving a dark red oil which resisted all attempts at crystallization. The crude oil was distilled with care and the fraction boiling at 160–165°/0.05 mm. was collected, yielding 46.0 Gm. (49%) of the hydrazone ester. The infrared spectrum in chloroform showed $\nu_{max.}$ 3300 cm.$^{-1}$, 3220 cm.$^{-1}$, 1700 cm.$^{-1}$.

Anal.—Calcd. for $C_{17}H_{18}N_2O_2S$: C, 64.94; H, 5.77; N, 8.91. Found: C, 64.63; H, 5.73; N, 8.83.

Ethyl 7-(Phenylthio)indole-2-carboxylate (III)—A mixture of 45 Gm. (0.15 mole) of II and 120 Gm. of polyphosphoric acid was stirred in a 500-ml. conical flask equipped with a thermometer. The mixture was carefully heated to 90° whereupon an exothermic reaction occurred. At this point about 100 ml. of ice water was added immediately to the reaction mixture. When decomposition of the excess polyphosphoric acid was complete, the semi-solid ester was collected by filtration. The residue was dissolved in 100 ml. of ether, and the solution was dried and concentrated. A gummy residue which weighed 30.0 Gm. (71%) was obtained. Upon standing, crystals formed in the residue. After recrystallization from ethanol, the yellow crystals melted at 133–135°. The infrared spectrum (KBr disk) showed $\nu_{max.}$ 3350 cm.$^{-1}$, 1675 cm^{-1}.

Anal.—Calcd. for $C_{17}H_{15}NO_2S$: C, 68.66; H, 5.09; N, 4.71. Found: C, 68.71; H, 5.67; N, 4.25.

7-Phenylthioindole-2-carboxylic Acid (IV)—To a solution of 101 Gm. (0.34 mole) of III in 200 ml. of absolute ethanol was added an excess of aqueous potassium hydroxide solution prepared by dissolving 50 Gm. of potassium hydroxide in 50 ml. of water. The solution was refluxed for 5 hr. After standing 16 hr. the solution was diluted with 500 ml. of water and extracted with chloroform. The aqueous layer was made acidic with 5% hydrochloric acid solution, and a red oil, which crystallized when scratched with a glass rod, separated from solution. The solid was filtered with suction, washed with water, and air dried. The crude solid (75 Gm.) was dissolved in 100 ml. of a 5% sodium bicarbonate solution and the resulting solution was extracted with both chloroform and ether. The aqueous solution was treated with charcoal and warmed to remove any remaining organic solvent. The mixture was filtered and the filtrate made acidic with a 5% hydrochloric acid solution. The acid which precipitated was collected by filtration and dissolved in methanol. When water was added, a pale yellow solid separated which was removed by filtration and air dried. Decolorization with charcoal and recrystallization from methanol–water gave 60 Gm. (91%) of the crude acid which melted at 150–160°. Recrystallization from benzene gave a crystalline product which melted at 158.5–160.5°. The infrared spectrum (KBr disk) showed $\nu_{max.}$ 3410 cm.$^{-1}$, 1660 cm.$^{-1}$. The NMR spectrum (DMSO) showed only an aromatic multiplet, extending from 6.9–7.9 δ, an acid singlet at 12.3 δ, and a broad NH area in the region of 8.5 δ. The integration of 1:1:10 for the acid, NH, and aromatic areas, respectively, agreed with the assigned structure.

Anal.[2]—Calcd. for $C_{14}H_{11}NO_2S$: C, 66.89; H, 4.12; N, 5.20; S, 11.90. Found: C, 66.67; H, 4.16; N, 5.05; S, 11.86.

(N,N-Dimethyl) - 7 - phenylthioindole - 2 - carboxamide (Va)—A solution of 5.0 Gm. (0.019 mole) of IV in 50 ml. of thionyl chloride was stirred for 2 hr. at room temperature. The thionyl chloride was removed under vacuum, and the residue which remained was dissolved in 30 ml. of tetrahydrofuran. A solution of 1.6 Gm. (0.038 mole) of dimethylamine in tetrahydrofuran was added dropwise from a dropping funnel to the solution of the acid chloride. After 15 min. of stirring, the mixture was filtered and the filtrate was evaporated to dryness. The residue which remained was dissolved in 50 ml. of chloroform, and the chloroform solution was extracted successively with 15-ml. portions of 5% hydrochloric acid solution, 5% sodium hydroxide solution, and water. The chloroform layer was evaporated to dryness and the 4.5 Gm. (82%) of crude amide which remained was dissolved in hot methanol, decolorized with charcoal, and filtered. The white crystalline amide which separated melted at 191–193°. The infrared spectrum ($CHCl_3$) showed $\nu_{max.}$ 3440 cm.$^{-1}$, 1600 cm.$^{-1}$. The NMR spectrum ($CDCl_3$) showed a singlet at 3.07 δ (CH_3), a multiplet at 7.25 δ (aromatic), and a broad NH absorption band far downfield. Other data are in Table I.

(N,N - Diethyl) - 7 - phenylthioindole - 2 - carboxamide (Vb)—The procedure described for *Va* was followed. The infrared spectrum ($CHCl_3$) showed $\nu_{max.}$ 3440 cm.$^{-1}$, 1600 cm.$^{-1}$. The NMR spectrum ($CDCl_3$) showed a triplet at 1.1 δ (CH_3), a quartet at 3.5 δ (CH_2), and a multiplet at 7.25 δ (aromatic). Other data are in Table I.

1-(7-Phenylthio-2-indolylcarbonyl)piperidine (Vc)—The procedure described for *Va* was followed.

[2] Analyses by Microtech Laboratories, Skokie, Ill.

The infrared spectrum (KBr disk) showed $\nu_{max.}$ 3440 cm.$^{-1}$, 1600 cm.$^{-1}$. Other data are in Table I.

4 - (7 - Phenylthio - 2 - indolylcarbonyl)morpholine (Vd)—The procedure described for V*a* was followed. The infrared spectrum ($CHCl_3$) showed $\nu_{max.}$ 3440 cm.$^{-1}$, 1600 cm.$^{-1}$. Other data are in Table I.

2 - (N,N - Dimethylaminomethyl) - 7 - phenyl thioindole (VIa)—Lithium aluminum hydride, 540 mg. (0.015 mole) was added in portions to 75 ml. of tetrahydrofuran. The mixture was stirred for 15 min. A solution of 2.0 Gm. (0.007 mole) of (*N,N*-dimethyl)-7-phenylthioindole-2-carboxamide in 25 ml. of tetrahydrofuran was slowly added and the mixture was stirred for an additional 30 min. Water was added dropwise with caution until no visible reaction could be detected, and the mixture was stirred for an additional 15 min. After filtration and evaporation of the solvent, the oily residue which remained was dissolved in ether. The ether solution was extracted with 30 ml. of 5% hydrochloric acid solution and the amine hydrochloride separated as an oil. The hydrochloride and the acidic aqueous layer were combined and made basic with 5% sodium hydroxide solution. After extracting with ether, the ethereal extracts were dried. Addition of an excess of ethereal hydrogen chloride precipitated the white hydrochloride salt as a solid. Recrystallization from 2-butanone gave 1.6 Gm. (74%) of crystalline hydrochloride melting at 164–166°. The infrared spectrum of the free amine ($CHCl_3$) showed $\nu_{max.}$ 3440 cm.$^{-1}$. The NMR spectrum ($CDCl_3$) of the hydrochloride showed a singlet at 2.75 δ (CH_3), a singlet at 4.45 δ (CH_2), a singlet at 6.6 δ (3 position proton), a multiplet at 7.2 δ (aromatic), and the NH and HCl proton absorption bands far downfield. Other data are in Table II.

2-(N,N-Diethylaminomethyl)-7-phenylthioindole (VIb)—The procedure described for VI*a* was followed. The infrared spectrum of the free amine ($CHCl_3$) showed $\nu_{max.}$ 3450 cm.$^{-1}$. The NMR spectrum of the free amine ($CDCl_3$) showed a triplet at 0.9 δ (CH_3), a quartet at 2.45 δ (CH_2), a singlet at 3.6 δ (CH_2), a singlet at 6.3 δ (3 position proton), a multiplet at 7.2 δ (aromatic), and an NH absorption band far downfield. Other data are in Table II.

7-Phenylthio-2-piperidinomethylindole (VIc)—The procedure described for VI*a* was followed. The infrared spectrum of the hydrochloride ($CHCl_3$) showed a $\nu_{max.}$ 3225 cm.$^{-1}$ and a broad NH absorption band in the region 2630 cm.$^{-1}$ and 2120 cm.$^{-1}$. The NMR spectrum of the hydrochloride ($CDCl_3$) showed multiplets at 1.8, 2.8, and 3.2 δ (piperidinomethylenes), a doublet at 4.3 δ (CH_2), a singlet at 6.55 δ (3 position proton), a multiplet at 7.2 δ (aromatic), and the NH and HCl proton absorption bands far downfield. Other data are in Table II.

2-Morpholinomethyl-7-phenylthioindole (VId)—The procedure described for VI*a* was followed. The infrared spectrum of the hydrochloride ($CHCl_3$) showed $\nu_{max.}$ 3225 cm.$^{-1}$ and a broad NH absorption band in the region 2630 cm.$^{-1}$ and 2120 cm.$^{-1}$. The NMR spectrum of the hydrochloride ($CDCl_3$) showed multiplets at 3.15 and 3.9 δ (morpholino methylenes), a singlet at 4.4 δ (CH_2), a singlet at 6.6 δ (3 position proton), a multiplet at 7.2 δ (aromatic), and the NH and HCl proton absorption bands far downfield.

Absorption Kinetics of Griseofulvin in Man

By M. ROWLAND, S. RIEGELMAN, and W. L. EPSTEIN

The distribution and elimination kinetics of griseofulvin have been examined in man. The drug was administered intravenously in polyethylene glycol 300 *via* a saline drip. The plasma-concentration time curve was satisfactorily described by a bi-exponential equation, the half-life for the first exponent was found to be 0.70–1.7 hr. and the second 9.5–21.0 hr. It was also shown that the area under the plasma-concentration time curve was proportional to the dose administered. Griseofulvin was then given orally and from the plasma concentration, the kinetics of the absorption of this drug were calculated. Absorption was found to occur up to 30 hr. after administration and 27–72.5 percent of the dose was absorbed.

SINCE ITS introduction in 1958 (1) griseofulvin still remains the only effective oral antifungal agent for the treatment of dermatophytic infections and much interest has been shown in the absorption of this drug. It was the evidence of Sharp and Tomich (2), that the oral toxicity in rats and mice was much lower than that following intraperitoneal administration, which first led to the suggestion that griseofulvin may be incompletely absorbed. This was confirmed by Davis *et al.* (3) who recovered 30–64% of an oral dose in the feces of rats. Numerous workers have since shown inefficient absorption of griseofulvin in man and have increased the degree of absorption by reduction of particle size (4–9), concomitant administration of fat (10, 11), and the preparation of a supersaturated solution of the drug in polyethylene glycol (PEG) 400 (12). However, only a change in the degree of absorption has been demonstrated and in no case has the actual amount of drug absorbed been assessed in man. The present paper reports a study of the kinetics of distribution, metabolism, and excretion following intravenous administration of griseofulvin in man. A standard dose of micronized griseofulvin was then given orally and both the percentage of drug absorbed and the kinetics of absorption were determined.

EXPERIMENTAL

Intravenous Study—A parenteral product of griseofulvin in PEG 300 (30 mg./ml.) was prepared as follows. Griseofulvin (recrystallized from benzene) was suspended in PEG 300 (Union Carbide), the suspension flushed with N_2, and autoclaved for 30 min. at 121°. Autoclaving resulted in solution of the griseofulvin in the PEG 300. The concentration of griseofulvin was determined by accurately weighing about 1 Gm. of the preparation and diluting to 100 ml. with spectroscopic grade ethanol. A 100-fold dilution of the ethanolic solution was prepared in distilled water (approximately 3 mcg. griseofulvin/ml.) and the absorbance measured at 292 mμ. The concentration of griseofulvin was calculated by reference to a standard curve of griseofulvin in 1% v/v ethanol in water (no absorbance at 292 mμ was observed with PEG 300 after autoclaving and assaying in the above manner).

Five healthy Caucasian male volunteers, 35 to 48 years of age, were used in the study. Each subject received griseofulvin intravenously, usually at two dose levels on occasions at least 1 week apart. The dose of griseofulvin 90–180 mg. (3–6 ml. PEG 300) was administered over a 3–6 min. period with a Harvard infusion pump (model 600-900) and diluted into a saline drip just before entering the vein. The drip was run in at 15 ml./min. so as to ensure that no precipitation of griseofulvin occurred in the vein. In one subject the drug was infused at a known constant rate for 2 hr., with the saline drip adjusted accordingly. The infusion pump was fitted with a 10-ml. glass syringe which had previously been calibrated so that the volume of PEG preparation administered was accurately known. Blood samples (5 ml.) were usually drawn at 0, 0.5, 1, 2, 3, 4, 5, 7.5, 10, 24, 28, 32, 36, and 48 hr. after drug administration. The sample was collected in a heparinized test tube, centrifuged, and the plasma stored at 4° until required for analysis.

Oral Study—The same volunteers as in the intravenous study were used. Each subject ingested one 0.5-Gm. micronized griseofulvin tablet (McNeil, Grifulvin, batch No. EL 9066) on an empty stomach with approximately 200 ml. water and no food was taken for at least 3 hr. Blood samples (5 ml.) were drawn at 0, 1, 2, 3, 4, 5, 6, 8, 11, 24, 28, 32, 36, and 48 and occasionally up to 72 hr. after drug administration. At least 1 month later the study was repeated in four subjects. The blood samples were collected and stored as in the intravenous study. All subjects had the same diet and were instructed to avoid drugs and food which might interfere with griseofulvin assay (especially salicylates).

Spectrophotofluorometric Assay of Griseofulvin—The plasma concentration of griseofulvin was determined by the method of Fischer and Riegelman (13) with the following modification. Plasma (0.5–1.0 ml.) was pipeted into a centrifuge tube containing 1.5 ml. distilled water, and extracted with 7 ml. distilled diethyl ether. A 5-ml. aliquot of the ether

extract was pipeted into a weighing bottle, evaporated to dryness, and redissolved in 5 ml. of triple distilled water. After reading the fluorescence of the sample, activation wavelength 315 mμ (uncorrected) and fluorescent wavelength 450 mμ (uncorrected), 0.2 ml. of 6 *M* sulfuric acid was added to 2 ml. of the sample and the fluorescence again noted. The change in fluorescence before and after the addition of acid was used to calculate the concentration of griseofulvin. A standard curve was obtained by reading the fluorescence of known aqueous solutions of griseofulvin (0.01, 0.02, 0.04, 0.1, 0.2 mcg./ml.) before and after the addition of acid.

In the intravenous studies, it was found necessary to be able to determine levels as low as 0.1 mcg. griseofulvin/ml. plasma. With the previous assay, this was not possible as blank values equivalent to 0.2–0.3 mcg. griseofulvin/ml. plasma were frequently obtained. However, griseofulvin does not fluoresce in strongly acidic aqueous media (pH less than 1.0), whereas very little change occurred with blank plasma samples. This modification in the assay procedure enabled the blank reading to be reduced to less than 0.03 mcg./ml.

Calculation of the Absorption of Griseofulvin—The absorption of drug at various times was calculated by the method of Loo and Riegelman (14).

$$\text{Amount absorbed } A_t = VpCp + k_{13}Vp\int_0^t Cpdt + VpC_T \quad \text{(Eq. 1)}$$

$$\text{and percent of absorbed drug } \left(\frac{A_t}{A_\infty} \times 100\right) = \frac{\left[C_p + k_{13}\int_0^t Cpdt + C_T\right]}{k_{13}\int_0^\infty Cpdt} \times 100 \quad \text{(Eq. 2)}$$

where A_t is the cumulative amount of drug absorbed at time t, and Cp, C_T are the corresponding plasma concentration and tissue concentration (calculated and expressed relative to the plasma) at time t, while $\int_0^t Cpdt$ and $\int_0^\infty Cpdt$ are the areas under the concentration-time curve up to time t and infinity, respectively; k_{13} is the rate constant for metabolism and excretion and Vp is the volume of the central compartment. The equation is essentially one of mass balance in that the amount of drug absorbed at any time is the summation of that in the central compartment ($VpCp$), that eliminated ($k_{13}Vp\int_0^t Cpdt$) and that in the tissue compartment (VpC_T). As with the Wagner-Nelson method (15) the value of A_t/Vp is calculated until an asymptote (A_∞/Vp) is reached indicating that absorption has ceased. The total amount of drug absorbed was calculated by the following equation:

$$\text{percent administered dose absorbed} = \frac{\text{dose}_{\text{i.v.}}}{\text{dose}_{\text{oral}}} \times \frac{\left(\int_0^\infty Cpdt\right)_{\text{oral}}}{\left(\int_0^\infty Cpdt\right)_{\text{i.v.}}} \times 100 \quad \text{(Eq. 3)}$$

where $\left(\int_0^\infty Cpdt\right)_{\text{oral}}$ and $\left(\int_0^\infty Cpdt\right)_{\text{i.v.}}$ are the total areas under the plasma concentration-time curve which result from the oral and intravenous dose, respectively.

RESULTS AND DISCUSSION

Intravenous Study—Before the absorption kinetics of any drug can be adequately described, the pharmacokinetics following an intravenous dose of that drug must first be defined. In the case of griseofulvin, this presents a problem in that it is a neutral insoluble molecule (aqueous solubility 10 mcg./ml.) and one would require 10–20 L. of saline in order to give a 100–200 mg. dose. This difficulty may be overcome by administering griseofulvin in PEG 300 whereby a concentration of 30 mg./ml. is achieved. Although several of the low molecular weight polyethylene glycols were found to be suitable solvents for griseofulvin, PEG 300 was chosen owing to its low toxicity in man and its acceptance in several parenteral pharmaceutical products. As much as 80 ml. of this solvent has been given intravenously, over a 4-month period, without any reported ill effects (16). However, there is the problem of precipitation of griseofulvin in the vein if the PEG preparation were injected directly, and for this reason the product was given *via* a rapidly flowing intravenous saline drip.

In all the intravenous studies, it was found that the griseofulvin plasma level curve could be described by a bi-exponential equation (*e.g.*, Fig. 1). The initial, or distribution, phase had a half-life of approximately 1 hr. while the second or elimination phase had a half-life varying from 9.5 to 21.0 hr. (Table I). This bi-exponential curve can be interpreted in terms of a two-compartmental open system (17), as depicted in Fig. 2. From the bi-exponential equation, the distribution rate constants k_{12}, k_{21}, and the metabolism and excretion rate constant, k_{13}, were evaluated together with the sizes of the central (Vp) and peripheral (V_T) compartments (Table II). Since the urinary excretion of griseofulvin is negligi-

E	90	0.14	0.20	0.130	60,000	103,000
	180	0.17	0.21	0.130	64,000	116,000

[a] Calculations based on a 2-compartmental open system. [b] Vp = dose/A + B (see Table I). [c] $Vd_{ss} = Vp + V_T = Vp + k_{12}/k_{21}\ Vp$ (*Reference 21*).

ble, being less than 0.5% of the administered dose (18–20; personal observation), it may be ignored for the purpose of this model. Consequently the rate constant k_{13}, is almost exclusively associated with metabolism and it was found to have a twofold (0.08–0.16 hr.$^{-1}$) variation in this study (Table II).

In practice, there is probably at least a three-compartmental model, which would then give rise to a tri-exponential blood concentration-time curve. The first compartment into which griseofulvin distributes, depicted by a dotted circle in Fig. 2, can be considered to be the blood, liver, kidney, and other vascular rich tissues. This compartment is not seen, however, because the drug is infused over 3–6 min. so that griseofulvin can distribute into other tissues, such as muscle, skin and vascular rich fat tissue; consequently, the value of about 50,000 ml. for the central compartment (Vp) is much larger than one would have anticipated. However, as will be shown, absorption of griseofulvin is relatively slow compared to this initially expected, although not observed, distribution. Therefore, only a small error will occur in the calculation of the absorption of this drug by conceiving the body to be a two- instead of three-compartmental model. In contrast, since the observed apparent distribution phase is approximately 5 hr. following the i.v. dose (Fig. 1) any absorption rate calculations for griseofulvin must take this distribution phase into account, and therefore the model cannot be reduced further without introducing large errors.

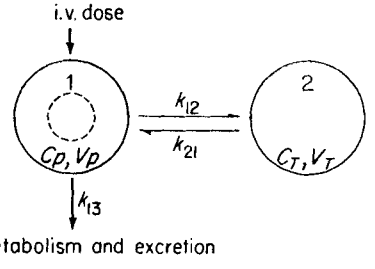

Fig. 2—Two-compartmental open model describing the distribution and elimination of griseofulvin in man. Key: 1, central compartment; 2, peripheral tissue compartment.

Regarding the second, or peripheral compartment, this can be considered to be the vascular poor fat tissue and is of significance owing to the high lipid solubility of griseofulvin. The size of this compartment is the same as that of the central compartment, so that the volume of distribution Vd_{ss} ($= Vp + V_T$; *Reference* 21) is approximately 100 L. indicating a marked extravascular concentration of this drug. It should be emphasized here, however, that the above model does not necessarily have any physiological meaning, but rather is the minimum model required to fit the data.

Another prior requirement to any quantitative absorption measurements from plasma level data is that the area under the plasma-concentration time curve must be proportional to the dose administered. This relationship was shown to hold with griseofulvin following intravenous doses of 90–180 mg. (Table I). In addition, the values of the rate constant k_{12}, k_{21}, and k_{13}, are essentially unchanged between studies showing that these parameters do not vary with time (Table II). These findings are contrary to that noted in rabbits when no relationship between an i.v. dose and the corresponding area could be established (13). The latter result may be explained by the very large interanimal

variation which these workers observed and the difficulty in using any rabbit repeatedly. In one study where they did manage to use an animal on three occasions, proportionality between dose and area appeared reasonably linear.

Oral Study—In the reported intravenous studies it was shown that, under the condition of administration, the data may be fitted by a two-compartmental open system model. Prior to proceeding to analyze data obtained after administering the dose orally, it was deemed essential to prove that the method of analyzing the resultant blood data will result in a true assessment of the absorption rate of griseofulvin. Therefore, griseofulvin was infused at a known zero-order rate (12.8 mg./min.) for 2 hr. From the values of the constants, k_{13}, k_{12}, and k_{21}, previously determined after a single rapid intravenous injection, the amount entering the body with time was calculated according to the method of Loo and Riegelman (14). The calculated absorption rate data are shown in Fig. 3 while in the insert are the plasma levels resulting from the single intravenous and zero-order infusion to that subject. The excellent fit between the known, 12.8 mg./min., and estimated, 12.4 mg./min. rate of infusion (absorption) of the drug shows that both the proposed model and the method of calculation for the absorption of this drug are acceptable.

Typical griseofulvin plasma levels following the oral dose of 0.5 Gm. micronized drug are shown in Figs. 4 and 5, together with their corresponding intravenous data. Without the intravenous study a long biological half-life might be calculated for this drug whereas in this study the levels are shown to be primarily the result of prolonged griseofulvin absorption. In fact, the dosage form exhibits the properties of a prolonged release product in that a plasma level is rapidly achieved and then maintained for 10–20 hr. Subsequent analysis of the area under the concentration time curves, following the oral and intravenous dose, shows that only 27–72% of the drug was absorbed (Table III). This not only demonstrates the variable and incomplete absorption of this drug but also illustrates one of the difficulties in trying to assess factors which might increase the extent of absorption. Obviously, the area under the plasma concentration-time curve for the person absorbing 72% drug can only increase by a further 39% whereas a 270% increase can occur with the person absorbing only 27%. Hence, the suggestion that the former was a poor responder to such factors could be misleading if, at the same time, the actual amount of drug absorbed was not determined. A further complication is that the absorption from

D	12 May	58.4	48.5
	25 July	32.4	27.0
E	28 June	33.4	52.3
	25 July	46.0	72.5

[a] Following an oral dose of 0.5 Gm. micronized griseofulvin.

repeated doses of the same batch of griseofulvin is not reproducible resulting in large differences in some subjects (Table III).

Several workers have used the rationale that the area under the concentration time curve is a measure of "available griseofulvin" (4–6). This is a satisfactory response parameter only if a suitable crossover experiment is designed. However, Duncan *et al.* (6) noted a threefold variation in this parameter within a group of subjects on a standardized preparation of griseofulvin and inferred that this was due to absorption differences within this group. Obviously caution must be taken before relating area to absorption alone. In Table III both Subjects C and D gave an area value of 32.4 mcg. hr./ml. Whereas this indicates 58% drug absorption with the former, it only corresponds to 27% in the latter subject. The reason for this is clear from the following relationship:

$$\text{Area}\left(\int_0^\infty Cpdt\right) = \frac{\text{dose absorbed}}{k_{13}Vp} \quad \text{(Eq. 4)}$$

Therefore, a low area can be attributable to either poor absorption, fast metabolism (high k_{13}), or a high Vp value. With Subjects C and D, the volume Vp was essentially the same and the difference in amount absorbed for the same area is primarily due to the metabolic rate constant (k_{13}) being twice as large in Subject C as in Subject D (Table II). Consequently, within a given group on a single dose study differences in absorption can only be ascertained by reference to the intravenous dose.

Additional information was obtained by calculating the amount of griseofulvin absorbed at various times following drug ingestion (Fig. 6). From such data, it is seen that of the total drug absorbed approximately 50% occurs in the first 3–10 hr. Thereafter, absorption continues but much more slowly for a further 20–30 hr. suggesting that absorption probably takes place along the majority of the gastrointestinal tract.

Analysis for the absorption rate from the cumulative absorption plots demonstrates even more strikingly the rapid rate of absorption throughout the first 2–3 hr. following ingestion of griseofulvin (Fig. 7). After this period the absorption rate drops sharply even though only 7–28% of the drug has been absorbed. One possible explanation is that dissolution of the drug from griseofulvin particles may rate limit the absorption process in the upper part of the gut,

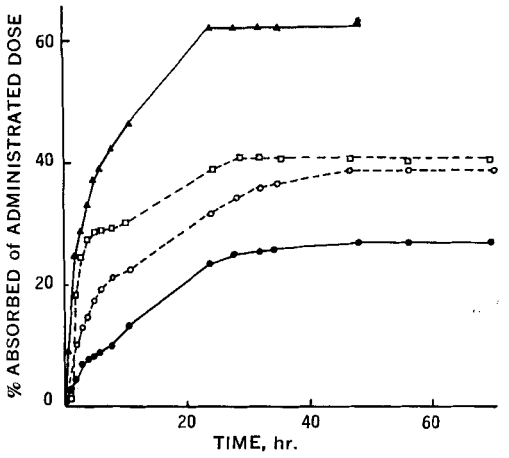

Fig. 6—Cumulative amount of griseofulvin absorbed following oral administration of 0.5 Gm. micronized griseofulvin. Key: ○, Subject A; □, Subject B; ▲, Subject C; ●, Subject D.

while further along intestinal absorption becomes the rate-limiting step. The finding by Davis *et al.* (3), that plasma griseofulvin levels fell while substantial amounts of griseofulvin was still present in the alimentary tract of rats, favors this hypothesis. Bedford *et al.* (18), suggested a simlar rationale for the absorption of this drug in cats. Alternately, the present results may have a physical rather than a biological explanation. Thus, it might be assumed that a certain fraction of the dose occurred as microfine readily dispersed particles which rapidly dissolved and was easily absorbed while a larger fraction was less readily available due to a much smaller surface for dissolution. Further studies are under way to distinguish between these two proposed explanations.

The present results confirm those of previous workers in showing that griseofulvin absorption is incomplete in man and was found to be 27–72% of the administered dose in this study. Absorption of

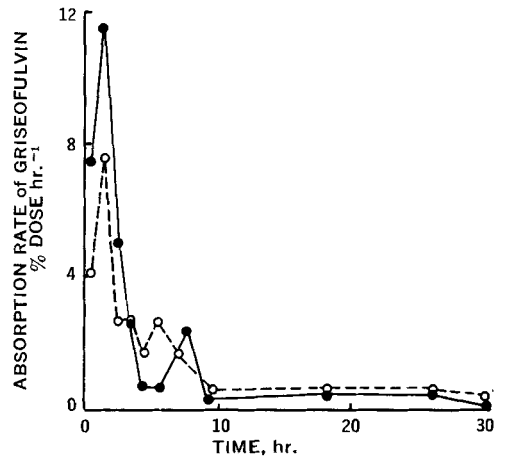

Fig. 7—Rate of absorption of griseofulvin after oral administration of 0.5 Gm. micronized drug to man. Key: ●, Subject C; ○, Subject D.

this drug was slow and whether it is due to physical or physiological factors has yet to be ascertained. Polyethylene glycol 300 has proved to be a useful solvent for griseofulvin and this and other low molecular weight polyethylene glycols might enable the pharmacokinetics of other insoluble neutral drugs to be evaluated in man.

Analgesic and Anti-Inflammatory Evaluation of Thymotic Acid and Certain Homologs

By FRED J. MAROZZI and MARVIN H. MALONE

Ortho-thymotic acid and nine homologs were submitted for general, analgesic, and antistress evaluations in the rat. While all appeared to be nonspecific central nervous system depressants, only 2-methyl-5-*tert*-butylsalicylic acid appeared to have significant analgesic ability in the rat tail flick test. 2-Hydroxy-4-methyl-5-isopropylbenzoic acid, 2-hydroxy-4-isopropyl-6-methylbenzoic acid, and 2-hydroxy-3-methyl-6-isopropylbenzoic aicd were superior to sodium salicylate and inferior to morphine sulfate in providing significant protection from stress induced by unilateral hind leg tourniquets. The latter two compounds were active in suppressing the acute inflammatory process produced by pedal injection of carrageenin, but were ineffective against chronic inflammation induced by the *Mycobacterium butyricum* adjuvant.

O'BRIEN AND Thoms (1) investigated the antipyretic and analgesic activity of the sodium salts of *o*- and *p*-thymotic acid in 1958. Von Kaulla (2) demonstrated in 1965 that *o*-thymotic acid possessed significant fibrinolytic activity. More recently, Rader and Wulf (3) investigated the fibrinolytic activity of nine homologs of *o*-thymotic acid on the human and cat fibrinolytic systems and were able to show that several compounds possessed significant fibrinolytic activity beyond that of *o*-thymotic acid. The present investigation is concerned with the analgesic and general evaluation of certain of these homologs along with *o*-thymotic acid, itself.

EXPERIMENTAL

The compounds shown in Table I were obtained in limited amounts from the Division of Medicinal Chemistry of the University of Connecticut. This group was selected so as to reveal possible structure–activity relationships. Table I also summarizes the fibrinolytic activity of the various homologs as determined by Rader and Wulf (3, 4).

this drug was slow and whether it is due to physical or physiological factors has yet to be ascertained. Polyethylene glycol 300 has proved to be a useful solvent for griseofulvin and this and other low molecular weight polyethylene glycols might enable the pharmacokinetics of other insoluble neutral drugs to be evaluated in man.

inary gross observational screen of all test compounds. Adult albino Holtzman rats (320–500 Gm.) were injected intraperitoneally using at least three logarithmetically spaced dosage levels (at least one of which was lethal), and qualitative and semiquantitative symptomatology was observed and noted on a standardized work sheet (5) at the required times.

Tail Flick Studies—A conduction dolorimeter (Metro Scientific Inc., Long Island, N.Y.) was used to measure the rat tail flick response to a thermal stimulus. The apparatus was modified by the addition of a photo cell in series with a timer in order to provide more accurate recordings of reaction times. Adult albino rats of the Wistar strain (Steinhilber) weighing between 125–150 Gm. were used for the initial analgesic evaluation of each test compound. Each compound was tested on at least five animals per dosage level. All test compounds and the two reference standards (morphine sulfate and sodium salicylate) were injected intraperitoneally in 0.25% agar after determination of control reaction times. Reaction times were again determined at +15, 30, 45, 60, and 120 min. after injection. A reaction time of 20 sec. was considered indicative of 100% analgesia and any animal failing to respond within 20 sec. was manually removed from the dolorimeter. Percent analgesia was calculated for each animal according to the following formula:

$$\% \text{ analgesia} = \left[\frac{R_x - C_0}{20 - C_0}\right] 100$$

where R_x = reaction time in sec. of an individual rat at time x; C_0 = the control reaction time in seconds of the same individual at time 0. Due to the limited amounts of drug available, the compounds were screened for analgesic activity at only one dosage level (100 mg./Kg.). This dosage was considered to be sublethal and without major CNS effects considering the hippocratic screening data.

Hepatic Glutathione Depletion—The methods used were essentially those described by Cooper *et al.* (6). Adult male rats of the Wistar strain (Steinhilber) ranging in weight between 260–375 Gm. were injected intraperitoneally with the test compounds dissolved or suspended in 0.25% aqueous agar. One-half hour after this injection, unilateral right hind limb tourniquets were tied around the thigh muscle proximal to the hip joint using heavy suture thread (Dermalon skin sutures, size 3). Food and water were allowed *ad libitum*. Four hours after the application of the tourniquets the rats were sacrificed by cranio-vertebral dislocation and peripheral portions of the central lobe of the liver (approximately 2 Gm.) were excised immediately and frozen using dry ice. Sacrifice of all animals was arranged so as to occur between the hours of 3:30 and 7:30 p.m. to control for the diurnal variation in liver sulfhydryl content reported by Beck (7). Hepatic glutathione (GSH) levels were determined amperometrically according to the method described by Benesch and Benesch (8, 9). Filtrates of the liver samples were prepared by homogenizing 500 mg. wet weight of liver in 10 ml. of 2.5% sulfosalicylic acid, followed by centrifugation and filtration. Aliquots of each filtrate were then titrated using 0.0005 *N* silver nitrate and a rotating platinum electrode (10).

Acute Antiphlogistic Evaluation—Using methods similar to those described by Winter *et al.* (11), nonfasted male and female Wistar strain rats (Steinhilber) were randomized into 12 cages (2 males and 2 females per cage) to which the test treatments were randomly assigned. Volume changes in the rats' paws were recorded using a modified plethysmographic apparatus similar to that described by Harris and Spencer (12). All drugs were administered orally as aqueous suspensions in 0.25% agar to hydrated animals. One hour after drug administration, 0.05 ml. of a 1.0% suspension of carrageenin in sterile physiological saline was injected into the plantar aponeurosis of the left hind paw. Volume changes in the injected paw were recorded 3 hr. later. The antiphlogistic properties of the three compounds tested were compared statistically to a series of reference agents using Duncan's multiple-range test (13).

Chronic Anti-Inflammatory Activity—Young adult male albino rats (Steinhilber) were used in this study. Foot thickness was determined daily with a vernier caliper for both the injected and contralateral paws. The inflammatory state was induced by the injection of 0.05 ml. of a suspension of desiccated *Mycobacterium butyricum* cells in light liquid petrolatum prepared according to the method of Nuss (14, 15). The test drugs were administered orally daily (100 mg./Kg.) as aqueous suspensions in 0.25% agar for a period of 13 days after which drug treatment was discontinued. Measurements of body weight and foot thickness were continued for another 17 days. Both food and water were freely accessible throughout the test period, and consumption records were maintained. The percent inhibition of the inflammatory response on days 13 and 30 of the test period was calculated according to the following formula (16):

$$\% \text{ inhibition} = 100\left[\frac{1 - (a - x)}{(b - y)}\right]$$

where y = mean injected foot thickness of control rats before injection; b = mean injected foot thickness of control rats on a particular day (13th or 30th); x = mean injected foot thickness of treated rats before injection, and a = mean injected foot thickness of treated rats on a given day (13th or 30th). Thirty animals constituted the control group, and five rats were used for each of the test treatments.

RESULTS AND DISCUSSION

Qualitative Screening—All of the compounds tested were qualitatively similar in their gross pharmacologic effects. Dose-response patterns for decreased motor activity were seen as well as generalized central nervous system depression. The latter appeared to be nonspecific and was characterized by decreased spontaneous motor activity, ataxia, and decreased skeletal muscle tone. Analgesia was evaluated subjectively by observing an animal's response to sharp pressure applied to one of the hind paws by the operator's thumb nail. Analgesia, when noted, was accompanied by ataxia. Compound I differed from all others in that some delayed onset stimulatory activity was noted. *Para*-thymotic acid (VII), in addition to CNS depression, induced personality changes (fearful reactions) at all doses studied (56.2, 100, 177.8, 316.2 mg./Kg.). The following gross estimates of the intraperitoneal lethal dosages were made: compound VI and VII: $\leqslant 100$; compound V, VIII, IX, and X: $\leqslant 237$; compound II and IV: $\leqslant 316$; compound III: $\leqslant 562$; compound I: $\leqslant 1{,}000$ mg./Kg.

Tail Flick Studies—As shown in Table II, the rat tail flick evaluation indicated either a lack of or a very low order of analgesic activity for all compounds tested with the exception of morphine sulfate. This is consistent with the fact that thermal methods have proven generally unsatisfactory for the detection of nonnarcotic analgesics except when these drugs have been administered in very high doses.

Decreased reaction time from preinjection values for the 0.25% agar control animals is indicated by a tendency for "negative analgesia" as shown in Fig. 1.

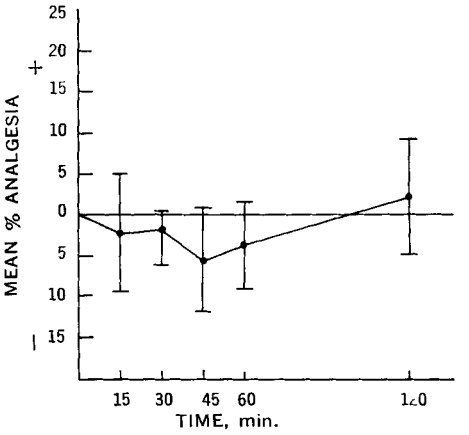

Fig. 1—Analgesic effect of 25 control rats receiving 0.15% aqueous agar solution intraperitoneally, 5 ml./Kg. I, 95% C.L.

This is indicative of a conditioning phenomenon whereby animals prematurely react to sensations of warmth rather than at the actual painful stimulus. Individual variation among control rats (as indicated by 95% C.L. in Fig. 1) was quite small and remained constant at the various times of measurement. In contrast, large variations were observed in responses after the test compounds. These large variances are consistent with similar results which have been reported in the literature (17). The very wide range of values which was seen following 10 mg./Kg. of morphine sulfate, a very potent analgesic, indicated that the extreme values encountered with the test homologs need not be considered aberrant. Of all the test compounds, only compound V may have some analgesic potential since significant analgesia was detected up through the 60-min. readings. In contrast, compound IV definitely appeared to facilitate the pain response, and compound III, likewise.

The study of O'Brien and Thoms (1) concluded that *o*- and *p*-thymotic acid possessed both analgesic and antipyretic activity. Using Davies' modification of the classical D'Amour-Smith technique (17), they reported sodium *o*-thymotate to possess 15 times the analgesic activity of sodium salicylate and

TABLE II—ANALGESIC SCREENING OF TEST COMPOUNDS AND REFERENCE ANALGESICS

Treatment	Mean % Analgesia +15	+30	+45	+60	+120 min.
Control[a]	−2	−2	−6	−4	+2

V	100	9	150.3	0.08	>0.50
VI	100	9	160.3	0.96	>0.50
VII	100	10	193.2	4.30	0.025–0.05
VIII	100	10	212.0	17.02	<0.001
IX	100	10	222.8	15.10	0.001–0.005
X	100	10	221.5	27.02	<0.001

one-tenth the activity of morphine sulfate. In the present study neither *o*- nor *p*-thymotic acid were found to possess significant analgesic activity. The discrepancy between these results and those of O'Brien and Thoms appears to lie in the manner chosen for the evaluation of the tail flick data.

Hepatic Glutathione Depletion—The effectiveness of unilateral hind leg tourniquets in inducing hepatic depletion of glutathione was clearly demonstrated. Statistical comparison of animals receiving 5 ml./Kg. of a 0.25% aqueous agar solution and no tourniquet (no pain) to animals receiving the same dose of agar and unilateral hind leg tourniquets for 4 hr. revealed a highly significant difference between the two means (Table III). In all comparisons, the variances of the control animal populations and the respective test animal populations were not significantly different at $p = 0.05$ (F test).

When the test compound means were compared to tourniquet means, morphine sulfate (10 mg./Kg.), sodium salicylate (400 mg./Kg.), and compounds VII, VIII, IX, and X (100 mg./Kg.) could be considered active ($p < 0.05$). Although tested only at one dosage level, the degree of effectiveness relative to each other can be estimated from the levels of significance presented in Table III. Morphine and compounds VIII, IX, and X all have definite protective capacity, as compared to the moderate activity of sodium salicylate and the slight but detectable effects of compound VII. Considering mg./Kg. dosage levels, compounds VIII, IX, and X are clearly more potent than sodium salicylate but less potent than morphine sulfate. The highly significant protection afforded by morphine indicated the nonspecificity of protection from hepatic GSH depletion as a biochemical metameter for nonnarcotic analgesia. Takesue and Miya (18) have reported protective activity with morphine sulfate (10 mg./Kg.) and phenobarbital (50 mg./Kg.), and concluded that protection from liver GSH depletion is not specific for the nonnarcotic analgesics. The finding that sodium salicylate was able to provide some protection from GSH depletion is significant inasmuch as this compound has been reported (18) as being capable of inducing hepatic GSH depletion (in small doses) in the absence of stress (tourniquets). This observation may be a reflection of the diurnal variation in rat sulfhydryl reported by Beck (7) in 1958.

The exact mechanisms whereby a drug may prevent stress-induced hepatic GSH depletion are at present unknown. It has been postulated that activation of the adrenal medulla under stress with resulting release of epinephrine and increased intermediary metabolism may be responsible for this phenomenon (19). This seems to be supported by Krimsky and Racker's finding that glutathione functions as a prosthetic group in glyceraldehyde-3-phosphate dehydrogenase (20), however, the mechanism (or mechanisms) by which a drug may interfere with the normal hepatic glutathione depletion induced by stress are not immediately accessible from current data and literature reports. Hepatic GSH depletion appears to be more indicative of biochemical alterations induced by stress rather than a true metameter of pain, however, the stress component in the human experience of pain cannot be neglected.

It is interesting to observe that compound V which appeared most active of the homologs in the rat tail flick evaluation (as well as equivocally active compounds III and IV) did not prevent stress-induced GHS depletion. Only compound VIII of the homologs appeared active by both techniques (equivocal: rat tail flick; highly significant: GSH depletion protection).

Acute Antiphlogistic Evaluation—Table IV shows a division of the various treatments employed in this study into subsets according to their relative activity at the administered doses. This Table indicates that while chlorpromazine, cryogenine, papain, compound VIII, and compound X were all significantly different from the controls at a dosage of 100 mg./Kg. orally ($p < 0.05$), indomethacin was clearly the most potent compound tested (5 mg./Kg.).

Chronic Anti-Inflammatory Activity—The results of a chronic anti-inflammatory screen of compounds VIII and X are presented graphically in Figs. 2 and 3. Compound IX was not tested by this procedure due to its lack of activity during the acute anti-inflammatory testing (Table IV) and general scarcity of the compound. Figure 2 indicates that compound VIII was of no benefit in reducing the inflammatory state and, in fact, appeared to aggravate the inflammatory response. Compound X (Fig. 3) did not affect the inflammatory state since the plotted test data closely parallel that of the large control population. Figure 4 depicts the anti-inflammatory response profile of acetylsalicylic acid, an agent of known effectiveness. None of the test agents significantly affected food and water consumption and rate of weight gain. The percentage inhibition of the increase in thickness of the injected foot of the animals treated with compound VIII was −10 and

TABLE IV—MULTIPLE-DRUG COMPARISONS OF ANTI-INFLAMMATORY ACTIVITY IN RATS WITH ACUTE CARRAGEENIN-INDUCED PEDAL EDEMA

Treatment	Oral Dosage, mg./Kg.	Mean Increase in Paw Volume, ml.	Significant Subsets[a]
Control	—	0.45(0.37–0.56)[b]	A
Control	—	0.44(0.39–0.54)	A
IX	100	0.46(0.38–0.64)	A
X	100	0.40(0.34–0.54)	B
VIII	100	0.36(0.31–0.40)	B
Papain	100	0.35(0.29–0.40)	B
Cryogenine[c]	100	0.27(0.19–0.36)	B
Indomethacin	5	0.22(0.18–0.31)	B
Chlorpromazine	100	0.21(0.05–0.33)	B

[a] The treatments effects represented by A and B differ significantly from each other ($p < 0.05$); however, the treatments within these subsets do not differ significantly ($p \geq 0.05$) from one another. [b] The figures within the parentheses represent the observed range of the four experimental values. [c] An alkaloid from *Heima salicifolia* Link and Otto recently shown to have anti-inflammatory potency (15).

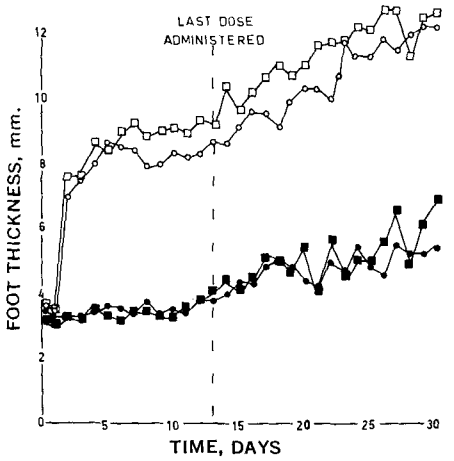

Fig. 2—Effect of 2 weeks of daily oral administration of 100 mg./Kg. of compound VIII on the development of adjuvant-induced polyarthritis. Key: ○, mean width of injected foot (controls); ●, mean width of contralateral foot (controls); □, mean width of injected foot (VIII); ■, mean width of contralateral foot (VIII).

−7% on Days 13 and 30, respectively. The calculated values for compound X were −0.3% on Day 13 and +1% on Day 30. The effectiveness of aspirin in inhibiting the inflammatory response in this study is indicated by a +33% inhibition on Day 13 and a +29% inhibition on Day 30.

SUMMARY

General hippocratic screening indicated that *o*-thymotic acid and nine homologs possessed some CNS depressant activity of a rather nonspecific nature. Rat tail flick data indicated a general lack of morphine-like analgesic activity, although 2-methyl-5-*tert*-butylsalicylic acid appeared to have some potential. Evidence obtained from hepatic glutathione depletion assays indicated that 2-hydroxy-4-isopropyl-6-methylbenzoic acid, 2-hydroxy-4-methyl-5-isopropylbenzoic acid, and 2-hydroxy-3-methyl-6-isopropylbenzoic acid may have some antistress effects being more potent than sodium salicylate and less potent than morphine sulfate in this regard. Only 2-hydroxy-4-isopropyl-6-methylbenzoic acid and 2-hydroxy-3-methyl-6-isopropylbenzoic acid were shown to have some acute anti-inflammatory activity, although their potency was clearly inferior

Lag Time Before Essentially Constant Urinary Excretion Rate Is Attained

By JOHN G. WAGNER and JACK I. NORTHAM

If a substance is continuously infused intravenously at a constant rate, the plasma concentration will increase until it reaches an asymptotic concentration. If the urinary excretion rate of the substance is directly proportional to its plasma concentration, the urinary excretion rate will become essentially constant as the asymptotic plasma concentration is approached. Analogously, if a metabolite is formed at a constant rate, due to saturation of an enzyme system metabolizing the drug, the plasma concentration of the metabolite would be expected to approac hsome asymptotic concentration. If the urinary excretion rate of the metabolite is directly proportional to its plasma concentration, the urinary excretion rate of the metabolite would become essentially constant as the asymptotic plasma concentration is approached. Equations were derived to estimate the lag time between initiation of the maintained constant input rate to the plasma compartment and the time when, for all practical purposes, the asymptotic plasma concentration and the constant urinary excretion rate may be considered to have been reached for both the one- and two-compartment open models. The theoretical expectation is that, if the cumulative excretion curve is nearly linear, then there must be an appreciable negative intercept when the line is extrapolated back to zero time. It is theoretically impossible for a cumulative urinary excretion curve to be linear and the line extrapolate through the origin corresponding to zero excretion at zero time.

IF A SUBSTANCE is continuously infused intravenously at a constant rate the blood (serum or plasma) concentration will increase until it reaches an asymptotic value (1). However, as the curves of Rescigno and Segre (1) and Wagner and Nelson (2) illustrate, it requires an appreciable time to approach the asymptotic concentration. If the urinary excretion rate of the substance is directly proportional to its plasma concentration, then the urinary excretion rate will become essentially constant, and the cumulative urinary excretion curve will become essentially linear, as the asymptotic plasma concentration is approached.

Analogously, if a metabolite is formed at a constant rate, due to saturation of the enzyme system metabolizing the drug, the plasma concentration of the metabolite would be expected to approach some asymptotic value,

Lag Time Before Essentially Constant Urinary Excretion Rate Is Attained

By JOHN G. WAGNER and JACK I. NORTHAM

If a substance is continuously infused intravenously at a constant rate, the plasma concentration will increase until it reaches an asymptotic concentration. If the urinary excretion rate of the substance is directly proportional to its plasma concentration, the urinary excretion rate will become essentially constant as the asymptotic plasma concentration is approached. Analogously, if a metabolite is formed at a constant rate, due to saturation of an enzyme system metabolizing the drug, the plasma concentration of the metabolite would be expected to approac hsome asymptotic concentration. If the urinary excretion rate of the metabolite is directly proportional to its plasma concentration, the urinary excretion rate of the metabolite would become essentially constant as the asymptotic plasma concentration is approached. Equations were derived to estimate the lag time between initiation of the maintained constant input rate to the plasma compartment and the time when, for all practical purposes, the asymptotic plasma concentration and the constant urinary excretion rate may be considered to have been reached for both the one- and two-compartment open models. The theoretical expectation is that, if the cumulative excretion curve is nearly linear, then there must be an appreciable negative intercept when the line is extrapolated back to zero time. It is theoretically impossible for a cumulative urinary excretion curve to be linear and the line extrapolate through the origin corresponding to zero excretion at zero time.

IF A SUBSTANCE is continuously infused intravenously at a constant rate the blood (serum or plasma) concentration will increase until it reaches an asymptotic value (1). However, as the curves of Rescigno and Segre (1) and Wagner and Nelson (2) illustrate, it requires an appreciable time to approach the asymptotic concentration. If the urinary excretion rate of the substance is directly proportional to its plasma concentration, then the urinary excretion rate will become essentially constant, and the cumulative urinary excretion curve will become essentially linear, as the asymptotic plasma concentration is approached.

Analogously, if a metabolite is formed at a constant rate, due to saturation of the enzyme system metabolizing the drug, the plasma concentration of the metabolite would be expected to approach some asymptotic value,

Received November 2, 1967, from the Upjohn Company, Kalamazoo, MI 49001

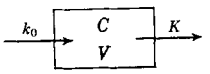
after a certain time. If the urinary excretion rate of the metabolite is directly proportional to its plasma concentration, then the urinary excretion rate of the metabolite will become essentially constant, and the cumulative urinary excretion curve will become essentially linear, as the asymptotic plasma concentration of the metabolite is approached. In the case of a metabolite some finite additional time would also be required for absorption of the drug and build up of blood concentration of unchanged drug which would be necessary before an enzyme system couid become saturated. This additional time would have to be added to the lag time between initiation of the constant (zero-order) formation rate and the time the asymptotic plasma concentration is approached, to estimate the total time required for the cumulative urinary excretion curve to become essentially linear.

The two most common pharmacokinetic models, which apply to the above situations, are the one- and two-compartment open models. One purpose of this report is to show how one may estimate for these models the time lag necessary between the start of the zero-order input into the plasma compartment and the time when, for all practical purposes, the asymptotic plasma concentration and the constant urinary excretion rate is attained. Another purpose is to show how the maximum excretion rate may be estimated before it is attained if the rate constant for elimination is known.

EXPERIMENTAL

One-Compartment Open Model

Intravenous Infusion at a Constant Rate—The model is shown in Scheme I. Here k_0 is the constant (zero-order) infusion rate with dimensions mass/time, V is the apparent volume of distribution, and C is the plasma concentration of the substance infused at time t, and K is the first-order rate constant for elimination by all processes. For this model the appropriate classical equation *during the infusion* is:



Scheme I

$$C = \frac{k_0}{VK}(1 - e^{-Kt}) \qquad \text{(Eq. 1)}$$

where t is the time from the start of the infusion. If urinary excretion rate is directly proportional to plasma concentration, then

$$dA_u/dt = fVKC \qquad \text{(Eq. 2)}$$

where dA_u/dt is the urinary excretion rate and f is the fraction of substance reaching the plasma compartment which is ultimately excreted in the urine. Substitution of Eq. 1 into Eq. 2 and simplifying gives

$$dA_u/dt = fk_0(1 - e^{-Kt}) \qquad \text{(Eq. 3)}$$

Let t_a be the time that the excretion rate reaches some proportion, p, of the maximum rate, fk_0. Then,

$$dA_u/dt = p.f.k_0 \qquad \text{(Eq. 4)}$$

when

$$e^{-Kt_a} = 1 - p \qquad \text{(Eq. 5)}$$

Taking logarithms of both sides of Eq. 5 we find

$$t_a \simeq 3/K \qquad \text{when } p = 0.95 \qquad \text{(Eq. 6)}$$

$$t_a \simeq 4.6/K \qquad \text{when } p = 0.99 \qquad \text{(Eq. 7)}$$

If one substitutes $\ln 2/t_{1/2}$ for K, where $t_{1/2}$ is the half-life, into Eq. 5, takes logarithms, and rearranges, one finds

$$t_a = -1.443 \ln (1 - p) \cdot t_{1/2} \qquad \text{(Eq. 8)}$$

Hence,

$$t_a/t_{1/2} = 4.322 \qquad \text{when } p = 0.95 \qquad \text{(Eq. 9)}$$

and,

$$t_a/t_{1/2} = 6.645 \qquad \text{when } p = 0.99 \qquad \text{(Eq. 10)}$$

Hence, the time, t_a, for the excretion rate to reach the same proportion, p, of the maximum rate, fk_0, and the plasma concentration to reach the same proportion, p, of the asymptotic value, k_0/VK, is directly proportional to the half-life of elimination if the one-compartment open model applies.

Integration of Eq. 3 yields

$$A_u = fk_0\left[t - \left(\frac{1 - e^{-Kt}}{K}\right)\right] \qquad \text{(Eq. 11)}$$

where A_u is the cumulative amount excreted in the urine to time t. Substitution of values for f, k_0, K, and various t values would yield a curve of A_u *versus* t by application of Eq. 11. If one chose two points, $(A_u^{T_2}, T_2)$ and $(A_u^{T_1}, T_1)$, on this curve, joined them with a straight line, then extrapolated the line back to time zero corresponding to an intercept $(A_u)_{t=0}$, then the slope, $\Delta A_u/\Delta t$, of the line may be shown to be

$$\frac{\Delta A_u}{\Delta t} = fk_0\left[1 - \left\{\frac{e^{-KT_1} - e^{-KT_2}}{K(T_2 - T_1)}\right\}\right] \qquad \text{(Eq. 12)}$$

The value of the intercept may be shown to be:

$$(A_u)_{t=0} = \frac{fk_0}{K}\left[\left(\frac{T_2e^{-KT_1} - T_1e^{-KT_2}}{T_2 - T_1}\right) - 1\right] \qquad \text{(Eq. 13)}$$

The equation of such a line will be:

$$\hat{A}_u = \left(\frac{\Delta A_u}{\Delta t}\right)t - (A_u)_{t=0} \qquad \text{(Eq. 14)}$$

The line will cross the time axis when $\hat{A}_u = 0$ at a point, $t_{(A_{u=0})}$, given by

$$t_{(A_{u=0})} = \frac{(T_2 - T_1) - (T_2e^{-KT_1} - T_1e^{-KT_2})}{K(T_2 - T_1) - (e^{-KT_1} - e^{-KT_2})} \qquad \text{(Eq. 15)}$$

Utilizing Eqs. 12 through 15 we can show that

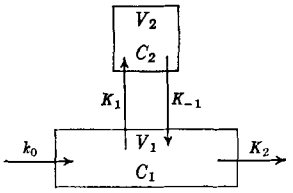
$$k_0 = \frac{(A_u)_{t=0}}{t_{(A_u=0)}\left[1 - \left\{\frac{e^{-KT_1} - e^{-KT_2}}{K(T_2 - T_1)}\right\}\right]} \quad \text{(Eq. 16)}$$

Hence, if an estimate of K is available, one may estimate the maximum excretion rate, fk_0, even from a markedly curved segment of the cumulative excretion plot.[1]

Metabolite Formation at a Constant Rate—If a metabolite is formed at a constant rate, then Scheme I may apply but the symbols have to be redefined. In this case k_0 would be the constant formation rate, V would be the volume of distribution, C the plasma concentration of the metabolite at time t, and K would be the first-order rate constant for elimination of the metabolite by all processes. If the metabolite was completely excreted in the urine (*i.e.*, $f = 1$), then K would be the first-order rate constant for urinary excretion of the metabolite. The same equations as above would apply.

Two-Compartment Open Model

Intravenous Infusion at a Constant Rate—The model is shown in Scheme II.



Scheme II

Here k_0 is the constant (zero-order) infusion rate with dimension mass/time; K_2 is the first-order rate constant for elimination of the substance infused by all processes; V_1 is the volume of the inner (plasma) compartment; and C_1 is the concentration of the substance infused in this compartment at time t; V_2 is the volume of the outer compartment, and C_2 is the concentration of the substance infused in this compartment at time t; K_1 is a first-order rate constant representing the instantaneous fraction of substance in the inner compartment being transferred to the outer compartment; and $K_{-1} = (V_1/V_2)K_1 = VK_1$, where $V = V_1/V_2$.

The solutions of the appropriate differential equations for this model were given by Gaudino (3). Rewritten in the nomenclature of Wagner and Northam (4) the equation for the concentration, C_1, is:

$$C_1 = \frac{k_0}{V_1K_2}\left[1 - \left(\frac{K_2 - \beta}{\alpha - \beta}\right)e^{-\alpha t} + \left(\frac{K_2 - \alpha}{\alpha - \beta}\right)e^{-\beta t}\right] \quad \text{(Eq. 17)}$$

where

$$\alpha = {}^1/_2[(K_1 + K_2 + K_{-1}) + \sqrt{(K_1 + K_2 + K_{-1})^2 - 4K_{-1}K_2}] \quad \text{(Eq. 18)}$$

[1] One may also estimate fk_0 with only one point on the curve by use of Eq. 11.

$$\beta = {}^1/_2[(K_1 + K_2 + K_{-1}) - \sqrt{(K_1 + K_2 + K_{-1})^2 - 4K_{-1}K_2}] \quad \text{(Eq. 19)}$$

If D is the total dose infused and T is the infusion time, then

$$k_0 = D/T \quad \text{(Eq. 20)}$$

It should be noted that $\alpha > \beta$, and Eq. 17 only applies when $t < T$. If urinary excretion rate is directly proportional to the concentration C_1, then:

$$dA_u/dt = fV_1K_2C_1 \quad \text{(Eq. 21)}$$

Substitution of Eq. 17 into Eq. 21 and simplifying yields

$$dA_u/dt = fk_0\left[1 - \left(\frac{K_2 - \beta}{\alpha - \beta}\right)e^{-\alpha t} + \left(\frac{K_2 - \alpha}{\alpha - \beta}\right)e^{-\beta t}\right] \quad \text{(Eq. 22)}$$

If t_a is the time required for the excretion rate to reach some proportion, p, of the maximum rate, fk_0, then

$$dA_u/dt = p.f.k_0 \quad \text{(Eq. 23)}$$

when

$$\left(\frac{K_2 - \beta}{\alpha - \beta}\right)e^{-\alpha t_a} - \left(\frac{K_2 - \alpha}{\alpha - \beta}\right)e^{-\beta t_a} = 1 - p \quad \text{(Eq. 24)}$$

Division by K_2 in Eq. 24 yields

$$(1 - \beta/K_2)e^{-\alpha/K_2(K_2t_a)} - (1 - \alpha/K_2)e^{-\beta/K_2(K_2t_a)} - (1 - p)\left(\frac{\alpha}{K_2} - \frac{\beta}{K_2}\right) = 0 \quad \text{(Eq. 25)}$$

For given V_1/V_2 and K_1/K_2 ratios, α/K_2 and β/K_2 remain constant, so that for a given p, the value of K_2t_a is unique. Based on Eqs. 18, 19, and 25 a digital computer program was written which allowed print-out of t_a and $t_a/t_{1/2}$, where $t_{1/2} = \ln 2/K_2$, for given values of V_1/V_2, K_1/K_2, K_2, and p. For $p = 0.95$ and 0.99, $K_1/K_2 = 0.1$, 0.25, 0.5, 1, 2, 5, 10, and 100 and $V_1/V_2 = 0.125$, 0.25, 0.5, 1, 2, 4, and 8, values of $t_a/t_{1/2}$ were estimated. Hence 112 values of $t_a/t_{1/2}$ were calculated and these values served as the basis for Figs. 1 and 2.

Integration of Eq. 22 yields

$$A_u = fk_0\left[t - \frac{(K_2 - \beta)}{\alpha(\alpha - \beta)}(1 - e^{-\alpha t}) + \frac{(K_2 - \alpha)}{\beta(\alpha - \beta)}(1 - e^{-\beta t})\right] \quad \text{(Eq. 26)}$$

One may plot a curve of A_u *versus* t by substituting appropriate values into Eq. 26. If one chose two points, $(A_u{}^{T_2}, T_2)$ and $(A_u{}^{T_1}, T_1)$, on this curve, joined them with a straight line, then extrapolated the line back to zero corresponding to the intercept, $(A_u)_{t=0}$, then the slope, $\Delta A_u/\Delta t$, of the line may be shown to be

$$\Delta A_u/\Delta t = fk_0\left[1 - \frac{1}{T_2 - T_1}\left\{\frac{K_2 - \beta}{\alpha(\alpha - \beta)}(e^{-\alpha T_1} - e^{-\alpha T_2}) - \frac{K_2 - \alpha}{\beta(\alpha - \beta)}(e^{-\beta T_1} - e^{-\beta T_2})\right\}\right] \quad \text{(Eq. 27)}$$

The value of the intercept may be shown to be

$$(A_u)_{t=0} = fk_0\left[\left(\frac{V+1}{V}\right)\left(\frac{1}{K_2}\right) - \frac{K_2-\beta}{\alpha(\alpha-\beta)}\left\{e^{-\alpha T_2} + \frac{T_2}{T_2-T_1}(e^{-\alpha T_1} - e^{-\alpha T_2})\right\} + \frac{K_2-\alpha}{\beta(\alpha-\beta)}\left\{e^{-\beta T_2} + \frac{T_2}{T_2-T_1}(e^{-\beta T_1} - e^{-\beta T_2})\right\}\right] \quad \text{(Eq. 28)}$$

The equation of the line is as given by Eq. 14 except the slope and intercept are defined by Eqs. 27 and 28. The line will cross the time axis at a point, $t(A_{u=0})$, given by

$$t(A_{u=0}) = \frac{\left(\frac{V+1}{V}\right)\left(\frac{1}{K_2}\right) - \frac{K_2-\beta}{\alpha(\alpha-\beta)}\left\{e^{-\alpha T_2} + \frac{T_2}{T_2-T_1}(e^{-\alpha T_1} - e^{-\alpha T_1})\right\} + \frac{K_2-\alpha}{\beta(\alpha-\beta)}\left\{e^{-\beta T_2} + \frac{T_2}{T_2-T_1} \times (e^{-\beta T_1} - e^{-\beta T_2})\right\}}{1 - \frac{1}{T_2-T_1}\left\{\frac{K_2-\beta}{\alpha(\alpha-\beta)}(e^{-\alpha T_1} - e^{-\alpha T_2}) - \frac{K_2-\alpha}{\beta(\alpha-\beta)}(e^{-\beta T_1} - e^{-\beta T_2})\right\}} \quad \text{(Eq. 29)}$$

Utilizing Eqs. 27 through 29 one can show that

$$fk_0 = \frac{(A_u)_{t=0}}{t(A_{u=0})\left[1 - \frac{1}{T_2-T_1}\left\{\frac{K_2-\beta}{\alpha(\alpha-\beta)}(e^{-\alpha T_1} - e^{-\alpha T_2}) - \frac{K_2-\alpha}{\beta(\alpha-\beta)}(e^{-\beta T_1} - e^{-\beta T_2})\right\}\right]} \quad \text{(Eq. 30)}$$

It should be noted that as T_1 and T_2 become large then

$$(A_u)_{t=0} \to fk_0\left(\frac{V+1}{V}\right)\left(\frac{1}{K_2}\right), \quad t(A_{u=0}) \to \left(\frac{V+1}{V}\right)\left(\frac{1}{K_2}\right), \Delta A_u/\Delta t \to fk_0$$

and

$$fk_0 \to (A_u)_{t=0}/t(A_{u=0})$$

Metabolite Formation at a Constant Rate—If a metabolite is formed at a constant rate, then Scheme II may apply but the symbols have to be redefined. In the metabolite case, k_0 would be the constant formation rate and K_2 would be the first-order rate constant for elimination of metabolite by all processes. If the metabolite was completely excreted in the urine (*i.e.*, $f = 1$), then K_2 would be the first-order rate constant for urinary excretion of the metabolite, V_1 would be the volume of the inner compartment, C_1 the concentration of metabolite in this compartment at time t; V_2 would be the volume of the outer compartment, and C_2 the concentration of metabolite in this compartment at time t. K_1, K_{-1}, and f would have the same significance except the reference to metabolite rather than unchanged drug. Then Eqs. 17 through 30 would apply.

RESULTS

Table I gives values of the lag time, t_a, corresponding to different half-lives and rate constants for the one-compartment open model. The lag times listed were calculated with Eqs. 9 and 10.

Figures 1 and 2 are plots of the ratio $t_a/t_{1/2}$ *versus* K_1/K_2 on log-log scales for the two-compartment open model. Here $t_{1/2}$ is the half-life of elimination estimated from K_2 (*i.e.*, $t_{1/2} = \ln 2/K_2$). Figure 1 gives values of $t_a/t_{1/2}$ when $p = 0.95$, and Fig. 2 gives value of $t_a/t_{1/2}$ when $p = 0.99$. The values of t_a were estimated with an appropriate digital computer program based on Eqs. 18, 19, and 25.

Figure 3 has two examples illustrating use of Eqs. 11 through 16. Letting fk_0 be 1 unit/hr. and K be 1.0 hr.$^{-1}$, values of A_u corresponding to t = 0.5, 1, 1.5, 2, 2.5, 3, 3.5, 4, and 4.6 hr. were calculated using Eq. 11; these correspond to the circled points in Fig. 3. Letting T_1 = 1.5 hr. and T_2 = 3.0 hr., a straight line was drawn joining the ($A_u{}^{T_2}$, T_2) and ($A_u{}^{T_1}$,T_1) points and the line extrapolated back to zero time; the equation of this line is $\hat{A}_u = 0.8845t - 0.6037$ corresponding to Eq. 14. Hence this line intersects the ordinate at $(A_u)_{t=0} = -0.6037$ and it crosses the time axis at the point $t(A_{u=0}) = 0.6825$ hr. The slope, $\Delta A_u/\Delta t$, estimated from these points, is 0.8845 indicating the excretion rate has reached only 88.45% of its maximum value. Using Eq. 16, however, the true maximum excretion rate of unity may be estimated. Letting T_1 = 3.0 hr. and T_2 = 4.6 hr., another straight line was drawn joining the points corresponding to these times, and the line was extrapolated back to the ordinate; the equation of this line is $\hat{A}_u = 0.9752t$

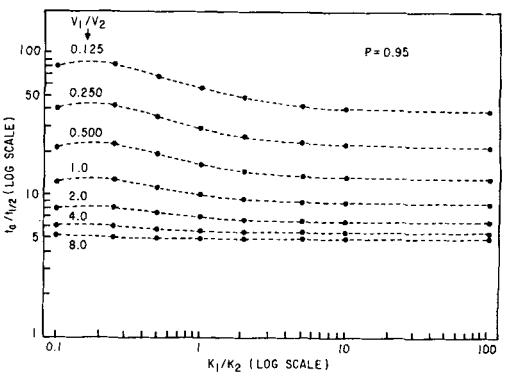


Fig. 1—Plot of the ratio $t_a/t_{1/2}$ versus *the ratio* K_1/K_2 *on a log-log scale for the two-compartment open model when* p = 0.95.

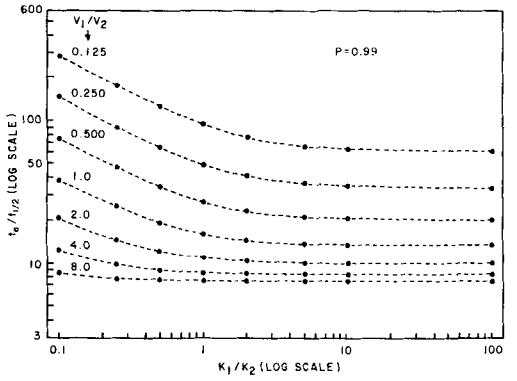

Fig. 2—Plot of the ratio $t_a/t_{1/2}$ *versus the ratio* K_1/K_2 *on a log-log scale for the two-compartment open model when* p = *0.99.*

— 0.8758 corresponding to Eq. 14. Hence this second line intersects the ordinate at $(A_u)_{t=0}$ = −0.8758 and it crosses the time axis at the point $t(A_{u=0})$ = 0.8981 hr. The slope, $\Delta A_u/\Delta t$, estimated from these points, is 0.9752 indicating that the excretion rate has reached 97.5% of its maximum value. Using Eq. 16 the time maximum excretion rate of unity may be estimated.

Figure 4 has two examples illustrating use of Eqs. 26 through 30. Letting fk_0 = 1 unit/hr., K_2 = 1 hr.$^{-1}$, K_1 = 5 hr.$^{-1}$, and V_1/V_2 = 2, use of Eqs. 18, 19, and 26 allowed calculation of the plotted points in the figure corresponding to the same times as in the one-compartment case. A straight line was drawn joining the points corresponding to 1.5 and 3.0 hr. and the line was extrapolated back to time zero; this line has the equation $\hat{A}_u$ = 0.7606 t − 0.5965. This line intersects the ordinate at $(A_u)_{t=0}$ = −0.5965 and it crosses the time axis at the point $t(A_{u=0})$ = 1.153 hr. The slope, $\Delta A_u/\Delta t$, estimated from these points, is 0.7606 indicating that the excretion rate has reached 76.06% of its maximum value. Using Eq. 30, however, the true maximum excretion rate of unity was estimated. A second straight line was drawn joining the points corresponding to 3.0 and 4.6 hr. and the line was extrapolated back to time zero; this line has the equation $\hat{A}_u$ = 0.9124t − 1.0518. This second line intersects the ordinate at $(A_u)_{t=0}$ = −1.0518 and it

crosses the time axis at the point $t(A_{u=0}) = 1.153$ hr. The slope of 0.9124 indicates the excretion rate has reached 91.24% of its maximum value. Using Eq. 30 the true maximum excretion rate of unity may be estimated.

DISCUSSION

Cummings and Martin (5, 6) advanced theoretical considerations suggesting that the first-order rate constant for urinary excretion of a metabolite will not exceed 3 hr.$^{-1}$ and that it will probably not exceed 1 hr.$^{-1}$, even if the metabolite exhibits the maximum renal clearance. In light of this a maximum value of $K = 3$ hr.$^{-1}$ was used in Table I, and a value of $K = 1$ hr.$^{-1}$ was used in constructing Fig. 3 for the one-compartment open model. Analogously, a value of $K_2 = 1$ hr.$^{-1}$ was used in constructing Fig. 4 pertaining to the two-compartment open model.

Although an observed cumulative urinary excretion curve may *appear* linear before the theoretically required lag time for a given half-life of elimination, it would be wise to use the equations and figures in this report as a guide to the expectation of linearity of such curves. Cumulative urinary excretion curves are extremely insensitive indicators (2, 7–9). The excretion rate time plot, corresponding to the cumulative plot, should always be drawn also (7, 9). One would be unwise to infer constant formation rate of a metabolite, for example, unless the excretion rate time plot indicated an essentially maximum sustained rate *which commenced after some lag time* estimated by Eqs. 8 or 24.

Analogously, if all the drug administered in a dosage form is suspected of being absorbed at a constant rate, then the same consideration would apply as discussed here for constant-rate intravenous infusion. In such a case one would not expect the plasma concentration to plateau, nor the urinary excretion rate to become nearly constant, until the drug had been released and absorbed at a constant rate for a period of time which may be estimated by means of Eqs. 8 or 24. Since gastrointestinal transit time past the absorbing surface area is limited, and since this period of time is near or less than the lag time, t_a, for most drugs predicted by the equations in this report, it would be a rare event for constant-rate absorption to lead to a constant blood level or a constant urinary excretion rate after a single dose of drug in such a dosage form. For example, assume the one-compartment open model applies to the drug. If the half-life of elimination is 2.77 hr., corresponding to a rate constant of 0.25 hr.$^{-1}$, it would require about 12 hr. to reach 95% of the asymptotic plasma concentration and about 28 hr. to reach 99% of the asymptotic plasma concentration if the drug entered the blood at a constant rate. Gastrointestinal transit times *at the absorbing surface area* are usually of this order of magnitude or less.

If a metabolite is formed at a constant rate, due to saturation of an enzyme system metabolizing the drug, the above considerations indicate that it is theoretically impossible for the plot giving the cumulative urinary excretion of the metabolite as a function of time to be linear *and* the line extrapolate through the origin corresponding to zero excretion at zero time.

It should be noted that $t_a/t_{1/2}$ for the two-compartment open model is always greater than the corresponding value for the one-compartment open model for a given p value and when $0.125 \leq V_1/V_2 \leq 8$ and $0.1 \leq K_1/K_2 \leq 100$. Also, for given values of p and K_1/K_2, $t_a/t_{1/2}$ increases as V_1/V_2 decreases for the two-compartment open model. The examples shown in Figs. 3 and 4 are illustrative of the situation with very polar metabolites and drugs with short half-lives since a rate constant of 1 hr.$^{-1}$, corresponding to a half-life of 0.693 hr., was used in their construction. If the half-life of elimination is greater, the time scale on comparable plots would become greater. For example, Table I indicates that if the half-life of elimination is 6.93 hr. and the one-compartment model applies, then it would require 30 hr. to reach 95% of the maximum excretion rate if there was zero-order input to the blood; it would require greater than 30 hr. if the two-compartment open model applied.

CONCLUSIONS

The theoretical expectation is that if the cumulative urinary excretion curve is essentially linear, due to zero-order rate of formation of a metabolite or constant-rate intravenous infusion, then there must be an appreciable negative intercept when the linear portion is extrapolated back to zero time.[2] It is theoretically impossible for a cumulative urinary excretion curve to be linear *and* the line extrapolate through the origin corresponding to zero excretion at zero time.

[2] Proof of this for both the one- and two-compartment open models has been provided. Intuitively, one would expect the conclusions to hold for any compartment model.

Validation of Methanol-Sulfuric Acid Colorimetry as a Stability Assay Method for Quinestrol by Comparison with a Gas Chromatographic Procedure

By LESTER CHAFETZ, MICHAEL G. BOUDJOUK, DIMITRI C. TSILIFONIS, and FOO SONG HOM

Excellent correlation was obtained between assay values by the methanol-sulfuric acid colorimetric method and a highly selective gas-chromatographic procedure, the specificity of which was demonstrated by separations on two different columns. Quinestrol, ethinyl estradiol 3-cyclopentyl ether, was assayed by both methods after intentional degradation by heating long periods in hydrogen peroxide, hydrochloric acid, or sodium hydroxide solutions, and the identifiable products were measured quantitatively by gas chromatography. The colorimetric method was found to be a valid stability assay for quinestrol.

COLORIMETRIC DETERMINATION of quinestrol, ethinyl estradiol 3-cyclopentyl ether, provides a facile and accurate means for measuring microgram amounts of the estrogen in dosage forms. Since colorimetry eliminates the need for specialized apparatus and technique and provides a considerable advantage in speed, it is preferred to the use of chromatographic techniques for routine and, especially, for occasional assays. The purpose of the study reported here was to determine the validity of the colorimetric assay used in these laboratories for determination of quinestrol in the presence of its degradation products.

The pink color formed by reaction of ethinyl estradiol or its 3-ethers, quinestrol and mestranol, with a methanol–sulfuric acid reagent was shown to be a highly selective means for determining these estrogenic steroids by Tsilifonis and Chafetz (1); several closely related estrogens give either no color or noninterfering yellow colors under the prescribed conditions. Khoury and Cali (2, 3) recently described a fluorometric assay for ethinyl estradiol and mestranol which makes use of 90% sulfuric acid as the fluorogenic reagent. The reaction product with either reagent appears to be identical. Excitation and fluorescence spectra obtained with methanol–sulfuric acid reagent and ethinyl estradiol and its ethers are identical with those reported by use of 90% sulfuric acid, and the methanol–sulfuric acid fluorophore has been used to measure nanogram amounts of quinestrol contamination in other drug dosage forms here.

Khoury and Cali (2, 3) inferred that sulfuric acid-induced fluorescence is specific for undegraded ethinyl estradiol from their finding that only the undegraded steroid gave a fluorescent spot on a thin-layer chromatogram of thermally or photochemically degraded material. This report describes validation of the previously reported colorimetric assay (1) as a stability method for quinestrol dosage forms. A linear correlation is demonstrated between assay results obtained by the colorimetric method and a specific gas chromatography procedure on quinestrol samples partly degraded by heating with acid, alkali, or hydrogen peroxide. A colorimetric procedure which obviates interference from ethinyl estradiol, the gas chromatographic method, and observations on the stability of quinestrol is presented here.

EXPERIMENTAL

Equipment and Supplies—Absolute methanol, Phillips "pure" grade isooctane, and common laboratory reagents were used. Ethinyl estradiol USP, estrone 3-cyclopentyl ether (Warner-Vister Institute), estrone NF, and quinestrol reference standard were used in this study. The separators used in the colorimetric assay were fitted with Teflon stopcocks. Absorbance measurements were made in 1-cm. silica cells in a Beckman DU instrument and a Cary model 14 recording spectrophotometer. The gas chromatographic instrument and operating parameters are described below.

The *chromogenic reagent* was made by cautiously

adding concentrated sulfuric acid to 30.0 ml. of chilled methanol in a 100-ml. volumetric flask, in small increments and with frequent agitation so that the mixture was made to the mark at room temperature. Too rapid addition of acid to alcohol results in a yellow reagent.

Degradation with Peroxide—Mixtures of 2.0 ml. of 1 mg./ml. methanolic quinestrol were heated at reflux in 250-ml. flasks with 50 ml. of methanol and 50 ml. of water containing 0.5, 1.0, 1.5, or 2.0 ml. of 30% hydrogen peroxide solution for about 22 hr. in one set of experiments and about 40 hr. for another. The mixtures were evaporated to dryness under reduced pressure in a rotary-film apparatus at about 40°. The residue was taken up in 15 ml. of chloroform and washed three times with 5-ml. volumes of water to remove residual peroxide. The washed chloroform was evaporated to dryness, and the residue was dissolved in 3.0 ml. of chloroform. The samples were apportioned for colorimetric and gas chromatographic assay.

Acid and Base Degradation—Mixtures of 2.0 ml. of 1 mg./ml. quinestrol in methanol were heated at reflux in 250-ml. flasks with 50 ml. of methanol and 50 ml. of 0.1 *N*, 1.0 *N*, 3.0 *N*, or 6 *N* hydrochloric acid or with 0.1 *N* or 1 *N* sodium hydroxide for periods of about 20 hr. The solutions were neutralized and evaporated to dryness at about 40°. The residues were extracted with 15 ml. of chloroform, the extracts were evaporated to dryness, and the residues were taken up in 3 ml. of chloroform. Portions of each sample were taken as assay samples in each method.

Colorimetric Method—Prepare the *standard preparation* by the following procedure: accurately weigh about 50 mg. of reference standard quinestrol, dissolve it in methanol, and dilute the solution to 100 ml. Further dilute 2.0 to 50 ml. with methanol to obtain a 20 mcg./ml. solution.

Dilute 1.0 ml. of the chloroform sample obtained by partial degradation to 25 ml. with methanol. Transfer 1 ml. containing the equivalent of about 20 mcg. of quinestrol to a 125-ml. separator. Add 10 ml. of water and 5 drops of concentrated hydrochloric acid. Extract the mixture with about 75 ml. of isooctane, shaking for 2 min. Allow the phases to separate, and discard the lower layer. Quantitatively transfer the isooctane to a second, *scrupulously dry* separator through a solvent-wetted cotton pledget filter, using about 10 ml. of fresh isooctane to effect the transfer. Equilibrate the isooctane solution with exactly 5.0 ml. of *chromogenic reagent* by shaking 2 min. Discard 2–3 drops of the pink lower phase through the stopcock bore, and collect about 4.5 ml. of the pink solution into a 15-ml. glass-stoppered centrifuge tube. Withdraw by pipet exactly 4.0 ml. and add exactly 0.4 ml. of absolute methanol. Mix thoroughly, and centrifuge the contents to dispel air bubbles. Determine the absorbance of the solution, A_u, *versus* a solvent blank at the maximum, about 540 mμ.

Concomitantly develop a color with 1.0 ml. of the *standard preparation*, beginning with, "Add 10 ml. of water and 5 drops of concentrated hydrochloric acid." Designate the concentration of quinestrol in the standard in mcg./ml. as C and the absorbance obtained as A_s.

$$\text{quinestrol, mcg./sample} = A_u/A_s \times C \times \text{dilution factors}$$

Gas Chromatography—Place a volume of the sample used for the colorimetric assay equivalent to 10–100 mcg. of quinestrol in a 7-ml. glass vial. Add 1.0 ml. of an 80 mcg./ml. chloroform solution of *n*-dotriacontane,[1] the *internal standard*. Evaporate the solvent on the steam bath with the aid of a gentle stream of nitrogen. Take up the cooled residue with 0.2 ml. of chloroform. Mix thoroughly and inject 5 μl. on the column of the gas chromatograph. The following conditions were used:

1. A 1.2-m. 6-mm. (4 ft. 1/4 in. o.d.) glass U-tube column packed with 4% OV-17[1] on 80/100-mesh Gas Chrom Q[1] was used in an F & M Scientific model 402 instrument, which provides on-column injection and dual columns and detectors. The temperature was maintained isothermally at 253° for the column and 263° for the flame-ionization-detector chamber. Helium carrier gas flow rate was maintained at 120 ml./min. and hydrogen gas flow to the detector was set at 60 ml./min.

2. A second system was used as a check on separations, where all of the operating parameters were identical with the first, but the column used was a 1.2-m. 6-mm. o.d. glass U-tube packed with 3% SE-30 on 80/100 mesh Diatoport S.[2]

The response factor for quinestrol was determined by injecting 10-, 50-, and 100-mcg. amounts of quinestrol with the internal standard. Where the response of quinestrol is R_Q, the internal standard response R_I, the weight of internal standard W_I, and the weight of quinestrol standard W_Q:

$$\text{Factor } (F) = R_Q/R_I \times W_I/W_Q$$

The amount of quinestrol in the sample is calculated:

$$\text{mcg. quinestrol} = R_Q/R_I \times W_I/F$$

Response factors were determined in a similar manner for ethinyl estradiol, estrone, and estrone-3-cyclopentyl ether.

RESULTS AND DISCUSSION

Specificity of the Gas Chromatographic Assay—Quantitative results were obtained using the OV-17 column described in system 1 above, however, the separations were checked on the alternate column given in system 2. Correspondence of sample peak retention times to those of the standard substances in two systems provides a high degree of specificity of identification. The retention times obtained for the standard substances on the two columns are given in Table I. The only quinestrol degradation products found in significant amounts were ethinyl estradiol and, in one case, estrone-3-cyclopentyl ether (*v.i.*). Quantitative measurements were made by the peak height method.

Comparison of Methods—Both methods provided recoveries of 98%. Relative standard deviations were 1.7% for the colorimetric assay and 1.6% for the gas chromatographic procedure. As noted earlier (1), the colorimetric method does not distinguish between quinestrol and ethinyl estradiol, and it has been used in these laboratories with a thin-layer limit test for ethinyl estradiol. (A procedure for selective colorimetric assay of quinestrol in the presence of ethinyl estradiol is described

[1] Applied Science Laboratories, State College, Pa.
[2] F & M Scientific, Division of Hewlett-Packard, Avondale, Pa.

below.) Ethinyl estradiol was found in significant amounts, however, only in the experiments in which quinestrol was heated in at least 0.5 *M* hydrochloric acid for 20 hr. Figure 1 shows the correlation obtained by plotting the quinestrol assay value by the colorimetric method against the total of quinestrol and ethinyl estradiol (as quinestrol) determined by the gas chromatographic procedure. The close correspondence obtained between assay values on the same samples establishes the empirical colorimetric assay as a valid stability-indicating method for quinestrol, if provision is made to measure ethinyl estradiol by an independent method or eliminate it in the isolation scheme.

Degradation with Peroxide—Results obtained by both assay methods on the peroxide-degraded samples are presented in Table II. The pot temperature of the 50% methanol solutions was about 77°. Poor correlation was obtained between the amount of peroxide added and the percent of quinestrol which remained. This may reflect differences in handling the work-up after the reflux period, for residual peroxide was present in every case, and it would be concentrated during the evaporation steps. Failure to wash out peroxide residues led to low assays by the gas chromatographic procedure, indicating further reaction on the hot chromatographic column. The experimental design does not permit any estimates of the rate of quinestrol degradation by hydrogen peroxide, nor was this within the scope of the present study. Summation of the measurable peaks does not provide material balance; unidentified peaks were noted at retention times of 3.4 and 31.4 min. and on the reverse slope of the quinestrol peak (about 28 min.) using the OV-17 column.

Degradation with Acid—Heating quinestrol at reflux with 0.05 *M* hydrochloric acid in 50% methanol led to no detectable degradation. The amount of ethinyl estradiol formed by hydrolysis of the ether function increased with acid concentration as shown in Table III. The pot temperature was again about 77°. Unidentified peaks were noted in chromatograms run on the OV-17 column with the two higher concentrations of acid. A peak with a retention time of 34.6 min. was observed after heating with 1.5 *M* acid. Additional peaks were observed after heating with 3 *M* hydrochloric acid at 5.8, 14.6, 16.6, 41.8, and 50.4 min.

Table I—Retention Times of Standard Steroids on Two Columns

Compound	Retention Time, min. Column I	Retention Time, min. Column II
Estrone	8.0	3.2
Ethinyl estradiol	9.4	4.0
n-Dotriacontane	11.4	18.0
Estrone-3-cyclopentyl ether	22.4	9.0
Quinestrol	27.4	11.6

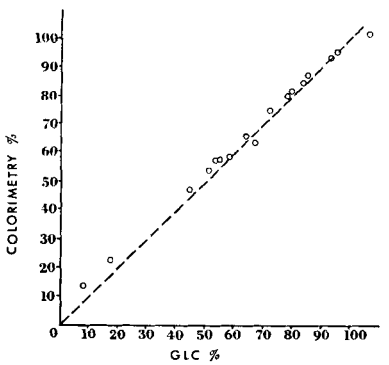

Fig. 1—Correlation of colorimetric and gas chromatographic assay values on degraded quinestrol samples. See text. Dashed line represents perfect correlation.

Degradation in Alkali—Heating quinestrol in 0.05 *M* alkali gave values of 95% quinestrol by the colorimetric method and 95.2% by gas chromatography. In this concentration of base, less than 1% of quinestrol was found converted to estrone-3-cyclopentyl ether, but unidentified peaks were noted with retention times of 1.6, 2.2, 3.2, and 5.2 min. In 0.5 *M* methanolic sodium hydroxide, 58% intact quinestrol was found by the colorimetric method and 54.7% by gas chromatography. Estrone-3-cyclopentyl ether was found in 6.5% concentration (expressed as quinestrol), and less than 1% estrone was seen. The unidentified peaks noted were the same as in the lower base concentration experiment. Talmage *et al.* (4) and Boughton and his co-workers (5) used estrone as the internal standard for gas chromatographic determination of ethinyl estradiol. It would appear that this is a poor choice, for the estrone is both a synthesis precursor and a possible degradation product. Langecker (6) has demonstrated the presence of estrone and acetylene after treating ethinyl estradiol with 1 *N* sodium hydroxide for 30 min.

Selective Colorimetric Assay for Quinestrol—The previously reported procedure (1) has been modified to provide fewer manipulations and to eliminate interference from ethinyl estradiol. The following procedure is recommended.

Transfer a weighed sample equivalent to about 20 mcg. of quinestrol to a 125-ml. separator containing 10 ml. of water and 1 ml. of methanol. Add 4–5 drops of concentrated hydrochloric acid, and extract the mixture with about 75 ml. of isooctane, shaking for 2 min. Allow the layers to separate, and discard the lower phase. Wash the isooctane layer with 5 ml. of 1 *N* sodium hydroxide, shaking the mixture about 1 min. Discard the alkali layer, and transfer the isooctane phase quantitatively to a second, *scrupulously dry* 125-ml. separator through a solvent-wetted cotton pledget filter, using about 10 ml. of fresh isooctane to effect the transfer. Continue the procedure as described above under *Colorimetric Method*, beginning with, "Equilibrate the isooctane solution with exactly 5.0 ml. of *chromogenic reagent*. . . ."

Use of 1 *N* sodium hydroxide to remove any ethinyl estradiol present was checked by adding 20- and 30-mcg. amounts of ethinyl estradiol to 20-mcg. amounts of quinestrol and going through the procedure described. There was no difference in absorbance values for quinestrol to which an equal or 1.5-fold excess of ethinyl estradiol was added and samples without added ethinyl estradiol. Recoveries of quinestrol added to placebo tablets were identical whether the alkali wash was used or water was employed.

SUMMARY AND CONCLUSIONS

Assay of quinestrol solutions partly degraded by heating with hydrogen peroxide, hydrochloric acid,

or sodium hydroxide by a colorimetric method (1) and by a highly selective gas chromatographic method shows excellent correlation in values. The colorimetric method has thus been established as a valid stability-indicating assay for quinestrol, providing that ethinyl estradiol is measured by an independent limit test or eliminated in the isolation scheme. Ethinyl estradiol was found in significant amount only in those samples degraded by heating in 0.5 *M* or stronger hydrochloric acid. The specificity of the gas chromatographic procedure used was established by obtaining separations on two different columns. Both provided excellent separations of quinestrol from ethinyl estradiol, estrone, estrone-3-cyclopentyl ether, and unidentified peaks noted in several of the chromatograms.

Gas-Liquid Chromatography of Niacin and Niacinamide

By A. R. PROSSER and A. J. SHEPPARD

A procedure has been developed for the qualitative and quantitative determination of niacin and niacinamide by gas-liquid chromatography. Niacin was determined as its ethyl ester (ethyl nicotinate) or as *N*-ethylnicotinamide. Niacinamide was determined as niacinamide or converted to either ethyl nicotinate or *N*-ethylnicotinamide. An immobile biphase of 2.5 percent NPGS–10 percent SE-30 was the most satisfactory immobile phase evaluated. The results revealed that, in general, this sensitive gas-liquid chromatographic method could detect 5, 8, and 10 ng. of ethyl nicotinate, *N*-ethylnicotinamide, and niacinamide, respectively, using the hydrogen flame-ionization detector. The β-argon ionization detector (Ra_{226}) detected 15, 20, and 25 ng. of each compound, respectively. It was found that increasing quantities of ethyl nicotinate, *N*-ethylniacinamide, and niacinamide gave linear responses.

NIACIN (nicotinic acid) and its analog niacinamide (nicotinic acid amide) are important members of the B-complex vitamins. Niacinamide is included as an ingredient in decavitamin capsule and tablet composition requirements of the USP (1).

Chemical and biological methods are now widely used. The 10th edition of "Official Methods of Analysis" of the A.O.A.C. (2) includes both a chemical and biological method; the USP method (1) is based on a chemical technique. The chemical methods generally utilize the König reaction (3, 4) in which pyridine and its derivatives react with cyanogen bromide and an aromatic amine. In this reaction polymethine dyes are formed and are measured spectrophotometrically at 450 mμ. However, the chemical method is undesirable because the color development is pH sensitive and has low stability, which makes it difficult to reproduce results.

Biological methods provide the most specific quantitative assay presently available. The dog and chicken have been used for biological assay for total niacin activity. However, microbiological methods have been more popular and are far more practical from the standpoint of sensitivity, time, and expense. The A.O.A.C. method (2) uses *Lactobacillus plantarum*, which measures total niacin activity and can be used to specifically assay nicotinic acid in the presence of nicotinamide if the latter is first converted to 3-aminopyridine (6). Johnson has used *Leuconostoc mesenteroides* to measure nicotinic acid (5).

A polarographic method (7) and a thin-layer chromatographic method (8, 9) are available but have not been widely accepted.

Although a number of satisfactory methods are available for their separation and identification, a more rapid and simple method specific for niacin and niacinamide is needed. Since previous work from this laboratory (10, 11) has shown that vitamin B_6 of the water-soluble vitamin series is amenable to gas-liquid chromatography (GLC), it was felt that niacin and its analogs could also be measured by GLC. The present report is a summary of the feasibility of utilizing the gas chromatograph for the analysis of niacin and niacinamide.

Received January 10, 1968, from the Division of Nutrition, Food and Drug Administration, Washington, DC 20204
Accepted for publication March 4, 1968.

EXPERIMENTAL

Instrumentation—A model 5000 series Barber-Colman gas chromatograph (Barber-Colman, Rockford, Illinois) fitted with a high temperature hydrogen flame-ionization detector (FID) and a β-argon ionization detector (AID) with a 56 μc Ra_{226} foil was used with a 5-mv., 2-sec., 28-cm.-(11-in.) strip-chart recorder.

Materials—Niacin, niacinamide, and ethyl nicotinate were purchased from Eastman Organic Chemicals, Distillation Products Industries, Rochester, New York. *N*-Ethylnicotinamide was purchased from Aldrich Chemical Co., Milwaukee, Wisconsin. Pure grade *n*-hexane was obtained from Phillips Petroleum Co., Special Products Division, Bartlesville, Oklahoma. All other reagents were A.R. grade and used without further purification. Whatman No. 4 filter paper was used for all filtrations.

Preparation of Derivatives—Ethyl nicotinate was prepared by two methods (12): (*a*) direct action of ethanol and sulfuric acid on either niacin or niacinamide; (*b*) interaction of niacin with thionyl chloride followed by the reaction of the nicotinyl chloride hydrochloride product with ethanol and subsequent neutralization. Two methods of preparing niacinamide were used: (*a*) treatment of ethyl nicotinate with concentrated ammonia (12); (*b*) action of thionyl chloride on niacin followed by treatment of the resulting acid chloride with ammonia (13). *N*-Ethylnicotinamide was prepared by the following reactions: (*a*) action of thionyl chloride on niacin and treatment of the resulting acid chloride with ethylamine hydrochloride; (*b*) direct action of ethylamine on niacin in the presence of phosphorus pentoxide; (*c*) action of an aqueous solution of ethylamine on ethyl nicotinate.

Standard Solutions—Niacinamide and *N*-ethylnicotinamide were dissolved in enough ethanol and ethyl nicotinate in enough *n*-hexane so that a constant injection volume of 2 μl. was maintained throughout the investigation. Calibration standards were prepared from commercially obtained materials.

Gas-Liquid Chromatography—Three different column packings were used in this study. Column

1: 183 cm. × 3 mm. i.d. packed with a biphase mixture of 2.5% neopentyl glycol succinate (NPGS) and 10% SE-30 (w/w) on 100/120 mesh Gas Chrom P (silanized). Operating conditions: ethyl nicotinate: column, 180°; detector, 230°; flash heater, 220°; carrier gas, 50 ml./min. Niacinamide and *N*-ethylnicotinamide: column, 230°; detector, 280°; flash heater, 270°; carrier gas, 50 ml./min. Column 2: 244 cm. × 3 mm. i.d. packed with 5% NPGS (w/w) on 100/120 mesh Gas Chrom P (silanized) for the analysis of ethyl nicotinate. Operating conditions: column, 180°; detector, 260°; flash heater, 250°; carrier gas, 80 ml./min. Column 3: 244 cm. × 4 mm. i.d. packed with 2% neopentyl glycol sebacate (NPGSeb) (w/w) on 100/120 mesh Gas Chrom P (silanized) for the analysis of niacinamide and *N*-ethylniacinamide mixtures. Operating conditions: column, 210°; detector, 250°; flash heater, 230°; carrier gas, 60 ml./min.

All columns were U-shaped Pyrex glass and were preconditioned 24 hr. at 235° with carrier-gas flow rate of 60 ml./min. Argon was used as the carrier gas throughout the study. Compressed air and hydrogen flow rates were 460 and 36 ml./min., respectively, with the FID. A d.c. cell voltage of 900 was used at all times with the AID. Electrometer output was 1×10^{-14} amp. when FID was used and 3×10^{-9} amp. when the AID was used. The electrometer output is stated as full-scale output into a 5-mv. recorder unless otherwise stated in the text. Peak areas were determined by triangulation (width at half-height × height = peak area).

RESULTS AND DISCUSSION

The applicability of gas chromatography to niacin is limited by the presence of an acid group in the niacin molecule, its insolubility in most organic solvents, and the fact that niacin sublimes. It was therefore necessary to convert niacin to a derivative volatile enough for GLC. Ethyl nicotinate and *N*-ethylnicotinamide were chosen because of their relatively low boiling points, ease of preparation, and stability. Although niacinamide has an amide group, it is soluble in some organic solvents, has a low melting point, and is suitable for GLC analysis.

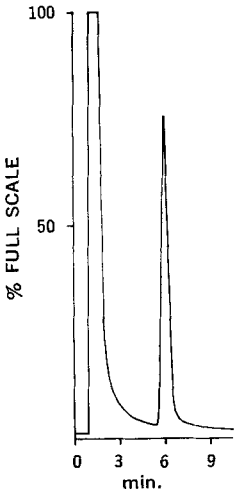

Fig. 1—Chromatograms of 1.0 mcg. ethyl nicotinate in n-hexane on a 2.5% NPGS–10% SE-30 biphase column at 180°.

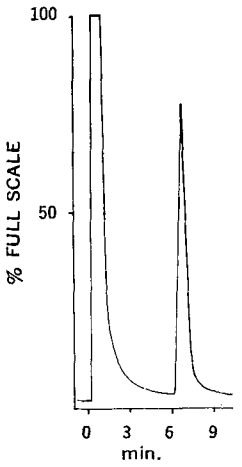

Fig. 2—Chromatogram of 2 mcg. niacinamide in ethanol on a 2.5% NPGS–10% SE-30 biphase column at 230°.

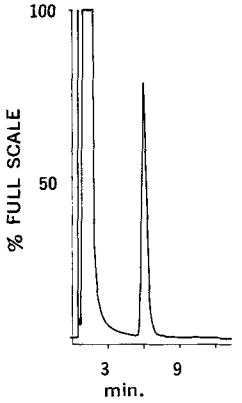

Fig. 3—Chromatogram of 1.25 mcg. ethyl nicotinate in n-hexane on a 5% NPGS column at 180°.

Derivative Preparation Efficiency—The yields of three derivatives were in good agreement with existing literature values (12, 13). GLC scans of the prepared derivatives indicated no contaminants present. The structures of the reaction products were confirmed by IR and UV spectroscopy.

Effect of Immobile Phase—The elution peaks of the three niacin analogs were typical adsorption isotherms on SE-30, QF-1, and biphase mixtures of NPGS–SE-30 when the ratio of NPGS to SE-30 was less than 1:4. The preceding immobile phases were rejected on the basis of their tailing adsorption isotherms. The 2.5% NPGS–10% SE-30 column at 180° gave a satisfacory elution peak for ethyl nicotinate (Fig. 1). When the temperature was increased to 230°, niacinamide produced a usable elution peak exhibiting slight tailing (Fig. 2). On this column, *N*-ethylniacinamide was found to precede niacinamide. The results suggest that by varying the column temperature and carrier solvents, GLC may be a potential means of screening for analogs of the vitamin.

Ethyl nicotinate exhibited a nearly symmetrical elution peak on the 5% NPGS immobile phase column (Fig. 3) whereas the other two analogs gave

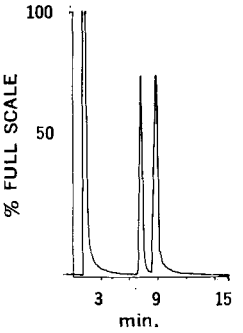

Fig. 4—Chromatogram of a mixture of 1.0 mcg. N-ethylniacinamide (7.6 min.) and 1.2 mcg. niacinamide (9.2 min.) on a 2% NPGSeb column at 210°.

broad tailing elution peaks at much longer retention times. The 2% NPGSeb column eluted *N*-ethylnicotinamide ahead of niacinamide (Fig. 4). At 210°, ethyl nicotinate was eluted along with the carrier solvent. This column will resolve all three niacin analogs at 180° but the retention times for *N*-ethylniacinamide and niacinamide are extended and the elutions peaks were quite broad and were, therefore, less desirable for quantitative analysis.

Effect of Quantity Injected—Response data for ethyl nicotinate, *N*-ethylnicotinamide, and niacinamide using the biphase column of 2.5% NPGS and 10% SE-30 are given in Table I. It can be seen from these data that as the quantity of compound increased the response was linear. The response lines for *N*-ethylnicotinamide and niacinamide are almost identical but the response line for ethyl nicotinate was not closely related to those of the other two analogs.

Sensitivity—The GLC method for niacin and niacinamide is very sensitive. By using the FID, an attenuator setting of 1, an electrometer output of 1×10^{-10} amp., and a 0–1-mv. recorder, 5 ng. of ethyl nicotinate and 10 ng. of niacinamide were detectable. The AID, with an attenuation of 1 and an electrometer output of 3×10^{-9} amp., detected 15, 20, and 25 ng. of ethyl nicotinate, *N*-ethylnicotinamide, and niacinamide, respectively. Quantitation at these low levels, however, is difficult because of the noise-to-signal ratio and because there is less control over the quantity injected.

CONCLUSIONS

It has been established that it is possible to detect and analyze three analogs of the vitamin niacin, *i.e.*, nicotinic acid as the ethyl ester, nicotinamide, and *N*-ethylnicotinamide. Studies are currently underway on applying the GLC analysis to pharmaceuticals containing niacin and niacinamide. Preliminary results indicate that the GLC analysis of the vitamin niacin is adaptable to pharmaceutical products.

Influence of Certain Factors on the Coating of a Medicinal Agent on Core Tablets

By WERNER M. K. SEIDLER and E. J. ROWE

The influence of core tablet shape, mixing of coating powders, dilution ratio of diluent to medication, and composition of diluent on the efficiency in the coating of a medicinal onto core tablets by the conventional method was investigated. It was found that tablet shape and type of mixing did not influence the efficiency in this procedure. The overall percent recovery of medicament depending on the variations introduced was from 85 to 90.9 percent in the procedure. Significant factors were drug to diluent ratio and composition of the diluent. Two new methods of drug application were employed, namely, the air-atomized system and the airless-spray-coating system. The air-atomized system was found less efficient than the conventional coating procedure. The airless-spray-coating system, on the other hand, showed a nearly 100 percent efficiency in medication coating.

PROCESSES AND TECHNIQUES employed in the coating of tablets have been surrounded with secrecy. Only one specific report was found in the literature about the efficiency of coating a medicinal agent onto solid cores. Welti (1) investigated the efficiency of applying medication onto pellets on a small scale by the conventional coating method. He found that losses of medication are considerably smaller when the medicament is applied in a powder mixture to previously wetted pellets than when the medicament is applied in the form of a suspension. In general, Welti experienced a loss of medicament ranging from 18 to 44.8%. The loss was dependent on the size of the coating pan, the method of application, and the type of drying.

It was the purpose of this study (*a*) to investigate the efficiency of coating a medicament onto solid cores by the conventional coating procedure, (*b*) to present two new film-coating methods of medicament coating and to show their efficiency, and (*c*) to evaluate some factors influencing the efficiency of medicament coating with respect to the conventional coating procedure and the two new methods.

It was hoped that a comparison between these three methods of application would reduce the general loss of medication as experienced by Welti and give a better way for medicament coating.

Received May 8, 1967, from Eli Lilly and Co., Indianapolis, IN 46206

Accepted for publication February 14, 1968.

Presented to the Industrial Pharmaceutical Technology Section, APhA Academy of Pharmaceutical Sciences, Las Vegas meeting, April 1967.

Abstracted from a thesis presented to the Graduate Division of Butler University College of Pharmacy, Indianapolis, by Werner M. K. Seidler in partial fulfillment of the requirements for the degree of Master of Science.

The author wishes to thank Eli Lilly Research Laboratories, Indianapolis, Ind., for the supply of chemicals and use of equipment.

EXPERIMENTAL

Two types of tablet shape were used in all experiments: Type 1—round deep concave, and Type 2—elliptical. The tablet weight was in both cases 365 mg. The tablets were subcoated with four applications of a coating solution consisting of sucrose (35% w/v) and acacia (27% w/v) and a coating powder consisting of talc (87%) and acacia (13%) in the conventional manner before medication coating was applied. The medicament used in these experiments was quinine hydrochloride. Each tablet was coated with 15 mg. of quinine hydrochloride, theoretically. No excess was used in any of the experiments.

Conventional Coating Procedure—Twenty-four experiments were carried out to investigate the conventional coating procedure. In each experiment 5,000 subcoated tablets were placed into a 14-in. pear-shaped copper coating pan rotating at 24 r.p.m. The tablets were wetted with an aqueous sucrose-acacia solution after which a powdered diluent–medicament mixture was applied. Alternate wetting and powdered diluent–medicament application was continued until all of the powdered medicament mixture was applied. This was followed by two applications of syrup. Drying was accomplished after each addition with warm air and full exhaust. The tablets were then dried for 24 hr. at room temperature. Ten tablets were picked at random from each experiment and a single tablet assay performed for quinine hydrochloride.

The variations introduced in the conventional coating procedure involved (*a*) the ratios 50:50, 20:80, and 5:95 of powdered diluent to medicament, (*b*) the mixing of the components in a twin-shell blender and in a ball mill for 5 hr. in both cases, and (*c*) the use of two different powdered diluent–medicament mixtures. The composition of the powdered diluent formulas was as follows:

1.	Calcium sulfate	49% w/w
	Milk sugar	49% w/w
	Magnesium stearate	2% w/w
2.	Calcium carbonate	44.5% w/w
	Starch powder	6.0% w/w

Calcium sulfate	44.5% w/w
Silicon dioxide	5.0% w/w

The diluents were chosen as being representative of those commonly used in the pharmaceutical industry.

Film-Coating Procedure—In the film-coating procedure, utilizing the air-atomized system and the airless-spray system, quinine hydrochloride was incorporated in the film-forming solution. The two film-forming solutions used in the experiments consisted of:

1. Hydroxypropyl methylcellulose 10	3.0% w/v
Glycerin	0.3% v/v
Quinine hydrochloride	5.0% w/v
Methylene chloride and methanol 50:50 v/v, a sufficient quantity	
2. Polyvinylpyrrolidone	4.0% w/v
Acetylated monoglycerides type 9-40	1.0% v/v
Acetylated monoglycerides type 5-00	3.0% w/v
Quinone hydrochloride	7.5% w/v
Isopropanol and methylene chloride 40:60 v/v, a sufficient quantity	

For the application of quinine hydrochloride film-coating solution in the air-atomized system, a De Vilbiss spray gun with the spray nozzle No. 92 was used. A variation introduced in the air-atomized system involved a change in air pressure (10 p.s.i. and 25 p.s.i., respectively). The pan size, pan speed, and batch size were the same as in the conventional coating procedure. The coating solution was continuously sprayed onto a moving bed of tablets. The spray rate for Solution 1 was 17.2 ml./min.; for Solution 2 it was 11.4 ml./min., both at 10 p.s.i. At 25 p.s.i. the spray rate of Solution 1 was 23 ml./min.; for Solution 2 it was 19 ml./min. Sufficient exhaust was provided on the outside of the pan to carry off the solvent vapors during the spraying. After drying the tablets for 24 hr. at room temperature, 10 tablets were picked at random from each of eight experiments and assayed for quinine hydrochloride content.

In the airless-spray system the film-coating material to be applied was pumped under high pressure through a special nozzle. In four experiments a Nordson pump model No. 100 060 (16:1 pressure ratio) with a Nordson Versa gun was used. Nozzle 9C11 was used for coating Solution 1 with an air pressure of 500 p.s.i.; nozzle 6C7 for coating Solution 2 with an air pressure of 800 p.s.i. All experiments utilized a noncirculating system. To better accommodate the spray to the coating pan and to the tablets the lot size was increased to 7,500 subcoated tablets per experiment. The pan size and the pan speed were the same as in all previous experiments. The Nordson system did not allow a continuous spray, as was the case with the air-atomized system, since no air to facilitate drying was introduced during the actual spray cycle into the pan. A cycle of 3 sec. spraying time and 25 sec. drying time was established. No exhaust or hot air was used during the actual spray cycle. Again, after 24 hr. drying at room temperature, 10 tablets were selected at random from each experiment and assayed for quinine hydrochloride content.

Assay Procedure—The quinine hydrochloride content of each tablet was determined spectrophotometrically. Correction for the interference due to the water-soluble film-forming agent was determined from a placebo tablet subjected to the entire assay procedure.

RESULTS AND DISCUSSION

A total of 36 experiments was carried out (24 for the conventional coating procedure, 8 for the air-atomized system, and 4 for the airless-spray-coating system), and 358 single-tablet assays were performed. Table I gives the averages for the conventional coating procedure according to the variations introduced. The assay range differential is understood to be the difference in assay results between the lowest and the highest assay in this grouping. It can be seen that the type of mixing and tablet shape did not have any significant influence on the coating efficiency as shown by the percent recovery or on the assay range differential. The variations which were found to be significant are (*a*) the medicament ratio and (*b*) the type of powder diluent formula used. There was little difference between powdered medicament–diluent in the ratio of 50:50 and 20:80, but the 5:95 ratio showed the highest assay results and the least assay range differential. Powder diluent Formula 1 showed greater percent recovery than powder diluent Formula 2; however, the assay range differential was higher. The overall percent recovery in the conventional coating procedure, depending on the variations introduced, was from 85.0 to 90.9%.

Table II gives the averages for the film-coating procedures. In the air-atomized system the nature of the film-forming solution and the pressure applied have a significant influence on the quinine hydrochloride content of the finished tablets. The higher the pressure the greater the medicament loss. The overall recovery of quinine hydrochloride in this system ranges from 69.4 to 74.0%, depending on the air pressure and the film-forming solution used. The assay range differential is about the same regardless of the variations introduced.

In the airless-spray-coating system, the tablet shape seems to have an influence on the actual amount of quinine hydrochloride found on the tablet. Also, film-forming Solution 2 shows a greater percent recovery and a smaller assay range differential than film-forming Solution 1. However, it must be recalled that a larger nozzle and a lower pressure was required for film-forming Solution 1 in order to obtain a satisfactory spray. The range of the individual assay results was the greatest in the airless-spray-coating system compared to either the conventional coating procedure or the air-atomized system; however, the actual amount of quinine hydrochloride found on tablets was close to theory.

Statistical Evaluation—Analysis of variance showed (Table I) that in the conventional coating procedure the powder diluent–medicament ratios and the powder diluent formulas are factors which influence medicament coating. In the air-atomized system the pressure and, to a lesser degree, the film-forming solution are factors which influence medicament coating (Table II). In the airless-spray-coating system (Table II) the variations used appear to make no difference in the results.

SUMMARY AND CONCLUSIONS

The following conclusions are drawn from this study:

1. In the conventional coating procedure the medicament loss was found to range from 0.7 to 24.3% based on individual assay.

2. The type of mixing of the powdered diluent–medicament mixture and the tablet shape did not influence the efficiency of the conventional coating procedure.

3. Best yields and smallest tablet-to-tablet variations in medicament content were obtained with the highest powder diluent–medication ratio.

4. Two new methods of application were employed, namely, the air-atomized coating system and the airless-spray-coating system.

5. With the two new methods it was found that the tablet shapes used in this study did not influence the drug content of the tablets.

6. The air-atomized system gave a more consistent range in tablet-to-tablet medicament content than either the conventional coating procedure or the airless-spray-coating system; however, the percent recovery of the applied medicament was the lowest, in the range of 65 to 75%, depending on the air pressure used.

7. The airless-spray-coating system was found

to be the most efficient method of medicament application to a tablet core. Nearly 100% quinine hydrochloride recovery was obtained with this method.

8. Of the three methods investigated, the air-atomized coating system showed the greatest loss of medicament. The airless-spray-coating system showed hardly any loss of medicament. The conventional coating procedure was intermediate in medicament content with respect to the atomized systems.

From this study there appears to be an advantage in applying medication by the airless-spray system. Such a system eliminates the excess medication which must be added in the conventional coating procedure and would thus result in a savings in labor and material.

Enhanced Mortality of Selected Central Nervous System Depressants in Hypoexcretory Mice

By B. A. BECKER, K. L. HINDMAN*, and J. E. GIBSON

The mortality of nine central nervous system depressant drugs was compared in normal and hypoexcretory mice. Anuria was produced in mice by penile ligation; cholestasis was produced by bile duct ligation. The intraperitoneal administration of prochlorperazine, trifluoperazine, perphenazine, meprobamate, and chloral hydrate produced significantly elevated mortality rates in anuric mice whereas promazine, perphenazine, and meprobamate showed elevated mortality rates in cholestatic mice. The mortality of chlorpromazine and phenobarbital was not altered in hypoexcretory mice.

CHOLESTATIC OR anuric mice may be more susceptible to some pharmacologic agents than mice without excretory impairment as shown by Gibson and Becker (1). In that work the acute lethality of ouabain was found to be enhanced in cholestatic mice; digoxin and digitoxin had higher mortality rates in anuric mice. Possible alteration in acute lethality of nine central nervous system depressant drugs were similarly studied in cholestatic and anuric mice: five phenothiazine tranquilizers (Table I) including two from the propyldimethylamine subgroup, promazine and chlorpromazine; three from the propylpiperazine subgroup, prochlorperazine, trifluoperazine, and perphenazine; the nonphenothiazine tranquilizer, meprobamate; and three sedative-hypnotics, pentobarbital, phenobarbital, and chloral hydrate.

METHODS

Male Swiss-Webster mice weighing 25–40 Gm. and allowed free access to food and water throughout the experiment were rendered anuric by penile ligation under light ether anesthesia by the method of Becker and Gibson (2). Cholestasis was induced by ligation of the common bile ducts of other male mice of the same strain under ether anesthesia. The surgical wound was closed by 9-mm. wound clips. The general experimental procedure followed that previously reported (1). Preliminary experiments were performed on intact mice to determine suitable dosages of the test agents. Since the anticipated responses were enhancement or no change in mortality rates, dosages were sought which would be in the low lethal range, *e.g.*, LD_{10}–LD_{50}, as enhancement of mortality rates by dosages in the high lethal range, LD_{50}–LD_{99}, would be difficult to demonstrate with any degree of statistical confidence. The selected drugs were administered intraperitoneally in aqueous solution or 0.5% sodium carboxymethylcellulose suspension. The desired dosage of the selected agent was administered 2 hr. after penile ligation (PL) or 24 hr. after bile duct ligation (BDL); sham-operated animals, similarly treated, served as standards. Vehicle-treated operated and sham-operated mice served as controls. Since none of the control animals died under the conditions used, control data were eliminated from

the results. The percent kill was recorded 12 hr. after drug administration to PL mice and 24 hr. after drug treatment of BDL mice. The 12-hr. observation period was selected in the case of PL mice as previous studies had uniformly shown PL mice to survive for more than 18 hr. before succumbing to the effects produced by anuria; a 24-hr. observation period was unsuitable because approximately 30% of PL mice died in that period (2). Standard errors of the percent kill and statistical significance ($p<0.05$) of differences in percent kill between hypoexcretory and standard groups were determined by the binomial expansion method (3).

RESULTS

In cholestatic mice, the 24-hr. acute mortality was significantly enhanced when the animals were treated with dosages of promazine, perphenazine, or meprobamate (Table II).

The agents which exhibited significantly elevated mortality rates in anuric mice were: prochlorperazine, trifluoperazine, perphenazine, meprobamate, and chloral hydrate (Table II).

Pentobarbital but not phenobarbital had significantly reduced mortality rates in either anuric or cholestatic mice (Table II).

DISCUSSION

Increase in the mortality rates of pharmacologic agents in hypoexcretory animals is presumably the consequence of the inability to excrete the agent or metabolic products. The metabolic products may be toxic, or on the other hand, accumulation of nontoxic metabolites may contribute to enhanced mortality rates by preventing the metabolic alteration of the parent substance according to the law of mass action.

Examination of the results presented in Table II reveals two agents, meprobamate and perphenazine, whose mortality rates are increased when either urinary or biliary excretion is impaired, suggesting that these compounds may be excreted by both major excretory routes in mice. The results also show an interesting structure-action correlation among the phenothiazines (Table I). Phenothiazines with propylpiperazine moieties are uniformly more toxic when the urinary route of excretion is blocked while the propyldimethylamine subgroup is not so affected. When the biliary route of excretion is impaired, the phenothiazines affected, promazine and perphenazine, are found to belong to different subgroups with respect to both N substitution and ring substitution (Table I).

Little is known of the metabolism and excretion of the phenothiazine compounds in the mouse. In man, rats, and dogs, however, the metabolism and excretion of the phenothiazines has been the subject of considerable investigation. The metabolism of the phenothiazines is extensive and the role of

metabolism in the excretion of these compounds is recognized (4). The excretion of chlorpromazine in rats is divided equally between the urinary and biliary routes, the major routes of drug excretion. Only about 12% of the original dose of chlorpromazine is recovered in the urine as the unchanged drug, whereas the remainder is present as metabolites (5). In the present study cholestasis or anuria did not increase the lethality of chlorpromazine in mice, indicating that either the urinary or biliary route of excretion may serve adequately to remove chlorpromazine and its metabolites in mice.

In contrast to chlorpromazine, promazine is excreted primarily in the urine (70–80%) by the rat with the remainder excreted *via* the feces (6). Under these conditions it might be expected that the mortality of animals treated with a toxic dose of promazine might be enhanced if the urinary route of excretion were blocked. In mice, however, it was observed that the lethality was enhanced if the biliary route of excretion was blocked. This finding suggests that the primary excretory route of promazine and its metabolites may be different in mice than in rats or that a toxic metabolite of promazine is excreted primarily *via* the biliary route.

Phenothiazines having propylpiperazine moieties may be mainly excreted in the bile. In rats, triethylperazine, a propylpiperazine derivative of phenothiazine, is excreted largely in the bile with less than 10% of the dose appearing unchanged in the urine when given either orally or parenterally (7). The enhanced lethality of these compounds in anuric mice (Table II), however, may indicate that the urinary route of excretion for these compounds is more important in mice than in rats. Perphenazine appears to be dependent upon the function of both the urinary and biliary excretory routes in mice for detoxication since blockade of either route significantly increased the acute lethality of the compound.

Meprobamate is metabolized *in vivo* to hydroxymeprobamate, a pharmacologically inactive and nontoxic product. Both meprobamate and hydroxymeprobamate are conjugated with glucuronic acid and excreted *via* the urinary route in dogs (8). Ten percent of administered meprobamate is excreted unchanged and the remainder is excreted as metabolite in the urine. In mice the lethality of meprobamate is significantly enhanced when either the urinary or biliary routes of excretion is blocked (Table II). Since meprobamate and its metabolites are almost exclusively excreted by the kidneys in other species, the enhanced lethality of meprobamate in cholestatic mice is somewhat surprising. One explanation is that the mouse metabolizes or excretes meprobamate very differently from other mammalian species. Another possible explanation may be inhibition of meprobamate metabolism in the liver due to bile duct ligation thus resulting in delayed detoxication of the drug.

Chloral hydrate is reduced *in vivo* primarily to trichloroethanol, an active metabolite, and partially to trichloroacetic acid, an inactive metabolite. Both metabolic products may be conjugated with glucuronic acid and excreted either in urine or, to a smaller extent, bile (9). In mice, the acute lethality of chloral hydrate is increased by the anuric condition which correlates well with metabolism and excretion of chloral hydrate in man.

The significant reduction of lethality rates seen in hypoexcretory mice treated with pentobarbital but not phenobarbital cannot be readily explained. One possibility is that metabolites of pentobarbital accumulate in the blood of hypoexcretory animals and affect the equilibrium of pentobarbital toward increased tissue storage. Increased metabolism due to induction of liver microsomal enzymes is not believed to be an important factor in view of the short time (12 or 24 hr.) available for enzyme induction by pentobarbital. If enzyme induction were a significant mechanism, phenobarbital would also be expected to show a protective effect.

The dearth of information concerning metabolism and excretion of drugs in the mouse is not limited to the phenothiazines. Very little data of this type can be found in the literature. The authors are aware that extrapolation from one species to another is hazardous and must be done with great care. The above comments on metabolism and excretion in other species are germane to the findings described only if the metabolism and excretion of the drugs discussed are qualitatively the same in the mouse as in the other species.

The procedures employed in this study are relatively simple and can be carried out in a reasonable number of animals in a short time. The information gained from such procedures may prove to be of value in predicting the route of excretion of the drugs and/or their biotransformation products, and possible toxic reactions in the presence of reduced liver or kidney function. Such data may be of value in the safety evaluation of new drugs.

Synthesis and Pharmacology of Some Pyrroles and Indan Amines: Hexahydro Indeno (1,2-*c*) Pyrroles and Indan Amines

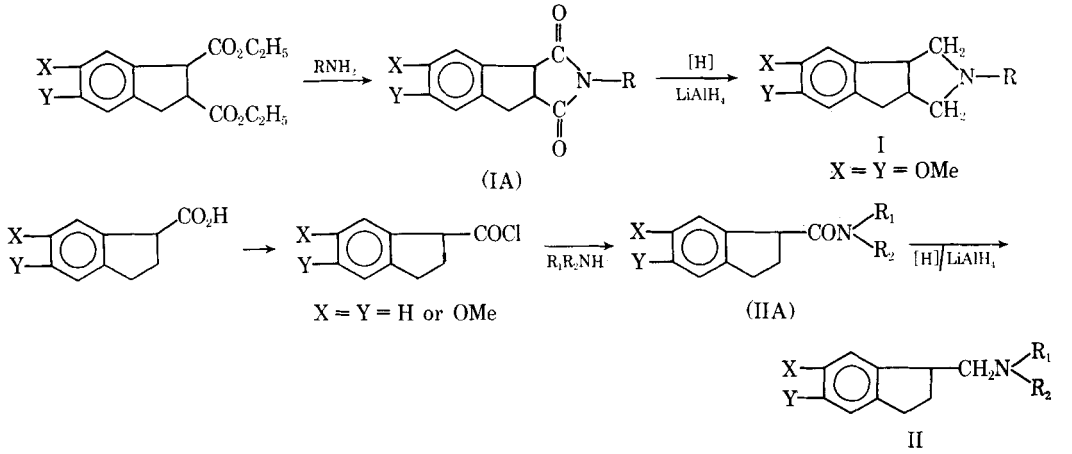
By SAMIR CHANDRA LAHIRI and BALAI PATHAK

Syntheses and pharmacology of a number of 1,2,3,3*a*,8,8*a*-hexahydro 5:6-dimethoxy indeno (1,2-*c*) pyrroles, 1-*N*-dialkyl amino methyl indans and 1-*N*-dialkyl amino methyl 5:6-dimethoxy indans were described. A few of these compounds showed oral hypoglycemic activity.

THIS PAPER, which is an extension of a previous one (1), is concerned with the syntheses of a few compounds of the types I and II and presents in summary form the salient features of their pharmacological activities.

RESULTS AND DISCUSSION

Chemistry—The reaction sequences leading to the formation of compounds I and II are shown n Scheme I:



Scheme I

Ethyl 5:6-dimethoxy indan 1,2-dicarboxylate (2) was heated with appropriate amine in a sealed tube to yield imides. The imides were reduced to indan pyrrolidines (I) by $LiAlH_4$ (3).

3-Carboxy indan-1-one (4) and its 5:6-dimethoxy derivative (5) were reduced to the corresponding carboxy acids by Clemmensen reduction (6, 7). The acids were converted to acid chlorides by thionyl chloride and were subsequently treated with appropriate primary or secondary amines to yield amides. The amides were converted to desired amines by $LiAlH_4$ reduction. In some cases, methylation of the secondary amines was carried out following a procedure of Bachmann (8). The hydrochloride salts were used for the pharmacological evaluation of hypoglycemic activity.

Structure Activity Relationship—Results of investigation of hypoglycemic activity of the compounds tested so far are summarized in Tables I and II. A close scrutiny of the above results revealed the following facts that among the compounds of the type I, substitution at N atom has some direct bearing on activity. Maximum activity was attained in the *n*-propyl or *n*-butyl substitution and activity disappeared in the *n*-amyl compound. The activity, however, reappeared in the *n*-hexyl compound of this series. Cyclohexyl or benzyl substitution also showed appreciable activity. Methoxy substitution at 5 and 5:6 positions of the aromatic ring also improved the activity in general (Table II). These compounds, however, were more effective against alloxan-induced diabetic animals than that of normal animals, and in a few cases they showed better response than the known standard drugs such as tolbutamide or chlorpropamide. One striking feature of these compounds is their slow onset of action and longer duration.

Among 1-*N*-dialkyl aminomethyl indans (Table I), activity was found to be very poor and methoxy substitution in the aromatic ring lowered the activitity in general. However, these compounds showed slight to moderate hypotensive, analgesic, and muscle-relaxant activities.

Complete pharmacology as well as mode of action of a few potent compounds along with their toxicology will be published soon. [1-Methyl-2-*N*-dialkyl aminomethyl indans and their 5:6 dimethoxy derivatives, however, showed appreciable hypoglycemic activity in both normal and alloxan-induced diabetic rabbits (9).]

Pharmacology Method—Normal, healthy, male rabbits, weighing between 1.5–1.8 Kg. were selected. Eight rabbits were used in each set. The animals were kept on fasting for 18 hr. prior to administration of the compound. Water was, however, allowed *ad libitum*. After taking the venous blood of the fasting rabbits, the animals were given the compounds (in the form of hydrochloride in aqueous solution) at the rate of 25 mg./Kg. of body weight by stomach tube and blood glucose concentration

was observed at different hours up to 24 hr. The maximum fall of blood glucose concentration was observed in between the 9th–12th hour. The blood glucose estimation was carried out in a manner as described by Hagedorn and Jensen (10). The hypoglycemic activity of the compounds tested were detailed in Tables I and II.

EXPERIMENTAL[1]

***N*-Substituted 5:6-Dimethoxy Indan 1,2-Dicarboximides (Ia)**—A mixture of 5:6-dimethoxy indan 1,2-dicarboxylate (2) (0.05 mole) and an appropriate amine (0.1 mole) was heated in a sealed tube for 8–12 hr. at 150° and the imide isolated following a similar procedure as reported earlier (1,3).

N-*n*-Hexyl 5:6-dimethoxy indan 1,2-dicarboximide was boiled at 188–190°/0.8 mm.

Anal.—Calcd. for $C_{19}H_{25}NO_4$: C, 68.9; H, 7.5; N, 4.2. Found: C, 68.7; H, 7.4; N, 4.2.

N-Benzyl 5:6-dimethoxy indan 1:2-dicarboximide was boiled at 210–215°/0.15 mm.

Anal.—Calcd. for $C_{20}H_{19}NO_4$: C, 71.2; H. 5.6; N, 4.1. Found: C, 71.2; H, 5.5; N, 4.2.

N-Cyclohexyl 5:6-dimethoxy indan 1,2-dicarboximide was crystallized from petroleum ether (60–80°); m.p. 118–120°.

Anal.—Calcd. for $C_{19}H_{23}NO_4$: C, 69.3; H, 6.6; N, 4.2. Found: C, 69.2; H, 6.5; N, 4.2.

1,2,3,3a,8,8a-Hexahydro 5:6-Dimethoxy 2-Alkyl Indeno (1,2-*c*)Pyrroles (I)—The appropriate imides were reduced by refluxing with $LiAlH_4$ with absolute

[1] All melting points are corrected and determined in Gallenkamp apparatus. Boiling points are uncorrected.

ether and amines were separated in the usual manner.

1,2,3,3*a*,8,8*a*-Hexahydro 5:6-dimethoxy *N*-*n*-hexyl indeno (1,2-c) pyrrole was boiled at 186–188°/0.6 mm.

Anal.—Calcd. for $C_{19}H_{29}NO_2$: C, 75.2; H, 9.6; N, 4.6. Found: C, 75.1; H, 9.5; N, 4.5. Hydrochloride (hygroscopic) was crystallized from ethyl acetate, m.p. 118–120°.

1,2,3,3*a*,8,8*a*-Hexahydro 5:6-dimethoxy *N*-cyclohexyl indeno (1,2-*c*) pyrrole was boiled at 192–195°/0.6 mm.

Anal.—Calcd. for $C_{19}H_{27}NO_2$: C, 75.7; H, 8.9; N, 4.6. Found: C, 75.6; H, 8.7; N, 4.5. Hydrochloride was crystallized from a mixture of ethyl acetate and absolute ethanol, m.p. 200–202°.

1,2,3,3*a*,8,8*a*-Hexahydro 5:6-dimethoxy *N*-benzyl indeno (1,2-*c*) pyrrole was boiled at 192–196°/0.4 mm.

Anal.—Calcd. for $C_{20}H_{23}NO_2$: C, 77.6; H, 7.4; N, 4.5. Found: C, 77.4; H, 7.3; N, 4.4. Hydrochloride salt crystallized from ethyl acetate, m.p. 172–173°.

1-Chlorocarboxy Indans—Indan 1-carboxy acid (5, 6) was converted to acid chloride by reacting with thionyl chloride. It boiled at 140–145°/1.5 mm. (74%).

Anal.—Calcd. for $C_{10}H_9ClO$: C, 65.9; H, 4.6; Cl, 19-11. Found: C, 65.9; H, 4.88; Cl, 19.01.

1-Chlorocarboxy 5:6-Dimethoxy Indan—A mixture of 3,4-dimethoxy phenyl succinic acid (5) (16 Gm.) and polyphosphoric acid (740 Gm.) was heated at 100° for 3 hr. under stirring. The keto acid thus formed was extracted with chloroform. The yield was 80%, m.p. 190–191° dec. The keto acid was then subjected to Clemmensen reduction and the 1-carboxy 5:6-dimethoxy indan distilled at 176–180°/0.7 mm., crystallized from benzene, mp. 114–116°.

Anal.—Calcd. for $C_{12}H_{14}O_4$: C, 65.86; H, 6.30. Found: C, 64.82; H, 6.28. The acid chloride was prepared by reacting with thionyl chloride but it was not distilled as it decomposed on distillation.

1-N-Dialkyl Carboxy Amido Indans (IIa)—The 1-chlorocarboxy indan or 1-chlorocarboxy 5:6-dimethoxy indan (1 mole) was added dropwise to a mixture of an appropriate amine (1.5 mole) and sodium hydroxide solution (10%; 1 mole) cooled in an ice bath. The amide was extracted with a suitable solvent and either distilled under reduced pressure or crystallized from a suitable solvent. The physical properties and analyses of the amides are listed in Table I.

1-N-Dialkyl Aminomethyl Indans (II)—The amide (1 mole) so prepared was reduced with $LiAlH_4$ (2 mole) in dry ether under reflux for 8–12 hr. in the usual manner. In some cases, the secondary amines, thus prepared, were methylated by heating a mixture of amine, formic acid, and formaldehyde on an oil bath in the usual manner (8). The bases were characterized as their hydrochlorides and other physical properties and hypoglycemic activities were listed in Table I.

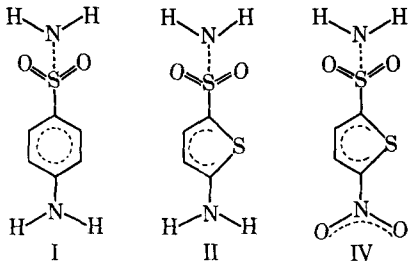
Thiophene Analogs of Sulfanilamide: Bacterial Growth Inhibitors

By J. BULKACZ, M. A. APPLE*, J. C. CRAIG, and A. R. NAIK

Structure *versus* activity study of thiophene analogs of sulfanilamides indicated: (*a*) the parent aminothiophene-2-sulfonamide is a better bacterial growth inhibitor than is sulfanilamide (I); (*b*) 5-aminothiophene-2-sulfonamide (II) is a better inhibitor than the 4-amino isomer (III); (*c*) substitution of the sulfonamide N with groups which enhance I's antibacterial activity does not necessarily similarly enhance the activity of the thiophene analog (VI, VII); (*d*) 5-(IV) and 4-nitrothiophene-2-sulfonamides(V) are more inhibitory than the corresponding 5- and 4-amino compounds (II, III) with the 5-nitro compound (IV) being bactericidal at very low concentrations. Folic acid or PABA reversed the growth inhibition produced by the thiophene-2-sulfonamides, indicating both the nitro and amino thiophene-2-sulfonamides prevent intracellular folic acid biosynthesis.

THE MODERN era of drug treatment of many bacterial infections originated with the finding of a selective effect of sulfanilamide on organisms which synthesize their own folic acid from *p*-aminobenzoate (1–3). The essential nucleus, a *p*-aminophenyl-sulfonamide, has been modified and sometimes improved extensively, mostly by addition of groups to the sulfonamide nitrogen (4). In the increasing frequency of instances of bacterial drug resistance transmitted by the multiple-drug resistance RTF episome, most often resistance to streptomycin, chloramphenicol, and tetracycline are gained simultaneously by the invading pathogen; there is a smaller incidence of concomitant sulfanilamide (I) resistance (5). Improved forms of I might be effective in such cases of multiple-drug resistance, or in cases where current I derivatives are only marginally effective. The authors report here the superior antibacterial effectiveness of modified forms of I, in which the phenyl ring of the parent molecule of the sulfanilamide family of drugs has been replaced by a thiophene ring (II, IV).



I II IV

MATERIALS AND METHODS

Salmonella typhimurium and *Proteus vulgaris* were obtained from the University of California, San Francisco, collection.[1] These bacterial strains were maintained on sensitivity test (ST) agar (Colab, Chicago) or brain heart infusion (BHI) agar (Difco, Detroit) slants or plates and subcultured on the same media at 37° in a candle jar as needed for anaerobic-high CO_2 conditions (8). The bacterial cells used as inoculum were grown overnight in tubes containing 8 ml. of BHI broth for approximately 15 hr., centrifuged at about 1500 × g in an International Clinical centrifuge (I.E.C. Co., Boston) at 25° and suspended in a pH 7.0 sodium phosphate buffer. The growth flasks consist of 300-ml. conical flasks, fitted with a closed-tube side-arm about 2.5 cm. from the flask bottom. The drug, if any, was added to these flasks and diluted with the growth medium consisting of 15 ml. of BHI broth supplemented with 0.5% lactalbumin hydrolysate (Difco, Detroit) and 0.6 m*M* $NaHCO_3$. To this medium the bacterial cells were added to about 25 mcg../ml. of dry weight equivalent and flasks placed at 37° on a gyrotary shaker (New Brunswick Scientific, New Brunswick, N. J.) at two shakes per sec. The bacterial growth was followed spectrophotometrically at 30-min. intervals.

Details of the synthesis and properties of the thiophene analogs will be published (6, 7). The compounds used and their melting points were:

	Compounds	m.p.
II	5-aminothiophene-2-sulfonamide	137–138°
III	4-aminothiophene-2-sulfonamide	132–133°
IV	5-nitrothiophene-2-sulfonamide	135–136°
V	4-nitrothiophene-2-sulfonamide	165–166°
VI	2-(5-aminothiophene-2-sulfonamide) pyridine	162°
VII	2-(5-aminothiophene-2-sulfonamide) pyrimidine	204–205°

To estimate *in vivo* toxicity of a compound, 25-Gm. male albino mice, random bred Webster-Simonsen Swiss (Simonsen Laboratories, Gilroy, Calif.), were given a single intraperitoneal injection each morning for five consecutive mornings. The animals were weighed daily and survival followed for 30 days. A tolerated dose was considered that dose which produced a readily reversible weight loss not exceeding 12% at any time and which caused no mouse deaths during the 30-day period.

RESULTS AND DISCUSSION

Superior Antibacterial Activity Associated with Thiophene Ring Modification—As seen in Fig. 1, the thiophene ring modification (Structure II) produced an increase in the antibacterial activity against streptococcus AHT, known to be a human pathogen, above that seen under these conditions with the phenyl ring compound (Structure I). The 5-aminothiophene analog, II, is considerably more effective as a growth inhibitor than is the 4-amino isomer (Fig. 1). The medium of cultures containing II turned a violet-brown after 24 hr.

The growth inhibition by II is much greater than I when tested on *Salmonella*, *Streptococcus*, and *Proteus* (Table I). Growth rate was significantly

[1] Streptococcus, human type, "AHT," was obtained from D. D. Zinner.

* To whom inquires should be addressed.

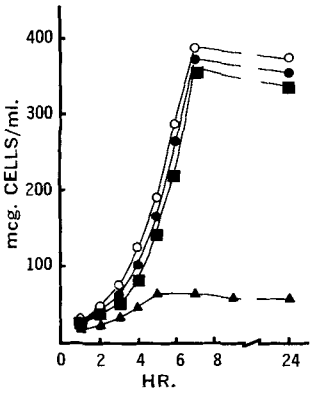

Fig. 1—Growth of Streptococcus *in the presence and absence of I and thiophene analogs of I. All drugs at 500 mcg./ml. Key: ○, control (no drugs); ●, I; ■, III; ▲, II.*

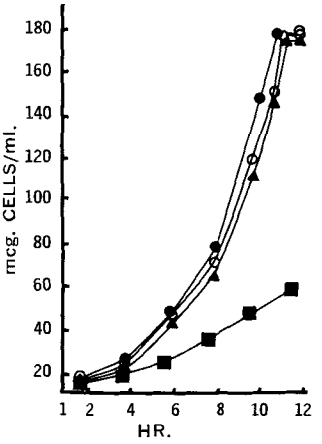

Fig. 2—Inhibition of Streptococcus *by IV and its reversal by PABA or folic acid. IV was added to 5 mcg./ml. Key: ○, control (no drugs); ■, IV only; ●, IV + 300 mcg./ml. PABA; ▲, IV + 100 mcg./ml. folic acid.*

slowed by II, which about doubled the time between cell divisions at concentrations at which I had no significant effect (Table I). Substitution of a pyrimidine on the thiophene sulfonamide nitrogen (Table I) produced a drug which was much more active than I.

Nitrothiophene Analogs As More Effective Growth Inhibitors Than Aminothiophene Analogs—The nitrothiophene compounds were both more inhibitory than the corresponding aminothiophene compounds (Table I). For example, I had no effect on *Salmonella* growth at 1 mg./ml., II inhibited *Salmonella* growth by 60% at 1 mg./ml., but both III and IV inhibited *Salmonella* growth by over 95% at concentrations of only 100 mcg./ml. (Table I). At 100 mcg./ml., IV was a more effective growth inhibitor than III against both *Salmonella* and *Streptococcus* (Table I).

Based on relative inhibition per mcg./ml. concentration, IV is about 1,000-fold more effective than I (*cf.* Fig. 2 and Table I).

Mechanism of Bacterial Growth Inhibition: Inhibition Reversal by Folate and p-Aminobenzoate—BHI growth medium contains folic acid and its metabolites. After limited growth at the slower rate by *Streptococcus* in the presence of II, the culture was found to be sterile: no viable cells could be found by the plating-out procedure using drug-free BHI or ST agar (9). The latter observation was

also made for *Streptococcus* exposed to either IV or V at the second lowest concentrations used (Table I), suggesting the organisms incorporate the drugs as they grow and the drugs then diminish some essential activity to a lethal extent, in a manner similar to the less effective I.

Consistent with the possible mode of action of these thiophene analogs in antagonizing *p*-aminobenzoate metabolism, II is probably closer in its three-dimensional structure to *p*-aminobenzoate than is III, since the large S atom essentially replaces two carbon atoms.

Experiments with *Streptococcus* using 100 mcg./ml. of the nitro compounds or 500 mcg./ml. of the amino compounds showed no significant inhibition reversal by 25 mcg./ml. of PABA except in the case of III. The inhibition by V (150 mcg./ml.) was reversed by 300 mcg./ml. PABA. The latter concentration of PABA also served to release the inhibition induced by 2–5 mcg./ml. of IV (Fig. 2).

The reversal of the IV-induced inhibition by PABA or folate (Fig. 2) suggests the biosynthesis of folate is the site of action of the nitrothiophene-2-sulfonamides as well as the amino compounds. This could be accomplished by intracellular reduction of the nitro compounds to the corresponding amino compounds, making the amino compounds the active forms. The same concentration of PABA (300 mcg./ml.), completely reversing effective inhibition by IV, produced only a slight reversal of the same extent of inhibition by II.

However, nothing is yet known about the relative transport rates of these thiophenes into cells, so no conclusions can be drawn about the relative effective concentration; it appears the nitro compounds, if they are reduced to the amino form, may be transported to the site of intracellular activity at a greater rate than the corresponding amino compound.

Antibacterial Activity of II and IV Exceeds That of Similar Compounds—The carboxamide corresponding to II, 5-aminothiophene-2-carboxamide, was inactive against *Streptococcus*, *Escherichia*, or *Diplococcus*, even at concentrations many times that at which sulfanilamide was active (10). The 5-amino-3-thiophene sulfonamide isomer of II was not inhibitory to a wide variety of bacterial genera concentrations at least tenfold greater than those used for II (11). Thus, II is a new structure with much increased biological activity over similar structures.

Although the 5-nitrothiophene-3-sulfonamide isomer has antibacterial activity, it is 500–1,000-fold less active against *Streptococcus* per μM concentration than IV (6). More significantly, compared with the data of Woods on sulfanilamide reversal (1), IV is at least 10,000-fold less susceptible to reversibility by PABA than is sulfanilamide.

In Vivo Toxicity—The substitution of the thiophene ring for the phenyl ring of I increases the water solubility and thus decreases the partition coefficient. Such changes are less significant to this study *in vitro* than they would be to study of the drug in pathogen-infected animals. Although a few mcg./ml. of IV appeared to be bactericidal, a daily injection (5 days) of 100 mg./Kg. of IV to adult Swiss mice was tolerated with a reversible weight loss. This suggests a body fluid level of up to several hundred mcg./ml. could be attained.

Essential Oil of *Anemopsis californica*

By RAMESH N. ACHARYA* and MADHUKAR G. CHAUBAL

The constituents of the hydrodistilled essential oil from the roots and rhizomes of *Anemopsis californica* have been examined. Thymol was identified from the phenolic fraction of the oil. Gas chromatography on Hyprose SP-80 followed by collection of effluent fractions and comparison of their IR spectra with those of pure samples confirmed the presence of methyleugenol as the major constituent. A third constituent of the oil was found to be piperitone. Methyleugenol (approximately 55 percent v/v of the oil), thymol (13 percent), and piperitone (5 percent) together make up approximately 74 percent of the oil. A fourth constituent, tentatively identified as an aromatic unsaturated ether, and other constituents are being investigated.

ONLY TWO reports on the chemical constituents of the roots and rhizomes of *Anemopsis californica* (Nutt.) Hook and Arn. (Fam. *Saururaceae*, Yerba del Mansa) are available. Horton and Paul (1) first reported the presence of methyleugenol (4-allylveratrole) in the steam-distilled oil. Childs and Cole (2) later confirmed the occurrence of methyleugenol in the petrol ether extracts of the rhizomes and also reported the presence of leucoanthocyanidins and an unidentified crystalline compound in these extracts.

This paper reports the results to date of the investigation of the essential oil of *Anemopsis* (Mansa oil).

EXPERIMENTAL

Crude Drug—Hathaway Allied Products[1] supplied the whole crude drug (roots and rhizomes) in following lots: Lot RM-65-167, Lot RM-65-1029 and Lot RM-67-91.

Extraction of Essential Oil—Approximately 3 Kg. crude drug was crushed to 12–6 mm. size. The crushed drug was hydrodistilled for 30 hr. (batches of 300 Gm. drug + 1800 ml. water). The distillate was collected in a modified Clevinger's apparatus for oils lighter than water. After separation for 10 hr. the oil was removed and dried over anhydrous sodium sulfate for 30 hr. The batches were pooled for further analysis.

Thin-Layer Chromatography (TLC)—To monitor the separation steps TLC was used under the following conditions: *Equipment*—Desaga,[2] variable thickness spreader. *Carrier Plates*—glass, 8 × 8 or 2 × 8 in. *Adsorbent*—Silica Gel G (25 Gm. suspended in 50 ml. deionized water and spread over five 8 × 8 in. plates), 250 μ thick. *Activation*—dried at 110° for 2 hr. and stored over anhydrous calcium sulfate[3] before spotting. *Sample Size*—10 μl. *Solvent System*—benzene + ethylacetate, 95:5 v/v. *Development*—room temperature (22–27°), 15 cm., 35–40 min. *Spray Reagents*—(A) Anisaldehyde (anisaldehyde, 3 drops in a mixture of 10 ml. methanol and 1 ml. glacial acetic acid + 2 ml. concentrated sulfuric acid just before spraying. Sprayed plates heated at 95° for 7 min.). (B) 2:4 Dinitrophenylhydrazine (2:4 DNPH) (3). (C) Diazotized sulfanilic acid (3).

Functional Group Separation—Scheme I shows the procedure used to achieve gross separation of the constituents of Mansa oil.

A negative test with 2:4 DNPH on TLC indicated initially that the oil was devoid of carbonyls. However, Stahl (4) has pointed out that ketones such as menthone, piperitone, and fenchone should be present in larger amounts to yield a positive color reaction with the reagent. If such ketones were present in Mansa oil in low concentrations, the negative test could be expected. In order to further test for the presence of carbonyls a procedure reviewed by Parsons (5) was adopted as follows. Analytical grade diatomaceous earth,[4] 10 Gm. was triturated with a solution of 500 mg. of 2:4 DNPH in 6 ml. phosphoric acid (d = 1.75) and 4 ml. of deionized water. The impregnated diatomaceous earth was then packed in a glass column (2.1 cm. i. d.) filled with cyclohexane. The cyclohexane was run off the column and the diatomaceous earth washed with benzene to remove excess 2:4 DNPH. A solution of 0.5 ml. oil in 0.5 ml. cyclohexane was then applied to the column and the column eluted with cyclohexane until the eluate gave no color with vanillin-sulfuric acid reagent (3). The column was now eluted with benzene. The benzene effluent was deep orange-red; a characteristic color of 2:4-dinitrophenylhydrazones. It was therefore apparent that small amounts of carbonyl compounds were present in Mansa oil and that these could not be grossly separated by the usual 2:4 DNPH treatment of the oil. A method similar to that of Teitelbaum (6) was therefore used to obtain the carbonyl fraction from the phenol-free oil (Scheme I). A mixture of 5 Gm. phenol-free oil, 5 Gm. Girard "T"[5] reagent, and 0.1 Gm. of a cation exchanger[6] were refluxed in a 50-ml. round-bottom flask with 10 ml. absolute ethanol for 1.5 hr., during which period Girard "T" dissolved. The hot solution was then stirred into 40 ml. ice water and allowed to stand for 0.5 hr. The aqueous mixture was extracted with ether (15 ml. × 3) and the combined ether extracts were dried over Na_2SO_4 anhyd. Removal of ether *in vacuo* gave the noncarbonyl fraction (4.15 Gm.). The aqueous phase was acidified by 10 ml. concentrated HCl and kept overnight. The oily carbonyl fraction which separated was extracted with ether (20 ml. × 3), the combined ether extracts dried over Na_2SO_4 anhyd., and the ether removed *in vacuo*

(0.85 Gm.). TLC of this carbonyl fraction now gave a 2:4 DNPH positive spot (Fig. 1B).

Gas Chromatography (GC) Apparatus—Autoprep[7] model A-700 with thermal conductivity detector. *Column*—Aluminum, 1/4 in. o.d., 20 ft. *Packing*—Hyprose SP-80,[7] 20% w/w on 60–80 mesh Chromosorb W (Hyprose SP-80, 20 Gm., in hot chloroform solution was deposited on 100 Gm. Chromosorb W with constant stirring. The solvent was then removed in a rotary evaporator under water-aspirator suction. The packed column was preconditioned overnight at 190° under a slow stream of nitrogen). *Carrier Gas*—Helium, 75 ml./min. at 50 p.s.i. inlet pressure. *Injection Port Temperature*—200°. *Column Temperature*—180°. *Detector Temperature*—250°. *Recorder Span*—1 mv. *Chart Speed*—1 in. 5 min. The effluent fractions were collected directly on KBr pellets placed in a KBr bottle[7] or by passing through a trap containing spectral grade carbon tetrachloride. The IR spectra were obtained with a Perkin-Elmer model 337 IR spectrophotometer.

RESULTS AND DISCUSSION

Approximately 250 Gm. of a dark green oil was collected. The average yield from several batches was 6.5% v/w of crude drug. Finer grinding of the crude drug increased the yield to approximately 7.5% however under these conditions charring of the fine powder occurred. The oil distilling in the initial stages was pale yellow gradually changing to dark green. The pooled oil had the following physical constants: d_{25}^{25} 0.9980; n_D^{25} 1.5195, and $[\alpha]_D^{25}$ less than −3.5° (dark color interfered).

The three spray reagents for TLC were selected so as to detect most of the common constituents of essential oils (3). Anisaldehyde gives colored spots with terpenes, phenols, steroids, and sugars and 10 well-marked spots were obtained with Mansa oil (Fig. 1A). The carbonyl compounds are detected, more or less specifically, with 2:4 DNPH. This reagent failed to give any colored spot with the oil. Diazotized sulfanilic acid gave only one yellow spot indicating the presence of one phenol (Fig. 1C).

Repeated extractions with aqueous KOH removed the phenol fraction from the oil. Addition of alkali to the oil changed the color of the oil to deep red as long as phenols were present. TLC of the dark brown oily phenol fraction (Scheme I) gave only one yellow spot with reagent (C) (Fig. 1D). The odor of the fraction was similar to that of thyme oil. Distillation of this fraction at 230–238° gave a clear heavy liquid which solidified on keeping at 4° for 4 hr. The oily film adhering to

[7] Wilkens Instrument and Research Inc., Walnut Creek, Calif.

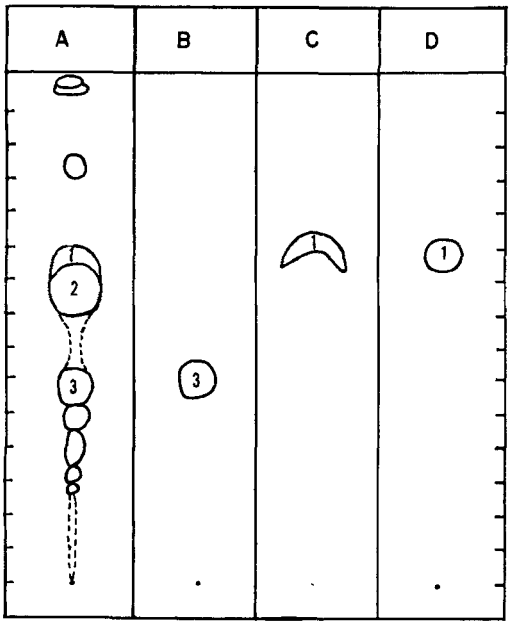

Fig. 1—Thin-layer chromatograms of hydrodistilled oil of Anemopsis californica. *Key: A, anisaldehyde; B, 2:4 DNPH, C, diazotized sulfanilic acid; carbonyl fraction of the oil; D, diazotized sulfanilic acid phenol fraction of the oil; 1, thymol; 2, methyleugenol; 3, piperitone.*

the solid was washed with chilled hexane and the solid recrystallized from boiling hexane (b.p. 68.7°). The purified solid was identified as thymol: m.p. 48–49° (49–50°) uncorrected; Positive thymolphthalein test; *N*-naphthylurethane—m.p. 106–107° (107–108°); α-naphthylurethane—m.p. 160° (161°); identical IR spectra, retention time (RT) on Hyprose SP-80 and R_f on TLC as that of pure thymol (reagent, Merck) (values in parentheses for thymol reagent, Merck).

The gas chromatogram of Mansa oil showed 20 peaks (Fig. 2). Four compounds (Peaks 1,2,3,12) were present in appreciable amounts and the authors concentrated on their identification. Tests with known samples[8] of common essential oil constituents had shown that, under these conditions, terpenes eluted out in the early region (0–5 min.), oxygenated compounds in the middle region (6–15 min.), and phenols and derivatives in the late region (16–40 min.) (Fig. 2). Injection of pure compounds showed that Peaks 1 and 2 (Fig. 2) were thymol and methyleugenol, respectively. The fractions from these peaks collected directly on KBr pellets gave IR spectra identical with those of the pure compounds. The GC of the carbonyl fraction (Scheme I) showed it to be enriched in the third major compound (Fig. 2, Peak 3). Successive injections of 5 μl. of the

[8] Supplied by Fritzsche Brothers Inc., New York, N. Y.

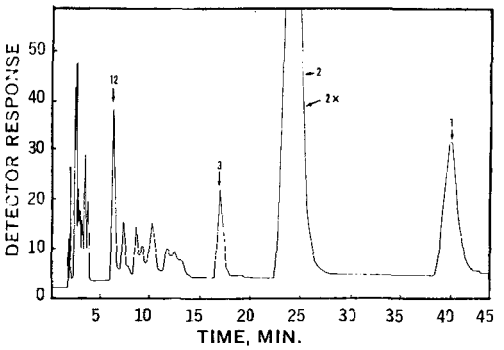

Fig. 2—Gas chromatogram of hydrodistilled oil o Anemopsis californica *(5 μl). Hyprose SP-80 stationary phase.*

carbonyl fraction were therefore used to collect sufficient quantity of Peak 3 in spectral grade carbon tetrachloride for IR analysis. The IR spectrum of the compound was identical with that of pure piperitone collected under identical conditions. The fourth compound (Fig. 2, Peak 12) collected in carbon tetrachloride gave an IR spectrum indicative of an aromatic ether (strong absorption at 1600–1500 $cm.^{-1}$ and at 1262 $cm.^{-1}$) with probably an isolated unsaturation (weak absorption at 1620 $cm.^{-1}$) and which is not monosubstituted (absence of absorption near 700 $cm.^{-1}$).

With pure methyleugenol and thymol as internal standards in GC the three identified compounds were found to be present in following amounts in the oil (% v/v); methyleugenol (55.30), thymol (13.57), and piperitone (5.19).

The aromatic ether and remaining 16 peaks constitute 25.94% of Mansa oil. In order to obtain sufficient quantities of these for identification, fractionation of the oil and subsequent GC on various stationary phases is under progress.

Alkaloids of *Peumus boldus*. Isolation of (+) Reticuline and Isoboldine

By D. W. HUGHES, K. GENEST, and W. SKAKUM

Chromatographic investigation of alkaloid fractions from the leaves of *Peumus boldus* Molina revealed the presence of 17 alkaloidal components. Four of these were correlated with previously isolated aporphine constituents and two others were isolated and identified as (+) reticuline and isoboldine.

THE LEAVES of the Chilean evergreen shrub *Peumus boldus* Molina (boldo leaves) have long been used as a choleretic, diuretic, stomachic, sedative, and anthelmintic (1). Preparations from the leaf have not been official in the NF since 1936, but the drug is still used, especially in "over-the-counter" remedies. Some 40 preparations containing the drug are currently available in Canada. The activity of the leaves has been variously ascribed to the alkaloid, the glycoside, or the essential oil content (1).

Boldine (I, $R_1 = R_3 = H$, $R_2 = CH_3$) was isolated from *P. boldus* by Merck in 1922 (2) and its structure determined 10 years later (3). By paper chromatography Rüegger, in 1959 (4), detected the presence of 11 alkaloids and he isolated and characterized three of these: isocorydine (II, $R = CH_3$), norisocorydine (II, R = H), and *N*-methyllaurotetanine (I, $R_3 = H$, $R_1 = R_2 = CH_3$).

This paper describes preliminary separation schemes for the isolation of some of the unknown alkaloidal constituents of boldo leaves and the isolation and identification of (+)-reticuline (III, (R = H) and isoboldine (I, $R_2 = R_3 = H$, $R_1 = CH_3$).

EXPERIMENTAL AND RESULTS

TLC Procedures—TLC plates of Silica Gel G (Merck) (layer thickness 0.25 mm.) were prepared according to standard techniques[1] using either water (for basic solvent systems) or 0.1 *N* sodium hydroxide (for nonbasic solvent systems).

The most useful solvent systems were: *A*, chloroform–methanol (85:15); *B*, ethyl acetate–acetone–methanol (50:20:30); *C*, benzene–methanol (80:20); *D*, ethyl acetate–acetone–methanol–diethylamine (45:30:20:5). The most commonly used spray reagents were: A, potassium iodoplatinate (5); B, Gibb's (6).

Extraction—Boldo leaves[2] were ground to a coarse powder in a Wiley mill and defatted by portionwise extraction in a Soxhlet apparatus with petroleum ether (b.p. 30–60°) for 6 hr. No alkaloids could be detected in this extract by TLC after separation of any bases by acid extraction. One-kilogram portions of the defatted powder were moistened with 5% ammonium hydroxide (1 L. and exhaustively extracted with chloroform in a percolator. The combined extracts from 5 Kg. of boldo leaves were reduced to 1.5 L. in a flash evaporator and extracted four times with 1 *N* hydrochloric acid (500 ml.) and once with 4 *N* hydrochloric acid (500 ml.). The acid extracts were neutralized with ammonia (pH 8–9) and extracted with chloroform until alkaloids could no longer be detected in the extracts by TLC. The combined chloroform extracts were reduced to 200 ml. in a flash evaporator (extract *a*). TLC examination (system *A*, spray reagent A) revealed the presence of 5 main alkaloid-positive areas at R_f 0.7 (isocorydine),[3] R_f 0.6 (*N*-methyllaurotetanine and norisocorydine), R_f 0.5 (boldine), R_f 0.3, and R_f 0.2.

Countercurrent Distribution—Extract *a* formed the lower phase of the first tube of a seven-tube counter-current distribution (in separators) between chloroform and an aqueous solution of 1% tartaric acid and 10% sodium chloride (200 ml. of each phase in each tube). After distribution was completed, the pH of each aqueous phase was adjusted to 10 by addition of ammonia and the chloroform layers were separated. Each aqueous phase was then extracted three times with 100 ml. chloroform and the combined chloroform extracts from each tube washed (water) and reduced to 50 ml. in a flash evaporator. The contents of tubes 2–4 and 5–7 were combined and the two resulting solutions again subjected to the countercurrent distribution. The contents of tube 1 were distributed (7 tubes) between chloroform and an aqueous solution of pH 6 (McIlvaine buffer). All tubes from these distributions having similar groups of alkaloids were combined to give four solutions (*1*, *2*, *3*, *4*). TLC examination (solvent system *A*; spray reagents A and B) showed that boldine (R_f 0.50) was present mainly in solutions *2* and *3* and isocorydine (R_f 0.73), *N*-methyllaurotetanine (R_f 0.60), and norisocorydine (R_f 0.58) were mainly in solution *4*. Other alkaloid-positive spots were located at R_f 0.16, 0.17, and 0.30 in solution *1*, R_f 0.32 in solutions *2*, *3*, and *4*, R_f 0.55 and 0.65 in solution *3*, and R_f 0.18 in solution *4*. After further resolution of these four solutions by column chromatography and preparative TLC, 17 alkaloids could be detected by TLC to be present in the extract of boldo leaves. They were numbered 1–17 according to increasing R_f value in solvent system *A*.

Isolation of (+)-Reticuline—A slurry of silicic acid (100 mesh) and 0.1 *N* sodium hydroxide was filtered and the solid dried by suction and then at 100°. Solution *2* was evaporated on alkali-treated silicic acid (12 Gm.) and the dried and pulverized powder packed on top of a column of the same silicic acid (25 × 2.5 cm.). The column was developed first with chloroform and then with chloroform–methanol mixtures containing increasing concentrations of methanol. Forty-five fractions (15 ml.)

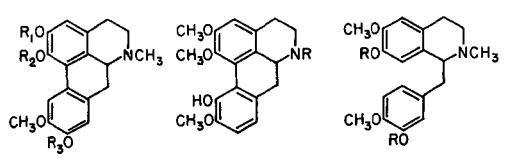
[1] Unoplan, Shandon Scientific Co. Ltd.

[2] Purchased from Dominion Herb Distributors, Montreal, Quebec, Canada.

[3] The authors are grateful to Dr. A. Rüegger, Sandoz Ltd. Basle, Switzerland, for authentic samples of isocorydine, norisocorydine, and *N*-methyllaurotetanine. Boldine was obtained from E. Merck (Darmstadt), Germany.

were collected and each fraction examined by TLC. Fractions 24–33 contained boldine (R_f 0.58; system *B*) in admixture with other alkaloids, mainly one (alkaloid 7) of R_f 0.50 (system *B*), characterized by giving a bright blue coloration with Gibb's reagent. Alkaloid 7 was concentrated by further column chromatography and a fraction was obtained which contained only boldine and alkaloid 7, in approximately equal amounts. After preparative TLC (system *A*) of this fraction, alkaloid 7 was obtained chromatographically pure. Further small amounts were obtained by preparative TLC of fractions obtained by chromatography of solutions *3* and *4*. The alkaloid was precipitated as an amorphous solid by *n*-hexane from ether solution, but attempts to crystallize it were unsuccessful. Yield 47 mg. (0.001%), m.p. 65–70°, $[\alpha]^{22}$ + 108°. The TLC (10 solvent systems, 11 spray reagents) and spectral (ultraviolet and infrared) properties of the alkaloid proved to be identical with those of an authentic sample of (±)-reticuline and the NMR spectrum ($CDCl_3$) was comparable with a published spectrum for (±)-reticuline taken in an unspecified solvent (7). It had a six-proton peak at 3.8 δ (two methoxyl groups), a three-proton peak at 2.44 δ (one *N*-methyl group), and a two-proton peak at 5.54 δ (two hydroxyl groups) which disappeared on addition of D_2O.

Alkaloid 7 was methylated with diazomethane in ethanol–ether solution for 20 hr., and the solution extracted with 1 *N* hydrochloric acid. This extract was made alkaline with ammonia, extracted in turn with chloroform, and the chloroform solution dried ($MgSO_4$), and evaporated. The product was amorphous and attempts to crystallize it were unsuccessful. It was shown to be homogeneous and identical with laudanosine[4] (III, R = CH_3) by TLC and infrared spectroscopy.



I II III

Isolation of Isoboldine—TLC comparison (system *A;* spray reagents A and B) of a sample of isoboldine[5] with solutions *1*, *2*, *3*, and *4* showed that alkaloid 11 (R_f 0.55) corresponded with isoboldine both in R_f and color reactions. The alkaloid was detected only in solution *3* and was concentrated by column chromatography and countercurrent distribution (chloroform *versus* 1% sodium carbonate, to separate it from boldine; chloroform *versus* 1% tartaric acid + 10% sodium chloride, to separate it from norisocorydine and *N*-methyllaurotetanine). Alkaloid 11 was obtained homogeneous only after preparative TLC and was shown to be identical with a sample of isoboldine by TLC (solvent systems *A–D*, 6 spray reagents) and by ultraviolet and infrared spectroscopy. Insufficient material was obtained for crystallization.

[4] Laudanosine was obtained from E. Merck (Darmstadt), Germany.

[5] The authors are grateful to Professor R. Tschesche, University of Bonn, West Germany, for an authentic sample of isoboldine and to Dr. R. H. F. Manske, Dominion Rubber Research Laboratory, Guelph, Ontario, Canada, for a sample of glaucine.

Alkaloid 11 was methylated with diazomethane in ethanol–ether solution for 72 hr. TLC examination of the product (3 solvent systems, 6 spray reagents) showed it to be identical with glaucine[5] (I, $R_1 = R_2 = R_3 = CH_3$).

DISCUSSION

Although the initial objective of this study was to characterize the alkaloids of boldo leaves by TLC alone, it soon became clear that, because of the large number of alkaloids present, preliminary resolution by countercurrent and chromatographic techniques was essential. After many purification steps it was possible to record unambiguously both color reactions and R_f values in various solvent systems for 17 alkaloids. Positive reactions with several alkaloidal spray reagents, in combination with the method of extraction, indicate that all 17 compounds are alkaloids. Furthermore, alkaloids 1–15 and 17 appear to be phenolic on the basis of positive reactions observed with other reagents. This was confirmed by repeated extraction of an ether solution of the alkaloids with 5 *N* sodium hydroxide, when only alkaloid 16 remained in the ether phase.

Considering the method of extraction used, the alkaloids detected in this study are probably nonquaternary. Preliminary work showed that acidification of the extracted boldo leaves, followed by further extraction with ethanol, yielded a fraction containing small amounts of quaternary bases. Alkaloids 8, 9, 14, 15, and 16 appear to be present in amounts too small to permit their isolation and identification, but work is in progress on the isolation and characterization of some of the other alkaloids, based on the purification processes described here.

Reticuline was originally isolated from *Cocculus laurifolius* and named coclanoline (8) but the name reticuline is now accepted by most workers and it has since been found in a number of plant species [*e.g.*, opium (*Papaver somniferum*) (7, 9), *Anona reticulata* (10), and *Romneyi coulteri* (11)]. Its isolation from *Peumus boldus* Molina is of interest since it is the first nonaporphine alkaloid to be isolated from this source and since it has been shown to be a key intermediate in the biogenesis of both the morphine (12) and berberine-protopine (13) series of alkaloids. It has also been postulated to be a biogenetic precursor of certain aporphines (14) and, although there is not yet direct *in vivo* evidence to support this hypothesis, reticuline has been converted *in vitro* in low yield into the aporphine isoboldine by oxidation with specific reagents (15). The two alkaloids have also been recently reported to occur together in opium (16). This prompted us, having isolated and characterized reticuline, to search for evidence for the presence of isoboldine in boldo leaves. The alkaloid was easily detected by TLC of solution *3* from the countercurrent distribution because of a characteristic green color given by it with potassium iodoplatinate reagent, all the other alkaloids giving the usual purple coloration. Separation of the pure alkaloid proved to be very difficult because of the presence of many interfering substances and because of the instability of the alkaloid. Enough was obtained, however, for comparison with an authentic sample of isoboldine by TLC, ultraviolet, and infrared spectroscopy. Furthermore, glaucine was shown by TLC identification to be the product of methylation with diazomethane.

The specific rotation of reticuline has been found to vary according to its origin between −55° and +132° and this is probably due to different rates of consumption of the two enantiomorphs in the biosynthetic pathways of the various species. Comparison with the value (+132°) found by Kusuda (8) for (+)-reticuline indicates that reticuline from *P. boldus* contains, at most, 10% (−)-reticuline.

Michaelis Constants for Isolated Cholinesterase Systems

By SAMUEL T. CHRISTIAN* and JAMES G. BEASLEY

The enzymatic hydrolysis of acetylcholine chloride by human plasma cholinesterase has been studied in detail. Results suggest that at substrate concentrations below 0.01 *M*, Michaelis-Menten kinetics are followed and enzyme hydrolysis rates are due to a single enzyme component. At higher substrate concentrations, a second enzyme component appears to contribute significantly to the total velocity of the reaction and a Lineweaver-Burk plot yields a hyperbolic-type curve. Apparent K_m values were calculated for the two components. The autohydrolysis rate for acetylcholine chloride at 26° was determined.

EVALUATION OF accurate Michaelis constants (K_m) has long been considered by the enzymologist to be practical only with highly purified isolated enzyme preparations. Nevertheless, enzyme kinetic constants from preparations of varying degrees of purity by investigators with divergent disciplinary backgrounds has led to the publication of a wide range of K_m values for most enzymes. This is particularly true in the case of human plasma (pseudo) cholinesterase (acylcholine acylhydrolase; E.C. 3.1.1.8) where many *apparent* K_m values (1–7) have been reported for the hydrolysis of butyrylcholine and benzoylcholine although comparatively little attention has been given to the hydrolysis of acetylcholine halides by the same enzyme. Acetylcholine is generally the substrate utilized in cholinesterase inhibitor evaluation.

In considering the variety of enzyme preparations (*e.g.*, commercial preparations,[1] Harvard fractions, IV-6-3 through IV-6-4 (8), Kabi fraction IV-6-3 (9), and completely unfractionated human serum (10), used for kinetic and inhibitor studies, it became of interest to ascertain the validity of expressing the Michaelis constants obtained with these preparations over wide ranges of substrate concentrations as valid, reproducible expressions of the true Michaelis constant.

METHOD

Acetylcholine chloride (Sigma Chemical Co.) was used as substrate in these studies; 17 different substrate concentrations covering a range from $3.00 \times 10^{-3}M$ to $1.50 \times 10^{-1}M$ were utilized. Enzyme initial velocity measurements were determined at 26.0° (±0.05°) with a continuous titration method (11) in a 0.15 *M* sodium chloride solution

Michaelis Constants for Isolated Cholinesterase Systems

By SAMUEL T. CHRISTIAN* and JAMES G. BEASLEY

The enzymatic hydrolysis of acetylcholine chloride by human plasma cholinesterase has been studied in detail. Results suggest that at substrate concentrations below 0.01 *M*, Michaelis-Menten kinetics are followed and enzyme hydrolysis rates are due to a single enzyme component. At higher substrate concentrations, a second enzyme component appears to contribute significantly to the total velocity of the reaction and a Lineweaver-Burk plot yields a hyperbolic-type curve. Apparent K_m values were calculated for the two components. The autohydrolysis rate for acetylcholine chloride at 26° was determined.

EVALUATION OF accurate Michaelis constants (K_m) has long been considered by the enzymologist to be practical only with highly purified isolated enzyme preparations. Nevertheless, enzyme kinetic constants from preparations of varying degrees of purity by investigators with divergent disciplinary backgrounds has led to the publication of a wide range of K_m values for most enzymes. This is particularly true in the case of human plasma (pseudo) cholinesterase (acylcholine acylhydrolase; E.C. 3.1.1.8) where many *apparent* K_m values (1–7) have been reported for the hydrolysis of butyrylcholine and benzoylcholine although comparatively little attention has been given to the hydrolysis of acetylcholine halides by the same enzyme. Acetylcholine is generally the substrate utilized in cholinesterase inhibitor evaluation.

In considering the variety of enzyme preparations (*e.g.*, commercial preparations,[1] Harvard fractions, IV-6-3 through IV-6-4 (8), Kabi fraction IV-6-3 (9), and completely unfractionated human serum (10), used for kinetic and inhibitor studies, it became of interest to ascertain the validity of expressing the Michaelis constants obtained with these preparations over wide ranges of substrate concentrations as valid, reproducible expressions of the true Michaelis constant.

METHOD

Acetylcholine chloride (Sigma Chemical Co.) was used as substrate in these studies; 17 different substrate concentrations covering a range from $3.00 \times 10^{-3}M$ to $1.50 \times 10^{-1}M$ were utilized. Enzyme initial velocity measurements were determined at 26.0° (±0.05°) with a continuous titration method (11) in a 0.15 *M* sodium chloride solution

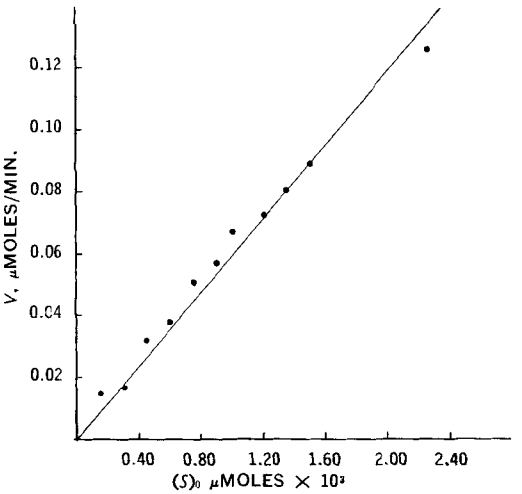

Fig. 1—Autohydrolysis of acetylcholine chloride at 26°. Key: S_0, abscissa, represents the initial micromolar substrate concentration; V, the ordinate, represents the reaction rate in μmoles/min. determined directly from titration curves for each substrate concentration; k = 5.59 × 10^{-5} min.$^{-1}$.

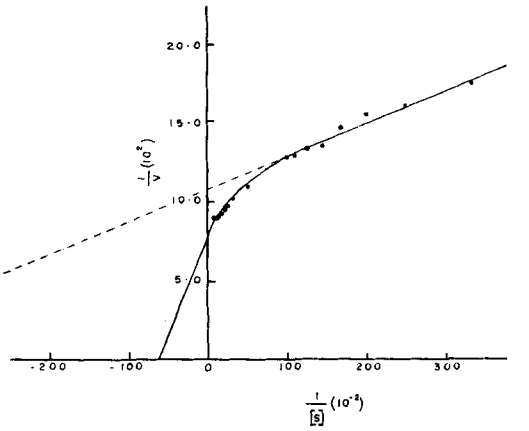

Fig. 2—Hydrolysis of acetylcholine chloride by human plasma cholinesterase at 26°, and pH 7.40 ± 0.05. Reactions were initiated by addition of 0.1 mg. of enzyme. Key: abscissa, reciprocal molar acetylcholine chloride concentration; ordinate, reciprocal enzyme initial velocity expressed in μmoles/min. per mg. of protein.

which was also 0.04 *M* in magnesium chloride. The total reaction volume was 15.0 ml. with each sample containing 0.1 mg. of enzyme (Type II Pseudo cholinesterase from human plasma; E.C. 3.1.1.8, Sigma Chemical Co.). The autohydrolysis of acetylcholine chloride was evaluated under the same conditions used for the enzyme reaction.

RESULTS AND DISCUSSION

The apparent first-order rate constant for the autohydrolysis of acetylcholine chloride as determined from Fig. 1 is 5.59 × 10^{-5} min.$^{-1}$. The effect of autohydrolysis on enzymatic initial velocities is negligible below substrate concentrations of 0.01 *M*; the data have been corrected for autohydrolysis effects at substrate concentrations above 0.01 *M*.

Walter (12), Dixon and Webb (13), and Reiner (14) have discussed the interesting case in which a reaction mixture containing two similar enzymes with different reaction rate constants is allowed to act on a single substrate; theoretically, if $K_{m1} \neq K_{m2}$, a Lineweaver-Burk (15) plot of such a reaction would show a hyperbolic relationship rather than the usual linear one. Reiner (14) has shown, by further theoretical treatment, that in order to distinguish between the two major enzyme components of such a system, the slopes of the two branches of the hyperbola must differ by 50% or more.

The authors have succeeded in demonstrating experimentally with human plasma cholinesterase[2] an actual example of a mixed enzyme system which adheres to this theoretical treatment.

A Lineweaver-Burk transformation constructed from our data for substrate concentrations ranging from 0.15 *M* to 0.003 *M* is presented in Fig. 2 and illustrates the hyperbolic-like relationship.

The results were not unexpected since Hess *et al.* (16) have previously demonstrated, by starch gel electrophoresis studies, the existence of six active butyrylcholinesterase fractions in human serum and Svensmark (17) has observed five fractions using DEAE-cellulose and DEAE-sephadex chromatography. However, from these studies it appears that in the enzyme preparations used, only two components were sufficiently active or present in sufficient concentration to contribute to the observed reaction rates.

A close look at the curve depicted in Fig. 2 shows that bending of the curve occurs at substrate concentrations greater than 0.01 *M*. Obviously, this bend is not caused by inhibition due to high ionic strength (18) but represents accelerated hydrolysis of substrate by a minor, kinetically distinct enzyme component.[3]

For substrate concentrations below 0.01 *M* it is apparent that this arm of the hyperbola is linear, as suggested by Walter (12) and is most probably due to a single, kinetically distinct major enzyme component. The K_m value determined for this component is 2.0 × 10^{-3} *M* (Fig. 2). This value is in good agreement with those previously reported using acetylcholine in low concentrations (<0.01 *M*) as a substrate (4, 20).

The wide range of K_m values previously reported may be due to the failure of some investigators to recognize the hyperbolic nature of this curve and to the inclusion of some high substrate concentration values in their K_m evaluation plots.

The relative importance of these findings should have special significance for investigators using plasma cholinesterase preparations to evaluate kinetically the effectiveness of various cholinesterase inhibitors.

From a practical standpoint, it appears safe to use acetylcholine in concentrations less than 0.01 *M* for evaluating enzyme-inhibitor kinetic constants[4] for

[2] Similar hyperbolic type curves were obtained from human plasma cholinesterase preparations supplied by Sigma Chemical Co. and by Cutter Laboratories, Inc. Berkeley, California.

[3] Humiston and Wright (19) have reported a similar break in the curve when acetylthiocholine iodide was used as a substrate for human plasma pseudocholinesterase.

[4] Dixon and Webb (13), in their treatment of a theoretical two enzyme system, suggest the practicability of this approach.

plasma cholinesterase systems. At these concentrations, the enzyme-substrate reaction follows classical Michaelis-Menten kinetics, suggesting a single enzyme–substrate interaction.[5] Although the apparent K_m value obtained from such plots appears reliable and reproducible, it does not necessarily represent a true K_m value but rather one intermediate between those for the two enzyme components present.

A complete kinetic analysis of pseudo (butyryl) cholinesterases must await separation and purification of each of the active enzyme species.

[5] The above suggestion does not apply to any rigorous kinetic treatment but is offered only as a guide for determining the relative potencies of cholinesterase inhibitors. Although unlikely, it is possible that specific inhibitors may have abnormally high affinities for minor enzyme components in impure cholinesterase preparations. Such a possibility cannot be ruled out completely on the basis of the available data.

Correlation of Ratios of Drug Metabolism by Microsomal Subfractions with Partition Coefficients

By ERIC J. LIEN and CORWIN HANSCH

A strong correlation between ratios of drug metabolism by microsomal subfractions with 1-octanol/water partition coefficient was found. Explanation for the spread of ratios is presented.

A VARIETY OF drug-metabolizing enzymes appear to be distributed between rough and smooth particles derived from the endoplasmic reticulum of liver cells (1–6). Using density gradient centrifugation, Fouts' group has separated the smooth-surfaced particles from the denser, rough-surfaced particles and then studied the metabolism of various drugs by the two types of particles. The rates of metabolism for each type of particle were obtained in terms of micromoles of drug metabolized per hr. per mg. of microsomal nitrogen. The ratios of enzymic activity in the two types of particles differed by almost 10-fold (depending on the drug). Fouts interpreted the different ratios as indicating different concentrations (activities) of enzymes in the two types of tissues. The authors wish to show that an alternative explanation can be advanced from a consideration of the physical properties of the substrates.

Equation 1 was derived *via* the method of least squares from the data of Fouts (2) and Gram *et al.* (6) in Table I. These data were obtained using Rothschild's method of preparation of microsome fractions. In Eq. 1, $R_{(s/r)}$ stands for the ratio of enzyme activity in the two types of particles (smooth/rough) and P is the partition coefficient of the drug in 1-octanol/water (7, 8), n is the number of data points used in deriving the equation, r is the correlation coefficient, s is the standard deviation from regression, and the figures in parentheses are the 90% confidence intervals. Addition of a term in $(\log P)^2$ to Eq. 1 does not result in an improved correlation (9). Three of the $\log P$ values in Table I were calculated (7, 10, 11). The value for benzpyrene was based on $\log P = 3.37$ for naphthalene, codeine was based on 0.76 for morphine, and amphetamine was based on 1.41 for 2-phenylethylamine.

$$\log R_{(r/s)} = \underset{(\pm 0.035)}{-0.101} \log P + \underset{(\pm 0.108)}{0.859}$$

[a] Experimentally determined values. Other values calculated. [b] From *Reference 2*. [c] From *Reference 6*. [d] Calcd. using Eq. 1.

Using Dallner's method of preparing microsomal subfractions from rabbit liver, Gram *et al.* (6) studied the metabolism of eight drugs. Using log P values from Table I Eq. 2 has been derived, omitting data on azosulfamide[1] for which log P is not available.

$$\log R_{(s/r)} = \underset{(\pm 0.034)}{-0.091} \log P + \underset{(\pm 0.103)}{0.553}$$

$$n = 7 \quad r = 0.923 \quad s = 0.089 \quad \text{(Eq. 2)}$$

DISCUSSION

Equation 1 indicates that the more lipophilic the drug is (the higher log P is), the smaller the ratio of metabolism or, the more hydrophilic, the larger the ratio. The linear relation between log P and log $R_{(s/r)}$ does *not* imply the higher the ratio, the faster the metabolic change. In each case we are comparing the same drug in two different types of particles. In Table I there are 10 drugs of quite different chemical structure being metabolized by an unknown number of enzymes. Although the ratios in Table I can be explained by postulating different concentrations (or activities) of different enzymes in the two types of particles, this approach does not lend itself to rationalizing Eq. 1. An alternative postulate is that approximately the same activities of enzymes are in each type of particle, but the availability of the drug to the enzyme is rate limiting and depends on the milieu in which the enzyme is set. If one postulates that each type of particle contains enzymes in a very lipophilic setting, this would explain why hydrophobic drugs such as benzpyrene and chlorpromazine are metabolized at ratios near 1. The smooth particles would then appear to have a set of enzymes accessible to hydrophilic drugs which would explain why drugs with low log P values yield higher ratios. In this respect it is interesting to compare the four examples of aromatic hydroxylation in Table I. It seems likely that the same type of enzyme (12) would be involved in each case. If this is so, then the differences in R must be due to differences in availability of drug to enzyme. Most interesting is the fact that log $R_{(s/r)}$ is correlated with log P regardless of the type of reaction. This also points to access of drug to enzyme rather than a difference in enzyme activity in the two particles.

The correlation with Eq. 1 still leaves 22% of the variance in the data "unexplained" ($r^2 = 0.78$). This of course must be attributed to the second rate-limiting process, that of action of the enzyme on drug. For these processes no stereo or electronic terms have been included in Eq. 1. Although the slope of Eq. 2 is very close to that of Eq. 1, the intercept is different. Thus for *isolipophilic* drugs one would expect higher ratios using Rothschild's method of preparation. The dependence of log $R_{(s/r)}$ on log P appears to be the same.

Fouts' work is quite important for an ultimate understanding of the role of the liver in drug metabolism. Looked at from the point of view of Eq. 1, it appears to indicate two different kinds of setting for microsomal enzymes. It is further support for Brodie's (13) observation of the great dependence of drug metabolism on lipophilic character of the drugs (14).

Essential Oils and Their Constituents XXXVII. Isolation and Structure of Khusenol, a New Sesquiterpenic Primary Alcohol from Oil of Vetiver

By I. C. NIGAM, C. RADECKA, and H. KOMAE

A new sesquiterpenic tricyclic primary alcohol has been isolated from Angola vetiver oil. It was found to be identical with the product obtained by $LiAlH_4$ reduction of methyl khusenate, and on oxidation with CrO_3 and Ag_2O it gave khusenic acid. The alcohol has, therefore, been assigned structure I and named khusenol.

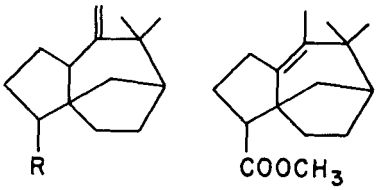
A NEW SESQUITERPENE alcohol has been determined to be the main constituent of the primary alcohol fraction of Angola vetiver oil. The present communication describes its isolation and properties, and records experimental evidence for its structure (I). The alcohol has been named "khusenol" in view of its structural relationship to another constituent of the oil, khusenic acid, which was shown to possess a novel carbon skeleton and assigned structure II (1).

A sample of angola vetiver oil, from which the free acids as well as the aldehydes and ketones had been removed previously, was treated with phthalic anhydride on a steam bath. The resulting hydrogen phthalate esters were saponified to give the primary alcohol fraction (35.5% of the oil sample), which was chiefly composed of khusenol (64% by GLC analysis). Fractional distillation of the primary alcohol fraction gave a 90% pure sample of khusenol. The alcohol may be characterized through its 3,5-dinitrobenzoate (m.p. 116°).

Dehydrogenation of khusenol with selenium at 300 ± 10° failed to yield any aromatic product. Catalytic hydrogenation showed the presence of one double bond, indicating the tricyclic nature of the compound. The infrared spectrum of the alcohol (Fig. 1) exhibited absorption bands at 1632 and 890 $cm.^{-1}$ characteristics of a $CH_2 = C <$ group. The NMR spectrum of the compound (Fig. 2) showed two triplets centered at 4.58 and 4.73δ, instead of the expected doublet for the olefinic protons, indicative of long range coupling. An additional NMR peak at 1.07δ with a shoulder ($\approx$1.06δ) was assigned to two methyl groups. A detailed study of the NMR spectra of khusenol, khusenic acid, and some related compounds will be reported shortly.

Treatment of khusenol with CrO_3–pyridine yielded a mixture of carbonyl compounds (mainly aldehydes, IR spectrum), which were oxidized with Ag_2O to the corresponding acids and converted into methyl esters by reaction with diazomethane. On gas chromatographic analysis, the mixture of esters was found to be chiefly composed of two products, one of which was methyl khusenate (III). Treatment of the ester mixture with HCl brought about isomerization of methyl khusenate to methyl isokhusenate (IV) (2).

The relationship between the alcohol and khusenic acid implied in these results was confirmed by comparing the properties of khusenol with those of the alcohol obtained by reduction of methyl khusenate with $LiAlH_4$. The IR and NMR spectra, and the m.p. of the 3,5-dinitrobenzoate of the two alcohols, as well as their gas and thin-layer chromatographic properties were identical. Khusenol is, therefore, assigned Structure I.



I, R = CH_2OH IV

II, R = COOH

III, R = $COOCH_3$

EXPERIMENTAL

Apparatus and other pertinent details for UV, IR, and NMR spectral measurements, microanalyses, and gas chromatographic determinations were described before (2).

Isolation of the Primary Alcohol Fraction of Angola Vetiver Oil—A sample of the oil (90.3 Gm.) from which the free acids as well as the aldehydes and ketones had been removed by reaction with Amberlite-IRA-400 ion-exchange resin (2, 3) and Girard T reagent (4), respectively, was treated with freshly sublimed phthalic anhydride (95 Gm.) on a steam bath for 2 hr. The resulting hydrogen phthalate esters of the primary alcohols were separated and saponified following the method of Elze as described by Sterrett (5). Yield of the primary alcohol fraction was 32.1 Gm. (35.5% of the oil). Gas-chromatographic examination of the isolate employing a 3% SE-30 column (2) showed the presence of one major constituent (64%; relative retention time 0.857, reference standard-phenanthrene).

Isolation of Khusenol—A portion (32.1 Gm.) of the fraction containing primary alcohols was submitted to fractional distillation (pressure: 3 mm.; reflux ratio: 10:1) using a Gallenkamp fractional distillation unit. When 11 fractions (total weight: 23.4 Gm.) had been collected, the distillation slowed down. At this stage the residue in the distillation pot was transferred to a small flask (25 ml.), and fractional distillation was resumed at 0.7 mm. pressure employing a Quickfit micro-distillation assembly. Three more fractions (total weight 5.3 Gm.) were collected. All 14 fractions were analyzed by gas chromatography on an SE-30 column (2) and found to be chiefly composed of khusenol. Fraction No. 13 (3.4 Gm.) was the purest (90%). An analytical specimen, prepared by gas chromatography on a 20% Reoplex 400 column (2), possessed the following properties. $b.p._{0.7}$ 140–142°; n_D^{27} 1.524;

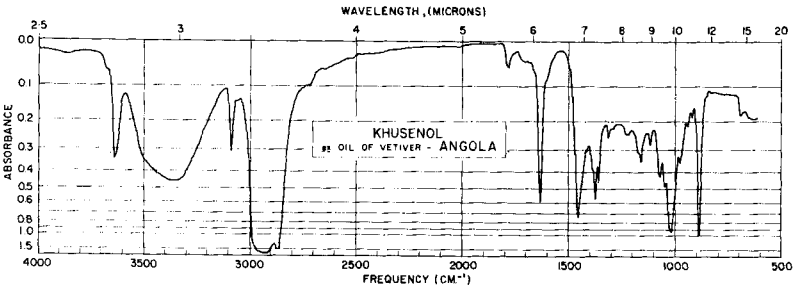

Fig. 1—Infrared spectrum of khusenol.

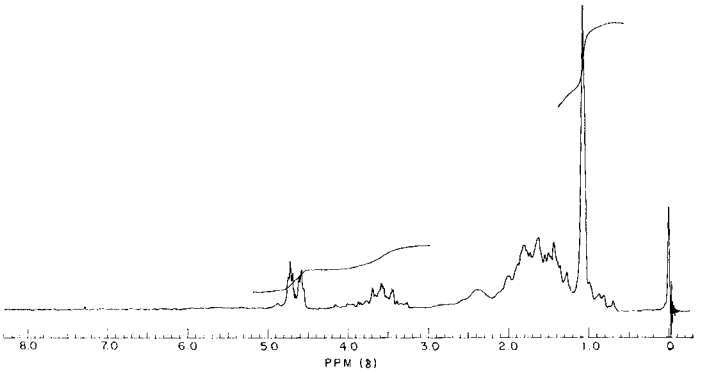

Fig. 2—NMR spectrum of khusenol. Solvent, $CDCl_3$; sweep width, 500. At sweep width of 100 a distinct shoulder near 1.06 δ was observed.

$[\alpha]_D^{29}$ + 14.5°; D_{26}^{26} 0.9740; 3,5-dinitrobenzoate, m.p. 116°.

Anal.—Calcd. for $C_{22}H_{26}O_6N_2$: C, 63.76; H, 6.32; N, 6.76. Found: C, 63.90; H 6.32; N, 6.75.

Dehydrogenation of Khusenol—A mixture of khusenol (381 mg.) and selenium (750 mg.) was heated at 300 ± 10° for 10 hr. under a stream of nitrogen. The reaction mixture was extracted with hexane (5 × 2 ml.), and the dark brown oil, which remained after evaporation of the solvent was chromatographed on alumina (grade I, 12 Gm.). Three fractions were collected: 1, (hexane, 30 ml.) 180 mg.; 2, (hexane, 30 ml.) 5 mg.; 3, (ether, 30 ml.) 58 mg. The fractions did not show any characteristic ultraviolet absorption and did not have any aromatic band in their infrared spectra.

Hydrogenation of Khusenol—Khusenol (135 mg. in glacial acetic acid (2 ml.) was hydrogenated in the presence of platinum oxide (5.2 mg.). The volume of absorbed hydrogen at 27°, 733 mm. was 16.6 ml. (1.2 moles).

Oxidation of Khusenol—Chromium trioxide (2.40 Gm.) in pyridine (36 ml.) was added to a solution of khusenol (2.98 Gm.) in pyridine (12 ml.) and the mixture was allowed to stand overnight at room temperature. The reaction mixture on conventional processing yielded a crude oxidation product (2.40 Gm.) which was purified by chromatography on grade II alumina (6) (Woelm; 100 Gm.). A mixture of hexane-benzene (3:1) eluted an oily product (468.2 mg., infrared absorption bands at 2712 and 1718 $cm.^{-1}$). Freshly prepared silver oxide, obtained from silver nitrate (169.2 mg.) (7) and a solution of sodium hydroxide (206.3 mg.) in water (2 ml.), was added to a portion of the product (107.1 mg.) dissolved in ethanol (0.2 ml.). The mixture was stirred at room temperature for 48 hr., filtered, acidified with 10% HCl, and extracted with ether. The yield of product was 100 mg.

Methylation of Acids—The above oxidation product (100 mg.) was dissolved in 3 ml. of a methanol–ether mixture (1:9) and methylated by introducing gaseous diazomethane (8). The product (99 mg.) on gas chromatographic analysis (SE 30 column) (2), showed 2 major peaks at 11.6 and 13.2 min. The former was identified as methyl khusenate.

Isomerization of Methyl Esters—The product of methylation (99 mg.) was refluxed with a mixture of ethanol (9 ml.) and concentrated HCl (1 ml.) for 1.5 hr. on a water bath. The usual processing of the reaction mixture yielded the isomerized esters (94 mg.). Gas chromatographic analysis of the product (SE-30 column) (2) showed the presence of two major constituents, appearing at 10.7 and 12.8 min. The earlier peak was identified as methyl isokhusenate. The peak corresponding to methyl khusenate was absent.

Uterine–Placental–Fetal Preparation *In Situ* on the Dog. Investigation of Metabolizing Activity and Tissue Distribution

By G. BENZI, F. BERTÉ, A. CREMA, and E. ARRIGONI

The extracorporeal perfusion technique *in situ* has been used to evaluate the metabolizing activity of the uterine–placental–fetal preparation on the dog. The pregnant uterus isolated from general circulation was supplied with a pump-oxygenator system. The method was tested studying the metabolic transformation of aminopyrine to 4-aminoantipyrine and *N*-acetyl-4-aminoantipyrine, and evaluating their distribution in fetal tissues.

TOXICOLOGICAL and pharmacological importance of drug metabolism in fetal and uterine tissues is well known. Nevertheless, the studies on pregnant animals *in toto* present complications related to maternal metabolism. The evaluation of the fetal physiological activities *in situ* can be performed while maintaining the fetus detached from its placental connection by an extracorporeal supporting system reproducing the placental circulation (1–7). Likewise, the uterine or placental influence on the transfer and utilization of the substances can be studied by the perfused placenta or pregnant uterus (8–14). Nevertheless, the lack of data prompted the study of drug metabolic activity of the fetus–uterus complex isolated *in situ*, so as to eliminate any interference of extrauterine tissues.

In a systematic investigation of the metabolism and tissue distribution during the pregnancy (15–17) the metabolic fate of aminopyrine was detected in the uterine–placental–fetal preparation *in situ* using a method of extracorporeal circulation. In the experimental arrangement, the pregnant uterus remained connected with the other parts of the body, except its blood circulation was supplied by a pump-oxygenator system.

EXPERIMENTAL

The experiments were carried out on 11 pregnant dogs (16.8 to 27.5 Kg.) preanesthetized with urethan (0.4 Gm./Kg. i.p.). Anesthesia was induced and maintained in closed circuit by nitrous oxide, cyclopropane, or ethyl ether. The animals were given artificial ventilation by a tracheal Warne tube after succinylcholine chloride (1 mg./Kg. i.v.) administration. Arterial blood pressure was measured from a cannula inserted into a femoral artery.

The abdomen was incised along the midline from xiphoid process to pubis; the uterine artery and vein on both sides of the uterus were isolated at the neck of the uterus. The vaginal, ovaric, and peritoneal vascular connections with the extrauterine tissues were occluded by ligature or compression. Both isolated uterine veins were ligated, cannulated, and connected with the venous reservoir of the pump-oxygenator system through the gravitational flow. Both isolated uterine arteries were cannulated and connected with the pump-oxygenator system; at this point the perfusion started.

Hematocrit, clotting time, pH, and arteriovenous blood oxygen were measured from samples of both extracorporeal and systemic circulation. The perfusion apparatus consists of: a venous reservoir, an oxygenator with gas meter, a roller-type pump with flow meter, a blood filter, an apparatus to eliminate the blood foam, a perfusion pressure regulator with manometer, and a blood exchanger with telethermometer (18).

Before the extracorporeal perfusion, the pump-oxygenator system was filled with 400–600 ml. of heparinized and defibrinated blood, previously obtained from the animal itself, filtered through cloth, preserved by ampicillin (1:10,000), and stored in a refrigerator. Before the perfusion the blood was filtered, diluted with Tyrode solution (to O_2 capacity = 13 ± 1 vol.%), and added to glucose (5%). The priming blood was circulated through the pump-oxygenator system, fully oxygenated, and warmed. A flow of O_2–CO_2 mixture (95:5) into the oxygenator was maintained at the rate of 5–10 L./min. During the extracorporeal circulation, the blood-flow rate was 10–12 ml./min./Kg.; the blood pressure was maintained at constant values of 80–110 mm. Hg; the time of perfusion was limited to 60 min.

The eventual leakage of perfusate into the systemic circulation was evaluated by taking samples from the general circulation of the blood and the lymph to verify the absence of the tested substance or its metabolites.

To investigate the metabolizing activity, the authors studied: (*a*) *demethylation*, by evaluating the transformation of aminopyrine to 4-aminoantipyrine using the method of Brodie and Axelrod (19) after addition of 100–200 mcg./ml. of aminopyrine into the extracorporeal circuit; (*b*) *acetylation*, by evaluating the transformation of 4-aminoantipyrine to *N*-acetyl-4-aminoantipyrine under the above-mentioned conditions and method.

At the end of the perfusion, the tissue distribution of aminopyrine and its two metabolites in some fetal organs (plasma, liver, kidney, lung, heart, brain, thymus, muscle, amniotic fluid, placenta) was determined, for every pregnant dog, pooling together the organs of its fetuses.

RESULTS

In the dog at eighth–ninth week of pregnancy, the uterine–placental–fetal preparation *in situ* shows a metabolizing activity. In fact, 29% (25 to 38%) of aminopyrine disappears in 60 min. and is partially replaced by the appearance of the 4-aminoantipyrine and *N*-acetyl-4-aminoantipyrine; an example is indicated in Fig. 1.

Figure 2 is a typical example of the fetal tissue concentration of aminopyrine and its two metabolites assayed after 60 min. of extracorporeal perfusion of an uterine–placental–fetal preparation. The following observations were made: (*a*) the diffusibility of aminopyrine across the placenta to the

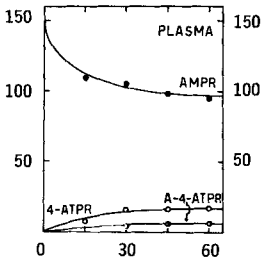

Fig. 1—Aminopyrine metabolism studied by the isolated uterine–placental–fetal preparation in situ *in a pregnant dog weighing 22.9 Kg. at ninth week of pregnancy; number of its fetuses = 6. Circulating blood in extracorporeal circuit = 680 ml.; blood flow rate of the extracorporeal circuit = 270 ml./min.; initial concentration of aminopyrine in the plasma of the extracorporeal circuit = 153 mcg./ml. On ordinate, the plasmatic concentrations (mcg./ml.) of aminopyrine* (AMPR), *4-aminoantipyrine* (4-ATPR), and N-*acetyl-4-aminoantipyrine* (A-4-ATPR). *On abscissa, time (in minutes) after aminopyrine addition.*

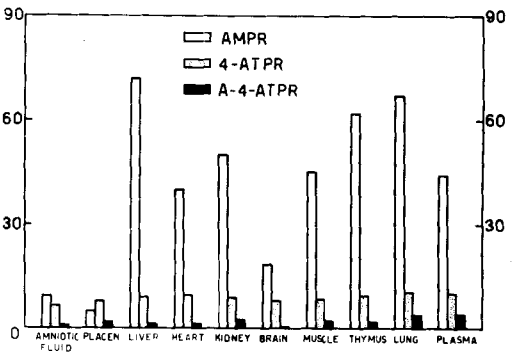

Fig. 2—Aminopyrine (AMPR), *4-aminoantipyrine* (4-ATPR), *and* N-*acetyl-4-aminoantipyrine* (A-4-ATPR) *concentrations (mcg./Gm. on ordinate) in the placental–fetal tissues 60 min. after adding aminopyrine into the extracorporeal circuit of the isolated uterine–placental–fetal preparation* in situ *of the pregnant dog as in Fig. 1. The concentrations are obtained by pooling together the organs from its six fetuses.*

fetuses; (*b*) the different concentrations of aminopyrine in the fetal organs studied; (*c*) the various proportions of aminopyrine to 4-aminoantipyrine and *N*-acetyl-4-aminoantipyrine in the fetal organs. Additional information will be necessary to state if these various proportions depend on a different ability in taking up the circulating metabolites.

In conclusion, the uterine–placental–fetal complex seems to be a useful method to investigate *in situ* both a detailed metabolizing activity and the drug-tissue distribution in the pregnant uterus normally connected with the body, except that its blood circulation is supplied by a pump-oxygenator system.

Radioprotective Effect of Magnesium Pemoline: A Comparison with Pemoline and Dextroamphetamine

By HOA LEVAN, and DELANO L. HEBRON

Magnesium pemoline, a central nervous system stimulant, is found to have a significant protective effect against ionizing radiations. Experimental results show that this drug is more potent than pemoline alone in exhibiting this radioprotective effect, and that dextroamphetamine does not possess this property. It is suggested that magnesium hydroxide, a component of magnesium pemoline, might enhance the absorption of pemoline to produce a more significant effect than when pemoline alone [without $Mg(OH)_2$] is used. The mechanism of this phenomenon is discussed, but no explanations are offered.

RECENTLY the authors reported the protective effect of magnesium pemoline against lethal doses of X-irradiations (1). Mice injected intraperitoneally with this drug showed a significant higher percentage of survival when exposed whole body to a total dose of 900 rads when compared with those injected with tragacanth. Further experiments were designed to compare the radioprotective effect of magnesium pemoline, of pemoline alone, and also that of another central nervous system stimulant, dextroamphetamine. Results of these studies are described and discussed in this paper.

METHOD

During the initial investigations, the experiments were designed to test the effect of magnesium pemoline on conditioned avoidance response in mice using X-rays as an unconditioned stimulus. Radioprotective effect of this drug was accidentally observed during these studies. Since then the experimental design has been changed to suit new objectives, although the same techniques were used in injecting and irradiating the animals.

Again CF_1 male mice (20–22 Gm.), 50 to 60 days old were used. The animals divided into five groups of 60 mice each were housed in standard plastic cages, 10 animals per cage. There was no restriction on food and water. On the first day of the experiment, 1 week after their arrival from the supplier, the mice in the first group were injected intraperitoneally with 0.6 ml. of magnesium pemoline (at a dose of 70 mg./Kg.), the second group with dextroamphetamine (0.7 mg./Kg.), the third group with pemoline alone (55 mg./Kg.), the fourth group with bacteriostatic water (0.3% tragacanth), and the fifth group with magnesium hydroxide, a component of magnesium pemoline (18 mg./Kg.). Magnesium pemoline, dextroamphetamine, pemoline, and magnesium hydroxide solutions were prepared with 0.3% tragacanth. All the mice were then exposed to 750 rads (at 80 rads/min.) of X-irradiations immediately after injection. A 400 Kv. Maxitron X-ray machine served as the source of radiation. The animals were then removed from the radiation room and returned to their original cages. Mortality in each group was observed and recorded daily. The experiments were repeated for three consecutive times. Data gathered from each group were then averaged each time and standard deviations obtained for all three experimental runs. Thus a total of 900 mice was used during this experiment.

Received December 8, 1967, from the University of Illinois, College of Medicine, Department of Radiology, Chicago, IL 60612

Accepted for publication January 19, 1968.

This work was supported in part by the Norval H. Pierce Research Fund, University of Illinois.

RESULTS AND DISCUSSION

As can be seen from Table I, the group injected with magnesium pemoline immediately before exposure to X-irradiation resisted against radiations longer than any of the other four groups. Comparing the magnesium pemoline group and the control group injected with tragacanth, one observes that this drug not only protects the animals against radiations (35% survival after 30 days) but also delays the damaging effect of radiation (100% survival on the seventh postirradiation day *versus* 79% in the control group). The rate of mortality was much less pronounced. On the thirteenth day after exposure while all the animals in the control group had died, 54% of the magnesium pemoline group still survived. Most of the mice in all groups died within the second postirradiation week. For the group treated with pemoline only, the delaying protective effect was not quite as significant when compared to the control (tragacanth) group. Nevertheless, 30-day mortality observation showed 15% of this group still survived, and at the end of the second week after exposure, 31% of the mice in this group were still alive *versus* 0% for the control group. Dextroamphetamine did not exhibit any protective effect against radiations. There was no significant difference between the mortality in this group and that in the control group. Magnesium pemoline is composed of 75 wt. % of pemoline and 25 wt. % of magnesium hydroxide. Table I also shows that the mice injected with $Mg(OH)_2$ died as fast as those in the control group and none survived 14 days after being exposed to lethal doses of ionizing radiations.

Comparing the radioprotective effect of magnesium pemoline and pemoline alone, one notes that the latter also offers protection but not as effectively as the former. On the eighth postirradiation day, the difference between the survival percentage of these two groups was quite significant ($p \ll 0.001$). Two weeks after exposure, this level of significance was still quite considerable ($0.05 < p < 0.02$). After 30 days while 15% of the animals in pemoline group survived, 35% were still alive in the magnesium pemoline group. Plotnikoff and Meekma (2) reported that magnesium pemoline was more potent in enhancing acquisition and retention of memory than pemoline alone, and that $Mg(OH)_2$ showed no significant effects. The results confirmed these findings as far as radioprotective effect of this drug was concerned. Comparing the doses used by these investigators and that used in these experi-

ments, our dose was much higher (70 mg./Kg. *versus* 1.25–5.0 mg./Kg.). The authors are in the process of studying this radioprotective effect at lower doses of magnesium pemoline and higher doses of pemoline alone. It has been generally suggested that magnesium hydroxide serves as a carrier for pemoline, thus the magnesium hydroxide component enhances the absorption of this drug. If this is the case, perhaps one could verify this by increasing the amount of pemoline in order to compensate for the slower rate of absorption when only pemoline is used. In any case, pemoline alone was responsible for the protection against lethal doses of radiation. So far, no pharmacological findings have offered any clues that could be used to explain this phenomenon. Lange *et al.* (3) have observed significant anticonvulsant activity 15 to 30 min. after oral administration of magnesium pemoline (100 mg./Kg.) and 60 min. after the administration of pemoline alone of the same dose. This delayed effect of pemoline without magnesium hydroxide seems to agree with the less radioprotective effectiveness in these experiments; however whether one can associate these findings with Lange's observations is still a question for further investigations. Furthermore, if this suggestion is true it would be difficult to explain the long-term protective effect of magnesium pemoline against ionizing radiations that we have observed.

SUMMARY

The following observations resulted from this study: (*a*) Radioprotective effect of both magnesium pemoline and pemoline alone are quite significant. (*b*) Magnesium pemoline is more potent than pemoline alone in exhibiting protective effect against ionizing radiation. (*c*) Dextroamphetamine does not possess this radioprotective effect. (*d*) Magnesium hydroxide, a component of magnesium pemoline, seems to enhance the absorption rate of pemoline in this effect.

Catharanthus Alkaloids XV. Isolation of Vindolinine from *C. lanceus* Leaves

By EDWARD M. MALONEY, HARRY H. S. FONG, NORMAN R. FARNSWORTH, RALPH N. BLOMSTER, and DONALD J. ABRAHAM

A continuing study of *Catharanthus lanceus* for antineoplastic alkaloids has resulted in the isolation of vindolinine (as HCl), which is reported for the first time from this plant. Perivine and yohimbine, reported previously, were also obtained in high yield.

In a previous communication (1) the isolation of perivine and yohimbine from the (B) fraction of *C. lanceus* leaves was reported. A reinvestigation of this fraction has resulted in the isolation of vindolinine, as the dihydrochloride salt. This is the first report on the isolation of vindolinine from *C. lanceus*, however it was initially isolated from the related *C. roseus* by two other groups (2, 3).

EXPERIMENTAL

Preparation of Crude Alkaloid Fraction—The alkaloid (B) fraction used in this investigation was derived from 267.5 Kg. of dried *Catharanthus lanceus* leaves, collected in Madagascar in July 1965.[1] Processing of the plant material as previously described (1) yielded 694 Gm. of crude alkaloid (B) fraction.

Isolation of Alkaloids—The crude fraction (694 Gm.) was dissolved in 6 L. of hot benzene, filtered, and cooled to room temperature. The residue on the filter pad was washed with cold benzene to remove brown coloring matter. This resulted in a yield of 43.92 Gm. of benzene-insoluble amorphous alkaloid, which was shown to be one-spot material following thin-layer chromatography (TLC), as previously described (4). The benzene filtrate, on standing at room temperature, formed crystals which were removed by filtration. The crystalline material when washed and dried, yielded 53.16 Gm. of alkaloid which was shown to be identical with the benzene-insoluble isolate. Concentration of the mother liquor to dryness *in vacuo*, and crystallization of the residue from acetone, yielded an additional 86.20 Gm. of alkaloid similar in all respects to the two previous crops. The three crystal crops were combined and an analytical sample was prepared by several crystallizations from hot acetone. After drying *in vacuo* at 50° for 24 hr. the crystals exhibited m.p. 232–233° dec. (cap., uncorr.). An ultraviolet absorption spectrum, in ethanol, showed maxima at 226 mμ (log $E^{1\%}_{1\,cm.}$ 3.20), 281 mμ (log $E^{1\%}_{1\,cm.}$ 2.52), and a shoulder at 290 mμ (log $E^{1\%}_{1\,cm.}$ 2.45). Thin-layer chromatography data in three solvent systems corresponded with that of yohimbine (4). An infrared spectrum (KBr) was identical with that of yohimbine, and the ultraviolet spectrum and melting point data were in agreement with published data for yohimbine (5).

After removal of the three crystal drops, the mother liquor was again taken to dryness and crystallized from hot acetone. After refrigeration, and standing overnight under refrigeration, crystals formed which were removed by filtration, washed with cold acetone, and dried to give a 79.9-Gm. yield. Thin-layer chromatography of this isolate indicated it to be similar, if not identical, with perivine (4). An analytical sample was prepared by several recrystallizations from acetone. The purified alkaloid was dried at 50° *in vacuo* for 24 hr., and was found to have m.p. 178–179° (cap., uncorr.). An ultraviolet absorption spectrum, in ethanol, exhibited a maximum at 316 mμ (log $E^{1\%}_{1\,cm.}$ 2.91) and a shoulder at 240 mμ, as well as an additional maximum being approached near 226 mμ. This spectrum is typical for the 2-acylindole moiety. An infrared spectrum of the isolate was identical with that of reference perivine, and the melting point and ultraviolet absorption data were consistent with literature values for perivine (5).

Following the removal of perivine, the mother liquor was again taken to dryness and 300 Gm. was dissolved in a minimum volume of benzene and the solution was applied to a chromatographic column (12 × 150 cm.) containing a benzene slurry of 14-Kg. Alcoa F-20 alumina, deactivated as previously described, by the addition of 120 ml. of 10% (w/v) acetic acid (1). Elution was initiated with benzene, followed by solvents and solvent mixtures of increasing polarity, and 1,000-ml. fractions were collected. The data for the operation of this column are presented in Table I. Fractions were combined on the basis of chromogenic responses of the resolved components to the ceric ammonium sulfate reagent (CAS), following TLC (4).

Fractions 28–101 (35.46 Gm.) from the column contained a major alkaloid which produced a red-orange color with the CAS reagent, and exhibited an R_f value consistent with that of vindolinine, in three different solvent systems (4). The alkaloid could not be induced to crystallize from the usual solvents, thus the fraction was taken to dryness, dissolved in ether, and HCl gas was passed through the ether solution. After 24 hr. the ether solution was filtered and the crude alkaloid hydrochloride was crystallized three times from methanol to yield 0.12 Gm. of pure vindolinine dihydrochloride. This exhibited m.p. 212–214° and an ultraviolet absorption spectrum having maxima at 245 mμ (log a_m 4.07) and 300 mμ (log a_m 3.63), with a minimum at 274 mμ (log a_m 3.35). An infrared spectrum (KBr) of the isolate was identical in all respects with that of a reference sample of vindolinine·2HCl[2]. The melting point and ultraviolet spectrum were in agreement with litera-

TABLE I—CHROMATOGRAPHIC SEPARATION OF *C. lanceus* LEAF ALKALOID (B) FRACTION[a]

Fraction No.[b]	Eluent	Fraction Wt., Gm.	Alkaloid Isolated	Yield, Gm.
1–3	Benzene	0.03		
4–7	Benzene	2.71		
8–18	Benzene	2.40		
19–27	Benzene	1.97		
28–101	Benzene	35.46	Vindolinine·2HCl	0.12
102–458	Benzene	29.50	Perivine	11.17
	Benzene–chloroform (99:1)			
	Benzene–chloroform (97:3)			
	Benzene–chloroform (95:5)			
459–580	Benzene–chloroform (3:1)	35.79	Perivine	13.56
			Yohimbine	9.42
581–608	Benzene–chloroform (3:1)	6.24	Yohimbine	3.46
609–623	Benzene–chloroform (3:1)	2.84	Yohimbine	0.91
624–640	Benzene–chloroform (3:1)	2.93	Yohimbine	1.09
641–735	Benzene–chloroform (3:1)	7.86		
736–788	Benzene–chloroform (2:1)	2.43		
789–806	Benzene–chloroform (1:1)	2.33		
807–842	Benzene–chloroform (1:1)	5.19		
843–901	Benzene–chloroform (1:1)	4.04		
902–1126	Chloroform	27.89		
1127–1151	Chloroform–methanol (99:1)	12.71		
1152–1518	Chloroform–methanol (99:1)	41.10		
	Chloroform–methanol (9:1)			
	Chloroform–methanol (3:1)			
	Chloroform–methanol (2:1)			
1519–1564	Methanol	14.65		

[a] 300 Gm. of alkaloid fraction was chromatographed on 14 Kg. of partially deactivated Alcoa F-20 alumina. [b] Each fraction was 1,000 ml. All fractions contained alkaloids.

ture reports for vindolinine·2HCl (3, 5), and the molecular weight for the alkaloid base was shown to be 336 by mass spectrometry (calcd. mol. wt., 336).

Fractions 102–458 (29.50 Gm.) from the column gave 11.17 Gm. of perivine on crystallization from acetone, benzene, and methanol. An additional 13.56 Gm. of perivine was obtained from fractions 459–580 (25.79 Gm.), from acetone, whereas the mother liquor of these fractions yielded 9.42 Gm. of yohimbine by crystallization from benzene and chloroform. An additional 5.46 Gm. of yohimbine was isolated from fractions 581–640 from the column, from benzene, chloroform, methanol, and acetone (see Table I for details).

This now brings to 19, the number of alkaloids that have been isolated from *C. lanceus* in this laboratory (1, 6–11).

A New Flavone from *Salvia triloba L.f* (*Labiatae*)

By A. ULUBELEN, S. ÖZTÜRK, and S. IŞILDATICI

Salvigenin was isolated from the air-dried leaves and stems of *S. triloba*. Seventy percent aqueous ethanolic extract of the plant yields ursolic acid, oleonolic acid, β-sitosterol, carnosol, and the above-mentioned new flavone, when separated on a silicilic acid–diatomaceous earth (3:1) column. Methylation of pectolinarigenin, C, H, and methoxy group determination, alcoholic KOH degradation, and UV, IR, and NMR methods led to the establishment of the following structure for salvigenin: 5-OH-6,7,4′-OCH_3-flavone or pectolinarigenin-7-methyl ether.

Salvia triloba L.f (*Labiatae*) which is a shrub 0.5–1.5 M. tall, is distributed from the Marmara sea to the Mediterranean. The plant is also known as mountain apple in Turkey.

A survey in literature showed that various salvia species such as *S. officinalis* (1–12), *S. braclyodon* (13), *S. pratensis* and *S. sclerae* (14), *S. miltiorrhiza* (15), *S. spinoza* (16), *S. splendens* (17), *S. glutinoza* (18) have been studied and ursolic acid I and II, oleolonic acid, sclareol, carnosol, tanshinone I, II, III, β-sitosterol, thujone, carene, azulene, α and β pinene, camphor, borneol, bornyl acetate, pentagalactosido sucrose, and acetyl anthocyans have been isolated and identified.

However, there are only a few papers on *S. triloba*. In 1954 Leiner (19) studied the ether extracts of *S. triloba* in this school and obtained ursolic acid I and II, oleonolic acid, a paraffin, a polyterpene and an oily compound, a flavone aglicon, a flavone glycoside, and a bitter substance. Ursolic acid I and II and oleonolic acid were obtained from the *S. triloba* in Greece (20). Brieskorn (21) found the same acids in *S. triloba*.

EXPERIMENTAL

The plant was collected from Marmara island, Marmara sea, Turkey, in May 1967. Five-hundred grams of the air-dried leaves and stems were pulverized and extracted with 3 L. of 70% aqueous alcohol. Alcoholic extract was evaporated under a vacuum and 20 Gm. of a green precipitate (I) was separated. The brown aqueous part upon evaporation to dryness yielded 100 Gm. of a residue (II).

Fifteen grams of I was chromatographed on a 3 × 50 cm. column, using silicilic acid–diatomaceous earth (3:1). Fifty fractions, 100 ml. of each, were collected using the following solvents:

Solvents for Collecting Fractions	Number of the fractions
Petroleum ether	1–2
Petroleum ether–benzene (9:1)	3–4
Petroleum ether–benzene (1:1)	5–6
Benzene	7–11
Benzene–chloroform (9:1)	12–13
Benzene–chloroform (1:1)	14–15
Chloroform	16–17
Chloroform–ether (9:1)	18–25
Chloroform–ether (1:1)	26–27
Ether	27–40
Alcohol	40–50

Received October 26, 1967, from Faculty of Pharmacy, University of Istanbul, Istanbul, Turkey.

Accepted for publication January 11, 1968.

This investigation was supported by the Scientific and Technical Research Council of Turkey (TAG-96).

The authors wish to thank Dr. A. Baytop and Dr. N. Tanker, University of Istanbul, for the identification of this plant, and Dr. Brieskorn, University of Würzburg, for supplying carnosol; also Dr. H. Wagner, University of Münich, for supplying pectolinarigenin and for taking NMR curves and some of the IR curves.

Each fraction was checked on thin layer and those which gave the same spots were combined, thus 1–6, 7–8, 9–11, 12–18, 19–20, 21–23, 23–50 yielded seven fractions.

Fractions 1–8, being the essential oils of the plant, were not studied; fractions 23–50 were left aside together with the residue II for future studies.

Fractions 9–11 showed two distinct and five minor spots on thin layer; upon crystallization from boiling alcohol 70 mg. of a white crystalline compound was obtained. Thin layer, mixed m.p.'s, and IR curve comparison showed that this compound was β-sitosterol. The second compound was not obtained in the crystalline form.

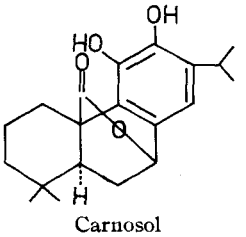
Fractions 12–18 when checked on thin layer showed one major and four minor spots; upon evaporation of the solvent these fractions yielded white needle-like crystals. Alcohol recrystallization yielded 1 Gm. of a compound; m.p. 286–290°, optical rotation $[\alpha]_D^{20}$ = +65 (in pyridin). Mixed m.p.'s and IR curve comparison as well as the optical rotation proved that this was ursolic acid.

Fractions 19 and 20 yielded two compounds, one of which was carnosol, the other was an unknown compound.

Fractions 21–23 yielded white crystals; alcohol recrystallization gave 250 mg. of a white crystalline material, m.p. 305°, optical rotation $[\alpha]_D^{20}$ = +83 (in methanol). Mixed m.p.'s and IR curve comparison as well as the optical rotation proved that this was oleonolic acid.

ISOLATION OF CARNOSOL

Fractions 19 and 20 when left aside yielded short, white, stick-like crystals (590 mg.) upon recrystallization from alcohol, the yield was 412 mg. Under the light, the crystals developed a blue-violet tinge. Melting point was 235–237°, UV spectra were taken using a Beckman DB recording instrument, $\lambda_{max.}$ 226 mμ (ε 12,100) and 288 mμ (ε 3,120) in ethanol. IR spectra (KBr) (Beckman IR-8) 3,570 $cm.^{-1}$ (intramolecular hydrogen bond), 3,330 $cm.^{-1}$ (OH groups), 2,980, 2,890 $cm.^{-1}$ (methyl groups), 1,720 $cm.^{-1}$ (lacton group), 1,580, 1,470, 1,450 $cm.^{-1}$ (aromatic ring), 1,380, 1,170 $cm.^{-1}$ (isopropyl group). NMR spectra (C_5D_5N) (TMS as internal



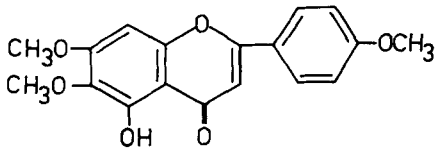
Carnosol

standard) (Varian Associates M-60) 0.8–1.05 p.p.m. (methyl groups in isopropyl chain), 1.3–1.5 p.p.m. (methyl groups in the nucleus), 6.93 p.p.m. (proton in the benzene ring), 5.62 p.p.m. (multiplet) (proton in the side chain), 1.65–4 p.p.m. (δ) (10 protons in the hydrogenated nucleus), and deuterium exchange show clearly the two OH groups.

Anal.—Calcd. for $C_{20}H_{26}O_4$: C, 72.72; H, 7.87. Found: C, 72.16; H, 7.87.

Infrared, NMR spectra, and analytical calculations suggested that this compound could be carnosol. Mixed m.p.'s and the IR curve comparison with the carnosol sample proved that these two compounds were identical.

Isolation and Identification of Salvigenin—The mother liquid of carnosol yielded green crystals; upon recrystallization from ethanol straw yellow-colored needles were obtained (70 mg.); m.p. 188°. UV maxima were 336 mμ (ϵ 31,000) and 280 mμ (ϵ 23,500). IR spectra suggested that this compound could be a flavone with a 5-OH group; 3,050 cm.$^{-1}$ (bonded OH), no free OH bands, 1,650 cm.$^{-1}$ (carbonyl group), 825 cm.$^{-1}$ (4′-OCH_3 group), 705 cm.$^{-1}$ (5-OH flavone). NMR spectra showed three methoxy groups at 4.0 p.p.m., 7.93, and 7.68 p.p.m. (aromatic H_2', H_6'); 7.1 and 6.93 (aromatic H_3', H_5'); 6.55 and 6.6 (aromatic H_8, H_3), and 11.6 p.p.m. (δ) (5-OH).



Salvigenin

Anal.—Calcd. for $C_{18}H_{16}O_6$: C, 65.85; H, 4.87; —OCH_3, 28.36. Found: C, 65.72; H, 5.1; —OCH_3, 26.96

Methylation of Pectolinarigenin—Ten milligrams of pectolinarigenin was dissolved in acetone and methylated with diazomethane in ether according to Merz (22). The reaction mixture was evaporated and the yellow residue was crystallized from ethyl acetate. A mixed m.p. of pectolinarigenin-7-methyl ether with salvigenin and the IR curve comparison showed that they were identical.

Hydrolysis of Salvigenin—Hydrolysis of salvigenin with 0.1 *N* H_2SO_4, then with more concentrated acids did not yield any sugar residue.

Degradation of Salvigenin—Twenty milligrams of salvigenin was refluxed with alcoholic KOH for about 5 hr. The acidic and the phenolic parts of the mixture were separated according to a previous paper (23). 4,5-Dimethoxy resorcinol and *p*-methoxy benzoic acid were found by thin-layer comparison.

SUMMARY

A new flavone was isolated from the leaves and the stems of *Salvia triloba L.f*, and its structure was found by using UV, IR, and NMR methods, as well as the alkaline degradation and the partial synthesis of the compound from pectolinarigenin. Carnosol which was found in *Salvia officinalis* was also found in this plant and identified as well as the following compounds: ursolic acid, oleonolic acid, and β-sitosterol utilizing thin-layer column chromatography, UV, IR, and when necessary, NMR techniques.

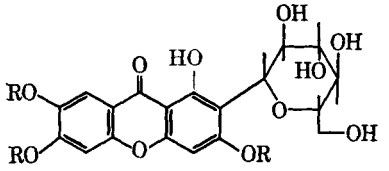
Occurrence of Mangiferin in *Hiptage madablota* Geartn.

By R. A. FINNEGAN, R. A. STEPHANI, G. GANGULI*, S. N. GANGULY*, and A. K. BHATTACHARYA*

A bright yellow, crystalline compound, m.p. 271–274°, isolated from the root-bark of *Hiptage madablota* Geartn. has been identified as mangiferin, 1,3,6,7-tetrahydroxy-2-C-β-D-glucosylxanthone, by direct comparison of its properties and those of its derived 3,6,7-trimethyl ether with those of authentic samples. Mangiferin was assayed in three biological test systems and the results are given.

In the course of studies on the structures of the endecaphyllins, a group of glucose polyesters of 3-nitropropanoic acid (1), the authors' attention was naturally directed to the report of Gorter (2) concerning hiptagin, a nitrogenous glucoside which was isolated from *Hiptage madablota* Geartn. (family *Malpighiacae*), since available evidence strongly suggested that hiptagin was very closely related to the endecaphyllins. Indeed, it was found that hiptagin (2) and endecaphyllin X (1) are identical and have the structure 1,2,4,6-tetra-*O*-(3-nitropropanoyl)-β-D-glucopyranoside (3). The authors deal here with the isolation of a new constituent of *H. madablota* and its identification as mangiferin (I).



I, R = H
II, R = CH_3

A granular solid which precipitated during acetone extraction of defatted root bark was collected and recrystallized several times from 50% aqueous alcohol to provide a bright yellow substance with melting point 271–274° dec. The spectroscopic properties of this substance pointed to the presence of a hydroxyxanthone moiety (4, 5) and quickly led to the supposition that the compound was mangiferin (I) on the basis of correspondence with published infrared (6), ultraviolet (4, 6, 7), and NMR (8) data in addition to agreement with the literature values for its melting point (9) and optical rotation (10). Furthermore, diazomethylation provided a derivative whose properties accorded with those of the known (7) trimethyl ether, II. Finally, the identification of the materials used was confirmed by direct comparison with authentic samples of I and II generously provided by Haynes (8, 11).

Although mangiferin has been long known as a constituent of the mango tree (*Mangifera indica* L., family *Anacardiaceae*), its structure has only recently been established (8, 12), thus permitting its inclusion in the rather unusual class of natural products, the *C*-glycosyl compounds. Reviews of earlier chemical studies have appeared (11). In addition to *M. indica*, and now *H. madablota*, the following species are reported to contain mangiferin: *Salacia prinoides* L. (*Hippocrateaceae*) (13), *Hedysarum obscurum* L. (*Papilionaceae*) (14), *Belamcanda chinensis* Adans (*Iridaceae*) (15), various *Iris* spp. belonging to sections Pogonoris, Apogon, and Pardanthopsis (*Iridacea* (15), *Athyrium mesosorum* Roth (*Polypodeaceae*) (16), *Apholoia madagascariensis* Clos (*Flacourtiaceae*) (17), *Cuscuta reflexa* Tourn. (*Convolvulaceae*) (17), *Smilax glycyphylla* Tourn. (*Liliacea* (10), *Madhuca utilis* Ridley (*Sapotaceae*) (7), and *Anemarrhenae rhizoma* B. (*Liliaceae*) (18).

The authors are aware of only two reports on biological properties of mangiferin. One of these describes increased diuresis in the adrenalectomized rat (19) while the other deals with the cardiotonic effects on the isolated frog heart (20). The cytotoxic effect of mangiferin on Sarcoma 180 cells grown in stationary cell culture has now been studied and the compound was found to be inactive. An ID_{50} value of 440 mcg./ml. was determined which is well outside the range (6 mcg./ml. or below) of potential interest. A number of more simply substituted xanthones have been subjected to this bioassay with a few showing significant activity. These data will be discussed in detail in a subsequent publication (21).

Results from two additional assays using cell-free systems from *Escherichia coli* have been kindly provided by Dr. C. Coutsogeorgopoulos at the Roswell Park Memorial Institute. Mangiferin (10^{-4} *M*) displayed low inhibitory activity (15–20%) on the polyuridylic acid-stimulated synthesis of polyphenylalanine (22) in the presence of ribosomes washed with ammonium chloride (23). In the second system, the reaction between puromycin and polylysyl-ribonucleic acid (23) was inhibited by mangiferin (10^{-4} *M*) to the extent of 35–40% whereas chloramphenicol showed 50–60% inhibition.

EXPERIMENTAL

Mangiferin—Finely ground, air-dried root bark (200 Gm.) of *H. madablota* was defatted with petroleum ether (b.p. 60–80°, 300 ml.) in a Soxhlet extractor for 30 hr. It was observed that after about 12 hr./extraction with acetone (300 ml.), a granular solid began to deposit. At the end of the extraction (48 hr.) the solid was collected on a filter and washed with acetone, yield 0.025%. Recrystallization from 50% aqueous ethanol afforded yellow crystals, m. p. 271–274° dec. Literature values, 271° (9), 268° (7), 269° (8); $\lambda_{max.}^{KBr}$ 3450–3100, 1650, 1625, 1600, 1570, 1500, 1260, 1100, 870 $cm.^{-1}$ $\lambda_{max}^{95\%\ ethanol}$ 244.5, 260.5, 321.0, 375.5 mμ, log ε 4.03, 4.13, 3.43, 3.41; $\lambda_{max.}^{95\%\ ethanol}$, NaOH 245, 261, 400 mμ, log ε 4.05, 4.10, 4.12. These spectra were identical with those of an authentic sample.

Received October 19, 1967, from the Department of Medicinal Chemistry, School of Pharmacy, State University of New York at Buffalo, Buffalo, NY 14214
Accepted for publication November 24, 1967.

Mangiferin Trimethyl Ether—A suspension of mangiferin (30 mg.) in 2 ml. methanol and 8 ml. ether was treated with an excess of ethereal diazomethane following the procedure of Hawthorne and co-workers (7). After twice being precipitated from aqueous acetone, the product had m.p. 298–299° and provided infrared and ultraviolet spectra identical with those of an authentic sample. Literature m.p. 298–299° (7).

Deficiency of Vitamin B_{12} in *Chlorella*

By ROBERTSON PRATT and EVELYN JOHNSON*

Repeated systematic attempts to detect vitamin B_{12} in two species of *Chlorella* at different times during the culture growth period failed to reveal consistent or significant evidence of B_{12} or B_{12}-like activity. The results are discussed in terms of other reports in the literature.

As PART of a continuing investigation of the vitamin content of two *Chlorella* species (1–4), extracts of *C. vulgaris* and of *C. pyrenoidosa* have been assayed for vitamin B_{12} (cyanocobalamin and related factors). This seemed of particular interest in view of the conflicting reports in the literature concerning occurrence of the vitamin in chlorophyllous plants—especially the algae and particularly the Chlorococcales.

In an important review of vitamin B_{12} in the metabolism of microorganisms, Ford and Hutner (5) state "B_{12} . . . is not present in green plants and yeast; it is synthesized by bacteria and probably by blue-green, brown, and red algae, but not by green algae." Others have suggested that B_{12} found associated with seaweeds (whether red, brown, or green) can be attributed to bacteria living epiphytically on the algae (6, 7) or to bacterial contaminants in the distilled water used in preparing specimens for assay (8).

Referring specifically to *Chlorella* (species unspecified), Hutner (9) commented on the lack of B_{12} in the organism while, in contrast, Hashimoto reported significant levels of the vitamin (av. 61 μ mcg./mg. dry wt.) in "pure cultured" *Chlorella ellipsoidea* and he considered this a sufficiently high level to warrant further study (10).

METHODS

Chlorella vulgaris and *C. pyrenoidosa* were cultured aseptically by both the column and the round-bottom flask techniques described previously (11): light intensity in the former was 600 ftc. and in the latter 1250 ftc. Column cultures were harvested at different times from Day 5 to Day 21; flask cultures were harvested at intervals from 3 weeks to 10 weeks postinoculation.

Assays were performed using *Euglena gracilis* (ATCC 12716) and *Ochromonas malhamensis* (ATCC 11532) in the appropriate Difco media. Acid-cleaned glassware and fresh glass-redistilled

Deficiency of Vitamin B_{12} in *Chlorella*

By ROBERTSON PRATT and EVELYN JOHNSON*

Repeated systematic attempts to detect vitamin B_{12} in two species of *Chlorella* at different times during the culture growth period failed to reveal consistent or significant evidence of B_{12} or B_{12}-like activity. The results are discussed in terms of other reports in the literature.

As PART of a continuing investigation of the vitamin content of two *Chlorella* species (1–4), extracts of *C. vulgaris* and of *C. pyrenoidosa* have been assayed for vitamin B_{12} (cyanocobalamin and related factors). This seemed of particular interest in view of the conflicting reports in the literature concerning occurrence of the vitamin in chlorophyllous plants—especially the algae and particularly the Chlorococcales.

In an important review of vitamin B_{12} in the metabolism of microorganisms, Ford and Hutner (5) state "B_{12} . . . is not present in green plants and yeast; it is synthesized by bacteria and probably by blue-green, brown, and red algae, but not by green algae." Others have suggested that B_{12} found associated with seaweeds (whether red, brown, or green) can be attributed to bacteria living epiphytically on the algae (6, 7) or to bacterial contaminants in the distilled water used in preparing specimens for assay (8).

Referring specifically to *Chlorella* (species unspecified), Hutner (9) commented on the lack of B_{12} in the organism while, in contrast, Hashimoto reported significant levels of the vitamin (av. 61 μ mcg./mg. dry wt.) in "pure cultured" *Chlorella ellipsoidea* and he considered this a sufficiently high level to warrant further study (10).

METHODS

Chlorella vulgaris and *C. pyrenoidosa* were cultured aseptically by both the column and the round-bottom flask techniques described previously (11): light intensity in the former was 600 ftc. and in the latter 1250 ftc. Column cultures were harvested at different times from Day 5 to Day 21; flask cultures were harvested at intervals from 3 weeks to 10 weeks postinoculation.

Assays were performed using *Euglena gracilis* (ATCC 12716) and *Ochromonas malhamensis* (ATCC 11532) in the appropriate Difco media. Acid-cleaned glassware and fresh glass-redistilled

Received November 13, 1967, from the School of Pharmacy, University of California, San Francisco Medical Center, San Francisco, CA 94122
Accepted for publication January 18, 1968.
* Present address: Department of Biology, University of California at San Diego, La Jolla, California.

water were used for all assays. Standard curves were determined in each assay using USP cyanocobalamin reference standard.

Three basic extraction procedures were employed: (*a*) water extraction with heat, (*b*) refluxing with 70% isopropanol, and (*c*) extraction with perchloric acid. A number of variations of these were tried including (*a*) addition of sodium cyanide (10 mg./ml.), (*b*) buffering with 0.01 *N* sodium acetate or adjusting pH with HCl, (*c*) heating at 90° or autoclaving, (*d*) subsequent digestion with papain, and (*e*) preliminary mincing in a mortar with crystalon abrasive.

No single procedure seemed consistently or distinctly superior for releasing B_{12} (if present) from the algae. In some instances extracts prepared with sodium acetate seemed to be slightly inhibitory for the *Euglena* test organism; use of isopropanol resulted in an extract containing lipids and other cell material that interfered with turbidity readings during actual assay; the perchloric acid technique resulted in extracts significantly inhibitory to growth of *Euglena*, due to inability to completely remove the perchloric acid, and the papain technique gave a high blank reading that overshadowed any possible B_{12} in *Chlorella*.

Therefore, the method recommended by the Analytical Methods Committee (12) was used routinely. In this procedure a suspension of cells with 0.01% NaCN (pH 4.5 with HCl) was heated in a water bath at 90° for 30 min. Recovery of added B_{12} was approximately 110%.

RESULTS

In seven different experiments between October 1966 and August 1967, each entailing several assays of extracts prepared from one to five harvests made at different times during the culture period, no significant or consistent levels of B_{12} or B_{12}-like activity were detected. Most frequently no B_{12} was found. Low levels (0.1 to 5 μmcg./mg. dry wt.) were found sporadically, generally in cultures 14 days or more postinoculation.

Although aseptic techniques are employed in setting up the algal cultures, the danger of bacterial contamination having occurred during subsequent manipulation cannot be totally eliminated, especially for older cultures. Therefore, the possibility of low-level bacterial contamination as the cultures age must be considered as a possible source of B_{12}.

Moreover, the B_{12} levels found were generally so low that often they were within the range of error inherent in the extraction and assay procedures.

The possibility exists that extraction procedures were not adequate for releasing B_{12} from the *Chlorella* cells but, in view of the variety of procedures and modifications employed, it seems unlikely that all of the methods would have been totally inadequate. Nonetheless, the possibility that B_{12} is protein bound and not readily released or that the tough *Chlorella* cell wall prevents release should not be overlooked.

Other possibilities are (*a*) the synthetic medium employed for culturing the algae precluded or interfered with biosynthesis of the vitamin, and/or (*b*) B_{12} is synthesized but so quickly transferred in one or more various synthetic pathways that it never accumulates in assayable levels.

However, under the conditions employed for culture and for the variety of techniques for extracting the cells and assaying the extracts, the authors have been unable to demonstrate the presence of B_{12} or B_{12}-like activity in *Chlorella vulgaris* and *C. pyrenoidosa*.

Studies on the Mechanism of Action of Salicylate II. Retardation of Wound Healing by Aspirin

By K. H. LEE

Aspirin, like cortisone, reduces the tensile strength of the healing skin wound in rats. The possible mechanism of action of these anti-inflammatory agents on wound healing has been discussed.

It is well known that cortisone reduces the rate of wound healing in experimental animals (1–3). It is also known that there is a time relationship between administration of cortisone and wound healing in rats (4). When cortisone is given during the entire healing period after infliction of the wounds, the healing processes are retarded. However, when cortisone is given 2 days or later after wound infliction, it exerts no effect on healing. Dunphy and Jackson (5) attribute the effect of cortisone on wound healing to its anti-inflammatory activity. Inflammation is a necessary process involved in the early stage of wound healing (6, 7). In the present study, it was found that aspirin, another anti-inflammatory agent, behaved exactly like cortisone in retardation of wound healing in rats.

METHODS

Wound Procedure—Sprague-Dawley rats of either sex weighing 450-500 Gm., were anesthetized with ethyl ether in an open mask. The hair on the back was depilatated with an electric clipper. One 6-cm. long incision was made, through the skin and cutaneous muscles, at a distance about 1.5 cm. from the midline on each side. No ligatures were used. Bleeding usually ceased spontaneously after a few min. The incisions were closed with continuous through-and-through sutures with stitches 0.5 cm. apart. Black silk surgical thread No. 000 or No. 30 and curved needles No. 19 were used. The continuous suture was pulled tight enough to secure good adaptation of the wound edges. The wounds were left undressed.

Administration of Drugs—Aspirin, neutralized with calculated amount of sodium carbonate solution before use, was fed to the rat daily through a short stomach tube (P.E. 160) attached to a blunted hypodermic needle (No. 17) connected to a 5-ml. syringe, starting 1 day before operation. Two dosage levels, 150 mg. and 75 mg./Kg. of body weight, were given to different groups of rats.

Measurement of Healing—Tensile strength, the force required to open a healing skin wound, was used to measure healing. The instrument for this measurement is called tensiometer which is usually designed on the same principle as the thread tester used in the textile industry (4). Since there was no commercially made tensiometer available, a simple instrument for the skin wound healing measurement was made. It consisted of a 6 × 12 in. board with one post of 4 in. long fixed on each side of the longer ends. The board was placed at the end of a table. A pulley (with bearing) was mounted on the top of one of the posts. An alligator clamp, with 1-cm. clamp width, was tied on the tip of the post without pulley by a piece of fishing line (20-lb. test monofilament) so that the clamp could reach the middle of the board. Another alligator clamp was tied on a longer piece of fishing line with a 1-L. polyethylene bottle tied on the other end. Before testing, the animal was anesthetized with ethyl ether in an open mask. The sutures of the wound were cut out with a pair of scissors. The animal was then placed on a stack of paper towels on the middle of the board. The amount of the towels could be adjusted so that the wound was on the same level of the tips of the posts. The clamps were then carefully clamped on the skin of the opposite sides of the wound at a distance of 0.5 cm. away from the wound. The longer piece of fishing line was placed on the pulley, and the position of the board was adjusted so that the polyethylene bottle was freely hanging in the air. Water was added to the polyethylene bottle at a rapid but constant rate by siphon from a large reservoir (20-L. bottle) until the wound began to open up. The amount of water in the polyethylene bottle was weighed and considered as the tensile strength of the wound. Two to three determinations were made on each wound. The mean of the determinations made on wounds on both sides of the animal was taken as the tensile strength of the wound. The tensile strengths reported in the paper were all measured on the seventh day after wounding.

RESULTS

Controls—The tensile strength of skin wound of untreated rats was determined after a healing period of 7 days. Usually three readings were taken on each 6-cm. long wound whenever possible. The tensile strength of wound on one side of the back did not differ greatly from that of the wound inflicted on the other side of the back. The averaged value for 21 animals tested was 438 ± 17.7 Gm. (Table I, Group I).

Treated Animals—Rats receiving an oral dose of 150 mg. of aspirin per kilogram of body weight daily, starting 1 day before wounding, have an averaged tensile strength of 262 ± 8.7 Gm. on the seventh day after wounding, which is about 40% inhibition (Table I, Group II). The inhibition is significant ($p < 0.001$).

When the dose of aspirin given was reduced to one half or 75 mg. (Group III), the averaged tensile strength of the wound was 343 ± 91 Gm. or 22% inhibition.

However, when the feeding of even the larger dose of aspirin (150 mg.) was started 2 days after the wounding, the averaged tensile strength was 350 ± 10.9 Gm. or 80% of the control. These results are in good agreement with those obtained by Sandberg (4) when cortisone was given under similar conditions.

Received November 13, 1967, from the School of Pharmacy, University of California, San Francisco Medical Center, San Francisco, CA 94122

Accepted for publication January 2, 1968.

Presented to The American Society for Pharmacology and Experimental Therapeutics, August meeting, 1967, Washington, D. C.

* This work was supported in part by a grant-in-aid from Eli Lilly and Company, Indianapolis, Indiana.

TABLE I—TENSILE STRENGTH OF HEALING WOUNDS

Group[a]	No. of Animals	Aspirin Fed Daily: Amt., mg./Kg.	Aspirin Fed Daily: Time Started	Averaged Tensile Strength, Gm.	% of Control
I	21	—	—	438 ± 17.7	100
II	13	150	1 day before wounding	262 ± 8.7	60
III	12	75	1 day before wounding	343 ± 21.0	78
IV	7	150	2 days after wounding	350 ± 10.9	80

[a] Differences between I and II, I and III, I and IV, II and IV are significant ($p < 0.001$).

The body weight of every rat was recorded at the beginning and the end of the experiment. The averaged change in body weight did not, in most of the cases, vary more than 10 Gm.

DISCUSSION

The importance of inflammation in wound healing has long been recognized by surgeons (5). Experimentally, Selye (7) has shown that the connective tissue response to a granuloma pouch made by injecting air subcutaneously can be varied directly with the degree of inflammation created in the pouch. The injection of croton oil or other irritants into the pouch sets up an acute inflammatory reaction followed by a rapid growth in connective tissue. The injection of cortisone inhibits the inflammation and reduces the subsequent production of connective tissue. Other studies on the effect of cortisone on wound healing (4) have shown that if cortisone is given during the entire healing period, it inhibits the inflammatory response and subsequent healing processes. However, if cortisone is given some time after the wounding, so that the initial inflammatory response has already taken place, it has no effect upon the healing.

It has been suggested that lysosomal enzymes are responsible for inflammation (8). Lysosomes are cytoplasmic organells which contain the bulk of acid hydrolases (9). The proteolytic enzymes in lysosomes can break down plasma proteins into polypeptides. Some of these polypeptides may increase capillary permeability and thus cause inflammation. Anti-inflammatory steroids: cortisone, hydrocortisone, prednisone, prednisolone, betamethasone can protect lysosomal membrane (10, 11). The protective action on lysosomal membrane is one of the current theories on the mechanism of action of anti-inflammatory steroids (10).

Aspirin is another anti-inflammatory agent which also protects lysosomal membrane (12). In the present study, it has been shown that aspirin also retards wound healing in the same manner as cortisone. It is very likely that aspirin shares the same mechanism of action in retarding wound healing as cortisone. This belief is further strengthened by the fact that when aspirin was given 2 days after the wounding the inhibitory effect was greatly reduced. This followed the same pattern when cortisone was applied this way (4).

SUMMARY

It has been demonstrated that aspirin retards wound healing in the rat and the mechanism of this action has been discussed.

A simple laboratory-made tensiometer has been described.

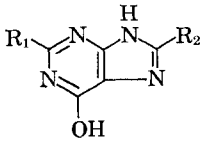
Pyrazoles I. Synthesis of 4-Hydroxypyrazolo[3,4-*d*]-*v*-triazine A New Analog of Hypoxanthine

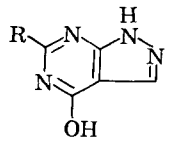
By C. C. CHENG, ROLAND K. ROBINS, KATHERINE C. CHENG, and DOLORES C. LIN

Treatment of 3-amino-4-pyrazolecarboxamide with nitrous acid yielded 3-diazo-4-pyrazolecarboxamide, which was cyclized to 4-hydroxypyrazolo[3,4-*d*]-*v*-triazine in aqueous solution. The latter is a structural analog of hypoxanthine as well as an aza analog of allopurinol.

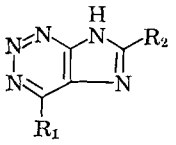
A STRUCTURAL ANALOG of hypoxanthine (Ia), 4-hydroxypyrazolo[3,4-*d*]pyrimidine (IIa, 4-HPP, allopurinol, Zyloprim), was synthesized and reported in 1956 (1, 2). Compound IIa has since been found to be effective against hyperuricemia associated with gout in man (3–11). It is remarkably well tolerated by patients, and serious side effects have not been encountered (12–16). Metabolic studies revealed that many compounds of this type are potent inhibitors of xanthine oxidase (4, 14, 17–23), the enzyme responsible for the oxidation of hypoxanthine (Ia) to xanthine (Ib) and to uric acid (Ic). This compound can, therefore, be used to reduce the hazard of uric acid nephropathy in patients with leukemias and lymphomas, in whom rapid lysis of cells is expected to occur (24). It has also been used to potentiate the therapeutic index of 6-mercaptopurine (17, 18).



I a, R_1, R_2 = H
b, R_1 = OH, R_2 = H
c, R_1, R_2 = OH



II a, R = H
b, R = OH



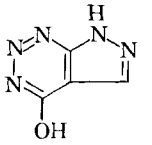
III a, R_1 = OH, R_2 = H
b, R_1 = NH_2, R_2 = H
c, R_1 = NH_2, R_2 = OH

Allopurinol itself is gradually metabolized *in vivo* by xanthine oxidase to 4,6-dihydroxypyrazolo[3,4-*d*]pyrimidine (25, 26) (IIb, isoxanthine, alloxanthine). Although IIb is still an inhibitor of xanthine oxidase, it is no longer as effective as allopurinol. Further metabolic oxidation of IIb to a uric acid-type analog is not feasible owing to the aza substituent in the original "purine-C_8" position.

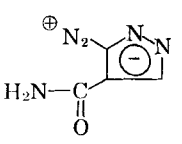
Some 2-azapurines (III, imidazo[4,5-*d*]-*v*-triazines) are also found to be inhibitors of xanthine oxidase (27). The most active one of this class, 2-azaadenine (IIIb), was reported to be rapidly attacked by this enzyme to form a somewhat less effective inhibitor, 8-hydroxy-2-azaadenine (27) (IIIc).

Since xanthine oxidase oxidizes purines at the 2, 6, or 8 position (28), synthesis of an aza analog of allopurinol (IIa), 4-hydroxypyrazolo[3,4-*d*]-*v*-triazine (IV) was proposed. Compound IV itself would not be subject to attack by xanthine oxidase, and thus could well be a better inhibitor of the enzyme. The fact that many 2-azapurines possess activity as inhibitors of neoplastic cells (29, 30) and of microorganisms (31) suggests that compounds such as IV might be useful as chemotherapeutic agents.

Treatment of 3-amino-4-pyrazolecarboxamide (1) with nitrous acid yielded a tan-colored compound which decomposed violently at *ca.* 165–170° on rapid heating. Although this product gave the correct elemental analysis for IV, a sharp, intense infrared absorption peak at the 4.5-μ region and a positive Bratton-Marshall test (32) indicated the presence of a diazo group. Hence the product was actually the uncyclized 3-diazo-4-pyrazolecarboxamide (V).



IV



V

Formation of a similar compound, 5-diazo-4-imidazolecarboxamide, from 5-amino-4-imidazolecarboxamide and nitrous acid has also been reported (33).

The desired cyclized compound, 4-hydroxypyrazolo[3,4-*d*]-*v*-triazine (IV, 4-HPT), can be readily obtained by treatment of V with dilute alkali or, less readily, with dilute acid. Compound IV did not give a positive Bratton-Marshall test (32), possessed no infrared absorption in the triple or cumulative double bond region. It can be recrystallized from water as a monohydrate.

Compound 4-HPT was tested as an inhibitor of xanthine oxidase from bovine milk. A 50% inhibition of the enzyme was observed by 4-HPT at a concentration of 7.4 μM in the presence of 8.1 μM of hypoxanthine as a substrate.

Received December 20, 1967, from the Midwest Research Institute, Kansas City, MO 64110
Accepted for publication January 31, 1968.
This investigation was supported in part by research grant No. C-2845 from the National Cancer Institute, and in part by contract No. DA-49-193-MD-2749 with U. S. Army Medical Research and Development Command. This paper is Contribution No. 257 from the Army Research Program on malaria.
The authors wish to thank Professor B. R. Baker for providing the information of xanthine oxidase inhibitory test, and to thank Mrs. Margaret L. Rounds and Mr. John R. Gravatt for their assistance in performing analytical and instrumental measurements.

EXPERIMENTAL[1]

3-Diazo-4-pyrazolecarboxamide (V)—To a finely powdered suspension of 35 Gm. (0.2 mole) of 3-amino-4-pyrazolecarboxamide hemisulfate (1) in 350 ml. of water cooled to 0° was added, with mechanical stirring, 16 Gm. (0.23 mole) of sodium nitrite dissolved in 60 ml. of water. The mixture was stirred for 3 hr. at 0° and the resulting tan solid was collected by filtration and washed successively with water, methanol, and ether. The yield after overnight air drying was 18 Gm. (66%), which, on rapid heating, decomposed violently with a sharp sound. The product, which is analytically pure, is surprisingly stable under ordinary storage conditions. It gave a positive Bratton-Marshall test (32) and exhibited a diazo absorption band at 4.5 μ. $\lambda_{max.}^{pH\ 1}$ 256 mμ (ϵ 6,000); $\lambda_{max.}^{pH\ 11}$ 311 mμ (ϵ 5,500).

Anal.—Calcd. for $C_4H_3N_5O$: C, 35.03; H, 2.20; N, 51.09. Found: C, 34.74; H, 2.36; N, 51.00.

4-Hydroxypyrazolo[3,4-*d*]-*v*-triazine Monohydrate (IV)—A white crystalline solid gradually separated on standing from the filtrate of the preceding experiment. The product was collected by filtration, washed with a small amount of cold water, and dried to yield 4 Gm. of IV. The compound, which is quite soluble in methanol, decomposed abruptly (but not as violently as V) at *ca.* 180° on rapid heating; slow heating did not cause it to decompose or melt up to 360°. The product is analytically pure but recrystallization from hot water changed the color of the solid from white to light yellow. The ultraviolet and infrared absorption spectra were, however, identical. Compound IV did not show a triple bond absorption peak and failed to yield a positive Bratton-Marshall test (32). $\lambda_{max.}^{pH\ 1}$ 270 mμ (ϵ 5,500); $\lambda_{max.}^{pH11}$ 312 mμ (ϵ 5,800).

Anal.—Calcd. for $C_4H_3N_5O \cdot H_2O$: C, 30.97; H, 3.25; N, 45.15; H_2O, 11.51. Found: C, 31.30; H, 3.53; N, 44.79; H_2O, 11.48.

The same product can also be obtained by the addition of 10 ml. of 10 *N* sodium hydroxide to the stirred suspension of 5 Gm. of V in 100 ml. of water. The resulting solution was allowed to stir for 40 min., filtered, and the filtrate acidified with dilute hydrochloric acid. Three and one-half grams of analytically pure light golden yellow plates were obtained.

[1] Melting points were taken on a Thomas-Hoover melting point apparatus. The infrared spectra were taken with a Perkin-Elmer infracord and the ultraviolet absorption spectra were determined with a Beckman DK-2 spectrophotometer.

Determination of 6-Demethyltetracycline HCl in 6-Demethylchlortetracycline HCl

By FORTUNATO S. CHICCARELLI

6-Demethyltetracycline, when heated with nitric acid, forms a stable colored derivative having an absorption maximum at 425 mμ. 6-Demethylchlortetracycline under the same condition is unstable. When 6-demethylchlortetracycline is heated with nitric acid, the color produced by the 6-demethyltetracycline fraction can be measured directly or extracted with *n*-butanol.

In the production of 6-demethylchlortetracycline (1)[1] small amounts of 6-demethyltetracycline are also formed. An automated method of assay for 6-demethylchlortetracycline based on the difference in the rates of conversion of these components to their respective anhydro forms has been presented (2). A manual procedure (3) based on the same principle has also been developed. To detect the presence of small concentrations of 6-demethyltetracycline in 6-demethylchlortetracycline, a direct analytical procedure was required.

Tetracycline, chlortetracycline, 6-demethyltetracycline, and 6-demethylchlortetracycline all undergo transformation to anhydro compounds when their respective solutions are heated with hydrochloric acid. The order of stability to HCl is 6-demethylchlortetracycline, 6-demethyltetracycline, chlortetracycline, and tetracycline with 6-demethylchlortetracycline being the most stable. Oxytetracycline forms colorless apoxytetracyclines (4).

With this in mind the above antibiotics were heated with other acids, one of which was nitric acid. A relatively stable intense yellow color remained in the 6-demethyltetracycline solution while the other solutions became relatively colorless. It was decided to investigate this difference in behavior.

EXPERIMENTAL

Scheme I shows the structural formula of the antibiotics tested. A diagrammatic scheme has been used to point up the differences and similarities.

	R_1	R_2	R_3
Tetracycline	H	CH_3	H
Chlortetracycline	Cl	CH_3	H
5-Hydroxytetracycline	H	CH_3	OH
6-demethyltetracycline	H	H	H
6-demethylchlortetracycline	Cl	H	H

Scheme I

Figure 1 shows the absorption spectra of tetracycline (TC), chlortetracycline (CTC), 5-hydroxytetracycline (OTC), 6-demethyltetracycline (DMTC), and 7-chloro-6-demethyltetracycline (DMCTC) from 300 mμ to 500 mμ at 25 mcg./ml. in 0.1 *N* hydrochloric acid.

Figure 2 shows the absorption spectra of each of the antibiotics after heating at 100° with nitric acid. Solutions of each were made with 200 mcg./ml. 0.07 *M* H_3PO_4. Forty ml. of the solution plus 20 ml. 4.0 *M* HNO_3 were heated in a water bath for 15 min. After cooling and diluting up to 100 ml., the absorption spectra were determined from 300 mμ–500 mμ. Of the five antibiotics studied, DMTC was unique in that a maximum appearing in the visible range (420–440 mμ) was retained. The product(s) of this reaction is now under study.

The effect of heating time at 100° with DMTC and DMCTC in the presence of nitric acid is shown in Table I. Solutions of each antibiotic were made with 200 mcg./ml. 0.07 *M* H_3PO_4. Forty ml. of this solution plus 20 ml. 4.0 *M* HNO_3 were heated in a boiling water bath for the time specified. At the end of each time interval the flasks were cooled and diluted up to 200 ml. with water. The absorbance of the solutions was determined at 425 mμ. The

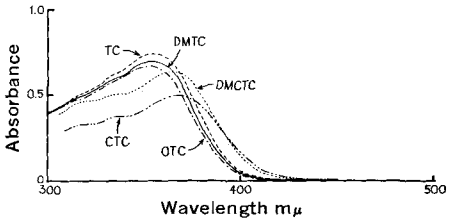

Fig. 1—Absorption spectra of tetracycline (TC), chlortetracycline (CTC), 5-hydroxytetracycline (OTC), 6-demethyltetracycline (DMTC), 6-demethylchlortetracycline (DMCTC) from 300 mμ to 500 mμ at 25 mcg./ml. in 0.1 N HCl.

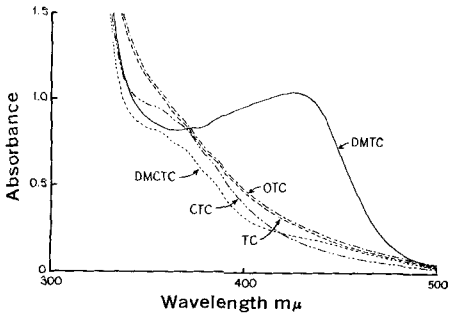

Fig. 2—Absorption spectra of tetracycline (TC), chlortetracycline (CTC), 5-hydroxytetracycline (OTC), 6-demethyltetracycline (DMTC), 6-demethylchlortetracycline (DMCTC), after heating at 100° with HNO_3 for 15 min.

Received September 28, 1967, from the Quality Control Section, Lederle Laboratories Division, American Cyanamid Co., Pearl River, NY 10965

Accepted for publication December 15, 1967.

The author thanks Mr. G. P. Cbrekian for his valuable assistance with this report.

[1] Declomycin is the registered trademark of American Cyanamid Co. for 6-demethylchlortetracycline HCl.

TABLE I—DIFFERENCE IN ABSORPTION WITH TIME OF HEATING AS A VARIABLE

Time, min.	Absorbance at 425 mμ DMCTC	DMTC
0	0.0	0.0
3	0.345	0.260
6	0.135	0.515
9	0.115	0.505
12	0.110	0.490
15	0.105	0.475
18	0.100	0.460
21	0.095	0.445

high absorbance value at 425 mμ after 3 min. heating suggests the formation of the DMCTC anhydro derivatives. Lower values at the 6-, 9-, 12-min. intervals may be attributed to oxidative cleavage of the anhydro molecule. The high absorbance at 425 mμ of the DMTC after heating in HNO_3 is probably due to a stable 7-nitro-anhydro DMTC.

Figure 3 shows the absorption spectra from 300 mμ to 500 mμ of butanol extracts of DMCTC standard solutions containing 0–8% DMTC. Determinations (*versus n*-butanol) were made with 1-cm. cells.

Figure 4 contains the spectra from 300 mμ to 500 mμ of standard solutions when measured directly with 10-cm. cells. The 0% treated standard solution is used in the reference cell.

Table II contains five separate results when a well-mixed synthetic sample of DMCTC containing 3% DMTC was assayed. The sample was made from standard DMCTC and DMTC.

Application of this procedure to refined DMCTC gave greater precision than the method previously used (5).

METHOD

Apparatus—Beckman spectrophotometer model DU 2400 equipped to handle 1-cm. or 10-cm. quartz cells. Cell correction was applied when necessary. Complete spectra were made with a Cary recording spectrophotometer.

Reagents—Nitric acid, 4.0 *M*, made from reagent grade which is free of yellow oxides of nitrogen; H_3PO_4, 0.07 *M*; *n*-butanol, reagent; NaCl, C.P. 6-demethylchlortetracycline HCl standard, 200 mcg./ml. (100 mg./500 ml.); and 6-demethyltetracycline HCl standard, 200 mcg./ml. (100 mg./500 ml.). Standard solutions are made in 0.07 *M* H_3PO_4.

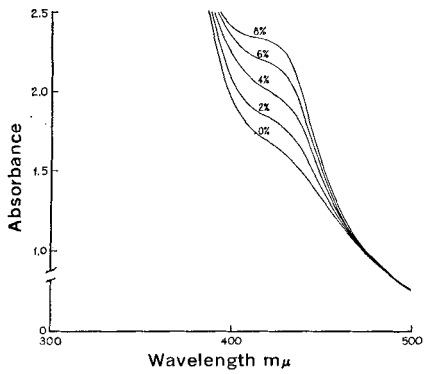

Fig. 3—Absorption spectra of demethyltetracycline (vs. n-butanol) standard solutions when measured after butanol extraction, with 1-cm. cells.

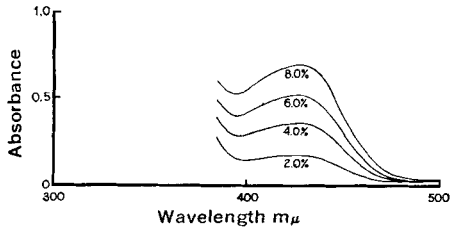

Fig. 4—Absorption spectra of demethyltetracycline standard solutions when measured directly, with 10-cm. cells.

TABLE II—RESULTS WITH SYNTHETIC SAMPLE

Determination	% DMTC
A	3.1
B	2.8
C	2.9
D	3.4
E	3.0

Procedure—Transfer an accurately weighed sample of about 100 mg. DMCTC to a 50-ml. volumetric flask. Add 0.07 *M* H_3PO_4 and mix until solution is complete. Make up to mark with 0.07 *M* H_3PO_4 and mix. Pipet a 40.0-ml. aliquot into a 100-ml. volumetric flask. Add 20 ml. 4.0 *M* HNO_3 and heat in a boiling water bath for exactly 15 min. with occasional swirling.

Standard solutions and samples should be treated at the same time. Pipet 2.0-, 4.0-, 6.0-, and 8.0-ml. aliquots of DMTC standard solution (200 mcg./ml., 0.07 *M* H_3PO_4) into separate 100-ml. volumetric flasks. Make each up to mark with DMCTC standard solution (200 mcg./ml., 0.07 *M* H_3PO_4) and mix. Transfer a 40.0-ml. aliquot of the DMCTC standard solution (0%) and 40.0-ml. aliquots from each of the 2.0, 4.0, 6.0, and 8.0% DMTC standards to separate 100-ml. volumetric flasks. To each add 20 ml. 4.0 *M* HNO_3 and heat in the same manner as the sample.

After heating is complete, remove all flasks, cool, and make to volume with water. Mix. The following alternatives can be used for the absorbance determination.

For 1-cm. cells transfer the solutions to individual separatory funnels containing 40 Gm. NaCl. Shake for 1 min. Add 10 ml. *n*-butanol and shake for 2 min. Collect the butanol extracts and centrifuge. Determine the absorbance (*versus n*-butanol) at 425 mμ using the 0.1 position of the scale. For 10-cm. cells fill the two 10-cm. cells with the 0% standard solution. Using one as the reference, measure the absorbance of the other at 425 mμ. The difference between this is the cell correction. Measure the standard and unknown solutions against the 0% reference solution at 425 mμ.

Plot a concentration curve using the 0, 2, 4, 6, and 8% absorbance values. Before the curve can be used, the sample absorbance must be corrected for the amount of antibiotic in the original weight taken.

Transfer a 5-ml. aliquot of the sample solution to a 100-ml. volumetric flask. Make up to mark with 0.07 *M* H_3PO_4 and mix. Determine its absorbance at 368 mμ. (Acid isobestic point of DMTC and DMCTC.) Repeat the determination with a 5-ml.

portion of the DMCTC standard solution treated in the same manner.

The corrected sample absorbance will give a direct measure of the DMTC when used with the standard curve.

Calculation—(*a*) mg. of antibiotic (DMTC and DMCTC) in sample weight:

$$\frac{\text{sample abs. at 368 m}\mu}{\text{standard abs. at 368 m}\mu} + 10.0 \times \frac{100}{1000} \times \frac{500}{5} = \text{mg.}$$

(*b*) corrected sample absorbance value to be used with concentration curve: $\frac{100}{\text{mg.}} \times$ abs. at 425 mμ (sample) = corrected value

SUMMARY

With the use of nitric acid, an assay for DMTC in DMCTC has been developed. DMCTC is unstable to nitric acid while DMTC is sufficiently stable for purpose of assay. The data presented suggest that DMTC could also be measured in the presence of CTC, TC, and OTC by this procedure.

Quantitative Thin-Layer Chromatography of Sympathomimetic Amines

By N. H. CHOULIS* and C. E. CAREY

Thin-layer chromatography for quantitative estimation of sympathomimetic amines has been used. Two methods were performed: the weight/area relationship and the elution of the spots and spectrophotometric determination in the ultraviolet. For the first method, solutions of the amines, in increasing concentration, were applied on cellulose thin layer, and a solution of unknown concentration of the same amines was run parallel to the standards. The spot was compared with the standards using a recording photoelectric densitometer. For the second method the standard spots were eluted from the cellulose plates and their absorption was measured. The absorptivity of a similarly eluted spot of unknown concentration, but parallel running, was measured and compared with the standards. The accuracy of the methods appeared to be between 95–98 percent.

THE APPLICATION of thin-layer chromatography to pharmaceutical analysis has been used increasingly during the past years. A number of methods for quantitative analysis have been employed since the technique was first introduced by Stahl (1) in 1956.

Seher (2) has suggested that in thin-layer chromatography the weight of the material and the spot area are proportional. Purdy and Truter (3) found that quantitation is based on a linear relationship existing between the square root of the area of a component after chromatographing, and the logarithm of the weight of the applied sample. According to them, Seher's data, as well as that of Stahl (4) and Breuner and Niederwieser (5), fit the relationship for loads of 1 to 80 mcg./spot. Pelka and Metcalf (6) examining long-chain tertiary amines, found the method applicable for loads of approximately 200 mcg.

Morrison and Orr (7), in an analysis of selected pharmaceutical mixtures in tablet and capsule forms and by using thin-layer chromatography, obtained quantitative results from the developed chromatograms. A linear relationship between the spot area, in sq. mm., and the weight of the spots was observed.

The method was applicable for concentrations up to 250 mcg. However, this method requires a satisfactory spray reagent, otherwise its use for quantitative work is doubtful.

Ganshirt *et al.* (8) used thin-layer chromatography for the quantitative assay of a number of bile acids, and Zollner *et al.* (9) found the method applicable for the quantitative estimation of cholesterol esters.

Millett *et al.* (10) described other techniques for

The absorptivity of a similarly eluted spot of unknown concentration, but parallel running, was measured and compared with the standards. The accuracy of the methods appeared to be between 95–98 percent.

THE APPLICATION of thin-layer chromatography to pharmaceutical analysis has been used increasingly during the past years. A number of methods for quantitative analysis have been employed since the technique was first introduced by Stahl (1) in 1956.

Seher (2) has suggested that in thin-layer chromatography the weight of the material and the spot area are proportional. Purdy and Truter (3) found that quantitation is based on a linear relationship existing between the square root of the area of a component after chromatographing, and the logarithm of the weight of the applied sample. According to them, Seher's data, as well as that of Stahl (4) and Breuner and Niederwieser (5), fit the relationship for loads of 1 to 80 mcg./spot. Pelka and Metcalf (6) examining long-chain tertiary amines, found the method applicable for loads of approximately 200 mcg.

Morrison and Orr (7), in an analysis of selected pharmaceutical mixtures in tablet and capsule forms and by using thin-layer chromatography, obtained quantitative results from the developed chromatograms. A linear relationship between the spot area, in sq. mm., and the weight of the spots was observed.

The method was applicable for concentrations up to 250 mcg. However, this method requires a satisfactory spray reagent, otherwise its use for quantitative work is doubtful.

Ganshirt *et al.* (8) used thin-layer chromatography for the quantitative assay of a number of bile acids, and Zollner *et al.* (9) found the method applicable for the quantitative estimation of cholesterol esters.

Millett *et al.* (10) described other techniques for

quantitative thin-layer chromatography using furoic acid and hydroxymethylfuroic acids as model compounds. Eble and Brooker (11) suggested an application of thin-layer chromatography for quantitative assay of tryptamine.

Choulis (12) recently used thin-layer chromatography for quantitative estimation of adrenaline.

The purpose of the present paper is to examine the applicability of the technique as a general method for quantitation for sympathomimetic amines in pharmaceutical formulations.

EXPERIMENTAL

Materials—Amphetamine hydrochloride, noradrenaline hydrochloride, normetanephrine hydrochloride, metanephrine hydrochloride, dopamine, ephedrine hydrochloride, isopropylarterenol hydrochloride, nordefrin hydrochloride, dopa, and phenylephrine hydrochloride were used.

Developing System—*n*-Butanol: acetic acid: water 4:1:5 v/v (the liquids were shaken together and set aside overnight; the organic layer was separated and used as the running solvent).

Detection—Amphetamine was detected by the *p*-nitroaniline diazo reagent described by Wickstrom and Salversen (13). The reagent was prepared by dissolving 0.25 Gm. *p*-nitroaniline in 25 ml. of 1 *N* hydrochloric acid and diluted to 50 ml. with ethanol. The solution was cooled in an ice bath and 0.1 Gm. sodium nitrate was added before use; the amphetamine was detected by the appearance of a pink spot.

Dopa, dopamine, and ephedrine hydrochloride were located by spraying with a solution of ninhydrin in *n*-butanol or acetone (0.2% w/v) and heating the plates at 100° for 4 min. (14).

All other amines were detected by using an aqueous solution containing 0.6% w/v potassium ferricyanide and 0.5% w/v sodium hydroxide (15).

An ultraviolet lamp was used also to locate the spots in cases where spraying reagents had to be avoided.

Preparation of the Plates—The plates (20 × 20 cm.) were coated with cellulose layer, 250 mμ thick, according to the method of Stahl (1), also (12).

General Procedure—Solutions of the amines were prepared by dissolving 200 mg. of the pure compounds in 10 ml. of a 5% solution of acetic acid in water, in 10-ml. volumetric flasks (master solutions).

Using accurately calibrated microliter pipets, samples of the solutions were applied to the plates, 1.5 cm. from the bottom edges, and ascending chromatograms were run at room temperature (about 23°). The solvent front was allowed to travel 10 cm.; the plates were removed, air dried, and sprayed with the appropriate reagent.

To all solvent systems used, small quantities of sodium metabisulfite were added as antioxidant. All chromatograms were carried out in chromatographic chambers enriched in nitrogen atmosphere.

Methods—(*a*) Spot area/concentration relationship—The relationship between spot area and concentration was established by spotting various concentrations of the amine solutions on thin layers. The chromatograms were developed and the spots were detected using various spray reagents. The detected chromatograms were positioned on the stage of a Photovolt Densitometer, model 52-C, and the spots were scanned perpendicularly to the direction of chromatographic development. Using a 1- × 10-mm. slit which covered the spots completely, the machine was adjusted to read zero absorbance at a point a few millimeters from the spot; scanning was begun and the peak area was traced on a Varicord recorder with a 6.5-in. paper. The area under the peak was integrated with the photovolt electronic integrator, and also calculated with the use of Gelman high-precision planimeter. Standard curves were constructed from plots of the area *versus* concentration of various amines.

(*b*) Ultraviolet absorption/concentration relationship—The relationship between ultraviolet absorption and concentration of the amines was established by spotting again various concentrations of the amine solutions on thin layers. The chromatograms were developed and the spots were detected using an ultraviolet lamp and marked. The marked areas, which corresponded to the spots, were carefully scraped off and the cellulose was quantitatively transferred to 20-ml. conical flasks. The amines were eluted from the coating material by adding about 7 ml. of the solvent; the flasks were shaken well for about 10 min., centrifuged, and filtered into 10-ml. volumetric flasks. Solvent was added to the volume. No amine residues were found on the filters testing with the appropriate amine reagent. A similar elution process was followed for a blank sample of the coating material alone.

Spectrophotometric measurements were carried out at λ maxima of each individual amine, using a Beckman DU spectrophotometer with 1-cm. cells, and standard curves of absorptivity *versus* concentration of the various amines (after reducing the absorbance due to the blank) were constructed.

RESULTS

Relationship Between Spot Area and Concentration—The quantitation of the amine spots, after spraying the chromatograms with the appropriate reagent, was calculated from plots of the peak areas *versus* concentrations with the standard deviation on the plate, and tabulated as indicated in Table I where the relationships for amphetamine hydrochloride and phenylephrine hydrochloride in concentration ranges between 1–15 mcg. were established. The average deviation from the theoretical value was calculated and expressed in percentages.

TABLE I—RECOVERY VALUES AND PERCENTAGE DEVIATION OF AMPHETAMINE HCl AND PHENYLEPHRINE HCl USING PHOTOELECTRIC DENSITOMETER

Compounds	Quantities Spotted on Plates, mcg.	Theoretical Values of Integrated Area Units, Pips	Received Mean-Values of Integrated Area Units, Pips	Av. Deviation from 100%
Amphetamine hydrochloride	1	8	8	
	3	16	16	
	5	32	31	−5
	7	48	46	
	9	54	58	
Phenylephrine hydrochloride	3	25	24	
	6	50	50	
	9	75	72	−3
	12	100	96	
	15	125	121	

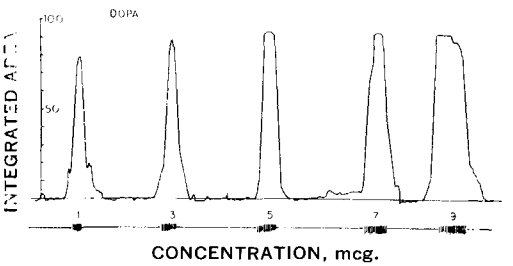

Fig. 1—Typical Varicord traced areas for dopa.

Figure 1 illustrates typical Varicord-traced areas for dopa, in concentration ranges between 1 and 9 mcg. Similar results were observed for all other examined amines using concentration areas between 2 and 40 mcg.

Relationship Between Ultraviolet Absorption and Concentration—The quantitation of the amine spots was determined from plots of absorbance *versus* concentration and tabulated, using the mean values from a number of measurements, as indicated in Table II, where the relationships of amphetamine hydrochloride and phenylephrine hydrochloride in concentration ranges between 0.1 and 5 mcg. were established.

Here also the average deviation from the theoretical value was calculated and expressed in percentages.

DISCUSSION

In the present investigation two methods for quantitative determination of sympathomimetic amines are employed, namely the spot area/concentration and the ultraviolet absorption/concentration.

All experiments were carried out in triplicate and the mean values were recorded.

For the first method, linear relationships between the spot areas and the weight of the compounds used were found using densitometric measurements. This relationship shows the dependence of the area of the spot upon the amount of the amine used. From the calculated mean values, a deviation of ±5% was observed.

Although the method is considered sufficiently accurate for routine pharmaceutical analysis, some limitations may be imposed. For example, a tendency to overload the capacity of the plates with an excess of spots, or even to overload the spots must be avoided. The best results were obtained with 25-mcg. or less quantities/spot, although higher concentrations can be determined accurately provided that the size of the initial spot application area should be as small as possible, due to the fact that the spot area is increased during the development of the chromatogram, and also that the photocell of the densitometer cannot detect areas outside its optical field.

Moreover, the temperature of the experiments (room temperature) must be constant, and the purity of the solvents used must be examined so that R_f values will be more reproducible.

The greater difficulty, however, is in the preparation of the appropriate plates, because variations in the thickness of the cellulose layer alter the light reflected by the background. Spray reagents which color the background will also lead to incorrect results, since the densitometer records the difference in intensity between the detected spot and the noncolored background.

Table II—Recovery Values and Percentage Deviation of Amphetamine HCl and Phenylephrine HCl Using Ultraviolet Spectrophotometer

Compounds	Quantities Spotted on Plates, mcg.	Theoretical Absorptivity Values	Absorptivity after Elution, Mean Value	Deviation from 100%
Amphetamine hydrochloride	0.3	0.06	0.06	
	0.6	0.12	0.11	
	0.9	0.18	0.19	−2
	1.2	0.24	0.24	
	1.5	0.30	0.28	
Phenylephrine hydrochloride	1	0.10	0.10	
	2	0.20	0.195	
	3	0.30	0.29	−4
	4	0.40	0.38	
	5	0.50	0.47	

Using the ultraviolet absorption/concentration method, linear relationships between the absorption density of the eluates and the weight of the compounds used were observed; the recovery of the compounds after elution of the spots was approximately 95% (±3%).

Previous observations (12) of a low recovery of the amines from cellulose layers had not recurred. Presumably the higher concentration of the acid solution used (5% instead of 2%) overpowered the influence of the absorption and partition forces, which otherwise operate exclusively on cellulose layers (16).

For quantitative estimation of sympathomimetic amines, the above-mentioned methods may be regarded as simple and accurate, and the use of these two techniques in routine microanalysis is suggested

Nonaqueous Titration of Theophylline Combinations with Acetous Perchloric Acid

By M. B. DEVANI, C. J. SHISHOO, and D. J. BHUT

Synthetic mixtures of theophylline and sodium acetate, salicylate, and glycinate are titrated with acetous perchloric acid using a potentiometer for the detection of the end points. Differentiation of the equimolecular mixtures could be realized in the solvent mixture containing benzene–acetic anhydride–acetic acid (18:4:1). The method is applied to assay theophylline combinations and their tablets. The results are compared to those obtained by official methods.

IN PHARMACY, various combinations of purines with acetates, salicylates, and glycinates are employed to increase their solubility and effectiveness. Therapeutically, they are extensively used as myocardial stimulants, diuretics, and coronary dilators. Various assay procedures for theophylline in pharmaceuticals have been reviewed (1). In NF, USP, and BP methods, theophylline is precipitated with a silver nitrate solution from an ammoniacal aqueous extract of the preparation; the excess silver nitrate is titrated with a standard solution of ammonium thiocyanate. The method is reported to give erratic results (2). The present investigation was undertaken for devising a simpler method for routine analysis.

Theophylline, being amphoteric, has been titrated both as an acid (3) and as a base (4) in nonaqueous media. Recently, caffeine (5, 6) and theobromine (7) have been estimated as bases in mixtures in water-free media.

In the present report, combinations of theophylline with sodium salts of organic acids are analyzed by differentiating nonaqueous titration. The titration solvent is a mixture of benzene–acetic anhydride–acetic acid (18:4:1), and the titrant is 0.1 *N* acetous perchloric acid. Titration is effected potentiometrically, using a glass-calomel electrode system. The method is applied to assay these combinations in tablet forms. The results by this method compare favorably with those obtained by official methods.

EXPERIMENTAL

Apparatus—All titrations were performed potentiometrically with a pH meter (Polymetron) employing a glass electrode and a calomel electrode with a salt bridge. A saturated solution of lithium chloride in glacial acetic acid formed the bridge.

Reagents and Solutions—Theophylline USP was recrystallized from water and dried at 105°. Sodium acetate BP and sodium salicylate BP were recrystallized from alcohol and dried at 105°. Theophylline sodium acetate NF and theophylline sodium glycinate NF were used without further purification. Theophylline sodium was prepared by mixing theophylline and alcoholic sodium hydroxide (1 *N*) in equimolecular proportions and evaporated to dryness on a water bath. Other chemicals and all solvents used in this study were reagent grade and were employed without further purification. A solvent mixture consisting of 18 parts benzene, 4 parts acetic anhydride, and 1 part acetic acid (benzene–acetic anhydride–acetic acid) was prepared and stored in a reagent bottle. A 0.1 *N* solution of perchloric acid in glacial acetic acid was prepared and allowed to stand 24 hr. prior to standardization against potassium acid phthalate dissolved in glacial acetic acid.

Differentiating Titration of Theophylline and Sodium Salt of an Organic Acid—Approximately 2.0 meq. of each theophylline and sodium salt of an organic acid, accurately weighed, was transferred to a 100-ml. beaker and dissolved by stirring magnetically in 50 ml. of solvent mixture. The solution was titrated potentiometrically with 0.1 *N* acetous perchloric acid. The end points were determined from the inflections of the titration curve obtained by plotting millivolts (mv.) *versus* volume (ml.) of titrant added.

Analysis of Theophylline Sodium Acetate NF—About 50 mg. of the sample, accurately weighed, was dissolved in 50 ml. of the solvent mixture in a 100-ml. beaker. The solution was titrated potentiometrically with 0.1 *N* perchloric acid.

Analysis of Glycine or Sodium Glycinate—About 2.0 meq. of the sample, accurately weighed, was dissolved in a mixture of acetic acid (2.5 ml.) and

acetic anhydride (10 ml.) in a 100-ml. beaker by warming on a water bath and allowed to stir for 5 min. Benzene (45 ml.) was added to the solution and titrated as described previously.

Analysis of Theophylline Sodium Glycinate NF—About 50 mg. of the sample, accurately weighed, was dissolved in a mixture of benzene (45 ml.) and acetic acid (2.5 ml.) by warming for 3 to 4 min. on a water bath. Salicylaldehyde (3 ml.) was mixed with it and stirred for 20 min. Acetic anhydride (10 ml.) was then added and the solution was stirred further for 5 min. The titration was carried out as described previously.

RESULTS AND DISCUSSION

The titration of purines in acetic acid against perchloric acid is reported to give unsatisfactory results. However, more distinct end points can be obtained by including acetic anhydride in the solvent mixture (5–8).

In preliminary studies, a series of solvent mixtures containing benzene, chloroform, acetic anhydride, and acetic acid in varying proportions were tested as titration media. Resolution of end points was most satisfactory in a mixture of benzene–acetic anhydride–acetic acid (18:4:1). Typical titration curves are illustrated in Fig. 1.

Curve A of Fig. 1 indicates only one potential break corresponding to theophylline content; whereas two distinct inflections are observed in the titration of theophylline sodium (Fig. 1, Curve D). The first end point corresponds to sodium content and the second to theophylline. Similar potential rises are noted in the titrations of equimolecular mixtures of theophylline-sodium salicylate and theophylline-sodium acetate (Fig. 1, Curves B and C). Both the components of each combination can be estimated with fair accuracy (Table I). The procedure was applied to determine the theophylline content of theophylline sodium acetate NF and its tablets. The difference between the first and second end points corresponds to the amount of theophylline. The results compare favorably with those obtained by NF method (Table II).

Figure 2, Curve E for theophylline sodium glycinate mixture indicates two inflections. The first corresponds to the sodium content and the second to the total basicity of theophylline and glycine. Since the theophylline–glycine mixture could not be differentiated in the solvent mixture used (Fig. 2, Curve B), the glycine was masked with salicylaldehyde. The resulting Schiff's base did not interfere with the titration of theophylline (Fig. 2, Curve D). Equimolecular mixtures of theophylline

TABLE II—ANALYSIS OF PHARMACEUTICAL PRODUCTS CONTAINING THEOPHYLLINE BY DIFFERENT METHODS

Preparations	Labeled Amount	Recovery of Theophylline by

Synthesis of Adamantyl Analogs of Analgesics

By A. NELSON VOLDENG, C. ALLEN BRADLEY, ROBERT D. KEE, EDDIE L. KING, and FRED L. MELDER

The synthesis of adamantyl esters related to heroin, meperidine, and aspirin is reported. Preliminary comparisons in mice indicate the adamantyl ester (V) is more potent and longer acting than meperidine hydrochloride.

THE INCORPORATION of the adamantyl moiety into drugs has been reported to increase the duration of action, and sometimes potency, of the parent compound. For example, 1-(1-adamantyl)-3-(*p*-tolylsulfonyl) urea, the adamantyl analog of tolbutamide, was found to be a very potent and long-acting oral hypoglycemic agent possessing activity two to fifteen times that of tolbutamide (1). The 17β-adamantoate ester of 19-nortestosterone is reported to be much longer acting with little androgenic activity as compared to other esters of the same steroid (2). This increase in duration of action was explained as being due to a decreased rate of enzymatic hydrolysis of the ester, thus making the 17β-hydroxyl group unavailable for biological oxidation to an inactive anabolic agent(2, 3).

In the penicillin series, resistance to penicillinase has been found by experiment to be associated with a side chain derived from a sterically hindered acid. Doyle and Nayler believe that restriction of rotation about the single bond linking the side chain to the amide carbonyl group constrains the molecule to adopt a conformation which is not readily accommodated at the active site of the enzyme (4). Substitution of the usual side chain with various adamantane carboxamide groups provides potent antibiotics that are penicillinase resistant and in some cases are active against Gram-negative bacteria (5–8).

Because of these profound pharmacological effects within different classes of drugs, the authors chose to prepare adamantyl analogs of known analgesics. The proposed compounds were expected to be much

Synthesis of Adamantyl Analogs of Analgesics

By A. NELSON VOLDENG, C. ALLEN BRADLEY, ROBERT D. KEE, EDDIE L. KING, and FRED L. MELDER

The synthesis of adamantyl esters related to heroin, meperidine, and aspirin is reported. Preliminary comparisons in mice indicate the adamantyl ester (V) is more potent and longer acting than meperidine hydrochloride.

THE INCORPORATION of the adamantyl moiety into drugs has been reported to increase the duration of action, and sometimes potency, of the parent compound. For example, 1-(1-adamantyl)-3-(*p*-tolylsulfonyl) urea, the adamantyl analog of tolbutamide, was found to be a very potent and long-acting oral hypoglycemic agent possessing activity two to fifteen times that of tolbutamide (1). The 17β-adamantoate ester of 19-nortestosterone is reported to be much longer acting with little androgenic activity as compared to other esters of the same steroid (2). This increase in duration of action was explained as being due to a decreased rate of enzymatic hydrolysis of the ester, thus making the 17β-hydroxyl group unavailable for biological oxidation to an inactive anabolic agent(2, 3).

In the penicillin series, resistance to penicillinase has been found by experiment to be associated with a side chain derived from a sterically hindered acid. Doyle and Nayler believe that restriction of rotation about the single bond linking the side chain to the amide carbonyl group constrains the molecule to adopt a conformation which is not readily accommodated at the active site of the enzyme (4). Substitution of the usual side chain with various adamantane carboxamide groups provides potent antibiotics that are penicillinase resistant and in some cases are active against Gram-negative bacteria (5–8).

Because of these profound pharmacological effects within different classes of drugs, the authors chose to prepare adamantyl analogs of known analgesics. The proposed compounds were expected to be much

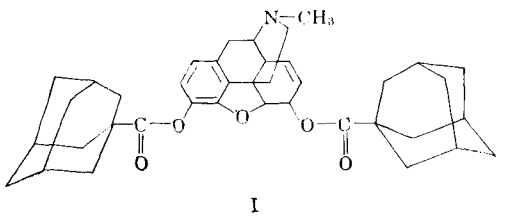
longer acting since the ester function would not be hydrolyzed as rapidly *in vivo*. In addition, these analogs should still retain some activity since the moiety being replaced is not essential for the analgesic action.

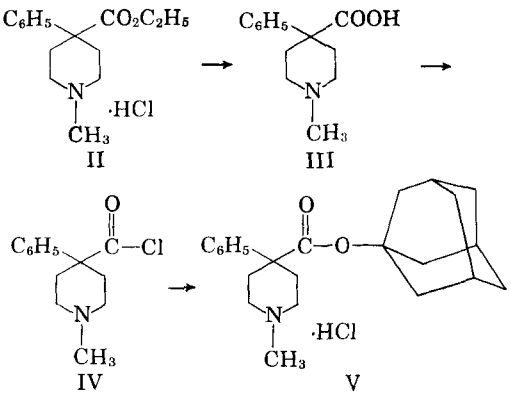
Certain esters related to dihydroheroin also possess analgesic activity (9). Both the 3,6-diglycyl and 3,6-di-(*o*-acetyl-L-tyrosyl) esters have the same toxicity as dihydromorphine but their analgesic actions are greater. Substitution of a propionyl or a carbomethoxy group for the 4-carboethoxy radical of meperidine does not materially alter activity (10). Other substitutions including larger ester functions such as phenyl or butyl at this point decrease the analgesic effect. Chlorthenoxazine, 2-(2-chloroethyl)-2,3-dihydro-1,3-benzoxazin-4-one, is an example of a cyclic derivative of aspirin (acetylsalicylic acid) and salicylamide. It is reported to be more potent and a longer-acting analgesic than either of the parent molecules (11).

The adamantyl analog of heroin, 3,6-diadamantoylmorphine (I), was prepared in 70% yield by reacting morphine with adamantoic anhydride (12). Attempts to simplify the procedure and improve the yield of I were not successful. Only starting materials could be obtained when morphine was heated with adamantoyl chloride (12) in the presence of pyridine, or when stirred with trifluoroacetic anhydride and adamantoic acid. The nitrate, sulfate, phosphate, and hydrochloride salts of the diester (I) were prepared but are not soluble in water. Since the compounds could not be pharmacologically evaluated by injection of a solution, the diester (I) was purified for analysis and testing as the free base.

Meperidine (II) was hydrolyzed to the acid (III) and esterified by reaction of the acid chloride (IV) with 1-adamantyl alcohol. Using the method of Ben-Bassat (13) comparison of the analgesic activity demonstrated the adamantyl analog to be more potent and longer acting than meperidine. The results are shown in Table I.

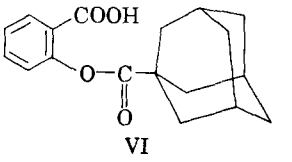


I



II III IV V

The adamantyl analog of aspirin, adamantoylsalicylic acid (VI), was prepared by reaction of salicylic acid with adamantoyl chloride (12) in the presence of pyridine.



VI

Attempts to prepare the adamantyl ester related to *d*-propoxyphene have been unsuccessful. The incorporation of the adamantyl moiety into appropriate positions of different classes of drugs and their pharmacological evaluation is presently being pursued in these laboratories.

EXPERIMENTAL[1]

3,6-Diadamantoylmorphine (I)—Anhydrous morphine was prepared by dissolving morphine sulfate in water and adding 10% sodium bicarbonate until precipitation was complete. The alkaloid was filtered, rinsed with water, and dried *in vacuo* for 24 hr. Anhydrous morphine (2.0 Gm., 0.007 mole) was added to a solution of 7.2 Gm., 0.020 mole, of adamantoic anhydride (12) in 15 ml. anhydrous toluene and the mixture heated for 24 hr. under reflux in an oil bath maintained at 130°. The solution was allowed to cool and the toluene removed *in*

[1] Melting points were determined on a Thomas-Hoover capillary melting point apparatus or a Fisher-Johns hot stage and are corrected. Infrared spectra were obtained using a Beckman IR10 spectrophotometer with KBr pellets. Elemental analyses were performed by Drs. G. Weiler and F. B. Strauss, Oxford, England. Adamantoic acid and 1-adamantanol were purchased from Aldrich Chemical Company.

vacuo. The oily residue was dissolved in anhydrous ether and a solution of hydrogen chloride in ether was added until precipitation was complete. The hydrochloride salt was filtered, added to a 10% sodium hydroxide solution (20 ml.), and extracted twice with 100-ml. portions of ether. The ether solutions were combined, washed with 20 ml. of water, dried over anhydrous magnesium sulfate, filtered, and the solvent removed *in vacuo*. A small amount of absolute methanol (5 ml.) was added to the oily residue, affording crystals of I (2.9 Gm., 70%) which were filtered, m.p. 239–241°. Recrystallization from ethyl acetate furnished an analytical sample, m.p. 240–241°. The infrared spectrum showed the characteristic ester C=O peaks at 1720 and 1750 cm.$^{-1}$ (14). The infrared spectrum of heroin, 3,6-diacetylmorphine (15) also showed two ester C=O peaks (1735 and 1755 cm.$^{-1}$).

Anal.—Calcd. for $C_{39}H_{47}NO_5$: C, 76.81; H, 7.76; N, 2.29. Found: C, 76.47; H, 7.65; N, 2.26.

1-Methyl-4-phenylisonipecotic Acid (III)—A solution of meperidine hydrochloride (II, 5.0 Gm., 0.018 mole) in 40 ml. of methanol was added to a solution of potassium hydroxide (5.0 Gm.) in 50 ml. of water and heated to reflux for 2 hr. The solution was allowed to cool and the methanol removed *in vacuo*. The alkaline solution was extracted with 30 ml. ether and adjusted to pH 6 with dilute hydrochloric acid. The white powder was filtered, rinsed with 50 ml. water, and dried for 24 hr. *in vacuo*, affording a quantitative yield of III, m.p. 310° dec. [lit. (16) m.p. 309–310°].

Adamantyl N-Methyl-4-phenylisonipecotate Hydrochloride (V)—A mixture of the acid III (2.7 Gm., 0.013 mole) and 5 ml. thionyl chloride was heated to reflux in an oil bath for 30 min., then 10 ml. of anhydrous benzene was added and heating continued for 30 min. After cooling, the acid chloride IV was filtered under suction and washed twice with 20 ml. anhydrous benzene as rapidly as possible. The white powder was quickly added to a solution of 1-adamantanol (3.0 Gm., 0.020 mole) in 20 ml. anhydrous benzene and the mixture was heated to reflux. A solution of anhydrous pyridine (1.2 ml., 0.015 mole) in 10 ml. of anhydrous benzene was slowly added and heating was continued for 4 hr. The flask was allowed to cool and the solvent removed *in vacuo*. To the white residue was added 80 ml. of water and the mixture was warmed to dissolve most of the material. After filtration under reduced pressure the insoluble material was stirred with 50 ml. of warm water. The mixture was filtered yielding 1.2 Gm. of unreacted 1-adamantanol. The aqueous solutions were combined, cooled in an ice bath, and 10% sodium carbonate was added until the extract was alkaline (pH 11). The mixture was placed in the refrigerator overnight and filtered affording 3.8 Gm. of the crude ester, V. Recrystallization from alcohol–water gave a white product which was dried *in vacuo* and dissolved in 30 ml. of anhydrous ether. A saturated solution of hydrogen chloride in anhydrous ether was slowly added with stirring and the white powder was filtered. Recrystallization from absolute alcohol gave an analytical sample of V (3.0 Gm., 60%), m.p. 267°. The infrared spectrum showed the characteristic ester C=O at 1725 cm.$^{-1}$ (14).

Anal.—Calcd. for $C_{23}H_{32}ClNO_2$: C, 70.84; H, 8.27; N, 3.59; Found: C, 70.74; H, 8.27; N, 4.31.

Adamantoyl Salicylic Acid (VI)—To a solution of 1.6 ml. of anhydrous pyridine and 2.7 Gm. of salicylic acid (0.020 mole) in 20 ml. of anhydrous benzene was added a solution of 3.9 Gm., 0.020 mole of adamantoyl chloride (12) in 20 ml. of anhydrous benzene. The mixture was heated to reflux for 3 hr. and allowed to stand at room temperature overnight. After filtration the solvent was removed *in vacuo*. The oily residue became crystalline upon standing at room temperature for 1 hr., affording 7 Gm. of crude VI, m.p. 145–147°. Recrystallization from alcohol–water gave an analytical sample of VI (4 Gm., 67%), m.p. 166–167°. The infrared spectrum showed the characteristic ester C=O at 1750 cm.$^{-1}$ and the broad acid C=O at 1690 cm.$^{-1}$ (14).

Anal.—Calcd. for $C_{18}H_{20}O_4$: C, 71.98; H, 6.71; Found: C, 71.91; H, 6.73.

Polarographic Study of the Interaction Between the Antimonyl Ion and Pyrazolone Derivatives

By JOSEPH L. ROOSEMONT

The antimonyl ion was examined by polarography with the dropping Hg electrode. The half-wave potential was found to be a function of the pH of the buffer systems. In the presence of antipyrine and aminopyrine complex formation was noticed. The differential behavior of Pb(II) and As(III) under identical working conditions was studied.

A SCOPE OF polarographic research is the investigation of the behavior of electro-active substances in the appropriate supporting electrolytes. The objective may be in this connection either to determine the formation of selective complexes between the additive and the ion or to deduce the nature of these compounds.

In this paper the polarographic behavior of the antimonyl ion, compared to Pb(II) and As(III) is studied with regard to possible complex formation. This preliminary study deals particularly with the influence of the pH on complex formation. It is evident that one buffer possessing buffering capacity over a rather large pH range is certainly more suitable than a series of buffers of different composition and a limited pH range. A "ternary" buffer mixture is therefore proposed covering the slightly acid, the neutral, and the alkaline ranges. For the acid side an ascorbate buffer is utilized. Ascorbic acid has been proposed by Šušić (1) as a supporting electrolyte. This buffer has been included in the author's research in order to study the polarographic behavior of the ions in the presence of the pyrazolone derivatives in the acid range.

EXPERIMENTAL

Test Solutions—Solutions of 0.01 *M* potassium antimonyltartrate, lead acetate, and arsenic trioxide were prepared in bidistilled water. The arsenic trioxide solution was prepared by dissolving the required quantity in a minimal volume of 2 *M* NaOH, adjusting the solution to pH 7, and making up to volume.

Supporting Electrolytes—The used ternary buffer is 0.5 *M* in succinic acid, glycocoll, and tris-(hydroxymethyl)aminomethane. By mixing with appropriate volumes of 0.5 *M* NaOH a buffering action was observed between pH 4.4 and 12. Mold growth was avoided by addition of 50 mg./L. thymol. The corresponding supporting electrolyte was prepared by mixing an equal volume of buffer and 1 *M* KNO_3.

The ascorbate buffer was obtained by neutralizing a solution of ascorbic acid (0.25 *M*) with NaOH (0.25 *M*). Only the buffer range between pH 3.6 and 4.8 was studied. The buffer functioned as the supporting electrolyte.

The electrolytes were inert in those areas where the ions concerned were polarographically active. Unless indicated, no maximum suppressor was added.

Complexing Agents—The pyrazolone derivatives (antipyrine and aminopyrine) used for this purpose were also inert in the interesting voltage ranges.

Instrumentation—A polarograph of the Metrohm E 261 R type with Ag/AgCl reference electrode and automatic registration was used. All determinations were made under identical working conditions and with the same capillary (rate of flow = 2.75_0 mg./sec. for a Hg pressure = 50 cm. $T = 25° \pm 0.1°$). The $E_{1/2}$ values refer to the saturated calomel electrode.

Procedure—A fixed volume (0.2 ml.) of a stock solution was diluted with the supporting electrolyte at the required pH to a total volume of 20 ml. Oxygen was removed from the solution by passing through pure nitrogen during 10 min. and the polarograms were registered. The complexes with the pyrazolone derivatives were examined by making the solutions 0.01 *M* with respect to these compounds. When using the ascorbate buffer appearance of disturbing maxima was avoided by adding 0.2 ml. gelatin solution (0.5 Gm.%).

RESULTS AND DISCUSSION

For the antimonyl ion the apparent $E_{1/2}$ values as a function of the pH are indicated in Fig. 1. From this figure it appears that the $E_{1/2}$ values become more negative as the medium becomes more alkaline. In the presence of antipyrine a complex formation was observed. The half-wave potentials were found to shift towards more negative values. In the

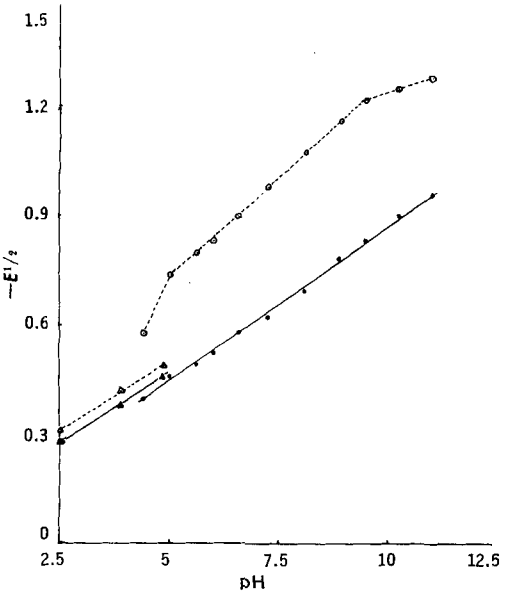

Fig. 1—Apparent half-wave potentials of the antimonyl ion as a function of the pH. Key: ●, in ternary buffer; ▲, in ascorbate buffer; ○, in ternary buffer with antipyrine; △, in ascorbate buffer with antipyrine.

Accepted for publication March 13, 1968.

TABLE I—APPARENT $E_{1/2}$ VALUES OF Pb(II)

Buffer	pH	$-E_{1/2}$[a]
Ascorbate	2.5	0.39
	3.7	0.41
	4.2	0.42
	4.8	0.43
Ternary	4.5	0.47
	6.5	0.48
	8.0	0.49
	8.9	0.52
	11.0	0.58

[a] With reference to the saturated calomel electrode.

ascorbate buffer a nearly constant shift is observed and the slope of the straight lines is about 0.08_2 v./pH. In the ternary buffer a nearly identical slope (0.08_5 v./pH) was found for the antimonyl ion. In presence of antipyrine however three breaks were noticed, the slope of the middle part ($5 \leqslant$ pH $\leqslant 9.5$) being about 0.11_2 v./pH. Aminopyrine showed a similar effect on the polarographic behavior of the antimonyl ion.

With regard to Pb(II) the apparent $E_{1/2}$ values are indicated in Table I. Generally for lead a rather slight shift of the half-wave potentials is observed as a function of pH. The pyrazolones show a practically negligible shift of the $E_{1/2}$ values.

The As(III) behaves in an entirely different way: the reduction waves only originate sufficiently with a pH $\leqslant 2.5$. Beyond this limit value they are badly shaped or even absent. Adding antipyrine causes distortion of the waves. The same effect occurs with aminopyrine.

Polarograms registered in the alkaline range show beside the accustomed cathodical waves polarographic currents emerging from potential zero. It concerns apparently anodic waves. These anodic waves have been shown to be generated for Sb and As in a strongly alkaline medium (0.1 to 1 *M* in KOH) by Kolthoff and Probst (2). These waves begin to appear at about pH 9. A shift of the $E_{1/2}$ values seems also to appear when the pH values increase.

CONCLUSION

Apparently the antimonyl ion distinguishes itself from Pb(II) and As(III) by the values of the half-wave potentials in the described buffers and furthermore also by the interaction with pyrazolone derivatives. Only the antimonyl ion shows a definite tendency to complex formation.

For the As(III) the occurrence of waves is limited to a determined pH range; the waves are distorted in the presence of the pyrazolones. The described data will be further developed with regard to possible analytical applications.

Stability of Prednisolone in an Organic Vehicle

By W. H. BOWLES

Prednisolone (0.7042 Gm.) was dissolved in 35 ml. of a vehicle (CMP) composed of 50 percent camphor, 25 percent *m*-cresyl acetate, and 25 percent *p*-chlorophenol, a mixture used in dentistry as a pulp-capping agent to reduce sensitivity in dental restorations. This preparation was assayed by the blue tetrazolium reaction and compared with an identically treated sample of USP reference standard prednisolone. The prednisolone–CMP mixture was then incubated at 60° with aliquots collected for assay at intervals of 24 hr., 5 days, 1 week, 2 weeks, and 6 weeks. At the end of 2 weeks of incubation, 99.3 percent of the prednisolone still remained; after 6 weeks' incubation, the prednisolone concentration had dropped to 72.4 percent of the preincubation concentration. Compared to literature values on the thermal stability of aqueous preparations of prednisolone, these results indicate that prednisolone in CMP is quite stable.

THE WIDESPREAD use of natural and synthetic steroids as anti-inflammatory agents in recent years has led to some concern as to the stability of these compounds in various preparations. Most of these preparations are suspensions of the steroid in aqueous or buffered aqueous media. Granulation procedures used in the manufacture of such preparations often involve exposure of the steroid to moisture and elevated temperatures (1).

Studies of prednisolone in aqueous suspensions of solid buffering agents, such as magnesium oxide, magnesium trisilicate, aluminum hydroxide, and calcium carbonate, have shown that agents which

increase the pH of the suspension, *e.g.*, magnesium oxide, cause rapid deterioration of the prednisolone when incubated at 37.5 (1). Guttman and Meister (2) showed that the rate of degradation of prednisolone in aqueous alkaline suspensions was dependent upon the concentration of alkali. In this study, the rate of anaerobic degradation was only slightly below the rate of aerobic degradation.

In a study of the effect of the concentration of buffers on the rate of prednisolone breakdown, Oesterling and Guttman (3) found that the rate of degradation increased as the concentration of buffer increased. It was also shown that addition of a sequestering agent (EDTA-Na_2) could greatly decrease the rate of degradation of prednisolone. In this same series of studies, when the temperature was increased from 35° to 70° the rate of degradation was increased approximately sevenfold at pH 8.

The present study is concerned with the stability of prednisolone in an organic medium (CMP), composed of 50% camphor, 25% *m*-cresyl acetate, and 25% *p*-chlorophenol. This combination, with prednisolone in 1% concentration, has been used as a pulp-capping agent to reduce thermal sensitivity in dental restorations since about 1960 (4, 5). Mosteller (5, 6) has expressed doubt as to the stability of the combination beyond a period of 90 days. However, apparently no studies have been done on the stability of prednisolone in organic vehicles and in view of the relative instability of prednisolone in aqueous and buffered suspensions, it was deemed worthwhile to examine the stability of prednisolone in the camphor–*m*-cresyl acetate–*p*-chlorophenol (CMP) mixture.

METHODS AND MATERIALS

Prednisolone (0.7042 Gm.) was dissolved in 35.0 ml. of the CMP vehicle, giving a concentration of 20.12 mg./ml. of prednisolone in CMP. For analysis, 0.10-ml. samples of this solution were dissolved in 200 ml. of 95% ethanol, giving a calculated prednisolone concentration of 10.05 mcg./ml. of alcoholic solution.

A blank was prepared by dissolving 0.10 ml. CMP in 200 ml. of 95% alcohol. A reference standard was prepared by dissolving 60.0 mg. of USP reference standard prednisolone in 3.0 ml. CMP; 0.1 ml. of this mixture was added to 200 ml. 95% ethanol, giving a prednisolone concentration of 10.0 mcg./ml. of alcoholic solution. Blank, samples, and reference standard solutions all contained identical amounts of the CMP vehicle.

Twenty-milliliter aliquots of these solutions were assayed by the tetrazolium blue reaction (7) as follows: into each 20-ml. aliquot was pipeted 2.0 ml. of 0.5% tetrazolium blue in ethanol and 2.0 ml. of 10% tetramethylammonium hydroxide in ethanol. The solutions were mixed and the color allowed to develop for 90 min. in the dark.

The absorbances of reference standard and samples were read against the blank at a wavelength of 525 mμ in a Beckman DB-G spectrophotometer, with attached Sargent recorder, model SRL. After initial triplicate assays of the prednisolone–CMP preparation, the solution was incubated at 60° in a stoppered bottle. Samples (0.10 ml.) in triplicate were removed for assay at intervals of 24 hr., 5 days, 7 days, and 14 days. One additional sample was assayed after 6 weeks of incubation at 60°.

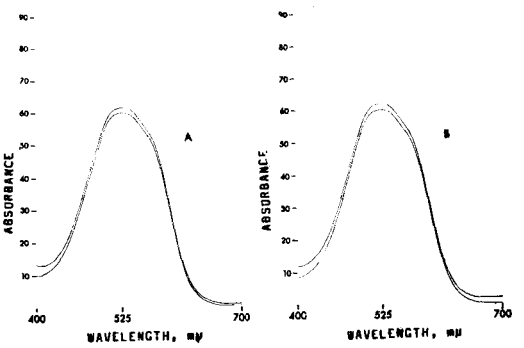

*Fig. 1—Stability of prednisolone after incubation at 60° in CMP (camphor—*m*-cresyl acetate—*p*-chlorophenol) compared to nonincubated USP reference standard prednisolone, as shown by tetrazolium blue assay. Key: upper curves, prednisolone; lower curves, nonincubated prednisolone; A, 24 hr.; B, 2 weeks.*

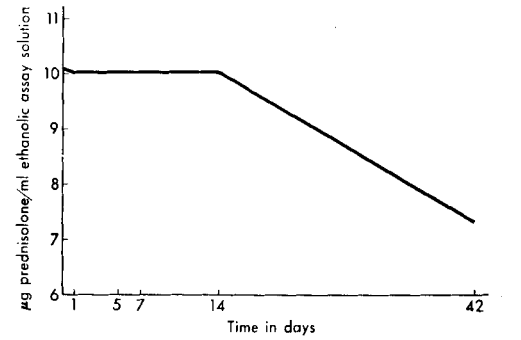

*Fig. 2—Stability of prednisolone in CMP (camphor—*m*-cresyl acetate—*p*-chlorophenol) incubated at 60°.*

RESULTS

Assay of the preincubation mixture gave a prednisolone concentration of 10.10 mcg./ml. of alcoholic solution. Assays after incubation at 60° for periods of 24 hr. to 2 weeks ranged from 10.03 to 10.05 mcg./ml. consistently (Fig. 1). After 6 weeks incubation of the prednisolone–CMP solution, the concentration of prednisolone was found to have dropped to 7.31 mcg./ml. of alcoholic assay solution (Fig. 2).

DISCUSSION

Prednisolone has been shown to be relatively unstable in aqueous suspensions at 35° (1), and even less stable when incubated at 35° in the presence of alkali (2) and trace metals (3). At pH 8, Oesterling and Guttman (3) obtained approximately a sevenfold increase in degradation rate when the temperature was increased from 35° to 70°. Thus the chief causes of prednisolone breakdown in pharmaceutical preparations have been shown to be alkalinity and trace metals, with degradation increasing as the temperature increases. In the organic vehicle, CMP, these catalysts of prednisolone degradation are absent and the preparation was found to be very stable at 60° for at least 2 weeks. Oesterling and Guttman (3) have shown prednisolone to be quite stable below pH 5. Thus good stability might be expected, since CMP is slightly acidic, due to the *p*-chlorophenol. It is suggested that the combina-

tion of 1% prednisolone in CMP, which is used in dentistry as a pulp-capping agent, would have a shelf-life of 2 to 5 years.

Aster pilosus (*Compositae*) I. Isolation of Hyperoside (Quercetin-3-β-D-mono-galactoside) from the Leaves

By NORMAN R. FARNSWORTH, HILDEBERT WAGNER, LUDWIG HÖRHAMMER, and HANNS-PETER HÖRHAMMER

Aster pilosus **leaves were investigated and found to contain several flavonoids, as evidenced by thin-layer chromatography. Purification of a crude ethanol extract, followed by polyamide column chromatography, resulted in the isolation of one of the flavone constituents, which was found to be identical with hyperoside (quercetin-3-β-D-mono-galactoside).**

ALTHOUGH SEVERAL HUNDRED SPECIES of the genus *Aster* have been botanically described, relatively little is known of the phytochemical constituents of this group of plants. *Aster tataricus* roots have yielded the triterpenes friedelin, epifriedelanol, and shionone, in addition to astersaponin (hederagenin glucoside) (1–6) and the flavone quercetin (7). Quercetin, carotenoids, and galactose have also been detected in the pollen of this species (8). The latter three compounds have similarly been detected in the pollen grains of *Aster yomena* and *A. ageratoides* var. *ovatus* (8). *Aster tripolium* roots have yielded the polyacetylene compound 2-*trans*:8-*trans*-matricarianol (9) and *A. spinosus*, *cis*-lachnophyllum ester (10). Also, 2-*cis*: 8-*cis* matricaria ester has been isolated from the roots of *A. mongolicus*, *A. lautureanus*, and *A. novae angliae* (9), and angelic acid ester from *A. novae belgii* (11). Delphinidin diglycosides have been detected in the flowers of *A. amellus* var. *riverslea* and *A. sinensis* (12), cyanidin-3, 5-dimonoside in the leaves of *A. ericoides* (13), and callistephin (pelargonidin-3-glucoside), as well as chrysanthemin (cyanidin-3-glucoside), have been isolated from *A. chinensis* (14). A number of volatile oil constituents has also been identified in *Aster indicus* by means of gas chromatography (15).

Several *Aster* species have been used as folkloric remedies in the treatment of skin diseases (*A. novae angliae*) (16), rectal disorders, angina, eye inflammation, and stomach acidity (*A. amellus*, *A. tripolium*) (16), syphilis, bone caries, and coughs. (*A. bakerianus*) (17), intestinal parasites, and abdominal pain (*A. erigeroides*, *A. filifolius*) (17), and headache (*A. muricatus*) (17). In addition, various species have been recorded as being toxic to livestock, having strong emetic and purgative activity, producing depression, and having antiseptic properties (16, 17).

On the experimental side, *A. pilosus* var. *demotus* (18), *A. scaber* (19), *A. tataricus* (19), and *A. japonicus* (20) have been reported to elicit antitumor activity, whereas *A. divaricatus* extracts have shown strong inhibitory action against *Mycobacterium tuberculosis* (21). Defatted ethanol extracts of several native *Aster* species have been shown to elicit varying degrees of central system depression and/or autonomic activity in mice (22) and *A. divaricatus* is inhibitory for the pseudorabies virus in tissue culture tests (22).

No definitve phytochemical studies have been reported in the literature for *Aster pilosus* and biological activity reports on this species are limited (22–24).

On the basis of a lack of phytochemical information on *A. pilosus*, and because of interesting folkloric uses recorded for this genus of plants, a preliminary chemical study of the leaves was initiated.

EXPERIMENTAL

Plant Material—The plant material used in this investigation was the dried leaves of *Aster pilosus* Willd. (*Compositae*), collected during September 1966 at Pittsburgh, Pa. and authenticated by Dr. L. K. Henry, Carnegie Museum, Pittsburgh, Pa.

Received December 7, 1967, from the Institut für Pharmazeutische Arzneimittellehre der Universität München, Munich, Germany, and the Department of Pharmacognosy, School of Pharmacy, University of Pittsburgh, Pittsburgh, PA 15213

Accepted for publication February 6, 1968.

This investigation was supported, in part, by a research grant-in-aid from Eli Lilly and Company, Indianapolis, Indiana 46206. One of the authors (N.R.F.) is grateful to the Alexander von Humboldt Stiftung for a research fellowship which made this work possible.

The authors wish to acknowledge the technical assistance of Mr O. Seligmann and Misses M. Seitz and E. Sedlaczek.

tion of 1% prednisolone in CMP, which is used in dentistry as a pulp-capping agent, would have a shelf-life of 2 to 5 years.

On the basis of a lack of phytochemical information on *A. pilosus*, and because of interesting folkloric uses recorded for this genus of plants, a preliminary chemical study of the leaves was initiated.

EXPERIMENTAL

Plant Material—The plant material used in this investigation was the dried leaves of *Aster pilosus* Willd. (*Compositae*), collected during September 1966 at Pittsburgh, Pa. and authenticated by Dr. L. K. Henry, Carnegie Museum, Pittsburgh, Pa.

Received December 7, 1967, from the Institut für Pharmazeutische Arzneimittellehre der Universität München, Munich, Germany, and the Department of Pharmacognosy, School of Pharmacy, University of Pittsburgh, Pittsburgh, PA 15213

Accepted for publication February 6, 1968.

This investigation was supported, in part, by a research grant-in-aid from Eli Lilly and Company, Indianapolis, Indiana 46206. One of the authors (N.R.F.) is grateful to the Alexander von Humboldt Stiftung for a research fellowship which made this work possible.

The authors wish to acknowledge the technical assistance of Mr O. Seligmann and Misses M. Seitz and E. Sedlaczek.

Voucher specimens representative of the collection have been deposited in the herbaria of Carnegie Museum and the Department of Pharmacognosy, University of Pittsburgh. The plant material was air-dried and milled to a coarse powder prior to extraction.

Preparation of Crude Flavonoid Extract—The dried leaves (2.56 Kg.) were continuously extracted in a Lloyd extractor with skellysolve B (*n*-hexane) for 72 hr. and the resulting extract was concentrated to remove all traces of solvent by means of a flash evaporator *in vacuo* at 40°. The green, oily residue weighed 37.1 Gm. (Fraction *A*). Next, the skellysolve-B exhausted plant material was continuously extracted in the Lloyd extractor for 72 hr. with methanol, and the methanol extract was concentrated to dryness to yield 435 Gm. of a dark-green powder (Fraction *B*).

Thin-layer chromatography of Fraction *B* on Kieselgel G, and polyamide plates, as well as paper chromatographic examination, revealed the presence of several flavonoid components, as evidenced by color reactions of resolved components after treatment of the chromatograms with lead subacetate solution, and viewing under ultraviolet light (25). At least three major and two minor flavonoids could be detected in this manner.

A 210-Gm. batch of Fraction *B* was mixed with 3 L. of distilled water and heated on a steam bath for several hours until the extract was concentrated to about 1 L. The mixture was refrigerated overnight, during which time a considerable amount of nonflavonoid material precipitated from solution, which was removed by centrifugation. The clear supernatant was again concentrated on a steam bath to about 0.5 L., followed by refrigeration overnight. Very little precipitation occurred following this treatment, and the extract was again clarified by centrifugation to yield a clear brown solution. Thin-layer chromatography of this extract revealed the presence of chlorophyll, thus it was diluted with an equal volume of water and again concentrated to about 0.5 L. and refrigerated. This treatment resulted in an additional precipitation of nonflavonoid pigments, which were removed by centrifugation.

This clarified extract was next extracted six times in a separator with separate 200-ml. portions of ethyl acetate, the combined extracts being taken to dryness *in vacuo* to yield 14.37 Gm. of Fraction *B-1*. The aqueous phase was then extracted with six separate 200-ml. portions of ethyl acetate–methanol (95:5). Removal of solvent *in vacuo* yielded 3.01 Gm. of Fraction *B-2*.

Isolation of Hyperoside—A glass chromatographic column (5.5 × 55 cm.) was filled with a methanol slurry of fine particle size polyamide, prepared as previously described (26), to a packed height of 48 cm. in the column. Fraction *B-2* (3.1 Gm.) was dissolved in methanol, mixed with a small amount of polyamide, and allowed to air dry. The mixture was then placed on the top of the prepared column and methanol was continuously added, with 25-ml. fractions being collected and monitored by means of TLC on Kieselgel G plates, using methanol as the developing solvent. In this manner, a total of 95 fractions was collected and combined as follows on the basis of TLC data: 1–11, 12–21, 22–27, 28–39, 40–46, and 47–95. Combined fractions 47–95 were taken to dryness, and crystallized from methanol to yield 0.017 Gm. of pale yellow crystals. After drying the crystals *in vacuo* at 100° for 24 hr., they exhibited an m.p. of 226–229° dec. Thin-layer chromatography of the isolate on Kieselgel G plates, using a solvent system of ethyl acetate–methanol–water (100:16.5:13.5) revealed a single spot at R_f 0.38 after treatment of the chromatogram with lead subacetate solution, and viewing under ultraviolet light (366 mμ). Further, TLC of the isolate on polyamide, using methanol as the developing solvent, revealed a single spot at R_f 0.28 under the same conditions. An infrared absorption spectrum (KBr) was superimposable with those of reference samples of hyperoside (quercetin-3-β-D-mono-galactoside) derived from natural sources, and synthesized (Fig. 1). Thin-layer chromatography of the isolate in the two systems previously described, showed it to have an R_f value identical with the two samples of reference hyperoside.

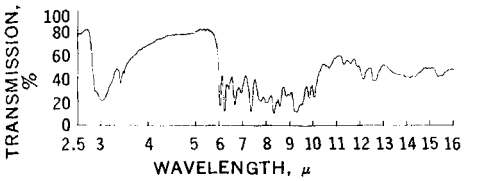

Fig. 1—Infrared absorption spectrum of hyperoside (KBr).

To further characterize the isolate, a small amount (2.0 mg.) in 5.0 ml. of methanol was hydrolyzed using 5.0 ml. of 10% hydrochloric acid under reflux for 2 hr. The hydrolysate was cooled and extracted several times with ether to remove the aglycone. Thin-layer chromatography of the concentrated ethereal extract on Kieselgel G plates, using a solvent system of benzene–pyridine–formic acid (36:9:5), showed the aglycone to have an R_f value of 0.25, and identical with that of reference quercetin, in addition to R_f values of 0.36 for the ethereal extract and reference quercetin after TLC on Kieselgel G, using a solvent system of toluene–ethyl formate–formic acid (5:4:1).

Identification of the sugar moiety was achieved by neutralizing the ether-extracted hydrolysate (*vide supra*) using silver oxide, concentrating the aqueous phase to about 0.5 ml., and spotting the extract on Schleicher and Schull No. 2043 b chromatography paper, followed by ascending development using solvent systems of isopropanol–pyridine–water–acetic acid (8:8:4:1), as well as *n*-butanol–pyridine–water (6:4:3), each for 18 hr. The aqueous hydrolysate and D-galactose both exhibited R_{GA} values of 1.0 following treatment of the dried chromatograms with benzidine spray reagent and heating at 105° for 15 min. These data are consistent with an identification of the isolate from *Aster pilosus* leaves as the flavone glycoside hyperoside (quercetin-3-β-D-mono-galactoside).

SUMMARY

An investigation of the leaves of *Aster pilosus* Willd. (*Compositae*) has resulted in the isolation of a flavone glycoside, which has been identified as hyperoside (quercetin-3-β-D-mono-galactoside). This flavone has been previously isolated from several higher plants (7), but this is the first report of its presence in any *Aster* species. The only flavonoid isolated from this genus previously is the flavone

aglycone quercetin, from *A. tataricus* roots and pollen (7, 8), and the pollen of *A. ageratoides* var. *ovatus* (8), as well as *A. yomena* (8).

The identity of additional flavonoids present in this plant will be reported at a later date.

Bacterial Contamination in Some Nonsterile Antibiotic Drugs

By MACK WHITE, FRANCES W. BOWMAN, and AMIEL KIRSHBAUM

Methods have been developed for the determination of microbial contamination in some nonsterile antibiotic preparations. Microorganism counts have been performed on both antibacterial and antifungal antibiotic powders. The highest counts were found in samples from the antifungal antibiotic.

In 1964, an extensive investigation into microbiological contamination of medical preparations was conducted in Sweden (1). A report of these findings was submitted to the Royal Swedish Medical Board, including a proposal for an upper limit of 100 bacteria per gram in nonsterile medicinals.

The *Antibiotic Regulations* of the Food and Drug Administration (FDA), the USP, and the NF require that antibiotics for injection be sterile, and they specify sterility tests for these preparations. None of these compendia, however, require sterility for oral or topical antibiotics, except for surgical powders and some ophthalmic and otic solutions. Tolerances are not specified in the official compendia for microbial contamination of nonsterile drugs except for one topical antibiotic preparation; the *Antibiotic Regulations* limits the contamination of this preparation to not more than 10 microorganisms per Gm. (2). No other oral or topical antibiotics undergo routine microbial examination as part of the antibiotic certification program.

Received January 10, 1968, from Division of Antibiotics and Insulin Certification, Food and Drug Administration, Washington, DC 20204
Accepted for publication February 9, 1968.

Recently, several batches of Agent F, an antifungal antibiotic, were found to be grossly contaminated with microorganisms, Although sterility is not required for the powder or dosage forms of this antifungal antibiotic, gross contamination would indicate a possible violation of the good manufacturing practices required by FDA (3). This possibility led to a study of the problem and to the development of suitable methods for the determination of microbial contamination in nonsterile antibiotic preparations.

EXPERIMENTAL

Materials—Prepare the following nutrient agar: peptone, 6.0 Gm.; yeast extract, 3.0 Gm.; beef extract, 1.5 Gm.; agar, 15.0 Gm.; and enough distilled water to make 1000.0 ml. The pH should be 6.5 to 6.6 after sterilization.

Prepare peptone water by dissolving 1 Gm. of peptic digest of animal tissue, USP or equivalent, in sufficient distilled water to make 1,000 ml. Dispense 99-ml. portions into flasks and sterilize in an autoclave at 121° for 20 min. The final pH should be 7.1 ± 0.1.

Method I—Powder—Place 1.0 Gm. of powder into 99 ml. of sterile peptone water. From this sus-

aglycone quercetin, from *A. tataricus* roots and pollen (7, 8), and the pollen of *A. ageratoides* var. *ovatus* (8), as well as *A. yomena* (8).

The identity of additional flavonoids present in this plant will be reported at a later date.

Bacterial Contamination in Some Nonsterile Antibiotic Drugs

By MACK WHITE, FRANCES W. BOWMAN, and AMIEL KIRSHBAUM

Methods have been developed for the determination of microbial contamination in some nonsterile antibiotic preparations. Microorganism counts have been performed on both antibacterial and antifungal antibiotic powders. The highest counts were found in samples from the antifungal antibiotic.

In 1964, an extensive investigation into microbiological contamination of medical preparations was conducted in Sweden (1). A report of these findings was submitted to the Royal Swedish Medical Board, including a proposal for an upper limit of 100 bacteria per gram in nonsterile medicinals.

The *Antibiotic Regulations* of the Food and Drug Administration (FDA), the USP, and the NF require that antibiotics for injection be sterile, and they specify sterility tests for these preparations. None of these compendia, however, require sterility for oral or topical antibiotics, except for surgical powders and some ophthalmic and otic solutions. Tolerances are not specified in the official compendia for microbial contamination of nonsterile drugs except for one topical antibiotic preparation; the *Antibiotic Regulations* limits the contamination of this preparation to not more than 10 microorganisms per Gm. (2). No other oral or topical antibiotics undergo routine microbial examination as part of the antibiotic certification program.

Received January 10, 1968, from Division of Antibiotics and Insulin Certification, Food and Drug Administration, Washington, DC 20204
Accepted for publication February 9, 1968.

Recently, several batches of Agent F, an antifungal antibiotic, were found to be grossly contaminated with microorganisms, Although sterility is not required for the powder or dosage forms of this antifungal antibiotic, gross contamination would indicate a possible violation of the good manufacturing practices required by FDA (3). This possibility led to a study of the problem and to the development of suitable methods for the determination of microbial contamination in nonsterile antibiotic preparations.

EXPERIMENTAL

Materials—Prepare the following nutrient agar: peptone, 6.0 Gm.; yeast extract, 3.0 Gm.; beef extract, 1.5 Gm.; agar, 15.0 Gm.; and enough distilled water to make 1000.0 ml. The pH should be 6.5 to 6.6 after sterilization.

Prepare peptone water by dissolving 1 Gm. of peptic digest of animal tissue, USP or equivalent, in sufficient distilled water to make 1,000 ml. Dispense 99-ml. portions into flasks and sterilize in an autoclave at 121° for 20 min. The final pH should be 7.1 ± 0.1.

Method I—Powder—Place 1.0 Gm. of powder into 99 ml. of sterile peptone water. From this sus-

pension, prepare a number of 10-fold serial dilutions by aseptically transferring 1 ml. to 9 ml. of sterile peptone water. From each dilution remove 1 ml. and add to separate sterile 20 × 100 mm. Petri dishes. Add 15 ml. of sterile liquid nutrient agar which has been cooled to 48–50°. Swirl the agar and allow to harden. Then add a 5-ml. overlay of nutrient agar and allow to harden. Invert the Petri dish and place in a 37° incubator for 48 hr. Remove and count colonies, using a Quebec colony counter.

Method II—Powder—Place a 0.45-μ solvent-resistant membrane filter, 47 mm. diameter, in a filter funnel fitted into a vacuum flask. Aseptically place 0.1 Gm. of powder into 50 ml. of sterile dimethylsulfoxide (DMSO) and allow to dissolve. Immediately filter the solution, using vacuum, through the membrane. Wash the membrane with 100 ml. of sterile peptone water, and allow to dry by continuing vacuum for 5 min. after filtration.

Place the membrane on the surface of 15 ml. of agar which has been previously allowed to harden in a Petri dish. Overlay with 5 ml. of agar and allow to harden. Incubate the plate in an inverted position for 48 hr. at 37°. Count the colonies that appear on the pad. (Ordinarily the agar overlay is not necessary, since the membrane pad is dry, and spreading growth will not occur. However, it is used here to prevent curling of the pad caused by the DMSO.)

Method III—Tablets—Use Method I, except use a sterile mortar and pestle to reduce the tablets to a powder for initial dilution. If 1 Gm. will not suspend properly, reduce initial concentration to 0.1 Gm.

Method IV—Ointment—Place 1 Gm. of ointment into 99 nl. of sterile *n*-hexane in a conical flask and shake until the ointment dissolves. Prepare a number of 10-fold serial dilutions by transferring 1-ml. aliquots to 9 ml. of sterile *n*-hexane. Filter each dilution and further proceed as described for filtration under II, omitting the 5-ml. agar overlay.

RESULTS AND DISCUSSION

Four different batches of contaminated powder were received for examination. Agar plate counts performed by conventional emulsion or surface swab methods gave unreliable results without any diminution in organisms per plate from lower to higher dilutions. The predominating contaminant was an aerobic, motile Gram-variable bacillus that resembled *Bacillus sphaericus* in its morphological and biochemical characteristics. According to Bergey's Manual (4), this organism usually grows in motile microcolonies of various shapes that move in large arcs from the point of inoculation and cover the plate in 1 day. The surface of poured agar plates should be dried by holding at room temperature for 2 or 3 days before use.

Therefore, unless extreme precautions are taken, the colonies do not remain as separate entities which can be related to a single parent; instead they will run together and counts will be erroneous. As an example, one count from another laboratory was reported to us as 2×10^{12} per Gm. Pelczar and Reid (5) report that it has been calculated that 1 Gm. of bacteria contains approximately 10^{12} bacteria. Therefore, a count of 2×10^{12} bacteria per Gm. of powder was unlikely even if the contaminating microorganisms were extremely minute. Such an inaccuracy results not from an arithmetic error, but from an illusion due to the spreading growth of the contaminant.

The use of the 5-ml. agar overlay described in Method I contains the individual colonies and prevents their spreading. Repeated tests showed good reproducibility with excellent arithmetic correlation of total counts obtained from different dilutions.

Because Agent F is relatively insoluble in water, the lowest dilution that was feasible was 10^{-2} as described in Method I. However, if the sample contains less than 100 organisms per Gm., the dilution in this technique precludes the recovery of microorganisms. Therefore, for samples contaminated with relatively few organisms, Method II should be used. In evaluating the results, the number of colonies are counted and multiplied by a factor of 10, since only 0.1 ml. is used, to obtain the number of organisms per Gm. Although the sample is dissolved in 50 ml. of DMSO, this dilution does not affect the final count because, during the filtration, the entire volume (50 ml.) passes through the membrane and the undiluted microorganisms are retained. Thus, if 8 colonies were observed on the membrane pad, the final count would be $8 \times 10 = 80$ organisms per Gm.

Using these techniques, counts for Agent F powder have ranged from 30 organisms per Gm to 4×10^8. The use of a grossly contaminated powder in the formulation of a dosage form such as a tablet or ointment resulted in a highly contaminated product. When the powder containing 4×10^8 microorganisms was used to make a tablet weighing 1 Gm. the tablet contained 9.4×10^7 microorganisms per Gm. The final dosage form was almost as heavily contaminated as the bulk although only a few mg. of the contaminated antibiotic was used in the formulation for each tablet. The excipient ingredients used in the tablet were also tested and less than 10 microorganisms per Gm. were found in each ingredient. Since the contamination of the tablet was greater than that originally introduced by the raw materials, the production procedures probably favored bacterial growth or additional contamination occurred during the manufacturing process. In any event, it was later shown that acceptable antibiotic preparations could not be made from heavily contaminated antibiotic powder.

After the manufacturing procedures were changed to yield a less contaminated powder, two batches of tablets were examined and found to be satisfactory. The antibiotic powder manufactured by the revised procedures contained 3×10^3 microorganisms per Gm. and the samples of the two batches of tablets made from this powder contained less than 50 microorganisms per Gm. An ointment was prepared from a powder having a count of 4×10^8 organisms per Gm. as an ingredient; the final product had a count of 4×10^5 per Gm. When a powder with a count of 1.2×10^2 was used in the formulation of an ointment, counts ranging from zero to a maximum of 100 organisms per Gm. were found in the ointment.

Because of the experiences with Agent F, other antibiotics were screened for bacterial counts. Among these were candicidin, kanamycin, bacitracin, neomycin, griseofulvin, nystatin, amphotericin, penicillin G, nafcillin, tyrothricin, and gramicidin.

TABLE I—VIABLE MICROORGANISMS PER GRAM FOUND IN NONSTERILE ANTIBIOTICS

Antibiotic Powders	Bacteria/Gm.	Molds/Gm.
Antifungal		
Antibiotic A	6,700	None detected
Antibiotic B	400	None detected
Antibiotic C	200	None detected
Antibiotic D	80	15
Antibiotic F (old process)	9,400,000	2
Antibiotic F (old process)	1,000,000	None detected
Antibiotic F (new process)	3,000	None detected
Antibiotic F (new process)	2,000	None detected
Antibacterial		
Nafcillin	None detected	None detected
Bacitracin	None detected	None detected
Neomycin	18	None detected
Zinc bacitracin	2	38
Penicillin	12	None detected
Tyrothricin	None detected	3

No other counts approached those of Agent F. As shown in Table I, the highest counts were found in samples of the antifungal antibiotics, indicating that they may present more of a problem than the antibacterial antibiotics.

The methods described here can be applied to bacterial counting of most antibiotics. However, the solvent systems should be modified according to the solubility characteristics of the antibiotic or antibiotic formulation under test. Any organic solvent used should, of course, be nontoxic to the contaminating microorganisms. Since the problem encountered with Agent F was gross bacterial contamination of a spore-forming organism, the tests were developed specifically for spore-forming bacteria. The techniques described may also be used for fungal contamination by using Sabouraud's agar in place of nutrient agar, incubating at 25° instead of 32°, and extending the incubation time from 2 to 5 days.

Antibiotic drugs, even those that are represented as being nonsterile, should be relatively free of microorganisms. Gross contamination is an indication of poor manufacturing practices. In addition, Curtis *et al.* (6) have stated that any organism, under certain conditions, can be considered pathogenic.

Synthesis of Imidazolthiones from 3,4-Diphenyl-4-oxazolin-2-thione

By S. CARBONI, E. GROTHE, and M. F. SAETTONE

The synthesis of some 4-hydroxyimidazolidin-2-thiones (VI) and 4-imidazolin-2-thiones (VII) by a method involving the reaction of 3,4-diphenyl-4-oxazolin-2-thione (IV) with primary amines is described.

A METHOD FOR THE preparation of imidazolones, based on the reaction of 5-unsubstituted 4-oxazolin-2-ones (such as V, Scheme I) with primary amines, was recently reported (1). In view of the interesting bacteriostatic (2, 3), fungistatic (3, 4), and CNS-depressant (5) activities reported for some 4-imidazolin- and imidazolidin-2-thiones, the authors have applied their method to the preparation of imidazolthiones from 4-oxazolin-2-thiones; some preliminary results are reported herein.

3,4-Diphenyl-4-oxazolin-2-thione (IV), prepared either from phenacyl alcohol (I) and phenyl isothiocyanate (II) through the intermediate 3,4-diphenyl-4-hydroxyoxazolidin-2-thione (III), or from V and P_2S_5, was chosen as a model compound for this study.

Treatment of IV with some primary amines gave good yields of 3,4-diphenyl-5-hydroxyimidazolidin-2-thiones (VI, see Table I). These could be easily dehydrated to afford the corresponding 4-imidazolin-2-thiones VII (Table II). In order to secure a structure proof for compounds of type VII, 1-

benzyl-3,4-diphenyl-4-imidazolin-2-thione (Compound 5) was independently synthesized (Scheme II) from 2-benzylaminoacetophenone (VIII) and phenyl isothiocyanate (II), following a known synthetic method (6) for 4-oxazolin-2-thiones.

In the course of the work, compounds of type VII were observed to differ noticeably in reactivity from their oxygenated analogs, 4-imidazolin-2-ones. A chemical investigation on these compounds is now in progress and will be the object of a further communication.

All new compounds described herein were submitted to a primary biological screening[1] aimed at detecting CNS, autonomic, antifungal, antibacterial, and antiviral activity. Compound 2 exhibited weak antiviral activity *in vitro*, and compound 10 showed smooth muscle relaxant activity *in vitro* (minimal effective dose 10 mcg./ml.). Both levels of activity were considered too weak to consider further study.

EXPERIMENTAL[2]

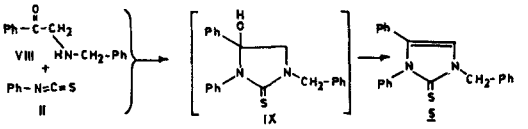
3,4-Diphenyl-4-oxazolin-2-thione (IV)—*From V*—A solution of 3,4-diphenyl-4-oxazolin-2-one (1) (V, 5.0 Gm., 0.021 mole) in xylene (150 ml.) was treated with P_2S_5 (10 Gm.) according to the procedure described by Gompper (7) for the preparation of 4,5-diphenyl-4-oxazolin-2-thione. The solution, after a 10-hr. reflux, afforded 2.85 Gm. (53%) of IV as colorless prisms, m.p. 159–161° after recrystallization from benzene, IR $\lambda_{max.}$ (nujol) 6.70, 6.91, 7.25, 7.42, 7.70, 8.81, 10.28, 10.61, 12.90, 13.31, 14.24 μ.

From I and II—A mixture of phenacyl alcohol (I, 13.6 Gm., 0.1 mole), phenyl isothiocyanate (II, 13.5 Gm., 0.1 mole), and pyridine (0.3 ml.) was heated at 120° for 4 hr., then allowed to cool. Trituration of the semisolid reaction mixture with benzene afforded 8.8 Gm. of an impure solid, which was fractionally crystallized from ethanol to afford 5.1 Gm. (18%) of a compound, m.p. 161–163° after recrystallization from benzene, IR $\lambda_{max.}$ (nujol) 3.17, 6.71, 6.94, 7.36, 7.68, 8.21, 9.41, 10.25, 13.02, 14.19 μ, which was identified as 3,4-diphenyl-4-hydroxyoxazolidin-2-thione[3] (III).

Anal.—Calcd. for $C_{15}H_{13}NO_2S$: C, 66.41; H, 4.83; N, 5.16. Found: C, 66.23; H, 4.63; N, 5.32.

Concentration of the mother liquor from III afforded unreacted phenacyl alcohol (2.0 Gm.), then a small amount (0.5 Gm.) of a compound with m.p. 173–175°, identified as 1,3,4-triphenyl-4-imidazolin-2-thione by comparison with an authentic sample[4].

A solution of III (8.13 Gm., 0.03 mole) in glacial acetic acid (25 ml.) was refluxed for 1 hr. After evaporation of the solvent under reduced pressure,



Scheme II

[1] Carried out by Bristol Laboratories, Syracuse, N. Y.

[2] Melting points were determined on a Kofler hot stage and are uncorrected.

[3] In no case phenacyl thiocarbanilate, open-chain tautomer of III, could be isolated. It should be pointed out that the oxygenated analog of III could never be obtained: phenacyl carbanilate, formed in the reaction between phenacyl alcohol and phenyl isocyanate, resisted all attempts at tautomerization to 3,4-diphenyl-4-hydroxyoxazolidin-2-one (*cf.* 1).

[4] Prepared according to McCombie and Scarborough (*cf.* 6). The compound originates probably in the reaction between *N,N'*-diphenylthiourea (formed as a secondary product in the reaction mixture) and phenacyl alcohol. Indeed, when equimolar amounts of these compounds were heated together at 160° for 4 hr., 1,3,4-triphenyl-4-imidazolin-2-thione was obtained in 67% yield.

the residue was crystallized from ethanol to afford 7.0 Gm. (92%) of IV, identical with the previously obtained material. The analytical sample was crystallized from ethanol and melted at 162–163°.

Anal.—Calcd. for $C_{15}H_{11}NOS$: C, 71.14; H, 4.37; N, 5.53. Found: C, 70.94; H, 4.24; N, 5.75.

Procedure for the Preparation of the 5-Hydroxyimidazolidin-2-thiones VI (Table I)—Solutions of IV (2.53 Gm., 0.01 mole) in the appropriate amine (benzylamine, 2-diethylaminoethylamine, 2-morpholinoethylamine or 2-pyrrolidinoethylamine, 15 Gm. *ca.*) were heated at 100° for 8–9 hr. The mixtures were then poured into ice cold water (1000 ml.); the product which separated was collected and crystallized from aqueous ethanol. A further crystallization from ethanol or from benzene–petroleum ether afforded the pure products in the yields reported in Table I.

Procedures for the Preparation of the 4-Imidazolin-2-thiones VII (Table II)—Compound 5 was prepared as follows: a solution of 1 (3.6 Gm., 0.01 mole) in ethanol (70 ml.) was treated with 1.0 ml. of concentrated H_2SO_4, then was heated to boiling. Crystalline 5 began to separate from the hot solution. After cooling, the product was collected and recrystallized from ethanol.

Compounds 6 and 8 were prepared by the same method, from 2 and 3, respectively. The acid ethanolic solution was treated with excess 10% Na_2CO_3 to precipitate the products; these were then crystallized from aqueous ethanol.

Compound 4 could best be dehydrated to 10 by the following procedure: a solution of 4 (1.1 Gm., 3.0 mmoles) in glacial acetic acid (2.0 ml.) was refluxed for 1 hr., then was poured into cold 10% Na_2CO_3 (50 ml.). The solid was collected and recrystallized from aqueous ethanol.

The hydrochlorides 7, 9, and 11 were prepared from the corresponding bases in the conventional fashion, and were purified by crystallization from absolute ethanol.

Structure Proof of 1-Benzyl-3,4-diphenyl-4-imidazolin-2-thione (Compound 5)—Treatment of 2-benzylaminoacetophenone hydrochloride (8) (VIII) with phenyl isothiocyanate, according to the procedure described by McCombie and Scarborough (*cf.* 6) for the preparation of 1,3,4-triphenyl-4-imidazolin-2-thione, gave a 15% yield of 5; IR $\lambda_{max.}$ (nujol) 6.70, 6.91, 7.15, 7.71, 7.95, 8.30, 9.35, 10.40, 13.40, 13.59, 14.24 μ.

New Compounds: *N*-Hydroxy- and *N*-Acetoxy-Metabolites of *N,N'*-(2,7-Fluorenylene)bisacetamide

By NELLIE W. PITZER and FRANCIS E. RAY*

The partial catalytic reduction of 2,7-dinitrofluorene (I) in dimethylformamide, ethyl acetate, and acetic anhydride has yielded: *N*-hydroxy-*N*-(2-fluorenyl-7-nitro)acetamide (VII); *N*-acetoxy-*N*-(2-fluorenyl-7-nitro)acetamide (II); *N'*-hydroxy-*N,N'*-(2,7-fluorenylene)bisacetamide (XI); *N,N'*-dihydroxy-*N,N'*-(2,7-fluorenylene)bisacetamide (VIII); and *N,N'*-diacetoxy-*N,N'*-(2,7-fluorenylene)bisacetamide (IV).

THE ISOLATION and subsequent synthesis of *N*-hydroxy-*N*-(2-fluorenyl)acetamide as a proximate carcinogenic metabolite of *N*-(2-fluorenyl)-acetamide (1) led to the undertaking of the synthesis of a similar *N*-hydroxy compound as a possible metabolite for *N,N'*-(2,7-fluorenylene)bisacetamide (VI) which is known to produce carcinoma of the glandular stomach in rats (2).

* Deceased November 25, 1966.

It has been reported recently that *N*-acetoxy-*N*-(2-fluorenyl)acetamide is an ultimate carcinogen of *N*-(2-fluorenyl)acetamide (3). Therefore the acetoxy esters synthesized have taken on increased biological interest.

The procedure for the catalytic partial reduction and the acetylation of 2-nitrofluorene in ethyl acetate and the subsequent hydrolysis in ammonium hydroxide (4) applied to 2,7-dinitrofluorene (I) gave a small yield of *N*-hydroxy-*N*-(2-fluorenyl-7-nitro)acetamide (VII).

After hydrolysis the ethyl acetate solution contained a mixture of reduction products. This prompted the use of *N*-(2-fluorenyl-7-nitro)acetamide (III) for catalytic reduction, as the only *N*-hy-

the residue was crystallized from ethanol to afford 7.0 Gm. (92%) of IV, identical with the previously obtained material. The analytical sample was crystallized from ethanol and melted at 162–163°.

Anal.—Calcd. for $C_{15}H_{11}NOS$: C, 71.14; H, 4.37; N, 5.53. Found: C, 70.94; H, 4.24; N, 5.75.

Procedure for the Preparation of the 5-Hydroxyimidazolidin-2-thiones VI (Table I)—Solutions of IV (2.53 Gm., 0.01 mole) in the appropriate amine (benzylamine, 2-diethylaminoethylamine, 2-morpholinoethylamine or 2-pyrrolidinoethylamine, 15 Gm. *ca.*) were heated at 100° for 8–9 hr. The mixtures were then poured into ice cold water (1000 ml.); the product which separated was collected and crystallized from aqueous ethanol. A further crystallization from ethanol or from benzene–petroleum ether afforded the pure products in the yields reported in Table I.

Procedures for the Preparation of the 4-Imidazolin-2-thiones VII (Table II)—Compound 5 was prepared as follows: a solution of 1 (3.6 Gm., 0.01 mole) in ethanol (70 ml.) was treated with 1.0 ml. of concentrated H_2SO_4, then was heated to boiling. Crystalline 5 began to separate from the hot solution. After cooling, the product was collected and recrystallized from ethanol.

Compounds 6 and 8 were prepared by the same method, from 2 and 3, respectively. The acid ethanolic solution was treated with excess 10% Na_2CO_3 to precipitate the products; these were then crystallized from aqueous ethanol.

Compound 4 could best be dehydrated to 10 by the following procedure: a solution of 4 (1.1 Gm., 3.0 mmoles) in glacial acetic acid (2.0 ml.) was refluxed for 1 hr., then was poured into cold 10% Na_2CO_3 (50 ml.). The solid was collected and recrystallized from aqueous ethanol.

The hydrochlorides 7, 9, and 11 were prepared from the corresponding bases in the conventional fashion, and were purified by crystallization from absolute ethanol.

Structure Proof of 1-Benzyl-3,4-diphenyl-4-imidazolin-2-thione (Compound 5)—Treatment of 2-benzylaminoacetophenone hydrochloride (8) (VIII) with phenyl isothiocyanate, according to the procedure described by McCombie and Scarborough (*cf.* 6) for the preparation of 1,3,4-triphenyl-4-imidazolin-2-thione, gave a 15% yield of 5; IR $\lambda_{max.}$ (nujol) 6.70, 6.91, 7.15, 7.71, 7.95, 8.30, 9.35, 10.40, 13.40, 13.59, 14.24 μ.

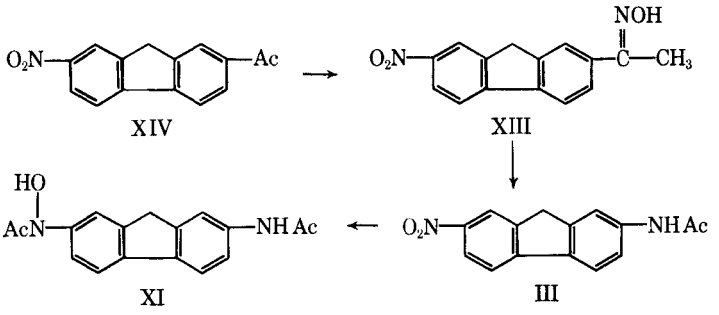
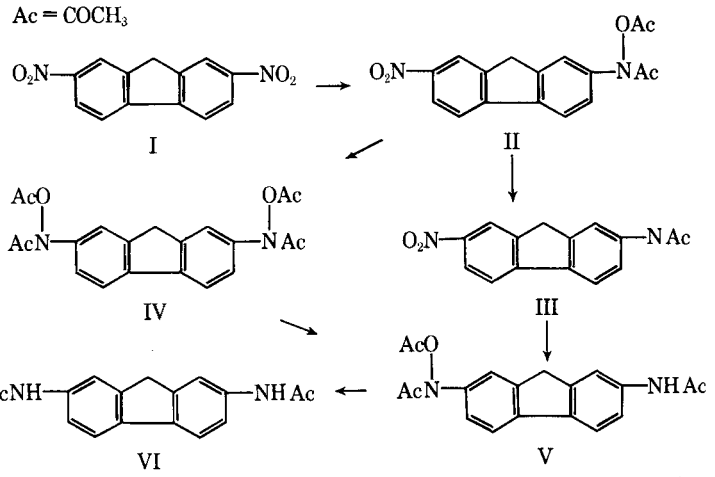


Scheme I



Scheme II (not isolated)

droxy derivative would then be *N'*-hydroxy-*N,N'*-(2,7-fluorenylene)bisacetamide (XI). The other probable product would be the known *N,N'*-(2,7-fluorenylene)bisacetamide (VI) (Scheme II).

A reduction of 2,7-dinitrofluorene in ethyl acetate and acetic anhydride yielded a compound, m.p. 248–249°, that was neither an *N*-hydroxy (negative to ferric chloride test) nor the known compounds, (III and VI). Microanalysis showed it to be *N,N'*-diacetoxy-*N,N'*-(2,7-fluorenylene)bisacetamide (IV) (Scheme II).

Since the one-step reduction from 2,7-dinitrofluorene (I) appeared to be unsatisfactory, due to the low solubility of I and the necessity for rapid reduction (25 min. or less), the two-step procedure with subsequent separation of products was devised.

EXPERIMENTAL

Ultraviolet spectra were obtained on a Hitachi Perkin-Elmer 139 UV-VIS spectrophotometer in 95% ethanol. Microanalyses were performed by Schwartzkopf Microanalytical Laboratories.

N'-Hydroxy-N,N'-(2,7-fluorenylene)bisacetamide (XI) from N-(2-Fluorenyl-7-nitro)acetamide (III)—*2-Acetyl-7-nitrofluorene oxime (XIII)*[1]—To a well-stirred mixture of 2.5 Gm. (0.01 mole) 2-acetyl-7-nitrofluorene (XIV) (5) heated in 150 ml. of *n*-butanol was added 1.4 Gm. (0.02 mole) of hydroxylamine hydrochloride dissolved in 3 ml. of water. Sodium acetate (1.4 Gm.) was added and the suspension heated on a magnetic stir plate for 1 hr. A few milliliters of water added near the end of the heating was necessary for complete solution. The yellow oxime (XIII) precipitated upon cooling. Yield, 2.3 Gm., 88%, m.p. 229–230°. Several recrystallizations from glacial acetic acid raised the m.p. to 236°.

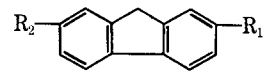
Anal.—Calcd. for $C_{15}H_{12}N_2O_3$: C, 67.15; H, 4.51; N, 10.44. Found: C, 66.77; H, 4.49; N, 10.38.

N-*(2-Fluorenyl-7-nitro)acetamide (III)*—The oxime (XIII) (5.4 Gm., 0.02 mole) was stirred into 200 Gm. of polyphosphoric acid and heated 3 hr. on the steam bath with occasional stirring. It was then poured into ice and water to decompose the acid, filtered, and washed well with water to give an orange solid (III). Yield, 5.6 Gm., 100%, m.p. 247–252°. Several recrystallizations from glacial acetic acid and from *n*-butanol yielded 4.5 Gm., m.p. 256–257° [Lit. (6) 250–253°]. Further proof of its identity was determined by preparation of two known derivatives: 2-amino-7-nitrofluorene [XII (7, 8)] and *N,N'*-(2,7-fluorenylene)bisacetamide [VI (9)].

N' - Hydroxy - N,N' - *(2,7 - fluorenylene)bisacetamide (XI)*—To a hot solution of 4 Gm. (0.015 mole) of *N*-(2-fluorenyl-7-nitro)acetamide (III) and 250 ml. of ethyl acetate in a pressure bottle was added as quickly as possible, 15 ml. of triethylamine, 20 ml. of acetic anhydride, and 0.15 Gm. of platinum oxide.

The hot mixture was placed on the Parr pressure reaction apparatus, and hydrogen was passed in

[1] This synthesis was begun by Ru-Jen L. Han in this laboratory.



VII, R_1 = N(OH)Ac, R_2 = NO_2
VIII, R_1 = R_2 = N(OH)Ac
IX, R_1 = NHAc, R_2 = NH_2
X, R_1 = R_2 = NH_2
XI, R_2 = N(OH)Ac, R_1 = NHAc
XII, R_1 = NH_2, R_2 = NO_2

(pressure dropped from 45 p.s.i. to 41.3 p.s.i.). The mixture was filtered, the filtrate was heated and stirred with 100 ml. of water and 50 ml. of ammonium hydroxide for 1 hr. The two layers were separated, the aqueous layer extracted twice with ethyl acetate. The combined ethyl acetate layers were washed with water, evaporated almost to dryness, ether added, and extracted with 0.5 *N* sodium hydroxide. The red alkaline solution was immediately acidified with concentrated hydrochloric acid. The precipitate was filtered, dissolved in boiling water, and the solution filtered hot through coarse filter paper and allowed to cool. Yield, 0.5 Gm., 11%, m.p. 177–179°. It gave a purple color with ferric chloride solution and formed a copper chelate, m.p. 235°. $\lambda_{max.}$, mμ 303 (ε 41,500), 311–317 sh (39,800).

Anal.—Calcd. for $C_{17}H_{16}N_2O_3$: C, 68.90; H, 5.44; N, 9.45. Found: C, 68.21; H, 5.64; N, 9.46.

N-Acetoxy and N-Hydroxy Derivatives of 2,7-Dinitrofluorene—N - *Acetoxy* - N - (2 - *fluorenyl* - 7-*nitro*)*acetamide* (*II*)—To a hot suspension of 3.8 Gm. of 2,7-dinitrofluorene (0.015 mole) and 100 ml. of dimethylformamide in a pressure bottle was added 20 ml. of acetic anhydride and 0.2 Gm. of platinum oxide. The hot mixture was placed on the Parr pressure apparatus and shaken with hydrogen (pressure dropped from 37 p.s.i. to 29 p.s.i. in less than 30 min.). The reaction mixture was filtered, the filtrate was stirred with 200 ml. of water for 1 hr., and filtered. Yield, 2.5 Gm., m.p. 160–166°. Combined runs (10 Gm.) of the crude material were extracted with benzene in a Soxhlet. Hexane, added carefully, precipitated out a red, gummy material. After most of this impurity was removed, a yellow, fluffy precipitate (II) formed spontaneously. Yield, 2.5 Gm., m.p. 174°. $\lambda_{max.}$, mμ 240–241 (ε 50,000), 336–341 (59,000).

Anal.—Calcd. for $C_{17}H_{14}N_2O_5$: C, 62.57; H, 4.37; N, 8.59. Found: C, 62.65; H, 4.34; N, 9.01.

N-*Hydroxy*-N-(*2-fluorenyl-7-nitro*)*acetamide* (*VII*)—Hydrolysis of II in ammonium hydroxide gave a yellow precipitate of the *N*-hydroxy, m.p. 204°. It gave a purple color with ferric chloride and formed a copper chelate, m.p. 235°. $\lambda_{max.}$, mμ 250–262 (ε 10,170), 355–361 (18,170).

Anal.—Calcd. for $C_{15}H_{12}N_2O_4$: C, 63.38; H, 4.26; N, 9.86. Found: C, 63.64; H, 4.60; N, 9.50.

N,N' - *Dihydroxy* - N,N' - (*2,7 - fluorenylene*)-*bisacetamide* (*VIII*) *and* N'-*Hydroxy*-N,N'-(*2,7-fluorenylene*)*bisacetamide* (*XI*)—To a hot suspension of 1.7 Gm. of *N*-hydroxy-*N*-(2-fluorenyl-7-nitro)-acetamide (VII) in 100 ml. of ethyl acetate in a pressure bottle was added 10 ml. of triethylamine, 15 ml. of acetic anhydride, 1 Gm. of 5% palladium on charcoal, and a few mg. of platinum oxide. The hot mixture was placed on the Parr pressure apparatus and shaken with hydrogen (pressure dropped from 37 p.s.i. to 35 p.s.i.). The reaction mixture was filtered and the filtrate stirred with 200 ml. of diluted ammonia for 1 hr. The products were then separated. A precipitate (VI) was filtered off. The aqueous and ethyl acetate layers of the filtrate were separated. The aqueous layer was extracted twice with ethyl acetate and discarded. The combined ethyl acetate solution was extracted: (*a*) with 5% sodium carbonate, which upon acidification with hydrochloric acid gave 0.39 Gm., m.p. 162–175°, of *N'*-hydroxy-*N,N'*-(2,7-fluorenylene)bisacetamide (XI). (*b*) With 0.5 *N* sodium hydroxide, which upon acidification yielded *N*-hydroxy-*N*-(2-fluorenyl-7-nitro)acetamide (VII). (*c*) With 5% sodium hydroxide, which upon acidification, yielded 0.18 Gm., m.p. 176–184°, of N,N'-dihydroxy - *N,N'* - (2,7 - fluorenylene)bisacetamide (VIII). A sample of VIII was prepared for analysis as follows: stirred with 0.5 *N* sodium hydroxide and filtered to remove any remaining VII and XI; dissolved in 5% sodium hydroxide, acidified, the precipitate filtered and dried; recrystallized from ethanol, m.p. 187–189°. It gave a purple color with ferric chloride and formed a copper chelate, m.p. 282°. $\lambda_{max.}$, mμ 305 (ε 34,700), 311–317 sh (30,400).

Anal.—Calcd. for $C_{17}H_{16}N_2O_4$: C, 65.37; H, 5.16; N, 8.97. Found: C, 65.23; H, 5.47; N, 8.56.

(*d*) With concentrated hydrochloric acid. The dark green solution was poured into water to give a precipitate of 2-acetylamino-7-aminofluorene (IX), m.p. 181–184° (6). $\lambda_{max.}$, mμ 301.5 (ε 45,000).

N,N' - *Diacetoxy* - N,N' - (*2,7 - fluorenylene*)*bisacetamide* (*IV*)—2,7-Dinitrofluorene (I) was reduced in ethyl acetate and acetic anhydride at 48 p.s.i. for 1 hr. and IV was isolated from the mixture of reaction products in trace amounts on a silica gel column eluted with ethyl acetate, m.p. 248–249°.

Anal.—Calcd. for $C_{21}H_{20}N_2O_6$: C, 63.63; H, 5.09; N, 7.07. Found: C, 62.89; H, 5.03; N, 6.57.

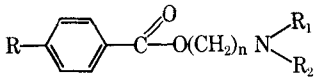
New Compounds: Certain Alkanolamine Esters Likely to Possess Anesthetic Activity

By L. R. ALPAD, M. KHALIFA, Y. M. ABOU-ZEID, and E. GABALI

The synthesis of a new series of alkanolamine esters is described. Esterification of 1,1′-iminodi-2-propanol with benzoyl chloride applying the Schotten-Baumann conditions afforded either the mono or diester according to the molecular ratio of the reactants but never the amide. With the more powerful acylating agent *p*-nitrobenzoyl chloride the diester-amide was always obtained even when equimolecular amounts of the reactants were used. Esterification of the *N*-methyl derivative of the amino alcohol with benzoyl chloride yielded in all cases the diester while esterification *via* the interaction of the dichloro analog of the amino alcohol and the appropriate silver salt invariably yielded the monoester even when excess of the silver salt was used.

THE VAST MAJORITY of the existing local anesthetics have been synthesized with the following fundamental structural requirements: an aromatic acid with or without a nuclear substituent in which the acid grouping has been esterified with an amino alcohol of simple or complex consititution.



Scheme I

In the present investigation, the mono- and diesters of 1,1′-iminodi-2-propanol (Table I) were prepared in the hope that the new products would show superior anesthetic activity[1] with less side effects.

The esterification of 1,1′-iminodi-2-propanol was successfully achieved *via* three different procedures: (*a*) the Schotten-Baumann conditions, (*b*) blocking the =NH prior to acylation to prevent amide formation, and (*c*) replacing the hydroxyl groups in the amino alcohol with halogen and reacting the halogeno derivative thus obtained with the appropriate silver salt.

Cope and Hancock (1), applying the Schotten-Baumann conditions to a number of alkyl amino alcohols, reported that the main product was the amide while Abou-Zeid and Gabali (2) disclosed that with diethanolamine only the diester was formed. With 1,1′-iminodi-2-propanol the authors have observed that the rate of the esterification depends solely on the molecular ratio of the reactants. When 1 mole of the amino alcohol interacted with 1 mole of benzoyl chloride, the monoester was produced, and if the amount of the acid chloride was doubled, the diester was obtained. The failure of amide formation with diethanolamine and 1,1′-iminodi-2-propanol may be attributed to the steric hindrance displayed by the bulky diethanol and di-isopropanol radicals flanking the =NH group. The fact that diethanolamine always affords the diester while 1,1′-iminodi-2-propanol affords either the mono- or diester according to conditions, may be easily accounted for by a consideration of the reactivity of the alcoholic groups in the two amino alcohols. It has long been known that in reactions in which the hydrogen atom of the alcoholic —OH is involved, a primary alcohol is far more reactive than a secondary (3). It follows, therefore, that the —OH in diethanolamine is more reactive than that in 1,1′-iminodi-2-propanol.

Using *p*-nitrobenzoyl chloride, which is a powerful acylating agent, resulted in attack of all available centers in the amino alcohol with the production of the diester amide, a result which is in accord with what has been reported earlier by other investigators (1, 2). As a consequence we resorted to Cope's method of blocking the =NH group by salt formation prior to acylation in order to prepare the diester amine which, however, was obtained but in poor yields. To improve the yield of the diester amine, its synthesis *via* the interaction of the dichloro analog of the amino alcohol and the appropriate silver salt was attempted. Application of this latter procedure, however, instead of affording the diester amine yielded a monoester with the second chlorine unreacted upon in spite of the use of excess of the silver salt. In the authors' opinion one of the contributing factors to the failure of the second chlorine atom to interact is steric hindrance.

EXPERIMENTAL

Schotten-Baumann Conditions—The dialkanolamine (the parent 1,1′-iminodi-2-propanol or its *N*-methyl derivative) (0.01 mole) mixed with 10% sodium hydroxide was treated with the acid chloride (0.01 or 0.02 mole) and cooling. In the case of benzoyl chloride, the insoluble viscous matter formed was washed and extracted with ether and the extract dried over anhydrous sodium sulfate. Then the ethereal extract was either concentrated until the separation of a crystalline solid mass (monoester) or completely evaporated and the oily material (diester) left converted to the corresponding picrate. The white solid forming with *p*-nitrobenzoyl chloride was washed with benzene and then crystallized again from benzene.

Cope's Conditions—1,1′-Iminodi-2-propanol (0.01 mole) dissolved in chloroform (25 ml.) was saturated with dry HCl gas till the separation of an oily top layer. Then finely powdered *p*-nitrobenzoyl chloride (0.01 mole) suspended in chloroform (25 ml.) was added and the whole was heated under reflux for 36 hr. The platelets separating were filtered, washed several times with ether, and crystallized from isopropyl alcohol.

Received September 19, 1967, from the Faculty of Pharmacy, Cairo University, Cairo, U.A.R.

Accepted for publication November 29, 1967.

[a] A, ethanol; B, benzene; C, isopropyl alcohol. [b] Analyses performed by Alfred Bernhardt, Germany and El Nasr Laboratories, U.A.R. [c] Melting points were performed by the capillary tube method and are uncorrected. [d] Isolated as the picrate. [e] Isolated as the hydrochloride.

Halide–Silver Salt Method—*β,β'-Dichloro-di(n-propyl)amine Hydrochloride*—Thionyl chloride (12 ml.) was slowly added to 1,1'-iminodi-2-propanol (2 Gm.) with stirring and cooling until a homogeneous liquid was obtained. Then the excess thionyl chloride was distilled *in vacuo* and the residue was washed several times with chloroform and acetone. The salt that was obtained in 86% yield as white microcrystals melted at 197–198°.

Anal.—Calcd. for $C_6H_{14}Cl_3N$: C, 35.12; H, 6.83; Cl, 51.22; N, 6.83. Found: C, 34.77; H, 6.73; Cl, 51.52; N, 6.73.

The aqueous solution of the salt was rendered alkaline with cold saturated sodium hydrogen carbonate solution and the freed base rapidly extracted with ether. Then the extract was dried over anhydrous sodium sulfate for 24 hr. before the ether was evaporated *in vacuo*. The base thus obtained was immediately used in the condensation reaction.

Condensation with the Appropriate Silver Salt—The silver salt (3 Gm.) was intimately mixed with the halogeno base (0.9 Gm.) in a 100-ml. round-bottom flask. A condenser was fitted to the flask and the whole setup was dipped into a preheated oil bath at 130–140° for a few minutes. The mixture was then allowed to cool, then benzene (40 ml.) was added and the whole was refluxed for 48 hr. after which it was filtered while hot. Light feathery crystals cropped out on cooling and concentrating the benzene solution.

Enzyme Inhibitors XXII. Identity of Inhibitor Binding Site on Adenosine Deaminase

Sir:

Investigators concerned with active sites or receptor sites in macromolecules have interest in the number and types of binding sites that exist in the biological sample. In enzyme systems, whenever competitive inhibitors are studied, it is possible that the inhbitor is complexed at the active site of the enzyme. However, it is also possible that the inhibitor is complexed to an entirely different site. When two or more inhibitors of an enzyme have been prepared and evaluated as enzyme inhibitors, it is possible that they complex to the same site on the enzyme or to different sites. It occurred to us that it might be possible to obtain information concerning the identity or nonidentity of inhibitor binding sites by combining in one inhibitor the moieties which make a contribution to binding in two different inhibitors. For example, in a variety of 9-substituted adenines, it has been found that the adenine moiety of these inhibitors makes a contribution to binding to the enzyme, adenosine deaminase (1). Furthermore, it has been observed (2) that adenosine deaminase possesses a hydrophobic area which is important in the formation of a complex with the 9-substituent of some 9-*n*-alkyladenines (I). In addition, adenosine deaminase has a specific hydroxyl binding site (2, 3) which makes a contribution to complex formation of the hydroxyl group in a compound such as 9-(2-hydroxyethyl)adenine. Therefore, if the adenine moiety of the 9-*n*-alkyladenines and the 9-(2-hydroxyethyl)adenine (II) is complexed to the same site on the enzyme, it should be possible to prepare very potent inhibitors by combining in one molecule the alkyl chain and the 2-hydroxyethyl group at the 9 position of the adenine nucleus. Such a class of compounds would be the 9-(1-hydroxy-2-alkyl)adenines (III). These compounds were prepared by a modification of a general procedure (4) which involves the condensation of the appropriate amino alcohol with 5-amino-4,6-dichloropyrimidine. The resulting 5-amino-6-chloro-4-(1-hydroxy-2-alkylamino)pyrimidine was cyclized with triethyl

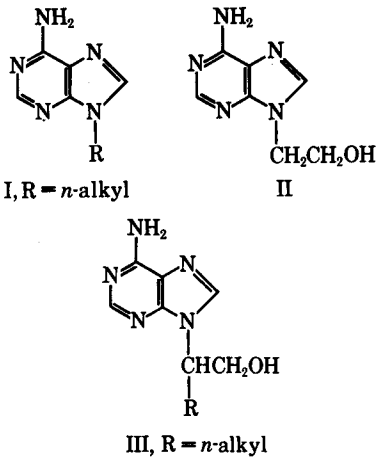
Enzyme Inhibitors XXII. Identity of Inhibitor Binding Site on Adenosine Deaminase

Sir:

Investigators concerned with active sites or receptor sites in macromolecules have interest in the number and types of binding sites that exist in the biological sample. In enzyme systems, whenever competitive inhibitors are studied, it is possible that the inhbitor is complexed at the active site of the enzyme. However, it is also possible that the inhibitor is complexed to an entirely different site. When two or more inhibitors of an enzyme have been prepared and evaluated as enzyme inhibitors, it is possible that they complex to the same site on the enzyme or to different sites. It occurred to us that it might be possible to obtain information concerning the identity or nonidentity of inhibitor binding sites by combining in one inhibitor the moieties which make a contribution to binding in two different inhibitors. For example, in a variety of 9-substituted adenines, it has been found that the adenine moiety of these inhibitors makes a contribution to binding to the enzyme, adenosine deaminase (1). Furthermore, it has been observed (2) that adenosine deaminase possesses a hydrophobic area which is important in the formation of a complex with the 9-substituent of some 9-*n*-alkyladenines (I). In addition, adenosine deaminase has a specific hydroxyl binding site (2, 3) which makes a contribution to complex formation of the hydroxyl group in a compound such as 9-(2-hydroxyethyl)adenine. Therefore, if the adenine moiety of the 9-*n*-alkyladenines and the 9-(2-hydroxyethyl)adenine (II) is complexed to the same site on the enzyme, it should be possible to prepare very potent inhibitors by combining in one molecule the alkyl chain and the 2-hydroxyethyl group at the 9 position of the adenine nucleus. Such a class of compounds would be the 9-(1-hydroxy-2-alkyl)adenines (III). These compounds were prepared by a modification of a general procedure (4) which involves the condensation of the appropriate amino alcohol with 5-amino-4,6-dichloropyrimidine. The resulting 5-amino-6-chloro-4-(1-hydroxy-2-alkylamino)pyrimidine was cyclized with triethyl

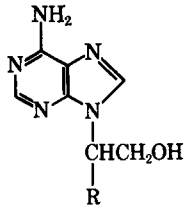


orthoformate to the 6-chloropurine intermediate, which on treatment with ammonia, gave the 9-(1-hydroxy-2-alkyl)adenines shown in Table I.[1]

When the series of compounds listed in Table I was evaluated as inhibitors of adenosine deaminase, it was found that as the alkyl group was lengthened, the compounds consistently became better inhibitors. Previously, on the basis of a study of the change in free energy of binding/methylene group with a series of 9-*n*-alkyladenines, it was found (2) that the $\Delta F/CH_2$ was greatest in those compounds bearing the 9-*n*-propyl through the 9-*n*-heptyl groups; *i.e.*, the main hydrophobic region of adenosine deaminase appears to extend from C_3 through C_7 in the conformation in which the 9-substituent is complexed to the enzyme. The average $\Delta F/CH_2$ group in proceeding from 9-*n*-propyl- through 9-*n*-heptyladenine was −350 cal. (2). An inspection of the $\Delta F/CH_2$ for the 9-(1-hydroxy-2-alkyl)adenines in Table I reveals that the main hydrophobic area also appears to terminate at approximately seven carbons in length[2] since the $\Delta F/CH_2$ for IX is −521 cal., whereas further increases in the carbon chain (X, XI, and XII) gave near minimum changes in free energy. However, note the unusually large change in free energy for the additional methylene unit when comparing V to VI. The magnitude of this change is clearly beyond simple hydrophobic transfer forces (5, 6) and might reflect a conformational change in the enzyme.

Finally, it should be noted that the 9-(1-hydroxy-2-alkyl)adenines are considerably more effective inhibitors than the corresponding parent

TABLE I—INHIBITION OF ADENOSINE DEAMINASE BY



Compd.[a]	R	$(I/S)_{0.5}$[b]	$\Delta F/CH_2$ (cal.)
II	H	1.1 ± 0.05[c]	—
IV	CH_3	1.2 ± 0.03	—
V	C_2H_5	0.49 ± 0.02	−521
VI	C_3H_7	0.071 ± 0.004	−1140
VII	C_4H_9	0.033 ± 0.006	−451
VIII	C_5H_{11}	0.015 ± 0.001	−467
IX	C_6H_{13}	0.0062 ± 0.0002	−521
X	C_7H_{15}	0.0047 ± 0.00003	−163
XI	C_8H_{17}	0.0039 ± 0.00002	−110
XII	C_9H_{19}	0.0030 ± 0.00006	−155

[a] None of these compounds served as substrates of adenosine deaminase. The enzyme (Type I, calf intestinal mucosa) was purchased from the Sigma Chemical Company. [b] The inhibition index $(I/S)_{0.5}$ is the ratio of the m*M* concentration of the inhibitor for 50% inhibition to the m*M* concentration of the substrate. The concentration of adenosine in all experiments was 0.066 m*M*. [c] Data taken from *Reference 2*.

inhibitors. For example, the $(I/S)_{0.5}$ for 9-*n*-heptyladenine is 0.32 (2) and for II is 1.1 (1), whereas the $(I/S)_{0.5}$ for IX is 0.0062. We interpret the enhanced inhibitory properties of the 9-(1-hydroxy-2-alkyl)adenines to be a result (*a*) of the identity of the adenine binding site utilized by I, II, and III and (*b*) of the close spatial relationship of the hydrophobic region and the hydroxyl binding region to the site to which adenine is bound on the enzyme.[3] Thus, the combination of a hydrophobic group and a properly positioned hydroxyl group at the 9 position of the adenine nucleus has resulted in the formation of compounds with greatly enhanced inhibitory properties.

Received February 12, 1968.
Accepted for publication March 19, 1968.

[1] The details of the synthesis of these compounds as well as the intermediates will be published in the full paper. All compounds gave acceptable combustion analyses for carbon, hydrogen, and nitrogen.

[2] For the purpose of comparing the chain length of the 9-(1-hydroxy-2-alkyl)adenines to the 9-*n*-alkyladenines, we have ignored the hydroxymethyl group; *i.e.*, V has an alkyl chain length of three.

[3] The close spatial relationship of the hydrophobic region and the hydroxyl binding region may be native or may be the result of a conformational change in the enzyme induced by the formation of the E···I complex.

Apparent Nonsteady-State Dissolution Phenomenon in Solutions of Colloidal Solubilizers

Sir:

It has been demonstrated in recent reports (1–3) that the dissolution rate of solids in solutions of surfactant above the critical micelle concentration cannot be predicted by the Noyes-Whitney equation (4). Higuchi (1) has suggested that the dissolution process in solutions of colloidal solubilizers may be quantitated by the diffusion layer theory. In a previous report (3) we have found reasonable agreement of diffusion layer theory with initial dissolution rate data obtained under well-stirred conditions. We have recently observed, however, that the initial dissolution rates of salicylic acid in micellar solutions of a nonionic polyoxyethylene surfactant represent presteady-state values. Accordingly, the enhancement of apparent steady-state dissolution rate by the colloidal solubilizer is significantly greater than predicted by diffusion layer theory.

Details of the experimental procedure will be presented in a subsequent report. Briefly, in each dissolution experiment nondisintegrating disks of salicylic acid were used which provided a constant surface area over the entire experimental time period. Dissolution was followed at 37° at a 50 r.p.m. agitation rate (provided by an overhead blade) in either 0.1 *N* HCl or in various concentrations of polyoxyethylene (23) lauryl ether[1] dissolved in 0.1 *N* HCl. The amount of salicylic acid in solution at various intervals of time was determined spectrophotometrically at 304 mμ.

A kinetic method has been devised to ascertain steady-state dissolution rates which introduces the concept of an *excess dissolution rate, i.e.,* $(DR_c - DR_w)$ where DR_c is the dissolution rate per unit area in the colloid system and DR_w is the dissolution rate per unit area in an aqueous system under equivalent hydrodynamic conditions. Both the Dankwerts theory (1, 5) and the diffusion layer theory (1) predict a first-order dependence of excess dissolution rate on $(C_M - C')$, the micellar phase concentration gradient.

According to Gibaldi and Feldman (6), dissolution in a simple aqueous system under constant-surface and nonsink conditions follows first-order kinetics and a plot of log $(C_S - C)$ *versus* time is linear (where C_S is the solubility of the drug in the dissolution medium and C is the concentration of drug in solution at time t). Since the excess dissolution rate is proportional to a concentration gradient term, it follows that a plot of log $(DR_c - DR_w)$ *versus* time should be linear.

A representative plot of the log of excess dissolution rate as a function of time is shown in the figure. As noted in the plot a significant time lag occurs before apparent linearity (attainment of steady state) is observed. A similar plot of log dissolution rate in 0.1 *N* HCl *versus* time shows

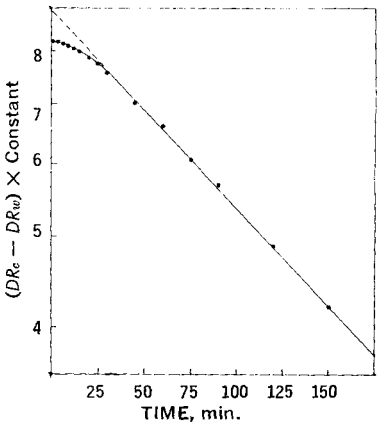

Fig. 1—Plot of the difference in dissolution rates of salicylic acid in 3% polyoxyethylene (23) lauryl ether solution, DR_c, *and 0.1 N HCl,* DR_w, *(on log scale)* versus *time under stirred conditions.*

Apparent Nonsteady-State Dissolution Phenomenon in Solutions of Colloidal Solubilizers

Sir:

It has been demonstrated in recent reports (1–3) that the dissolution rate of solids in solutions of surfactant above the critical micelle concentration cannot be predicted by the Noyes-Whitney equation (4). Higuchi (1) has suggested that the dissolution process in solutions of colloidal solubilizers may be quantitated by the diffusion layer theory. In a previous report (3) we have found reasonable agreement of diffusion layer theory with initial dissolution rate data obtained under well-stirred conditions. We have recently observed, however, that the initial dissolution rates of salicylic acid in micellar solutions of a nonionic polyoxyethylene surfactant represent presteady-state values. Accordingly, the enhancement of apparent steady-state dissolution rate by the colloidal solubilizer is significantly greater than predicted by diffusion layer theory.

Details of the experimental procedure will be presented in a subsequent report. Briefly, in each dissolution experiment nondisintegrating disks of salicylic acid were used which provided a constant surface area over the entire experimental time period. Dissolution was followed at 37° at a 50 r.p.m. agitation rate (provided by an overhead blade) in either 0.1 *N* HCl or in various concentrations of polyoxyethylene (23) lauryl ether[1] dissolved in 0.1 *N* HCl. The amount of salicylic acid in solution at various intervals of time was determined spectrophotometrically at 304 mμ.

A kinetic method has been devised to ascertain steady-state dissolution rates which introduces the concept of an *excess dissolution rate, i.e.,* $(DR_c - DR_w)$ where DR_c is the dissolution rate per unit area in the colloid system and DR_w is the dissolution rate per unit area in an aqueous system under equivalent hydrodynamic conditions. Both the Dankwerts theory (1, 5) and the diffusion layer theory (1) predict a first-order dependence of excess dissolution rate on $(C_M - C')$, the micellar phase concentration gradient.

According to Gibaldi and Feldman (6), dissolution in a simple aqueous system under constant-surface and nonsink conditions follows first-order kinetics and a plot of log $(C_S - C)$ *versus* time is linear (where C_S is the solubility of the drug in the dissolution medium and C is the concentration of drug in solution at time t). Since the excess dissolution rate is proportional to a concentration gradient term, it follows that a plot of log $(DR_c - DR_w)$ *versus* time should be linear.

A representative plot of the log of excess dissolution rate as a function of time is shown in the figure. As noted in the plot a significant time lag occurs before apparent linearity (attainment of steady state) is observed. A similar plot of log dissolution rate in 0.1 *N* HCl *versus* time shows

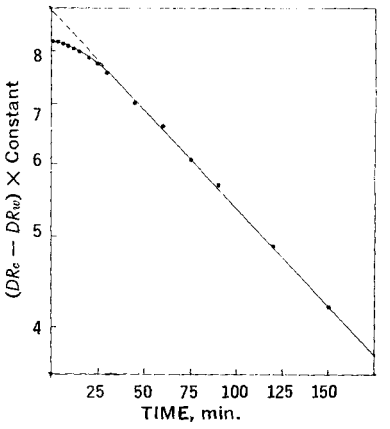

Fig. 1—Plot of the difference in dissolution rates of salicylic acid in 3% polyoxyethylene (23) lauryl ether solution, DR_c, *and 0.1 N HCl,* DR_w, *(on log scale)* versus *time under stirred conditions.*

[1] Brij 35 SP, Atlas Chemical, Wilmington, Del.

excellent linearity with no evident time lag. Extrapolation of this plot to $t = 0$ yields the value of the solubility of the drug in 0.1 N HCl as predicted by theory.

The presteady-state phenomenon indicates that the apparent initial contribution of the micellar phase to the dissolution process is much less than its contribution at steady state. This disparity is evident when the ratios of dissolution rates in 3% polyoxyethylene (23) lauryl ether solution and in 0.1 N HCl are compared. The initial dissolution data suggest a 50% increase in dissolution rate while a comparison of steady-state data indicates a 90% increase in the apparent first-order rate constant for dissolution.

The present findings suggest the possibility of a more general phenomenon. Initial dissolution rate data (obtained from apparent zero-order rate plots) in systems of colloidal solubilizers may represent presteady-state conditions and must, therefore, be used cautiously in attempting to explain dissolution phenomena.

Observations on the Instability of Cyclamate in Hydroalcoholic Solution

Sir:

Cyclamic acid, widely used as such and as its sodium and calcium salts for sweetening pharmaceuticals and other products, is generally conceded to be extremely stable in solution (1, 2). Hydrolysis of cyclamic acid has been reported to occur only under very rigorous conditions (3–5). Studies in our laboratories have affirmed that aqueous solutions of cyclamate degrade to sulfuric acid and cyclohexylamine at very slow rates, which are proportional to hydrogen ion concentration. The half-life for a solution at 25° buffered at pH 2.0 is calculated to be 60 years!

Stability studies on experimental formulations led to the discovery that cyclamate sweeteners degrade at markedly faster rates in hydroalcoholic vehicles than would be predicted by their behavior in aqueous systems. In one instance, samples of an antibacterial amine formulation stored 24 months at room temperature were found to assay substantially higher than the initial value for total amine by nonaqueous titration. The formulation contained 0.1% amine in a hydroalcoholic vehicle sweetened with 0.6% sodium cyclamate and buffered at an apparent pH of 4.0. The increased titer was found to be due to cyclohexylamine formed from the cyclamate, and a material balance was obtained by gas-liquid chromatographic (GLC) assay of cyclohexylamine content. In a second case, formulations in 85% alcohol sweetened with calcium cyclamate and sodium saccharin were found unchanged after several weeks of storage, while similar formulations sweetened with calcium cyclamate and saccharin *acid* were found to have increased in apparent pH and deposited a precipitate, identified as calcium sulfate after isolation and the usual tests for the ions. Again, degradation of cyclamate was confirmed by GLC assay of the cyclohexylamine produced. The apparent pH of the stable formulations was about 6.5, while that of the labile ones was 3.7.

Unbuffered 1% (w/v) solutions of cyclamic acid[1] were made up in distilled water, absolute alcohol, and alcohol–water mixtures of graded composition. Portions of the solutions were heated in flint glass screw-capped bottles at 80°

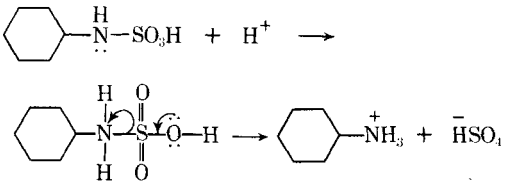
for periods of 2 and 22 hr., and the extent of degradation was determined by GLC assay of cyclohexylamine. Aliquots of the solutions were basified, and chloroform extracts were injected into a Perkin-Elmer model 801 gas chromatograph fitted with dual-flame ionization detectors. The GLC operating parameters were: (*a*) column—9.1 M. (6 ft.), 0.63 cm. (1/4 in.) o.d. glass helix packed with 5% potassium hydroxide, 10% polyethylene glycol 4000 on Anakrom ABS,[2] 80/90 mesh. (*b*) helium flow—40 ml./min. (*c*) temperature—column, 75°, injector block, 150°, detector, 150°.

Dimethylformamide was used as the internal standard. Under these conditions, cyclohexylamine has a retention time of 3 min. and the internal standard 7 min. Cyclohexylamine content was determined by the peak-height ratio method. Apparent pKa values were determined for each of the solutions at room temperature by potentiometric titration of a 50-ml. sample with 1 *N* sodium hydroxide added from a 1-ml. microburet.

The correlation of increasing alcohol content, and the concomitant increase in the apparent pKa of cyclamic acid, with the extent of hydrolysis is evident in Table I.

The degradation of unbuffered solutions of cyclamate would be expected to be autocatalytic, for the release of sulfuric acid increases hydrogen ion concentration. The results of these experiments are consistent with a mechanism involving attack by hydrogen ion on undissociated cyclamic acid, *viz.*;



More comprehensive studies on the degradation of cyclamate in low dielectric media are in progress and will be reported at a later date. This communication is intended to alert formulators to the necessity for avoiding an acidic pH range in cyclamate sweetened solutions of low dielectric constant. Such solutions should be buffered to at least 2 pH units above the apparent pKa of cyclamate in the vehicle.

THIS REVIEW of the literature represents a comprehensive cross-section of the research and development efforts in various selected disciplines of the pharmaceutical sciences. It is the sixth survey in this series (1–5). Numerous periodicals and selected sections of *Chemical Abstracts* were abstracted. The *Pharmacognosy* section has been discontinued. In order to maintain continuity with the previous pharmaceutical sciences reviews of the *Journal of Pharmaceutical Sciences*, their general format was retained.

GENERAL PHARMACY

Solmssen discussed pharmaceutical research with respect to the synthesis and testing of new drugs (6). Another survey reviewed the federal, state, and foreign drug regulations regarding stability testing and formulation research (7). Comments on the empirical and the rational method for the development of new drugs were the subject of another review (8). The similarities and differences of the pharmacopeial

standards and specifications for bulk drugs and solid oral dosage forms were discussed (9). The location pattern of the pharmaceutical industry was outlined by Smith *et al.* (10). Another paper pointed out methods of stimulating creative output in small laboratory groups (11). The teaspoonful dosage was critically evaluated. The authors pointed out that there was a great deal of variation with this type of dosing (12). Schwartz elaborated on the serious problem of penicillin allergy (13).

Excellent review articles on gastrointestinal enzymes, over-the-counter (O-T-C) depilatories, O-T-C antiobesity drugs, O-T-C anthelminthics, O-T-C burn and sunburn remedies, O-T-C poison ivy and poison oak remedies, O-T-C external analgesics, O-T-C psoriasis and eczema remedies, O-T-C deodorants and antiperspirants, O-T-C internal analgesics, O-T-C hemorrhoidal preparations, and O-T-C preparations for disorders of the scalp appeared in the *Journal of the American Pharmaceutical Association* (14–27).

Preservatives—Bean discussed the use of preservatives to protect pharmaceuticals from contamination (28). Another study was concerned with the preservation of pharmaceutical and cosmetic preparations against microbial spoilage (29). Chemical preservation of ointments and creams in cosmetics and pharmaceuticals was the subject of another paper (30). In addition, the physical, chemical, microbiological, and toxicological properties of several new preservatives were reviewed and their application in dermatologic and cosmetic preparations was demonstrated (31). The interaction of nonionic surfactants with preservatives was shown to be responsible for partial inactivation of the preservative (32). Vitez utilized sodium hyposulfite to eliminate the bacteriostatic effect of various chemical preservatives during sterility testing (33). Several derivatives of β-naphthol were found to have antimicrobial properties in very low concentrations against both bacteria and fungi (34).

Flavor, Color, and Aroma—A concise history of the development regarding the use of color additives in foods, drugs, and cosmetics was presented (35). Another review was concerned with dyes commonly used in foods, pharmaceuticals, and cosmetics (36). Raff reviewed the concept of color as a psychological-physical phenomenon and gave examples illustrating this viewpoint (37). An account was also given of the fundamental mechanisms which occur when coloring matter absorbs light (38). Another paper considered the limitations of conventional color measurements from the point of view of applicability to routine storage testing (39). The suitability of some natural dyes for coloring sugar-coated tablets was investigated (40).

Bedoukian discussed the progress in the use of perfumery materials (41). Another review concerned itself with the updating of flavoring materials currently in use (42). The influences of the methods of perfuming and the requirements of the perfume for various types of preparations were considered (43).

Adjuvants—The effect of water, surfactants, and binders on the adhesion of solid particles was studied by a centrifugation method (44). Mendes evaluated a number of selected new materials as binders for tablets (45). The application of bentonite in the technology of tablet preparation was the subject of a paper (46). The role of various adjuvants in the mechanism of tablet disintegration was the subject of a review (47). Dextran was investigated as a binding agent (48). Kaplan studied the effect of varying the ratio of isopropanol–water granulating solution on various tablet parameters. He found that the ratio affected the hardness, thickness, and disintegration of tablets (49). The role of starch in the mechanism of tablet disintegration was elucidated (50). Another group studied holocellulose and technical cellulose as substances that support the disintegration of tablets (51). The change in flow properties of sodium bicarbonate in the presence of small amounts of magnesium stearate was observed (52). It was also pointed out that surface-active quaternary ammonium and pyridinium compounds are adsorbed on colloidal silicic acid to different degrees depending upon the concentration (53).

Polyvinyl alcohol was found to be a useful ingredient in vehicles for ophthalmic solutions (54). Parker investigated the effect of solution additives upon the stability of intravenous fluids (55). The concepts of ophthalmic compounding were also the subject of another paper (56). A review and discussion of the use of parenteral water-in-oil emulsions as adjuvants administered with allergens in the treatment of seasonal allergy appeared in the literature (57). The effect of various solvents on the stability of reserpine was described (58).

Stability—Tingstad discussed the various aspects that should be considered in the design of stability studies in product development (59). Another review article by Garrett elaborated on the stability of drug solutions (60). A

review of the chemical and physical properties of epinephrine as related to its use in glaucoma was published (61). Microdiffusional analysis was successfully applied to the stability of drugs in the solid state (62). Stability of reconstituted drugs and intravenous fluids received some attention in several articles (63, 64). Therapeutic incompatibilities caused by drug interactions were reviewed (65).

The chemical mechanism that explains the accelerated hydrolysis demonstrated by aspirin in combination with an alkaline stearate in a solid dosage form was elucidated by employing a suspension technique (66). Undissolved sulfadimidine removed benzoic acid from solution in sulfadimidine mixtures (67). The stability of sulfacetamide ophthalmic drops was discussed (68). The degradation of aspirin in commercial products containing acetaminophen was found to be accompanied by the formation of diacetyl-*p*-aminophenol or *p*-acetoxyacetanilid (69). In another article Pellerin discussed the value of analytical methods which indicate the degree of purity and the effect of the latter on the stability of pharmaceutical preparations (70). A colorimetric method was outlined for studying the stability of certified dyes (71). The comparative hydrolytic rates of *N*-substituted 6-aminothiouracils were obtained in acidic and alkaline media (72). Pearl-shaped granules were found to be the most stable form of vitamin A (73).

The relative stability of penicillin salts was similar at pH 1.5–4.5 (74). Another study gained some insight about the reactions possible in aqueous pharmaceutical systems of amines buffered with di- and polycarboxylic acids (75). The change in color of aqueous solutions of sodium sulfathiazole was related to decomposition (76). The autoxidation of sodium salicylate solutions was followed by polarographic methods (77). The stability of the amide group of glutamine derivatives in aqueous solution was determined (78). Another group studied the effect of pH, temperature, nature of the stabilizers, and conditions on the stability of pyridoxine (79). The effect of gamma radiation on the stability of several drugs packaged in glass and plastic containers was the subject of another investigation (80). The acid-catalyzed anaerobic degradation of isoniazid was elucidated (81). Acetylcysteine was susceptible to oxidation during nebulization (82). Rubber closures containing substances that are relatively inert should be used for insulin preparations (83). Racemization of drugs sometimes attributes to stability problems (84). Cod liver oil stability was examined using an accelerated aging test for evaluation (85). The stability of dextran during prolonged storage was investigated (86). The oxidation reactions involving white lotion, paraffin, and linoleic acid indicated that peroxides were the degradation products (87–89). Stability studies were also carried out with novobiocin, tartar emetic, alcoholic solutions of iodine, methoclopramide, belladonna alkaloids in antacid tablets, ethionamide, and sulfonamides (90–96). Barry and Shotton checked the influence of 1-hexadecanol on the acid-catalyzed hydrolysis of sodium dodecyl sulfate (97). Another group followed the reaction between boric acid and *p*-aminosalicylates by thermal and conductivity measurements (98). Benzoyl peroxide stability in pharmaceuticals was determined (99). An improved theoretical calculation of the stability ratio for colloidal systems was proposed (100). A simple method was also described for testing light absorption of various glass, plastic films, and other wrappings (101).

Stability Kinetics—Connors and Favilla described a method for kinetic studies of reactions in which the concentration of one reactant was held essentially constant by the addition of that reactant throughout the course of the reaction (102). The general concept of chemical kinetics in relation to the study of drug stability was reviewed (103). In another study on stability kinetics, Seydel demonstrated the application of reaction kinetics in predicting stability of drugs and derived rate equations related to drug degradation (104). Several papers appeared which discussed the stability of some cardenolide preparations (105–107). The hydrolysis of solubilized aspirin in solution buffered from pH 1.7 was studied at 37° (108). Another group presented data on the hydrolysis of aspirin in aqueous solutions of polysorbate 80 (109). In an excellent review article Garrett discussed the rate–pH profile in solvolytic degradations (110). An improved iodometric technique was used to investigate the kinetics of the reversible reaction between methionine and iodine (111). The ultraviolet light-catalyzed reaction of chlorpromazine under anaerobic conditions appeared to be different from the reaction under aerobic conditions (112). Several papers appeared on the stability of *N,N'*-di-[α(1-naphthyl)-propionyloxy-2-ethyl]piperazine (113, 114). A mechanism for the hydrolytic deamination of cytosine arabinoside in aqueous buffer was proposed (115). The degradation kinetics of 6-aminopenicillanic acid was the subject of another paper (116). Hurwitz established the mechanism for the

degradation reaction of *N*-chlorosuccinimide in aqueous solution (117). The mechanism of the base-catalyzed hydrolytic reactions of isoalloxazine was proposed (118) while Guttman and Platek were investigating the hydrolytic behavior of the same compounds. Kinetic data indicate both ionized and unionized species underwent specific base-catalyzed reactions but at different rates (119). Reactions involving cyclic acid anhydrides in aqueous solution were studied in an effort to understand biological mechanisms and in predicting pathways by which drug mixtures may undergo decomposition (120).

A method was described to determine the chemical stability of labeled fluocinolone acetonide incorporated into pharmaceutical preparations (121). The kinetics for the decomposition of chlorophenyl-benzylpiperazine derivatives was considered in another study (122). The hydrolysis of solubilized esters and amides was the subject of several papers (123, 124). The kinetics of solvolysis of various sydnones was investigated spectrophotometrically as a function of HCl and NaOH concentrations, pH, and temperature by Garrett and Mehta (125).

5-Methyl-3(2*H*)-furanone was formed from the acid-catalyzed solvolysis of 2-deoxy-D-ribose (126). The effect of certain additives on the hydrolysis of phenobarbital was shown (127). Methylparaben hydrolysis was also the subject of another paper (128). Fractional factorial experiments were used to evaluate related liquid formulations (129). A kinetic study of the reaction between dehydroacetic acid and primary amines in various solvents was investigated (130). The kinetics of degradation of chlorothiazide in acidic and alkaline solution was also reported (131, 132). The decomposition of morphine was followed as a function of temperature and pH (133).

Antibiotic Stability—Schwartz and Pflug described the mechanism of hydrolysis of penicillins catalyzed by catechol using benzylpenicillin and methicillin as model compounds (134). Potassium penicillin G was found to be incompatible with *p*-hydroxybenzoate. The authors isolated and identified the products of the reaction (135). Another group determined and eliminated the cause of the yellow discoloration in penicillin after sterilization (136). It was also shown that magnesium ions overcome the activity of novobiocin by forming a complex with the antibiotic (137). The stability of tetracycline hydrochloride in the presence of pyridine compounds, magnesium salts, and aliphatic and aromatic hydroxyacids was the subject of several papers (138, 139). Nystatin exhibited excellent stability on prolonged storage when kept under phosphorus pentoxide (140). Monciu *et al.* studied the interaction of chlortetracycline[1] with various components and related this effect to the duration of activity (141).

Vitamin Stability—The color stability of ascorbic acid tablets containing eight commonly used lubricants and glidants was studied by light reflectance (142). The stability of ascorbic acid tablets prepared by three different methods was evaluated (143). The discoloration of ascorbic acid tablets under prolonged storage was traced to ingredients commonly used in tablet formulations (144). Phytic acid derivatives have been used successfully to stabilize ascorbic acid (145). Sodium ascorbate solutions maintained satisfactory potency in the presence of sodium sulfite and carbon dioxide; however, on prolonged storage oxidation due to the presence of trace metals was observed (146). Another study dealt with the behavior of ascorbic acid solutions subjected to ultrasonic treatment (147). The rate of ascorbic acid decomposition under aerobic and anaerobic conditions was reported (148). Quantitative changes in L-ascorbic acid occurred in aqueous solution (149). The *in vitro* evaluation of the interaction of vitamins was discussed (150). Another group examined the photodegradation and stabilization of vitamin K_1 (151).

Ophthalmic solutions containing vitamins neutralized with bicarbonate were not irritating and were relatively stable (152). Multivitamin tablets containing vitamin A, D_2, and B_{12} coated with a gelatin–sugar coating showed better stability in artificial gastric juice (153). The factors affecting the stability of polyvitamin hydrosols were reviewed (154). Another group studied the stability of thiamine salts and calcium pantothenate in various vitamin B complex preparations (155). It was also pointed out that vitamin A preparations were more stable when vitamin A was converted to anhydrovitamin A (156).

PHARMACEUTICAL TECHNOLOGY

Knoechel *et al.* designed an instrumented rotary tablet machine and showed its applicability in pharmaceutical research and development and in production (157, 158). The spray pan method of coating tablets was described. It involved applying coating materials in solution or suspension as a spray from a centrifugal disk atomizer (159). Another group developed a small coating machine for enteric coating small

[1] Aureomycin, Lederle Laboratories, Pearl River, N. Y.

batches of tablets (160). An apparatus for studying the disintegration of tablet coatings was designed (161).

The pharmaceutical application of internal reflectance spectroscopy and UV spectroscopy was the subject of several papers (162, 163). An excellent review containing 60 references on spray drying and its application in pharmaceutical systems appeared in the literature (164). The use of differential scanning calorimetry and its application in pharmacy was commented on with reference to the detection of polymorphism and purity (165). The B.E.T. method for determining specific surface area was described in detail (166). Campiglio reviewed the apparatus and techniques for microfiltration and microcrystallization (167). Ultrasonic treatment of alumina gel did not alter its adsorption heat (168).

Parenterals—Several papers were published dealing with the danger and control of particulate matter in parenteral solutions. They pointed out methods of estimating the number of particles in injectable solutions and the danger involved when an excess of particles are present (169–171). Extemporaneous mixing of parenterals often presents problems (172, 173). They often show some type of incompatibility (174). A change in pH may be an important factor contributing to the problem (175).

The sorption, leaching, tensile, and other properties of a series of butadiene–acrylonitrile rubbers from the medium high acrylonitrile group were evaluated to determine the suitability of this type of closure for multiple-dose vials (176). Anschel discussed the requirements for suitable solvents and solubilizers for use in injectable preparations (177). The separation of microcrystals in injectables containing calcium gluconate was investigated (178). Parenteral solutions were found to develop precipitates after storage for 2 years indicating that hydrolysis can occur even in supposedly stabilized preparations (179).

Parenteral solutions of papaverine were stabilized by the addition of disodiumethylenediamine tetraacetate (180). Another investigation dealt with the stability of epinephrine[2] in parenteral form (181). Parenteral solutions of certain fat-soluble vitamins were also the subject of another paper (182). A comparison of the efficacy of several glass filters commonly used to filter parenterals appeared in the literature (183). The interaction of various types of rubber with medicament was reviewed (184).

[2] Adrenalin, Parke Davis & Co., Detroit, Mich.

Sterility—The dynamics of air sterilization was presented by Dorman (185). Another excellent review article was prepared describing sterilization with ethylene oxide in medicine and pharmacy (186). A new aseptic processing unit for sterile products was introduced (187). Filters for removing pyrogens and bacteria from pharmaceutical injection solutions were evaluated (188). Anderson studied the hydrolysis of sulfacetamide solutions at sterilization temperatures (189). The effect of preservatives on the heat sterilization of sesame oil was the subject of another paper (190). The causes and prevention of pH change in glucose solutions during sterilization were investigated (191).

Tablets and Capsules—The *in vitro* evaluation of physiological availability of compressed tablets was the subject of a review (192). The compression characteristics of some pharmaceutical materials were investigated (193). Hardness and disintegration time of tablets as a function of compression force were studied. The results indicated that there was no relationship between hardness and disintegration time in water (194). The effect of moisture on the behavior of sodium chloride under compression was investigated by measurement of compaction and ejection forces (195). Another investigation was concerned with the various changes of compression by pressure measurements (196). Abdel Khalek *et al.* elaborated on the effect of humidity on mechanical strength weights and disintegration rates of tablets (197). A quantitative evaluation of the dissolution rates of active ingredients from tablets was discussed. The authors checked filler binder, lubricant, disintegrating agent, and hardness on the dissolution rate of sodium salicylate from tablet bases (198).

A new technique was described for the observation of the stresses involved during a compaction operation (199). Hanus studied the thermodynamic and resistivity effects involved in the compression of solids (200). Graphic illustrations of the effects of air temperature, air velocity, and layer thickness on the drying process appeared in the literature (201). Meanwhile, the effect of particle size on the strength of sodium chloride tablets was measured. The results show that there was no simple relationship between crushing strength and particle size over the range of particle size studied (202). The disintegration of tablets containing triamterene was classified according to the type of dispersion obtained (203). High molecular weight film-forming compounds were used by Daragan for coating tablets (204). The determination of

certain parameters of free-flowing pharmaceutical products was carried out (205). It was proposed that the uniformity of weight test may sometimes replace individual chemical assay when the percent of active ingredient is high (206). Tablet coatings were the subject of another investigation (207).

Williams and Shields discussed the segregation of granules in a vibrated bed (208). Another group measured the drying rates of beds of magnesium carbonate powder wetted with various liquids (209). The shape of the core of a tablet was found to have some effect on its ease of sugar coating (210). A bowl granulation process was described for the granulation of lactose (211). Tablets were also prepared containing chemically incompatible materials (212). Various pill bases were evaluated to improve the technology of pill making (213). Dissolution studies were carried out for commercial brands of phenylbutazone and phenindione tablets (214, 215).

Suspensions—Various theories of dispersion were critically presented. Dispersions take place in two stages, *i.e.*, the wettability of the substance by the medium and the stability which is inversely related to the number of particles flocculating per unit time (216). A review containing 34 references classified disperse systems and described their general physical properties (217). A detailed study was made of the destabilization of dilute clay suspensions with a cationic polymer under controlled conditions of pH, ionic strength, initial clay concentration, and intensity and duration of agitation (218). The stability of white lotion was increased by using zinc oxide with a high sedimentation volume and by machine dispersal of the solids (219). In another paper the theoretical principles involved in the preparation of a physically stable suspension were discussed, and some examples of successful application of these principles in pharmaceuticals were given (221). Smith discussed the physical properties of suspensions (222). Crystal growth in aqueous suspensions was the subject of a detailed study (223). A reduced form of the particle-size distribution function, designated "self preserving," satisfied the Smoluchowski equation of coagulation by Brownian movement (224). The viscosities of dilute solutions of carboxymethylcellulose and methylcellulose influenced the sedimentation rate of barium sulfate particles (225, 226). The structural and filtration properties of kaolin and kaolin clay dispersions were shown to be affected by surfactants and electrolytes (227). A relationship describing the structural strength of disperse systems was derived (228).

Several articles discussing the preparation and stability of barium sulfate suspensions appeared in the literature (229, 230). A study of the translation and rotation of rigid spheres, rods, and disks, as well as the deformation of fluid drops in pulsatile and oscillatory flow was conducted (231). A graphical method was utilized to compute sedimentation coefficients (232). Zeta potential measurements can be obtained with an electrically driven pendulum with viscous damping (233). The properties and applications of several different gel systems were elaborated on in a number of papers (234–237). Lanolin derivatives were utilized to disperse various pigments in aqueous media (238). A polymeric preparation, K-4, stabilized suspensions of natural and monocationic forms of clays (239). Mueller and Schneider studied the wettability of granular material and the wetting action of surfactant solutions (240).

The Gibbs equation for the adsorption of surface-active monovalent and polyvalent ions in the presence and absence of neutral salt was extended (241). In another publication Samyn and Jung investigated the negative thixotropy in flocculated clay systems (242). Micelle formation, micelle size, and critical micelle concentration in the presence of dissolved macromolecules were thoroughly investigated (243–245). Another study was conducted to determine the formation and structure of sediments in pharmaceutical systems (246). The acceleration of sedimentation of fine solid suspensions was also examined (247). α-Dialkyl-β-aminopropionic acid was found most useful in the modification of flow properties of lipophilic vehicles (248). The technology of the production of microcrystalline suspensions was also investigated (249). The stability of dispersions of alumina and aluminum hydroxide was affected by various chain length alcohols and water (250). Light transmission measurements on suspensions were made by Hepplestone and Lewis (251).

Emulsions—A review containing 30 references dealt with emulsification and the selection of nonionic surfactants (252). Several papers also appeared which discussed the theory of emulsification, characteristics of the emulsifier, and finally the selection of the emulsifier (253, 254). The more important principles and some fundamental aspects of disperse systems were presented (255). Another review concentrated on the factors which determine the choice of emulsifying methods, the phase volume ratio,

and the emulsifiers (256). Two excellent papers appeared on emulsification. The authors stated that the HLB value and the rheological properties of the interfacial films were important factors affecting emulsion stability (257, 258). Jass stressed the importance of controlling the process variables to insure emulsion stability (259). Smoluchowski's equations were used to determine the kinetics of the rapid coagulation of emulsions (260). Negative interfacial tension in mixed films of soaps and long chain alcohols results from a large depression between the aqueous and oil phase with its adsorbed alcohol monolayers (261).

A thermodynamic study of emulsions showed that the mechanism of action of the emulsifier was twofold and involved surface phenomena and solution stability (262). Centrifugation was used to evaluate the stability of emulsions (263). The influence of pH on the stability of emulsions formulated with hydrophilic colloids was considered (264). Rimlinger elaborated on the influence of containers, chemical variation of emulsion constituents, and the power of the third solvent in preparing stable emulsion systems (265, 266). It was pointed out that oil-in-water emulsions can be obtained when the emulsifier–water ratio is such that the emulsifier is in micellar solution (267). A mechanism for the action of specific electrolytes on emulsion systems containing certain nonionic polyoxyethylene ethers as emulsifying agents was postulated (268). Electrolyte solutions did not affect the creaming of fat emulsions. The variation in creaming was attributed to the differences in composition or purity of the phosphatide emulsifiers and to the differences in properties of the respective oils (269). In another study Mizutani investigated the relation between phase inversion temperature, cloud point, and HLB values for emulsions prepared from nonionic emulsifiers (270). Pepsin was utilized as an emulsifier to prepare a stable system (271). The stability of an emulsion is increased by using a stabilizer with a high free energy of adsorption and as low a compressibility as possible in the monolayer (272). Particle-size changes were monitored in determining the stability of oil-in-water emulsions (273). A new method of studying the particle-size distribution of mechanically prepared hydrocarbon-in-water emulsions was presented (274). The effect of mixing of oils and of nonionic surfactants on the phase inversion temperatures of emulsions was considered (275). Another study involved spontaneous emulsification caused by the lowering of interfacial tension (276). The interfacial surface effects in a homogeneous multicomponent liquid mixture were measured (277). The possibility of the appearance of a synergism in the decrease of interphase tension was examined by mixtures of surfactants differing only in the structure of the polar groups (278). An effective method for measuring the emulsifying properties of surfactants was presented (279). Low-pressure capillary homogenization was used to prepare emulsions. The stability of the resultant emulsion was followed (280). The formation of microemulsions can be affected by different hydrocarbons (281). Cavitation mills produced more homogeneous creams than did colloid mills, however, after prolonged storage the creams produced by the cavitation mills showed poorer stability (282). Peroxides were found to affect the rate of emulsification of mercury in anhydrous lanolin (283). The charge on the disperse phase particles influenced the stability of some water-in-oil type emulsions (284). Admixing oils was shown to control the activity of phenols in oil-in-water dispersions during storage at different temperatures (285). The distribution of benzoic acid in some emulsified systems revealed that its fungistatic activity was dependent upon the amount of free acid in the aqueous phase (286). Conductivity measurements were used to follow the creaming rate of aggregate systems (287). The emulsifying properties of several surfactants were evaluated (288). A new polysaccharide gum was announced as a potential emulsifier for pharmaceutical systems (289). Gum arabic and tragacanth were determined to be the most satisfactory agents for maintaining the stability of paraffin oil emulsions (290). The method of preparation had an effect on the initial size distribution of oil-in-water emulsions (291).

Ointments and Creams—Schlossman discussed various hand creams and lotions and listed typical formulas (292). Several new water-washable bases and their properties were described (293). Oil-soluble lanolins were used in the preparation of typical creams (294, 295). Several papers were published describing typical ointment bases useful for various externally applied medicinals (296–299). Lukas described a new synthesis of ointments with fatty acid lead salts (300). Formulas for chloramphenicol ointment were also described (301).

The evaluation of the chemical stability of ointment bases was determined by the method of accelerated aging (302). Polymyxin B sulfate was found to be most stable in an ointment base containing methylcellulose and polyethylene glycol[3] (303). Antioxidants were effective in

[3] Carbowax, Union Carbide Corp., New York, N. Y.

preventing the breakdown of ointment bases hydrated with rose water (304). A synergistic behavior was observed when ointments were prepared by incorporating β-naphthol, iodochlorhydroxyquin[4] and undecylenic acid into water-soluble bases (305).

The rheological behavior of various ointments of the suspension type was investigated (306). Penetration measurements using a rotating viscometer slightly modified by the addition of penetrators permitted the determination of consistency of ointments (307). Whitworth and Becker studied the release of soluble sulfonamides from ointment bases through a membrane for a 6-hr. period (308). In a similar study the liberation of active substances from ointment bases was followed by dialysis (309).

Suppositories—The methods used in a physical study of suppositories were described in detail (310). Several papers were written on the compounding of colored suppositories (311, 312). Plaxco *et al.* studied the effect of some nonionic surfactants on the rate of release of drugs from suppositories. Their data indicate that the HLB value of the surfactants had an influence on the rate of release of the drug (313). Several substances were evaluated as possible viscosity increasing agents for the suppository base lasupol-G (314). The use of 1,3-butylene glycol as a glycerol substitute in suppositories was investigated (315). It was also pointed out that amidopyrine was unstable in the presence of certain agents in suppository bases (316). The formulation and evaluation of new rectal dosage forms including a study of microcrystalline cellulose–carboxymethylcellulose gels as suspension vehicles were reported by Wakling (317).

Aerosols—A discussion of the theory of foaming, foaming properties of nonionic surfactants, and of foam stabilizers and foam inhibitors was published (318). Nonionic aerosol foams were studied with respect to emulsion stability, bubble size, foam stability, stiffness, and drainage as various fatty alcohols or acids were added (319). Silicone antifoams are often used to decrease the tendency for foaming (320). Kuebler commented on the dosage accuracy in aerosol preparations. He stated that the filling of aerosol preparations entails some dosage variation which increases as the container size decreases, however, the variations are within limits (321). An outline of the available literature on aerosols was presented (322). The development and application of aerosols in pharmacy were reviewed in several articles (323, 324). The quality control requirements for aerosols were outlined (325). Several authors discussed the significance and determination of particle size for oral inhalation aerosols (326, 327). Sciarra wrote a review article concerning the particle size of topical aerosols (328).

Several additional papers were published which described the measurement of aerosol particles by light scattering and by acoustical measurements, respectively (329, 330). In another paper a series of electrolytes were dispersed from solutions with a modified Dautrebande-type aerosol generator (331). The modification of an aerosol generator resulted in the preparation of sodium chloride aerosols of narrow particle-size distribution (332). The particle-size distribution of an aerosol continually reinforced by the introduction of particles and undergoing Brownian coagulation was calculated by integrating the equation of Smoluchowski modified to include a feed term (333). The effect of a weak electric charge on the rate of coagulation was studied using dioctyl phthalate (334). Several additional papers discussed propellant blends and perfumes commonly used in aerosols (335–337). Richman studied pressurized foams with emphasis on rheological evaluation (338). An experimental method for measuring the drop size distribution in liquid sprays was presented (339).

Sustained Release—A review was presented describing the means of prolonging medicinal action of various drugs and the various factors involved (340). Recent achievements in the field of pharmaceutical preparations with prolonged action were the subject of a survey containing 300 references (341). Another survey appeared which emphasized the importance of timed-release preparations (342). Drug latency, durability, metabolic activation, and water solubility were reviewed with respect to sustained-release dosage forms (343). Stuart offered a table of variable-release dosage forms and of the principles of the timed-release dosage forms (344).

Several papers appeared elaborating on the use of microencapsulation of pharmaceuticals (345, 346). An attempt was made to develop a parenteral form of an antibiotic by coacervation (347). Luzzi and Gerraughty commented upon the effect of additives on the controlled release from microcapsules (348, 349).

A modified half-change method was suggested to maintain proper enzyme levels during a prolonged-action test (350). Coated granules have been investigated in the preparation of phar-

[4] Trademarked as Vioform, Ciba Pharmaceutical Co., Summit, N. J.

maceuticals with prolonged action (351). Sustained-action thiamine tablets were prepared. The author studied the *in vivo* and *in vitro* release patterns (352). Ion-exchange resin adsorbates of aspirin were prepared and evaluated for sustained action (353). A carboxyvinyl polymer[5] was found to affect the dissolution rate of a tablet. It was concluded that this agent could be used successfully to prepare sustained-action tablets (354). The effect of surfactant concentration on the release rate of sulfaethylthiadiazole from synthetic wax particles prepared by aqueous dispersion was studied (355). Long-action compressed tablet formulation was prepared from a plastic matrix. Both *in vitro* and *in vivo* tests were carried out on the finished forms (356). Newly developed coating laquers made from acrylic resins were also used to prepare depot medicinal dosage forms (357). Another paper appeared which described the preparation and effectiveness of long-acting diethylstilbestrol injections for veterinary use (358).

Cosmetics—Moxey published a survey dealing with perfumery and cosmetic material (359). Another review dealt with the structure of emulsions, emulsifiers, and their use in the cosmetic industry (360). The application of silicones in cosmetic preparations was the subject of another article (361). It contained formulas for a number of preparations. A paper dealing with the use of modern surfactants in the manufacture of cosmetics appeared in the literature (362). Bergwein reviewed hair creams, commenting on their history and development in the various forms (363). Several interesting articles appeared relating the role of glycerin in modern cosmetic products (364, 365). Another author discussed the use of glyceryl esters in cosmetic emulsions (366). Fatty acid esters of xylitol were experimented with as possible ingredients in the preparation of cosmetics (367). Schmolka elaborated on the application of pluronic polyols in the cosmetic industry. He pointed out that these agents may aid the cosmetic chemist in improving current formulations and developing new products (368).

Diisopropyl adipate was evaluated as an ingredient for cosmetic formulations (369). New types of pearl pigments have been developed for cosmetics which previously were not practical because of natural limitations (370). Cosmetic grade propoxylated ethers were discussed and formulations were suggested to illustrate their application (371). The use of polymer microspheres as raw materials for cosmetics and toiletries was suggested (372). Cotta *et al.* described some important points relative to the production and control of tissue protein and their use in cosmetics (373). The importance and the influence of grain size in pigments used in cosmetic preparations was the subject of another paper (374). The synthesis of two new groups of alcohol-soluble aluminum compounds was described. Their antiperspirant activity was also measured (375). Because of unique properties of silicones it was pointed out that a variety of performance characteristics can be built into cosmetic formulations (376). Other papers listed several new active substances that were useful for the care of the skin (377, 378). It was also found that the application of a lipid film containing dewaxed lanolin was of value both in maintaining hydration and in serving as a potential lip barrier (379). A synthetic copy of the natural moisturizing factor present in human skin was formulated based on amino acid analysis (380). Several papers were presented dealing with the evaluation of sun screen agents (381–383). The background and practical application of gel formation in nonionic systems in relation to cosmetic preparations were discussed (384). Fatty acid chain length had some effect on the physical properties of cosmetic emulsions (385).

Packaging—Beal *et al.* described a comprehensive study on pharmaceuticals stored in plastic containers (386). Another study pointed out that direct measurements of light transmission of plastics is affected by diffusion and is not a trustworthy test of suitability for packaging (387). An excellent review on the structure problems of silicates and glass as a construction material, on its resistance to heat change, and on the physical and chemical properties of pharmaceutical containers was published (388). The quality requirements of the pharmaceutical industry for flasks and ampuls were outlined (389). The research and development of safety closures was the subject of another paper (390). Rehm conducted the testing of water resistance of container glass (391). Autian presented a review of the interaction between medicaments and plastics (392). Several papers discussed the problem of permeability of various components through polyethylene and polypropylene containers (393–395). Corrosion problems in aerosol packaging were reviewed (396). High polymer plastics with their flexibility, shock resistance, and other helpful aspects lend themselves well for developing interesting packages for cosmetics (397).

EQUIPMENT

Several papers were published concerning the

[5] Carbopol 934, B. F. Goodrich Co., Cleveland, Ohio.

use of vibration mills (398–400). The performance of several industrial mixers was compared using segregating materials (401). An excellent review article on the application of ultrasonics in pharmacy was written by Skauen (402). Unit-dose packaging was the subject of another article (403). The use of new automated techniques for the pharmaceutical industry has been reported (404). Several typical spray driers were described and their application to pharmaceutical systems was discussed (405). Another paper described the mechanical bottling of oral solutions under protective gas (406). A review, containing 175 references, concerned with automatic adjustments of the meniscus, the dosing adapters for pipets, special devices, the sources of error, and calibration of the dosing adapters was published (407). The construction and use of laminar flow rooms were described by Soltis (408). Another article appeared which described equipment utilized in high speed film coating of tablets (409).

PHYSICAL PHARMACY

The various aspects concerned with dissolution and diffusion studies have produced a number of interesting papers. A new method of studying the diffusion of liquids through gels has been noted (410). Nixon *et al.* have determined the concentration effect on diffusion coefficient (411). In another study, based on the first principles of diffusion, the authors derived appropriate equations to predict the transport of solubilized systems (412). The effect of high surfactant concentration on the kinetics of dissolution, the importance of sink conditions, and the simultaneous determination of dissolution and partitioning rates *in vitro* have been demonstrated (413–415). In regard to the solid dosage form, Singh *et al.* described the release rates from the inert matrices in cases where there existed noninteracting drug mixtures, as well as mutually interacting drug mixtures (416, 417). Formulation effects on the tablet dissolution pattern were also investigated (418, 419). An apparatus for determining the drug release from tablets has been described (420). The dissolution phenomenon has also been reported in somewhat of a different but definitely pertinent interest, *i.e.*, the dissolution of phosphate kidney stones by citrate buffer (421). In addition to dissolution rate studies, the deaggregation behavior is likewise relevant. Aguiar *et al.* have developed equations and demonstrated such rates quantitatively (422). The association of dissolution to insoluble compounds immediately directs itself to the effect of particle size. In fact, it was suggested that the use of an appropriate particle-size terminology be used in pharmacy (423). A review of particle size and surface area and critical evaluation of measurement methods were discussed (424). The following methods for determining particle size were described: photosedimentometer, ultramicroscope, permeability, sedimentation balance, X-ray, turbidimetry, and light scattering (425–434). Other results indicate significant influence of a polar nature of the solution on cluster formation when hindered setting was used for determining particle size (435). A study on the dispersion of clay for particle size determination was made (436). Relative to this, studies on particle reduction to μ size, the effect of grinding on precipitated magnesium hydroxide, and a new technique for fractionating powders were performed (437–439). A comparative study of commercial griseofulvin with reference to official standards was also investigated (440).

Solubility—Solubility determinations of the following systems were reported: the solubility of antibiotics in 26 solvents, purines, pyrimidines, and their nucleosides in urea and sucrose solutions, vinbarbital in ethanol–water systems, sodium bicarbonate in glycerol, and some aminoalkylphenothiazine tranquilizers and related compounds in water (441–445).

The increase of aspirin–water solubility was accomplished through the interaction with urea (446). The effect of urea on the solubilities of benzoic acid and the effect of salicylic acid on the dissolution of some polymers was also determined (447, 448). The solubility relations and solubilization by nonionic surfactants were noted in a number of cases such as, the ascorbic acid–water–polysorbate 80 system, lecithin in antibiotic preparations, benzocaine and homatropine, testosterone, hydrocarbons, hormonal steroids, and chloramphenicol (449–455). Several papers described the increased yields of essential oils when nonionics were utilized in the extraction process (456–458). A review with 167 references outlined the solubilization of drug compounds by polysorbates[6] (460). A study was also conducted on the solubilization of water from its vapor pressure over nonionic and ionic surfactant solutions in various nonpolar solvents (461). Kuettel described saturated and supersaturated systems prepared by solubilization (462). The effect of the cation on solubilization by oil-soluble surfactants and solubilization of polymers in aqueous cationic surfactant solution has been noted (463, 464). The use of some synthetic

[6] Tweens, Atlas Chemical Co., Wilmington, Del.

surface-active substances as well as the solution of sulfonamides with polyglycols was reported (465, 466). Bjaastad and Hall have investigated the value measure of relative solvent polarity in micellar solubilization (467). The solubilization and rate of dissolution of drugs in the presence of physiologic concentrations of lysolecithin were determined (468).

Complexation—Patel presented data to show that antimicrobial activity of several preservatives is primarily a function of the free or unbound preservative (469). A series of papers elaborated on the interaction between drugs and macromolecules (470–472). The calculation and determination of stability and dissociation constants have been reported (473–475). The stability of metal complexes of salicylic acid derivatives and caffeine with various benzoic acids has been evaluated (476, 477). Seventeen drugs were tested against seven ion-exchange resins and activated charcoal for binding capacity *in vitro* (478). Diffuse reflectance studies of solid–solid interactions of drugs were made and in the case of dye–adjuvant chemisorption, the results indicate that a metallic or polyfunctional adsorbent molecule is necessary (479). Evidence of the following complex formations has also been noted: epinephrine with boric acid in aqueous solutions, benzoquinone solutions with indole derivatives, adrenochrome–adrenolutin, weak organic acids and phenols with nylon-6, anionic detergents with cellulose, and starch with organic substances (480–485). The effect of neutral salts in gelatin–gum arabic complexes was also determined (486). A report on the hydrogen acceptor properties of griseofulvin and related compounds, in order that its physical behavior would allow a more rational approach to the formulation of dosage forms, was also reported (487). Interactions of penicillin with deoxycholic acid polymer-like structures have been shown (488). Soluble copper chelates were suggested for addition to injectable solutions such as iron saccharate (489). Also appearing in the literature, was a paper which describes complex formation in aerosol emulsions and foams (490). The use of complexes as antacid preparations has been evaluated for a new aluminum hydroxide complex as well as metal complexes of tris(hydroxymethyl)aminomethane (491, 492). NMR spectroscopy has been used to study molecular interactions and mobility at liquid–liquid interfaces (493).

Surface Phenomena—Aspects of surface-active agents in pharmacy, in which their classification and properties are given, were described (494). A review contained historical, chemical, and biological aspects of surfactants (495). Discussions were also given for the modern theory of fluid surface tension, physical basis of wetting, and some aspects of classical surface thermodynamics (496–498). The properties and chemistry of silicones and clay material have been reported (499, 500). Descriptions of nonionic and anionic surfactants have been noted (501, 502). Another paper contained data on the bactericidal properties of straight-chained alkyltrimethylammonium bromides in a simple emulsion system (503). A paper by Beckett *et al.* contained data on surface-active betaines (504). A review on the use and analysis of sucrose fatty acid esters also appeared in the literature (505). The structure and rheology of sodium dodecyl sulfate–cetyl alcohol–water can be found in a series of papers (506–508). Several other papers have noted micellar properties of sodium dioctyl sulfate (509–511). A study using monooctyldecyl phosphate included data which showed the surface viscosity of the monolayer increased linearly with time and this rate increased as the pH was lowered (512). Studies of the surface viscosity of monomolecular films of *n*-chain alcohols were also conducted (513). Other aspects of surface-active agents which have been reported included monolayers formed by mixtures of anionic and cationic surfactants, surface excess in solutions of surface-active agents, and the effect of composition on the critical surface tension of polyvinyl butyral (514–516). Another report included the physiochemical properties of monoglyceride sulfonate–water systems near the critical micelle concentration (517). Definitions of kinetics and kinematic surface tension on the physiochemical surface characteristics of moving surfactant solutions were given (518). Electrocapillary curves for the interfaces between aqueous solutions of inorganic electrolytes and oils containing detergents were published (519). A number of papers have considered the following aspects of the micellar state: the relationship with cloud point, influence of temperature, the effect of tracer dyes on the size distribution and transport properties, density, hydration, shape and charge, and the ionic dependence of micelle number (520–524). The determination of critical micelle concentration of cationic surfactants has been made through the use of alizarine red S (525). The osmotic coefficient and equivalence conductance of aqueous solutions of medical amine salts were used to determine aggregating properties (526). Quantitative measurements of the interfacial free energy of black lipid membranes

separating two aqueous solutions were made (527). A number of papers have included various facets in the measurement of surface tensions of surfactant solutions including methods (528–533). Ho and Higuchi used the RIDL multichannel particle counter and size analyzer to develop a method for studying the kinetics of aggregation of denatured proteins (534). Another paper described the use of flow ultramicroscopy in particle-size analysis (535). The kinetics of monolayer desorption at constant surface pressure was analyzed (536). Fluorine magnetic resonance was used to investigate micelle structure while the sedimentation equilibrium method was used to determine micelle molecular weight (537–538).

A geometric model of floc formation using Smoluchowski's rate equation for perikinetic flocculation was developed (539). The colloidal–chemical properties of nonionic surfactants is included in another paper (540). A number of papers included discussions on colloid stability (541–546). Another author presented the effects of low concentrations of electrolytes upon electrophoretic mobility of aqueous colloidal suspensions (547). The description of the double-layer structure of colloidal electrolytes was also made (548). Temperature effect on micellar state of surface-active semicolloids in aqueous solutions has been noted (549). Also presented in the literature was a paper which contains the description of liquid–solids separation with particle growth (550). Papers specifically directed to pharmacy included data on the application of surface-active agents to pharmaceutical preparations, the effect of griseofulvin upon lipid films at the air–water interface, and the work on the formation of micelles in topical anesthetics (551-553).

A general equation for adsorption isotherm was derived and the factors involved in adsorption at the solid–liquid interface were described (554, 555). A method and determination of surface areas of solids has been described in separate papers (556, 557). Investigations of adsorption have included that of the effect of aprotic solvents on phenol alumina, the adsorption of alkaloid salts on silica gel, and the adsorption of mixtures of organic substances from aqueous solutions by activated charcoal (558–560).

The homogeneity of powder mixtures and the segregation kinetics of particulate solids were discussed (561, 562). The aggregation of particles during the grinding process and a report on the development of cohesion in granular materials during comminution were noted (563, 564). The effect of the particle size of granulated drugs on free-flowing properties can be found in another paper (565).

Crystallization—A study was conducted on the mechanism of crystallization of hydrocortisone by ultrasonic irradiation (566, 567). Several authors presented data on the development of optimal crystal shape of basic pharmaceutical materials. This included the influence of solvents and solvent mixtures on crystal shape (568). The conversion of six cholesterol esters from crystalline solid to the isotropic liquid during heating and cooling was studied (569). It was also found that the rate of crystallization depended upon the concentration of starting materials in studies of the crystalline aluminosilicates (570).

Separate studies on sulfathiazole and methylprednisolone described heats of transition and fusion and crystal growth and dissolution rate of the two polymorphic forms of both compounds (571–573). The polymorphic forms of chloramphenicol palmitate and stearate were examined by IR spectrophotometry (574). The polymorphic forms of cortisone acetate and sulfamethoxydiazine were also reported (575, 576). The phase transformation of theophylline hydrate to an anhydrous form was measured at a variety of temperatures using X-ray powder diffractometry (577).

Rheology—The viscosity of some suspensions was studied in which an equation was derived for the effective viscosity of low concentration emulsions containing surfactants (578). It was also stated that the measured viscosity of a suspension depends upon the diameter of the tube of the capillary viscometer used in determining it (579). A Ferrante-Shirley cone and plate viscometer was used to estimate the spreading characteristics of pharmaceutical semisolids (580). An evaluation of the rheological properties of monodisperse latex systems flow curves of thickened latexes was made (581). The structure and rheology of dispersed and flocculated colloidal systems was reviewed (582). Another study described the rheology of surfactant solutions by a novel viscometer based on the principle of harmonic damped oscillations (583). The mathematical criteria of the thixotropy of starch gels were reported (584). Other studies included the viscosity of phospholipid solutions and the development of a standard gel for interlab comparison (585, 586). The Stormer viscometer in the measurement of certain pharmaceutical systems was evaluated (587). Studies reported on clays include: thixotropy and rheopexy of

clay suspensions, negative thixotropy, colloidal and surface properties, sedimentary volumes, structure formation in hydrothermal conditions, and rheological properties (588–594). Another worker determined the sorption and exchange capacity of cations in clay materials (595). The rheology of some oil-in-water emulsions and the rheological changes in emulsions on aging have been reported (596–598).

The following agents have been evaluated as to rheological properties: methylcellulose hydrogels, ternary system of sodium carboxymethylcellulose–glycerol–water, surfactants, sugars in pectin solutions, and the effect of cations on γ-carrageenan (599–605). Another report contained a description of the five general stages in the formation of ionotropic gels (606). The rheological and stabilizing properties of some soaps of naphthenic acid were also investigated (607).

The application of rheology in pharmaceutical cosmetic practice with plastic gels was described in a survey on the main principles of rheology (608). A study on the rheology of a thixotropic lotion and the rheological characteristics of emulsion ointment bases appeared in the literature (609, 610). A paper describing the alteration in flow properties of light mineral oil with an organic derivative of a special montmorillonite[7] was also noted (611).

PHARMACOCHEMICAL ASPECTS

Antibiotics—A review included the new derivatives of semisynthetic penicillin and their clinical applications (612). The pharmaceutics of the semisynthetic penicillins, the compatibilities, and the incompatibilities with other compounds, were presented (613). Gibaldi and Schwartz have determined, from literature data, the kinetics of absorption and elimination in the dog of a new penicillin derivative, penamecillin (614). New antibiotic preparations and other biologically active agents of natural origin have been reported (615). The biochemical mechanism of action of antibacterial antibiotics has been reviewed and the physical-chemical properties of novobiocin were discussed (616, 617). Several authors investigated the hygroscopic properties, thermostability, and solubility of oleandomycin salts (618).

Radiopharmaceuticals—Radiopharmaceuticals were reviewed quite extensively (619). The development, preparation, and application of nuclear pharmaceuticals were described (620). The problems of radiochemical purity, analytical methods, label stability, isotope effects, tissue residues, and clinical studies were considered in a review article (621). Equations were derived without steady-state assumptions for inactivation of enzymes in dilute aqueous solution by ionizing radiation (622).

BIOPHARMACEUTICS

This area appears to be commanding progressively more interest and it probably is the single most investigated area in pharmacy. Interesting work but perhaps least pertinent is that dealing with molecular aspects of drug–receptor interactions as noted in these papers (623–626). An interesting review was presented on alicyclic amines showing relations between structure and pharmacologic activity (627). Others worth noting include the material basis of drug activity and the concepts of the mode of action of drugs in which specific absorption is suggested as a basis of biological activity (628–631).

Studies related to biological systems included the determination of acetylsalicylic acid and salicylic acid in plasma (632). The behavior of erythrocytes in various solvent systems has been investigated (633, 634). Also reported were the excretion levels in the saliva of dogs in which the excretion levels in saliva paralleled the blood levels for salicylate, pentobarbital, and sulfanilamide (635). It was also noted that saliva added to meals significantly retarded gastric emptying while a review pointed out that gastrin was the most potent stimulator of gastric digestive processes (636, 637). Included in the literature was a report that blood plasma was a Newtonian fluid over a wide range of shear rates to cover any likely situation in a living animal (638). Drug accumulation and the storage of drugs have been treated in separate papers (639, 640).

Numerous papers have dealt with a wide range of drug-binding phenomena. These include antibiotic–metal ion interactions, complex formation of tetracyclines with different components of blood serum, protein-binding of local anesthetics, binding of cortisol, binding of phenothiazine derivatives, and sulfonamide binding by serum albumin (641–646). Others included studies of norchlorcyclizine and norcyclizine and the thiazole moiety of thiamine (647, 648). The correlation of serum binding of penicillins with partition coefficients and studies of the binding of phenoxazone compounds were reported (649–651). The competition phenomena in binding of drugs to albumin were discussed (652). A review contained the agents which affect enzyme activity and another the enzymatic degradation

[7] Marketed as Bentone 38, National Lead Co., Brooklyn, N. Y.

of drugs in the organism (653, 654). In another paper, the effect of proteolytic enzymes on tetracycline absorption was studied (655). In separate studies, the *in vivo* degradation of penicilloic and penilloic acid and the hydrolysis of acetylsalicylic acid in human blood were discussed (656, 657).

Studies in which the routes of administration were compared included the comparison of oral and parenteral calcium administration, the difference between parenteral and rectal administration of thiamphenicol, and the rate of equipotent oral and intravenous doses of propranolol and H56/28 (658–660). Species comparisons were also made in which the binding of salicylate to plasma proteins in different species, the comparative metabolism of griseofulvin-^{14}C in the rat and rabbit, and the species difference in duration of action of cardiac glycosides were studied (661–663). The dose dependence of drug plasma level decline in dogs was investigated, and the statistical analysis of log-dose response bioassay experiments were described (664, 665).

Effects of Physiochemical Properties—Evidence of there being a definite pKa which a sulfonamide must possess in order to exhibit maximum activity was discounted (666). In another paper, it was noted that the carbonate derivative is the prodrug of trichlorethanol (667). In a study of pharmaceutical potentiation of drugs, it was reported that the long-chain alkyl derivatives of *para*-aminosalicylic acid were characterized by sustained release and maintenance of high levels in body fluids for long periods (668). In another study, the complex of salicylic acid with caffeine appeared to affect the absorption of this drug in the rat stomach (669). Other authors compared the sulfate and *para*-chlorophenoxyacetate of DL-amphetamine (670). The enteric absorption of formosulfathiazole and phthaloylsulfathiazole was also investigated (671).

Effects of Formulation—An interesting paper on the effect of adjuvants in the manufacture of pharmaceutical preparations was reported. It was noted that the release of antibacterial active drugs from aerosil, white clay, and talc was dependent on the structural relation between the drug and adjuvant (672). The review by Higuchi described the diffusional models useful in biopharmaceutics drug release rate processes (673). Using a new estimation method for release of drugs from dosage forms, an estimate was made of the actual sulfamethylthiadiazole release from the tablet in the gut (674).

Other authors compared the activity, fate, and absorption of chloramphenicol in different suspensions, while Aguiar *et al.* studied the effect of polymorphism on the availability of chloramphenicol from the chloramphenical palmitate, on the degree and velocity of hydrolysis, and the extent of resorption (675–677). The crystalline phases of fluprednisolone were reported in which a comparison of the physical properties and biological activities was made (678).

The action of tetracyline hydrochloride, oxytetracycline, and monomycin was prolonged through the use of polyvinylpyrrolidone aqueous solution (679). A description of the ability of certain additives to influence the absorption of salicylic acid from solutions was given (680). In another report, *in vivo* tests revealed a slight delay in absorption of a sulfa from a topical suppository base (681). A review of the biochemical and physiological mechanisms underlying fat-emulsion preparations also was written (682). A sensitive analytical method was described for the effect of formulation in phenmetrazine levels in man (683). Polymeric pharmaceutical coating materials as enteric coating *in vivo* were evaluated and the intestinal absorption of quinine from enteric-coated tablets was determined (684, 685). A report contained a method for studying the *in vivo* disintegration of orally administered pharmaceuticals (686). In studies of griseofulvin, in which the dissolution rate and absorption in man were compared, a good correlation was seen (687). Paul *et al.* related the effect of varying the crystal size of orally administered nitrofurantoin on absorption in the rat and man and emesis in dogs (688).

Absorption Control—A number of examples have been reported in which the absorption of a compound is altered by the presence of another. One study showed the effect of EDTA on intestinal absorption of sodium *p*-aminohippurate (689). Nikethamide[8] was found to produce a marked decrease in the blood levels of chloramphenicol, and methimazole was found to decrease the absorption of iron in rats (690, 691). Similar studies included the effect of certain nonsteroid antirheumatic drugs on the active amino acid transport across the small intestine and the effect of phenobarbital and glutethimide on the biological half-life of warfarin (692, 693). It was also reported that acetylsalicylic acid reduced the excretory rates of sodium, chloride, calcium, and magnesium ions by about 50% (694). Another author considered the retention and distribution of vitamin B_{12} activity and requirement for B_{12} following parenteral adminis-

[8] Coramine, Ciba Pharmaceutical Co., Summit, N. J.

tration of hydroxycobalamin (695). Uropepsin excretion and the effect of antacid materials, the effect of chelating agents on the excretion of metals, and the effect of probenecid on riboflavin absorption and excretion was also reported (696–698).

Serum levels of vitamin A and β-carotene in patients with and without dermal diseases were determined (699). In another paper, the excretion of trancyclomine sulfate was increased from 1 to 8% after acidification of the urine (700). Levy noted the effect of bed rest on the distribution and elimination of drugs (701).

Absorption Mechanism—A review by Weiner described the mechanisms of drug absorption and excretion (702). The theory of the molecular transport phenomena through thin membranes can be found in another paper (703). A diffusional model for transport rate studies across membranes was proposed by Stehle and Higuchi while another group related drug transport to its solubility parameters (704, 705). Studies utilizing the isolated rabbit mesentery and the urinary bladder of the rabbit have also been reported (706, 707). Electrochemical properties of membranes and anion-exchange resins with inorganic groups of different structure have been noted (708). Several papers included the transfer of compounds across the intestine. Among the compounds studied were L-selenomethionine, basic amino acids, quaternary ammonium ions, and leucomycin (709–712). An interesting paper describes the mechanisms of water transport through nonaqueous liquid membranes (713).

Kinetic Studies—A review on pharmacokinetics was prepared (714). Wagner and Metzler described the estimation of rate constants for absorption and elimination from blood concentration data (715). Equations for excretion rates and renal clearances of exogenous substances not actively reabsorbed have also been derived (716). It was also reported that blood level data and urinary excretion data may lead falsely to the conclusion of zero-order kinetics (717). Martin appraised some aspects concerning the interpretation of drug urinary excretion data (718). Another paper related kinetic considerations to the accrual and elimination of drug metabolites (719).

Pharmacokinetic studies were reported separately on the following compounds: salicylamide, paracetamol, pentobarbital, and ioglycamate (720–723). The digital computer was used to describe the kinetics of the distribution of estradiol-^{3}H (724). Kinetic constants for mixed inhibitors of cholinesterase were evaluated (725). Several authors reported on the effect of repeated oral dosage of nalidixic acid, while others derived a formula for calculating effective levels after repeated doses of hyoscyamine (726, 727). Subcutaneous absorption kinetics were also reported in which benzyl alcohol was studied (728).

Drug Absorption—Krueger-Thiemer and Hansen reported on the solution of pharmacological problems by computers, and a new computer program to determine biological constants was written by others (729–731). A report was also noted on the formal theory of drug-dosage regimens in which the desired plateau effect was not reached if the product of the rate constant for absorption and the dosage interval was low (732). Perrin described the mathematics of the three-phase *in vitro* model and the *in vitro* model for soluble drug absorption (733, 734). Another paper provided a method of estimating relative absorption of a drug in a series of clinical studies in which blood levels were measured after single and/or multiple doses (735). O'Reilly discussed the biological factors in dosage design in which drug absorption was related to membrane transport mechanisms (736, 737). The absorption profiles of drugs were reported (738). In another paper the buccal absorption of basic drugs was applied as an *in vivo* model of passive drug transfer through lipid membranes (739). Reports on the absorption, excretion, and metabolism of the following compounds were made: dextroamphetamine, barbiturate, riboflavin-5′-phosphate, methyl anthranilate, pentaerythritol tetranitrate, methyridine, haloperidol, propranolol, 5-methyl pyrazote-3-carboxylic acid, alloferin, fenfluramine, dimethylsulfoxide, pilocarpine, and lidocaine (740–752). A review of drug and chemical metabolism outlines the fate and distribution of drugs (753).

Studies on the Mechanism of the Mannich Reaction

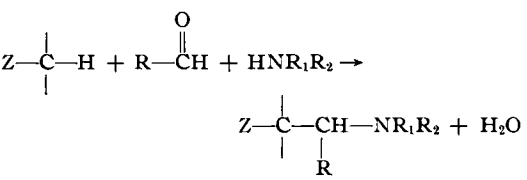
By W. LEWIS NOBLES* and N. D. POTTI

A study of the Mannich reaction has been carried out in which the importance of the nature of the amine component has been noted; with unsymmetrical bisamines, based on limited studies to date, the stronger base of the two amines involved in such a moiety appears to be always incorporated into the final Mannich product. Also, the importance of steric factors in the mechanism of the reaction has been noted.

FOR MORE THAN 60 years the Mannich reaction has been studied by several groups of workers, especially in the field of medicinal chemistry, primarily because of its synthetic utility and the favorable pharmacological properties of the Mannich bases and their derivatives. The mechanism of this reaction has been the subject of considerable discussion (1–13). Yet, thus far, no single mechanism which will account for all the experimental facts has been suggested.

Received June 12, 1967, from the Department of Pharmaceutical Chemistry, School of Pharmacy, University of Mississippi, University, MS 38677
Accepted for publication October 17, 1967.
Abstracted in part from a dissertation presented by N. D. Potti to the Graduate School of the University of Mississippi in partial fulfillment of Doctor of Philosophy degree requirements.
* Author to whom questions concerning the paper should be directed.

The reaction in its most generalized form may be represented as follows:



Several investigators (2, 5, 7, 14, 15) have indicated the possibility of considering a methylenebisamine as the most probable intermediate under normal reactions. A quasi-six-membered hydrogen-bonded transition state has been offered, in the case of the Mannich reaction with phenols as a plausible mechanism for the selective

Studies on the Mechanism of the Mannich Reaction

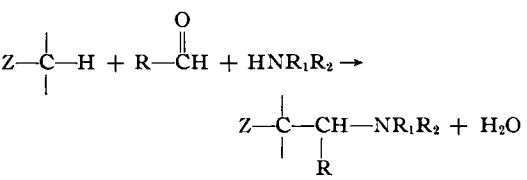
By W. LEWIS NOBLES* and N. D. POTTI

A study of the Mannich reaction has been carried out in which the importance of the nature of the amine component has been noted; with unsymmetrical bisamines, based on limited studies to date, the stronger base of the two amines involved in such a moiety appears to be always incorporated into the final Mannich product. Also, the importance of steric factors in the mechanism of the reaction has been noted.

FOR MORE THAN 60 years the Mannich reaction has been studied by several groups of workers, especially in the field of medicinal chemistry, primarily because of its synthetic utility and the favorable pharmacological properties of the Mannich bases and their derivatives. The mechanism of this reaction has been the subject of considerable discussion (1–13). Yet, thus far, no single mechanism which will account for all the experimental facts has been suggested.

Received June 12, 1967, from the Department of Pharmaceutical Chemistry, School of Pharmacy, University of Mississippi, University, MS 38677
Accepted for publication October 17, 1967.
Abstracted in part from a dissertation presented by N. D. Potti to the Graduate School of the University of Mississippi in partial fulfillment of Doctor of Philosophy degree requirements.
* Author to whom questions concerning the paper should be directed.

The reaction in its most generalized form may be represented as follows:



Several investigators (2, 5, 7, 14, 15) have indicated the possibility of considering a methylenebisamine as the most probable intermediate under normal reactions. A quasi-six-membered hydrogen-bonded transition state has been offered, in the case of the Mannich reaction with phenols as a plausible mechanism for the selective

formation of the *ortho*-substituted phenols (8). A similar complex transition state has been indicated (5) in the case of the Mannich reaction of nitroalkanes. Further strong intramolecular hydrogen bonding is indicated in Mannich bases in general (10,16).

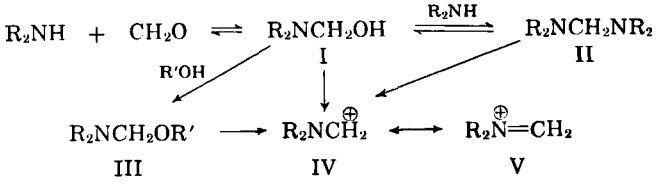
Methylenebispiperidine reacts faster than methylenebismorpholine in the Mannich reaction (5); since they are sterically quite similar, this has been attributed to their difference in basicity. One objective of the present investigation was to study the course of the Mannich reaction when an unsymmetrical methylenebisamine was used.

In previous mechanistic studies, there seems to have been little consideration of the steric effects of the reactants, even though there is a significant amount of published data available. The significance of this aspect is elaborated in this study to the point that it appears to account for several otherwise unexplained facts.

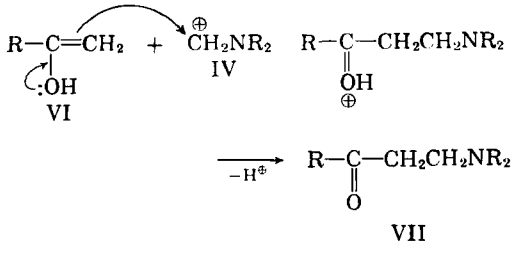
DISCUSSION AND RESULTS

The formation of a methylenebisamine (II) as the primary step of the Mannich reaction has been suggested by Lieberman and Wagner (2) even though later kinetic studies (3, 4) proved their mechanism to be incorrect. Alexander and Underhill (3) held the view that an aminomethylol (I) is the intermediate of the reaction. The possibility of the formation of an aminomethyl ether (III) in alcoholic medium also has been suggested (8, 17). (Scheme I.)

To date, one may accept most of the intermediates that have been proposed in the mechanistic considerations of this reaction. This is essentially true since, according to the current view (4, 18, 19), in slightly acidic medium the carbonium ion (IV) which is obtainable from all the above intermediates, attacks the enol form (VI) of the ketone in an electrophilic attack to give the Mannich base (VII).



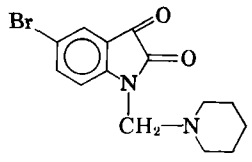
Scheme I



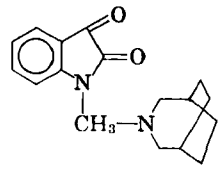
A more recent study (14) indicates that at 30° practically the entire quantity of the amine exists as the methylenebisamine when the secondary amine and formaldehyde are mixed. There is little evidence (17) to consider the aminomethyl ether as a possible intermediate in the normal Mannich reaction, since the rate of formation of this ether is very slow compared to the almost instantaneous formation of the methylenebisamine. Furthermore, Varma and Nobles (20), while attempting the Mannich reaction with indanedione, isolated a methylenebisamine dihydrochloride when the normal reaction failed. Fernandez and Fowler (5) have demonstrated the possibility of a six-membered hydrogen-bonded transition state in the Mannich reaction of nitroalkanes with a methylenebisamine. Burckhalter and Leib (8) offered a similar mechanism involving a chelated six-membered transition state in the Mannich reaction of phenol to account for the selective formation of the *ortho*-substituted derivative.

The present study extends the possibility of a similar six-membered (chelated) transition state to other types of Mannich reactions, especially those involving ketones and phenols as active hydrogen components. As a matter of fact, ketones, after enolization, appear to behave exactly as the phenols do from one mechanistic point of view.

Two unsymmetrical methylenebiasmines,[1] 5-bromo-1-piperidinomethylisatin (VIII) and *N*,*N*-3-azabicyclo[3.2.2.] nonylmethylisatin (IX) have been reacted with β-naphthol and acetophenone, respectively. The products obtained have been identified by independent synthesis as shown in Scheme II. The selective incorporation of the piperidine and AZBN moieties in the final product is in good agreement with the observation of Fernandez and Fowler (5).



VIII

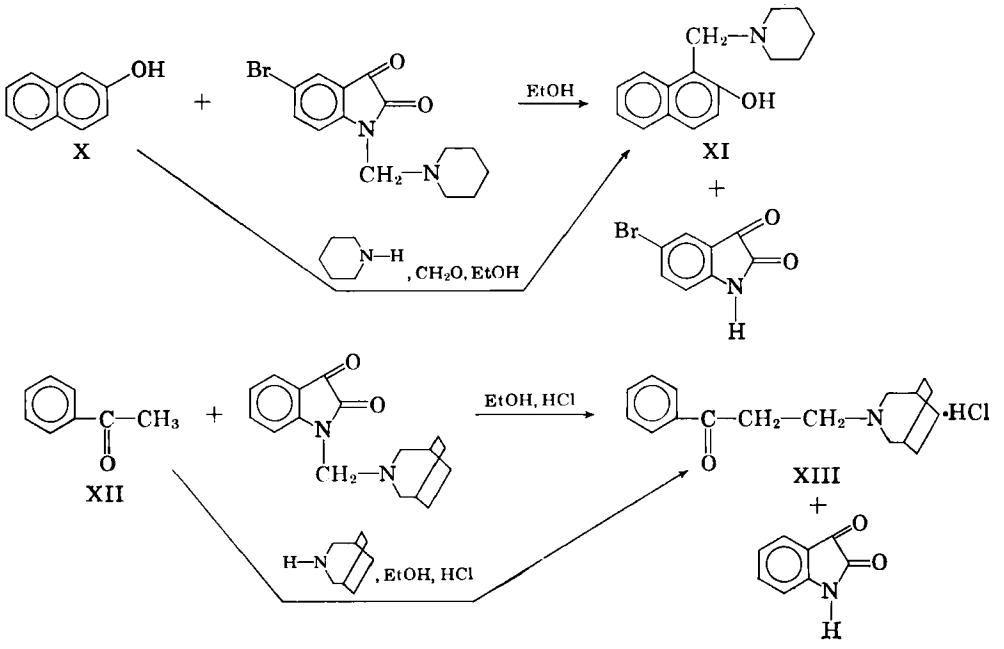


IX

The possible significance of this particular study is limited by the realization that isatin acts as a weak acid in aqueous solution, being soluble in cold alkali and yielding 2-aminophenylpyruvic acid on warming with aqueous alkali. Nonetheless, the leveling effect in comparing the relative strengths of acids and bases in various solvents should be noted; the range of comparisons is limited by the strength of the solvent as an acid or base.

Participation of isatin to date in the Mannich reaction has been limited to the observation that *N*-Mannich bases may be prepared by the action of

[1] Isatin is a very weak base (21) and forms a crystalline perchlorate, $C_8H_5NO_2 \cdot 2H_2O$.



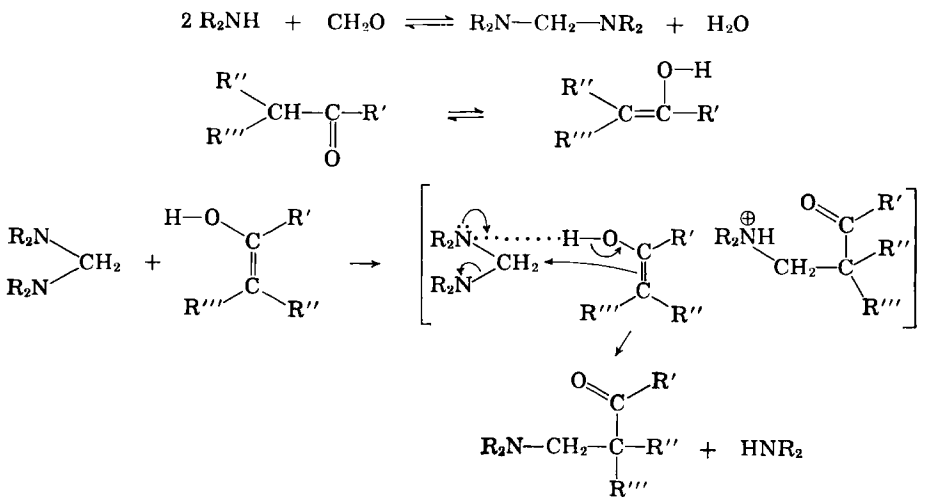
Scheme II

formaldehyde and a secondary amine with this lactam. Studies are currently underway in our laboratory to determine if it is possible to utilize the leveling effect of various solvents on amine strengths as bases in the utilization of isatin and related products as amine components in the Mannich reaction.

The stronger base should logically form a more effective hydrogen bond. The mechanism may be represented as in Scheme III; the primary step of the reaction is the formation of the methylenebisamine.

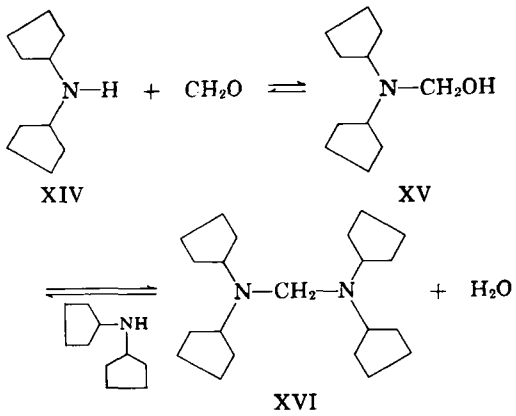
R′ and R″ may form a part of the ring in the case of cyclic ketones and phenols. In the case of phenols R‴ must necessarily be a hydrogen atom so that by enolization it can rearrange to the more stable phenol form.

Hitherto, it appears little attempt has been made to study the steric effects of the reactants. Diethylamine appears to behave quite differently in several situations (18, 22, 23) when compared with dimethylamine and piperidine. Dicyclohexylamine does not take part in the normal Mannich reaction (24). In the present study, an attempt has been made to condense dicyclopentylamine (XIV) both in acidic and basic media using acetophenone and β-naphthol, respectively, without success. Interestingly enough, heat is liberated when the amine is mixed with the formalin; this may indicate that the primary reaction, formation of the methylenebisamine, has taken place. Attempts to isolate the methylenebisamine dihydrochloride (XVI), however, have failed thus



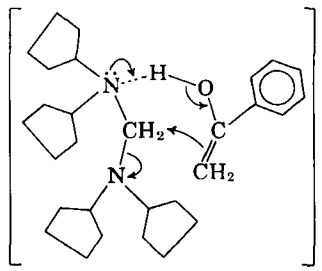
Scheme III

far. Instead, dicyclopentylamine (XIV) has been isolated; identity has been confirmed by independent synthesis. This is not surprising since the reaction is one of a reversible nature and a molecular model study indicates a considerable amount of steric hindrance would be involved in the formation of the methylenebisamine (XVI). But model studies would indicate no difficulty in forming the carbonium ion (XVII) from the aminomethylol (XV) and, according to the current view (4, 18, 19), XVII may result in the formation of the Mannich base (XIX) by an electrophilic attack on the enol form (XVIII) of the ketone.



The total failure of the reaction is contrary to the current view, but is in full agreement with the mechanism proposed; the attainment of the suggested transition state (XX) is difficult on steric grounds even if the methylenebisamine (XVI) were to be formed.

The present consideration satisfactorily explains the apparent existing ambiguity (18, 25) with respect to the predominant Mannich condensation at the most highly substituted position or the least substituted postion (12, 13, 26) in 2-substituted cyclic and branched ketones. Apparently, that which determines the nature of the products will depend on the steric environment of the ketone and the ability of the methylenebisamine to form an effective hydrogen-bonded six-membered (chelated) transition state. The situation can be explained as indicated in Scheme IV. The proportion of isomer A or B may vary from 0% to 100% depending upon the

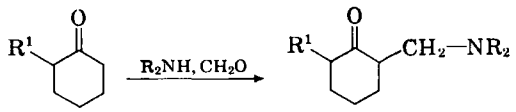


XX

steric contribution of the substituents R_1R_2 and R′; route I is preferrred but II is followed when these groups become more bulky in nature.

The reaction is controlled both thermodynamically and kinetically. House and Trost (18) found the ratio of isomer A to B (n = 3; R′, R_1, R_2 = CH_3) to be 70 to 30% and 65 to 35% in acidic and basic media, respectively, indicating that variation of pH does not affect the ratio of the isomers considerably. The proportion of B (n = 3, R′ = CH_3; R_1 = R_2 = C_2H_5) increases to about 42% when diethylamine is used (27) instead of dimethylamine as the former offers comparatively more resistance toward following route I.

2-Methylcyclohexanone appears to be a borderline case. Reichert and Mayr (28) report the formation of several Mannich bases of the general formula XXII in very good yields from 2-alkylcyclohexanones (XXI) having very large substituents at C_2. The reaction follows route II as shown in Scheme IV predominantly.



XXI XXII

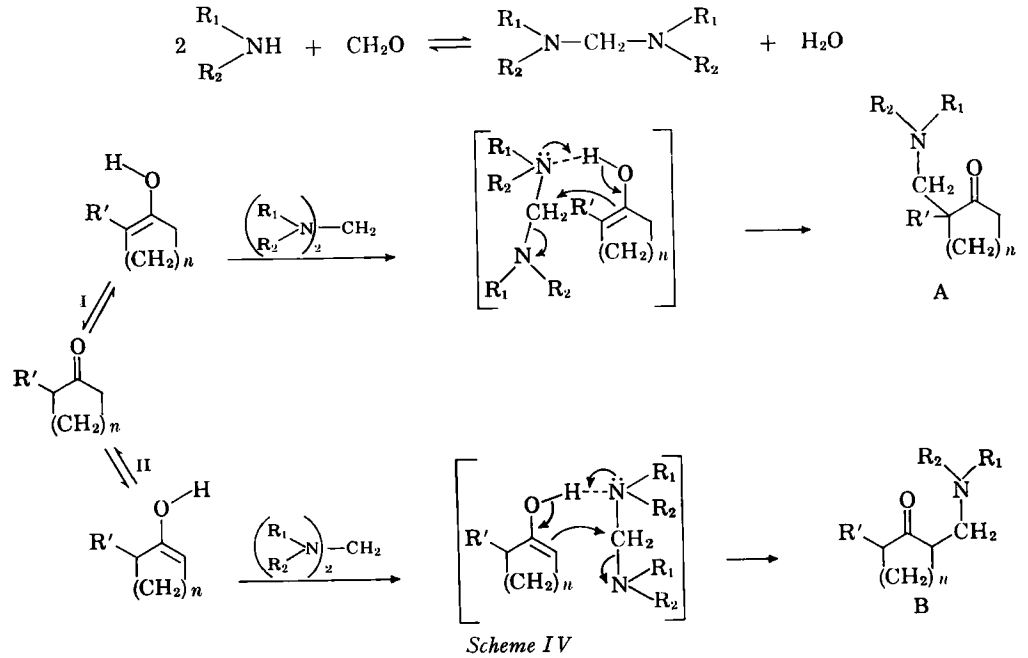
R^1 = —CH_2—CH(—CH_3)—$(CH_2)_n$—CH_3, n = 2, 3

R_2NH =

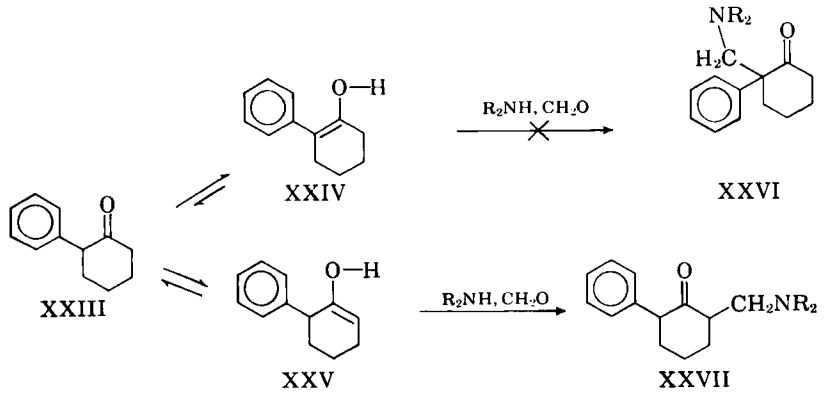
$(CH_3)_2NH$, $(C_2H_5)_2NH$, 
Bachmann and Wick (29) have demonstrated a similar course for 2-arylcyclohexanones; the less stable enol undergoes the Mannich condensation. For example, 2-phenylcyclohexanone (XXIII) gives the Mannich base XXVII in 62% yield. (Scheme V)

The same reasoning is applicable to the behavior of menthone (XXVIII) in the Mannich reaction (12). Mention may be made that the Mannich base XXX is less strained as compared to XXIX on the basis of nonbonded interactions.

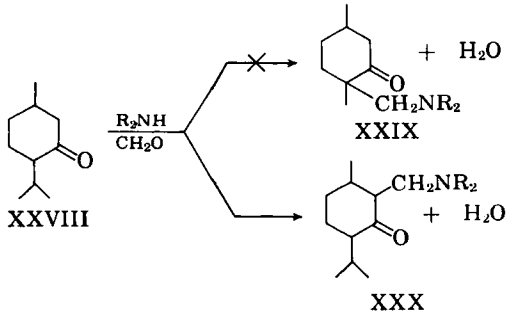
The proposed mechanism may be extended to explain the nature of the products obtained (22) from lawsone (XXXI). Contrary to expectation (12), the primary amine, instead of proceeding to the Mannich base XXXIII, gives the secondary amine, XXXII, which is the primary product of the reaction. When the complexity of the amine in-



Scheme IV



Scheme V

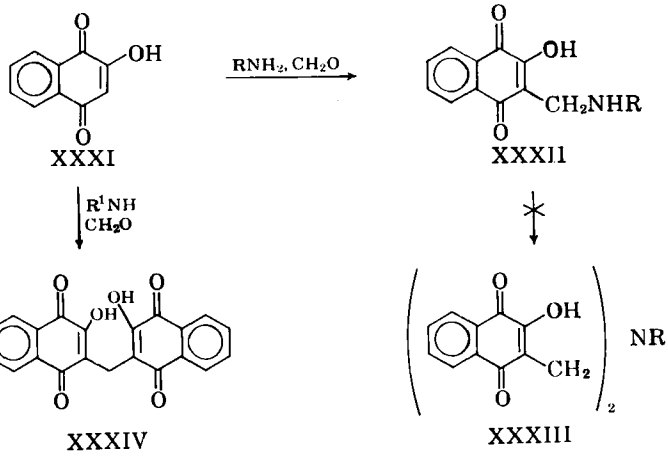


creases, the side reaction predominates so as to give the bis compound, XXXIV (Scheme VI).

Existing views (4, 18, 19) do not appear to explain all these facts; nor do they satisfactorily explain the selective formation of the *ortho* isomer in the case of the Mannich reaction with phenols. The *ortho* substitution of the phenol may be comparable to that of Claisen rearrangement (30) of allylic ethers, rather than a simple electrophilic substitution by the carbonium ion, IV, which is free to attack either the *ortho* or *para* position or both.

Para substitution in the *ortho* substituted phenols may take place through the participation of a second molecule of the methylenebisamine as is shown in Scheme VII; this makes it a termolecular reaction, the frequency of which is considerably less than that of a bimolecular reaction under identical conditions. Thus, it also explains why *ortho* substitution takes place in unsubstituted phenols in good yields.

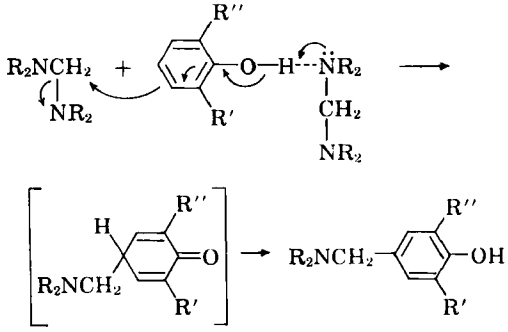
A considerable amount of confusion (4) exists as to the effect of pH on the Mannich reaction. Usually an acidic pH is not favorable for phenolic Mannich condensations. Too alkaline an environment also is not favorable since the sodium salt of naphthol (XXXV), under usual Mannich conditions, does not give the Mannich base XXXVI (Scheme VIII). Instead, it results in a resinous mass insoluble in both dilute alkali and dilute acid. The pH of the medium which affects unfavorably the formation and stability of the chelated transition state shown in Scheme III



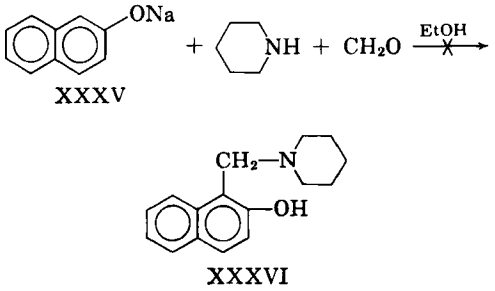
$RNH_2 =$ NH_2, $CH_3(CH_2)_3NH_2$

$R^1NH =$ $[CH_3(CH_2)_3]_2NH$, $(C_2H_5)_2NH$

Scheme VI



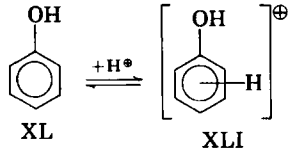
Scheme VII



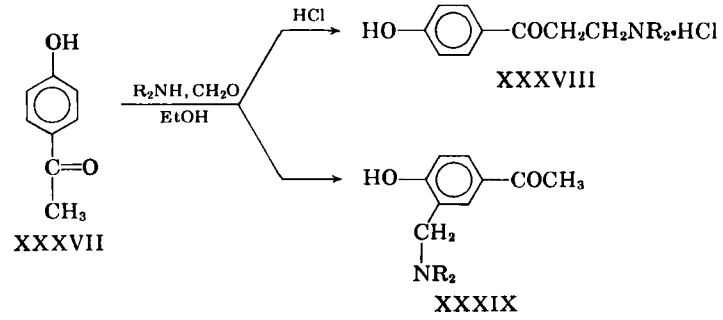
Scheme VIII

will delay the normal reaction and this in turn may result in the side reaction predominating.

Gautier and his associates (31) report the isolation of phenolic and ketonic Mannich bases from *p*-hydroxyacetophenone (XXXVII) with the reaction being carried out in basic and acidic media, respectively (Scheme IX). The products have been identified on the basis of the nuclear magnetic resonance spectra and also by chemical means. The acidic medium appears to deactivate the ring with respect to the Mannich condensation, whereas it will catalyze the enolization of the ketone, thus favoring the formation of the ketonic Mannich base, XXXVIII. This deactivation of the ring by acid may be attributed to the formation of a π-complex, XLI, between the phenol and the proton surrounding it. This results in the generation of a partial posi-



tive charge on the aromatic ring. It may be recalled that during the formation of the chelated transition state (Scheme III) the ring plays the role of a nucleophilic species and it is, therefore, evident that



Scheme IX

the aromatic ring carrying a partial positive charge will no longer effectively play the part of the nucleophilic species.

EXPERIMENTAL[2]

Essentially, the method followed by Varma and Nobles (32) was utilized for the preparation of VIII and IX.

5-Bromo-1-piperidinomethylisatin (VIII)—A mixture of 4.25 Gm. (0.05 mole) of piperidine, 11.3 Gm. (0.05 mole) of 5-bromoisatin, 5 ml. (0.06 mole) of formalin, and 50 ml. of ethanol (95%) was heated on a water bath for 1 hr. and then chilled in an ice bath. The crude product was filtered and crystallized from ethanol; yield 13 Gm. (81%), m.p. 135–136° [lit. (32) m.p. 135–136°].

N-N-3-Azabicyclo[3.2.2]nonylmethyl Isatin (IX)—A mixture of 7.3 Gm. (0.05 mole) of isatin, 6.25 Gm. (0.05 mole) of 3-azabicyclo[3.2.2]nonane, 5 ml. (0.06 mole) of formalin, and 50 ml. of ethanol (95%) was heated on a water bath for 1 hr. and chilled in an ice bath. The crude product was filtered and crystallized from ethanol; yield 9.2 Gm. (64.3%), m.p. 101–102°. [Lit. (32) m.p. 103–105°.]

2-Hydroxy-1-piperidinomethylnaphthalene (XI). Method A—A mixture of 1.44 Gm. (0.01 mole) of β-naphthol, 0.85 Gm. (0.01 mole) of piperidine, 1 ml. (0.01 mole) of formalin, and 3 ml. of ethanol was refluxed for 2 hr. on a water bath and chilled in an ice bath. The crude product was filtered and crystallized from ethanol; yield 1.6 Gm. (66%), m.p. 94–95°. [Lit. (33) m.p. 96°.]

Method B—From VIII—A solution of 3.23 Gm. (0.01 mole) of VIII in 15 ml. of ethanol was refluxed with 1.44 Gm. (0.01 mole) of β-naphthol, on a water bath for 15 min.; a yellow precipitate (2.1 Gm.) separated and was removed by filtration. This was found to be 5-bromoisatin, m.p. 255–256°. The filtrate was concentrated and chilled in an ice bath until crude XI weighing 1.8 Gm. (73%) separated. Crystallization from ethanol gave a colorless product, m.p. 94–95°. A mixed melting point determination with the product from *Method A* showed no depression. The infrared spectra of the products from both methods were found to be identical.

Phenyl-β-N-3-azabicyclo[3.2.2]nonylethyl Ketone Hydrochloride XIII. Method A—In a 100-ml. flask 2.4 Gm. (0.02 mole) acetophenone, 2.5 Gm. (0.02 mole) of 3-azabicyclo[3.2.2]nonane, 0.9 Gm. (0.03 mole) of paraformaldehyde, and 5 ml. of ethanol (95%) were mixed; the pH was adjusted to 5 with concentrated hydrochloric acid. The mixture was refluxed for 3 hr. The volume was reduced to one-half of its original volume and 30 ml. of acetone was added by stirring. The product separated on crystallization from ethanol; yield 3.4 Gm. (68%), m.p. 199–200°. [Lit. (34) m.p. 199–200°.]

Method B—From IX—A mixture of 1.2 Gm. (0.01 mole) of acetophenone, 2.84 Gm. (0.01 mole) of IX, and 5 ml. of ethanol was refluxed on a water bath for 1 hr. after adjusting the pH to 5 with concentrated hydrochloric acid; a yellow precipitate then appeared. It was filtered and identified as isatin, m.p. 197°. The filtrate was concentrated and 20 ml. of acetone was added; a light yellow precipitate, 1.9 Gm. (75%), separated; on crystallization from ethanol–acetone mixture this yielded colorless crystals, m.p. 198–199°. A mixture melting point determination with the sample from *Method A* showed no depression. The infrared spectra of both samples were found to be identical.

[2] All melting points were determined in a Thomas-Hoover capillary melting point apparatus and are uncorrected. The infrared spectra were determined on a Perkin-Elmer model 137 G Infracord spectrophotometer.

Spray-Congealed Formulations of Sulfaethylthiadiazole (SETD) and Waxes for Prolonged-Release Medication

Effect of Wax

By ANTHONY G. CUSIMANO* and CHARLES H. BECKER

Various spray-congealed SETD-wax products were prepared by pneumatic atomization using six waxes (white wax USP, glyceryl tristearate, carnauba wax, hydrogenated castor oil, cetyl alcohol NF, and glyceryl monostearate), two nozzle sizes, 0.20 and 0.25 cm. (0.08 and 0.10 in.) i.d., and three concentrations of the surfactant sorbitan monostearate (0, 1, and 5 percent w/w). The geometric mean diameters and the volume-surface diameters were affected primarily by the wax and the nozzle size used. All of the main effects, *i.e.*, wax, nozzle size, and concentration of surfactant, had a significant effect on the percent of SETD released in acid pepsin and alkaline pancreatin media. In general, the dissolution rate increased as the concentration of surfactant was increased. Faster dissolution rates were noted with formulations atomized through the smaller of the two nozzles. The most important factor that had an effect on the dissolution behavior of these products was the wax used in a particular formulation. This effect depends upon the following factors: the physical properties of the wax and the drug–wax particles, the chemical composition of wax, and the composition of the dissolution medium.

THE USE of spray-congealing techniques for modifying the physical, chemical, or physiological behavior of drugs has gained increasing attention within recent years. This process has proved to be an effective means of controlling the particle size of drug–wax particles. Therefore, spray congealing may be quite useful in controlling the dissolution behavior of drugs intended for prolonged-release medication.

In 1958, the utilization of this process was reported for the first time in the pharmaceutical literature (1). A sustained-release powder of sulfamethylthiadiazole (SMTD) was prepared by mixing the drug with molten hydrogenated castor oil and atomizing the resulting suspension. The same workers prepared a sustained-release powder of sulfaethylthiadiazole (SETD) by spray congealing a suspension of the drug using a centrifugal wheel atomizer (2).

Spray congealing has also been employed by others for enhancing the stability and palatability of such compounds as iron salts, vitamin A, and the B vitamins (3–7).

Scott *et al.* (8), were probably the first pharmaceutical investigators to conduct an extensive study on the production factors influencing the size and distribution of spray-congealed particles. In their work, stearic acid–ethylcellulose mixtures were spray congealed using a specially instrumented spray dryer and a centrifugal wheel atomizer. The variables studied included atomizer wheel speed, feed rate, and feed viscosity.

Recently, Cox (9) studied the effect of various production variables, *i.e.*, siphon height and atomizing pressure, on the particle size and dissolution behavior of spray-congealed particles of SETD-beeswax and SETD-glyceryl tristearate.[1] John and Becker (10) studied the effect of surfactant, *i.e.*, sorbitan monooleate, on the particle size and dissolution behavior of similar spray-congealed particles.

The purpose of this investigation was to determine the effect of several production and formulation variables on the particle size and dissolution behavior of various spray-congealed particles. This work was intended primarily to evaluate the effect of various waxes on the parameters studied. The experimental work conformed to a factorial design such that all of the possible combinations of the treatment variables were formulated and investigated.

EXPERIMENTAL

Materials—All materials used in this study, except some of the waxes, conformed to USP or NF specifications, or were of analytical reagent quality. The drug, sulfaethylthiadiazole (SETD) was obtained from American Cyanamid Co.

The six waxes used were white wax USP, glyceryl

tristearate, carnauba wax, hydrogenated castor oil,[2] cetyl alcohol NF, and glyceryl monostearate,[3] and these were designated as W_1, W_2, W_3, W_4, W_5, and W_6, respectively.

The surfactant, sorbitan monostearate,[4] was used in some of the formulations in concentrations of 0, 1, and 5% w/w, and these were designated as S_0, S_1, and S_5, respectively. Sorbitan monostearate was used rather than some of the more commonly employed surfactants because it is a solid at room temperature. This would eliminate or reduce the tendency of the spray-congealed products to become tacky.

Preparation of Spray-Congealed SETD-Wax Particles—Spray-congealed formulations were prepared using the six waxes as the carrier for the drug SETD. All formulations contained about 25% SETD by weight. These were atomized through one of two external-mixing pneumatic nozzles[5] having orifice diameters of 0.20 and 0.25 cm., and the latter were designated as N_8 and N_{10}, respectively. The apparatus used has been described previously (10).

The wax for a particular formulation was melted in a stainless steel beaker which was immersed in an oil bath maintained at 100 ± 2°. The sorbitan monostearate, where included, was dissolved in the melted wax after which the SETD was added. Suspension of the SETD was maintained by means of a variable speed mixer. A Teflon siphon tube, wrapped with a heating tape, maintained the melted wax–drug mixture at the desired temperature (100 ± 2°) while it passed up to the pneumatic nozzle. Dry air was passed through the nozzle at a pressure of 40 p.s.i. This was sufficient to deliver the melted wax–drug mixture to the nozzle, and then to bring about atomization. A higher pressure could not be used since this would have caused the molten mixture to congeal on the sides of the collection chamber rather than within it. Since the air was not heated prior to entering the nozzle, the latter was equipped with a heater and a thermocouple monitoring system. Thus, the spraying operation could be performed without interruption due to clogging of the nozzle by melted wax–drug congealing inside. The nozzle orifice was directed into the collection chamber such that the particles of melted wax–drug congealed in the air. This resulted in a very fine powder which was collected and then passed through a No. 30 U.S. Standard sieve before conducting any of the subsequent experiments.

Particle-Size Measurements—Particle-size measurements were conducted on each of the 36 products using a microscopic method. The microscope was equipped with a calibrated ocular micrometer. Calibration was performed with a stage micrometer, and each division of the ocular micrometer was equivalent to 1.175 μ at a magnification of 10×.

In order to measure the individual particles, deagglomeration of the samples was necessary. Adequate deagglomeration was attained by briefly shaking a small amount of the sample in a test tube with an aqueous solution of polysorbate 80[6] and washed sand.

Assay of Spray-Congealed SETD-Wax Particles—Each product was formulated to contain about 25% SETD by weight. Chemical analyses were then performed on each product to determine the exact SETD content.

Each sample was dissolved in hot chloroform, and the SETD was extracted with five portions of 0.10 *N* HCl. The acid extract was then assayed for SETD content by the Bratton-Marshall (11) procedure using a Klett-Summerson photoelectric colorimeter with a No. 54 filter.

A standard curve for SETD was also prepared and was found to be valid up to a concentration of 2.0 mg.% in SETD. Appropriate blank and standard solutions were run with all samples assayed.

In Vitro Dissolution Studies—The dissolution behavior of all spray-congealed products was determined using a rotating-bottle apparatus (12), and a procedure similar to that of Robinson and Swintosky (2).

About 0.5 g. of the product, equivalent to 0.1200 g. of SETD, as determined by prior assay, was accurately weighed into 90-ml. screw-capped bottles. To each bottle 60 ml. of acid pepsin medium (pH 1.1) was added. Duplicate samples were allowed to rotate end over end at a speed of 46 r.p.m. in a water bath maintained at 37 ± 1°. Samples were removed at specified time intervals, *i.e.*, at 0.25, 0.5, 0.75, 1.0, 1.25, 1.5, and 2 hr.

The samples were filtered, and an appropriate aliquot of the filtrate was then assayed for SETD content. If all of the SETD were released during the dissolution run, then the solution assayed would be equivalent to 2.0 mg.% in SETD.

Samples were also run for extended periods of time, *i.e.*, 24 and 48 hr., although equilibrium was not attained in acid medium.

Dissolution studies were also conducted in an alkaline environment in a similar manner. Again the equivalent of 0.1200 g. of SETD was weighed into each bottle, and 60 ml. of alkaline pancreatin medium (pH 8.3) was added. Samples were removed for assay at 0.25, 0.5, 0.75, 1.0, 2.0, 3.0, 4.0, and 6.0 hr. Studies were also conducted for a period of 12 hr. at which time equilibrium was attained in most of the samples.

RESULTS AND DISCUSSION

Manufacture of Spray-Congealed SETD-Wax Products—Most of the spray-congealed SETD-wax products were fine powders that initially were free flowing. The SETD-carnauba wax products were the best from an esthetic viewpoint since they were very fine, free-flowing powders that were not tacky. In addition, they showed no tendency to become lumpy in storage. The SETD-glyceryl monostearate products showed the greatest tendency to become lumpy.

The ease with which the products were sprayed depended primarily upon the wax and the nozzle size used. The production rates were greatest when white wax, glyceryl tristearate, and cetyl alcohol were used as the drug carrier. Formulations con-

taining glyceryl monostearate were the most difficult to spray, and these became increasingly difficult to spray as the concentration of sorbitan monostearate in the formulation was increased. This was due primarily to an increase in the viscosity of the melt when sorbitan monostearate was added. Sorbitan monostearate had little effect on the ease of production of the other formulations.

As one would expect, the larger nozzle (0.25 cm.) gave higher production rates for a given wax formulation.

Particle-Size Analysis—The particle sizes of the various spray-congealed SETD-wax products were found to be log-normally distributed. The particle-size distributions of the SETD-white wax products are shown in Fig. 1. These linear log-probability plots are typical of those obtained with all of the waxes used in this study. Other investigators have observed the log-normal distribution of spray-congealed SETD-wax particles (9, 10).

[a] Significant at $p < 0.01$. [b] The wax–nozzle interaction was not significant at the 5% level.

The geometric mean diameters ($\bar{d}$) and the volume-surface diameters (d_{vs}) of these particles were affected primarily by the wax and the nozzle size used. Sorbitan monostearate had no significant effect on these parameters (Table I).

The smallest particles, in terms of the geometric mean diameter, were produced from the SETD-glyceryl monostearate formulations atomized through the 0.20-cm. nozzle. These averaged about 20 μ. The SETD-white wax and the SETD-glyceryl tristearate formulations gave the smallest particles from the 0.25-cm. nozzle. These averaged about 25–26 μ. The largest particles were produced from the SETD-cetyl alcohol and the SETD-hydrogenated castor oil formulations atomized through the 0.25-cm. nozzle (Table II).

The results obtained in this study are in qualitative agreement with those reported by Scott *et al.* (8). These workers found that the volume-surface diameter of spray-congealed stearic acid particles varied inversely with the feed viscosity. In the present study, the SETD-cetyl alcohol formulations gave the highest values for the volume-surface diameter, *i.e.*, about 32 μ for the 0.20-cm. nozzle, and about 42 μ for the 0.25-cm. nozzle. These formulations, prior to atomization, were observed to be the least viscous of all the waxes used. The SETD-glyceryl monostearate formulations were found to be the most viscous, and these gave relatively low values for the volume-surface diameter. This was particularly the case with the glyceryl monostearate formulations atomized through the 0.20-cm. nozzle where the volume-surface diameter was about 23 μ.

The wax and nozzle size used also had a significant effect on the other micromeritic parameters, *i.e.*, bulk density, percent porosity, and specific surface. Sorbitan monostearate had no significant effect on these parameters (Table III).

[a] Significant at $p < 0.01$.

The SETD-carnauba wax products were the least porous, and these gave relatively low values for the specific surface. In addition, the SETD-white wax products were the most porous, and these gave relatively high values for the specific surface. In general, products atomized through the smaller of the two nozzles gave higher percent porosities.

In Vitro Dissolution Behavior of Spray-Congealed SETD-Wax Products—The drug SETD is much more soluble in an alkaline medium than in an acid medium. Therefore, the dissolution rate was much less in acid pepsin medium than that in alkaline pancreatin medium. In all samples, the percent of SETD released in the alkaline medium was much greater than that in the acid medium during the same time interval (Table IV).

A greater amount of SETD was released during the initial 15-min. period than in any subsequent 15-min. period. The percent of SETD released, from samples containing no sorbitan monostearate, during the initial 15-min. period in acid pepsin medium may be taken as an estimate of the amount of drug partially exposed on the surface of the particles and any free drug present in the samples. However, in all samples, the percent of SETD released during the initial 15-min. period in alkaline pancreatin medium was greater than that in acid pepsin medium. This may be due to the nature of the medium itself, as well as to the solubility factor mentioned previously. The alkaline medium contains ox bile extract which is a powerful surfactant due to the presence of bile salts. Apparently, a significant amount of the spray-congealed particles are emulsified, disintegrated, or solubilized during the initial 15-min. exposure to the alkaline medium. A similar effect was noted, even in the acid medium, for those samples containing sorbitan monostearate.

All of the main effects, *i.e.*, wax, nozzle size, and concentration of sorbitan monostearate, had a significant effect on the percent of SETD released in both media (Table V).

Effect of Sorbitan Monostearate—In general, the dissolution rate increased significantly as the concentration of sorbitan monostearate was increased. This was noted with four of the six waxes used, *i.e.*, white wax, glyceryl tristearate, carnauba wax, and hydrogenated castor oil (Figs. 2 and 3). The surfactant lowers the interfacial tension between the drug–wax particles and the dissolution medium, particularly since some sorbitan monostearate may be extracted into the medium. Therefore, wetting of the drug–wax particles is promoted, and the amount of drug released increased with the concentration of surfactant. In addition, the dissolution medium can more readily enter the porous, waxy clusters and dissolve the drug within the matrix. The drug is then transported away from the matrix into the medium. Some of the drug–wax particles may actually be emulsified, disintegrated, or solubilized, allowing the drug to be more readily dissolved due to an increase in the total surface area available to the medium.

An unusual surfactant effect was noted in the case of the SETD-cetyl alcohol and the SETD-glyceryl

[a] Significant at $p < 0.01$. [b] The wax–sorbitan monostearate interaction was not significant at the 2.5% level.

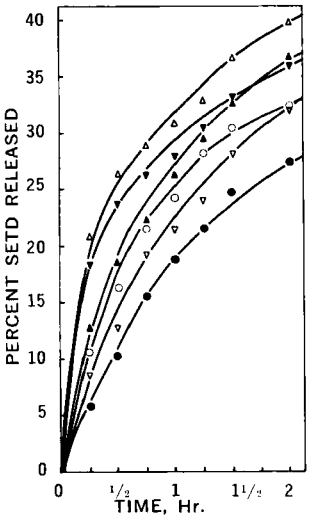

Fig. 2—In vitro *dissolution behavior of SETD-carnauba wax particles in acid pepsin medium. Key:* ▽, $N_8S_0W_3$; ▲, $N_8S_1W_3$; △, $N_8S_5W_3$; ●, $N_{10}S_0W_3$; ○, $N_{10}S_1W_3$; ▼, $N_{10}S_5W_3$.

monostearate particles, especially in acid pepsin medium. The amount of drug released from these particles decreased as the concentration of sorbitan monostearate increased (Fig. 4). This phenomenon may be explained in the following manner.

Although all of the waxes used in this study are insoluble in water, cetyl alcohol and glycerol monostearate differ from the others, with the exception of hydrogenated castor oil, in that they are somewhat hydrophilic. That is, cetyl alcohol and glyceryl monostearate are capable of being hydrated in an aqueous medium. The presence of sorbitan monostearate in the formulation reduces the tendency of these particles to become hydrated. This is to be expected since sorbitan monostearate has an HLB value of 4.7 and would make the drug–wax matrix more lipophilic than the one containing no sorbitan monostearate.

Effect of Nozzle Size—The nozzle used in atomizing the SETD-wax formulations also had a significant effect on the dissolution behavior of the spray-congealed particles. Faster dissolution rates were noted with formulations atomized through the 0.20-cm. nozzle than with the same formulations atomized through the 0.25-cm. nozzle.

This effect was apparently due to a difference in the total surface area of the particles prepared from

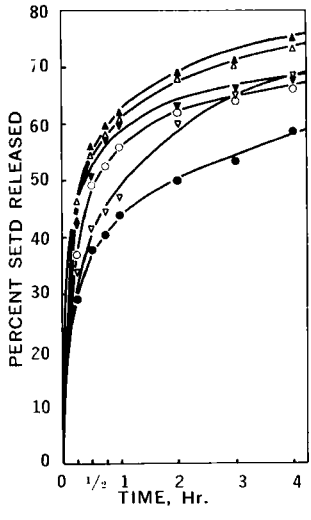

Fig. 3—In vitro *dissolution behavior of SETD-carnauba wax particles in alkaline pancreatin medium. Key:* ▽, $N_8S_0W_3$; ▲, $N_8S_1W_3$; △, $N_8S_5W_3$; ●, $N_{10}S_0W_3$; ○, $N_{10}S_1W_3$; ▼, $N_{10}S_5W_3$.

the two nozzles. Particles having smaller volume-surface diameters, and therefore larger specific surfaces, were those prepared with the smaller of the two nozzles. For example, the SETD-white wax particles prepared with the 0.20-cm. nozzle had an average specific surface of 2,124 cm.²/g., whereas those prepared with the 0.25-cm. nozzle had an average specific surface of 1,858 cm.²/g. Similar results were obtained with the other waxes.

Effect of Wax—The most important factor that had an effect on the dissolution behavior of the spray-congealed SETD-wax particles was the wax used in a particular formulation. The effect of wax apparently depends upon the following factors: the physical properties of the wax and the drug–wax particles, the chemical composition of the wax, and the composition of the dissolution medium. For all waxes the amount of drug released after a certain time interval in alkaline pancreatin medium was greater than that in acid pepsin medium. This effect is due to three factors. The drug SETD is much more soluble in the alkaline medium than in the acid medium. Secondly, the alkaline medium can emulsify, disintegrate, or solubilize the particles much more readily. Finally, the constituents of these waxes, notably the fatty acids and fatty alcohols, would be expected to be more soluble in the alkaline medium. In addition, the fatty esters, present in some of the waxes, may be more readily degraded or hydrolyzed in the alkaline medium.

SETD-White Wax Particles—The SETD-white wax particles released between 10 to 33% of the drug after a 2-hr. exposure to acid pepsin medium. In alkaline pancreatin medium these particles released between 55 to 80% of the drug after 2 hr. and between 80 to 95% of the drug after 6 hr. Sorbitan monostearate had a significant effect in increasing the dissolution rate from these particles.

The primary constituents of white wax are cerotic acid and the fatty ester, myricyl palmitate. The fatty acid would be more soluble in the alkaline medium than in the acid medium. In addition, the ester may be more readily hydrolyzed in the alkaline medium. These factors would facilitate the disintegration of these particles and increase the dissolution rate in the alkaline medium.

SETD-Glyceryl Tristearate—The SETD-glyceryl tristearate particles released between 20 to 42% of the drug after 2 hr. in acid pepsin medium. In alkaline pancreatin medium these particles released between 25 to 60% of the drug after 2 hr. and between 38 to 80% of the drug after 6 hr. Again sorbitan monostearate significantly increased the amount of drug released after a certain time interval.

The dissolution rate was greater in the alkaline medium than in the acid medium. It is possible that the ester is more susceptible to alkaline-catalyzed hydrolysis than to acid-catalyzed hydrolysis.

In general, the SETD-glyceryl tristearate particles gave the slowest dissolution rates of the six waxes used. This was the case in both media, and it is not surprising since glyceryl tristearate consists essentially of the triglyceride ester of stearic acid. Triglyceride esters of fatty acids are less susceptible to either acid- or alkaline-catalyzed hydrolysis than are the corresponding di- or monoglyceride esters.

However, the SETD-glyceryl tristearate particles released more drug in the acid medium than the SETD-white wax particles, whereas the former released less drug in the alkaline medium. This effect is also believed to be due to the chemical composition of the two waxes. White wax contains a high percentage of free fatty acids, notably cerotic acid. These fatty acids are essentially insoluble in the acid medium, but are readily soluble in the alkaline medium. Glyceryl tristearate contains no free fatty acids, but does contain a high percentage of glyceryl tristearate. The latter is slowly hydrolyzed in acid and alkaline media, and therefore the glyceryl tristearate particles disintegrate quite slowly. In addition, these particles were not readily wetted by the dissolution media.

SETD-Carnauba Wax Particles—The SETD-carnauba wax particles released between 27 to 40% of the drug after 2 hr. in acid pepsin medium (Fig. 2). In alkaline pancreatin medium these particles released between 50 to 70% of the drug after 2 hr. (Fig. 3) and between 65 to 78% of the drug after 6 hr. Sorbitan monostearate increased the amount of drug released from these particles in both media.

Carnauba wax consists chiefly of myricyl cerotate with smaller amounts of myricyl alcohol, ceryl alcohol, and cerotic acid. Its fatty alcohol and fatty acid content probably accounts, in part, for the higher dissolution rates in the alkaline medium.

Again it was noted, just as with the SETD-glyceryl tristearate particles, that the SETD-canauba wax particles released more drug in acid pepsin medium than the SETD-white wax particles, whereas the former released less drug in alkaline pancreatin medium than the SETD-white wax particles. Carnauba wax contains a lower percentage of free fatty acids (acid value from 2 to 10) than white wax (acid value from 17 to 24), but the former contains a somewhat higher percentage of fatty esters (ester value from 75 to 85) than white wax (ester value from 72 to 79).

For the same reason, the SETD-carnauba wax particles released more drug in the alkaline medium than the SETD-glyceryl tristearate particles since glyceryl tristearate contains no free fatty acids.

SETD-Hydrogenated Castor Oil Particles—The SETD-hydrogenated castor oil particles released between 35 to 48% of the drug after 2 hr. in acid pepsin medium. In alkaline pancreatin medium these particles released between 75 to 92% of the drug after 2 hr. and between 92 to 100% of the drug after 6 hr. Sorbitan monostearate also increased the amount of drug released from these particles in both media.

Hydrogenated castor oil consists primarily of partially hydrogenated glyceryl triricinoleate. It contains very little free fatty acids (acid value of 2) but a significant amount of hydroxyl groups (hydroxyl value of 158). A relatively large proportion of its fatty ester content is in the form of triglycerides of unsaturated fatty acids (iodine value of 38). These factors may account, in part, for the observed dissolution behavior of these particles.

The hydroxyl groups in this wax make it somewhat hydrophilic such that the particles were easily wetted, particularly in the alkaline medium. This would also account for the relatively high dissolution rates in the acid medium. The latter effect is also due to the relatively low free fatty acid content. In addition, the unsaturated fatty esters present in this wax are apparently more susceptible to acid- and

alkaline-catalyzed hydrolysis than the saturated fatty esters present in some of the other waxes.

SETD-Cetyl Alcohol Particles—The SETD-cetyl alcohol particles released between 32 to 44% of the drug after 2 hr. in acid pepsin medium (Fig. 4). In alkaline pancreatin medium these particles released between 85 to 93% of the drug after 2 hr. and between 90 to 96% of the drug after 6 hr. (Fig. 5). In these products the amount of drug released decreased as the concentration of sorbitan monostearate increased.

The official alcohol is a mixture of solid, fatty alcohols consisting chiefly of cetyl alcohol. Although it is insoluble in water, it is capable of being hydrated. Thus, of the waxes used in this study, cetyl alcohol is one of the most hydrophilic. Glyceryl monostearate and hydrogenated castor oil are also somewhat hydrophilic. This property is evident from the fact that these particles were readily wetted by the dissolution media, particularly in the alkaline medium.

Nearly complete removal of the drug was attained from these particles after about 6 hr. in the alkaline medium. The dissolution rates in the acid medium were relatively high also, that is, compared with the SETD-white wax and the SETD-glyceryl tristearate particles. The latter effect is due to the hydrophilic character of cetyl alcohol and also to the fact that this material contains no free fatty acids or fatty esters.

SETD-Glyceryl Monostearate Particles—The SETD-glyceryl monostearate particles released between 45 to 51% of the drug after 2 hr. in acid pepsin medium. In alkaline pancreatin medium these particles released between 83 to 97% of the drug after 2 hr. and between 86 to 100% of the drug after 6 hr. In these products the amount of drug released decreased slightly as the concentration of sorbitan monostearate increased. This phenomenon was not as pronounced as in the case of the SETD-cetyl alcohol particles.

Glyceryl monostearate is a wax-like ester. It has an acid value of less than 5, and is somewhat hydrophilic since each molecule of the pure ester contains two hydroxyl groups. For this reason, this material was readily wetted in both media. The dissolution behavior of these particles was quite similar to that of the SETD-cetyl alcohol particles since both are somewhat hydrophilic. They differ in that the SETD-glyceryl monostearate particles released more drug in the acid medium.

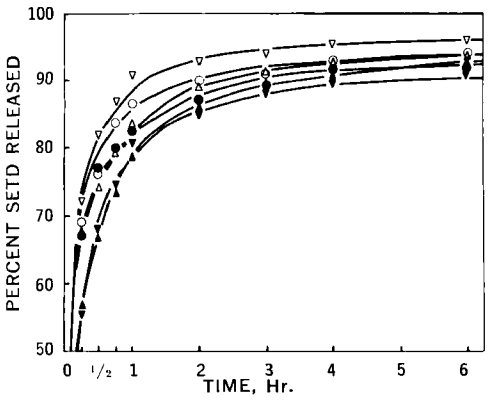

Fig. 5—In vitro *dissolution behavior of SETD-cetyl alcohol particles in alkaline pancreatin medium. Key:* ▽, $N_8S_0W_5$; ▲, $N_8S_1W_5$; △, $N_8S_5W_5$; ●, $N_{10}S_0W_5$; ○, $N_{10}S_1W_5$; ▼, $N_{10}S_5W_5$.

It is interesting to note the tremendous difference in the dissolution behavior between these particles and the SETD-glyceryl tristearate particles. In both media, the SETD-glyceryl monostearate particles released significantly greater amounts of the drug than the SETD-glyceryl tristearate particles. This may have been due to the combined effect of the following factors: the hydrophilic character of glyceryl monostearate, the fact that the SETD-glyceryl monostearate particles can be readily emulsified or disintegrated, and that glyceryl monostearate may be more readily hydrolyzed in acid and alkaline media than glyceryl tristearate.

In Vitro Dissolution Model for Spray-Congealed SETD-Wax Products—The dissolution data obtained in this investigation did not give a linear relationship when plotted in accordance with existing theories (13, 14). For example, a plot of the percent of SETD remaining in the particles ($C_e - C$) *versus* time was not linear. This would indicate that the dissolution kinetics were not zero order. In addition, a plot of the logarithm of the percent of SETD remaining in the particles *versus* time was not linear. Therefore, the dissolution process did not conform to first-order kinetics either. In accordance with the theory of Higuchi (14), the percent of SETD remaining in the particles was also plotted *versus* the square root of time. Again nonlinear relationships were obtained for all of the waxes used.

The nonlinear relationships obtained are not surprising in view of the assumptions involved in these theories. The most important assumption in both the Noyes-Whitney (13) dissolution rate law and the theory of Higuchi (14) is that the total surface area of the tablet or particles does not change significantly during the dissolution run. Therefore, it is presumed that the drug–wax matrix is completely inert or unaffected by the dissolution medium. However, this was not the case in the present study. For all of the waxes used, the particles were emulsified, disintegrated, or solubilized by the dissolution medium. This was particularly true in the alkaline medium.

A dissolution model previously proposed by Cox (9) was utilized in the present study. This model is represented by the equation

$$C = C_e[1 - (1 + t/d)^{-c}] \qquad \text{(Eq. 1)}$$

where C is the percent of drug in solution at a particular time (t), C_e is the percent of drug in solution at equilibrium, and c and d are constants for a particular formulation. This dissolution model is not a linear function of the unknown parameters c, d, and C_e. Therefore, a nonlinear least-squares curve fitting procedure was used to estimate the above parameters. Different values for c, d, and C_e were used in a computer program, and the estimated percent of drug in solution ($\hat{C}$) at a particular time (t) was calculated. The experimental values of the percent of drug in solution (C) at a particular time (t) were compared with the estimated values. The quantity $\Sigma\ (C - \hat{C})^2$ was minimized by adjusting the values of the three parameters, c, d, and C_e (Table VI).

TABLE VI—ESTIMATED[a] PARAMETERS FOR DISSOLUTION MODEL IN ACID PEPSIN MEDIUM

Wax	Sample Symbol	$C = C_e[1 - (1 + t/d)^{-c}]$ C_e	c	d	SS for Error	Instantaneous Dissolution Rate, $(c/d)C_e$

[a] Modified Gauss-Newton least-squares method (15).

Specifically, the procedure used in performing the nonlinear least-squares fit was a modified Gauss-Newton least-squares method (15). Setting up of the computer program and subsequent operations with the computer were performed in cooperation with the University of Florida Computing Center using an IBM 360 computer.

Equation 1 can be shown to be equivalent to

$$\log (C_e - C) = \log C_e + c \log d - c \log (t + d) \quad \text{(Eq. 2)}$$

Therefore, a plot of the logarithm of the percent of drug remaining in the particles $(C_e - C)$ *versus* the logarithm of $(t + d)$ should give a straight line.

In general, the agreement between the experimental and the predicted values for the dissolution data was good. The experimental data for the dissolution of SETD from the SETD-carnauba wax particles in acid pepsin medium are plotted on the lines predicted from the dissolution model in Fig. 6. The plot of the logarithm of the percent of SETD remaining in the particles *versus* the logarithm of $(t + d)$ was found to be reasonably linear. A similar plot for the dissolution of SETD from the SETD-cetyl alcohol particles in alkaline pancreatin medium is shown in Fig. 7. Again a reasonably good linear relationship was obtained.

Thus, the data obtained in this investigation, both in acid pepsin and in alkaline pancreatin media, agreed reasonably well with those predicted from a dissolution model in accordance with Eq. 1.

However, it should be pointed out that no correlation could be demonstrated between the instantaneous dissolution rates, *i.e.*, $(c/d)C_e$, and the parameters obtained from the particle-size studies, notably the specific surface. A possible explanation for this is as follows. In the particle-size studies, only individual particles were measured and not clusters of particles. In the samples used for the dissolution studies, many clusters of particles were also present in addition to the individual, spherical

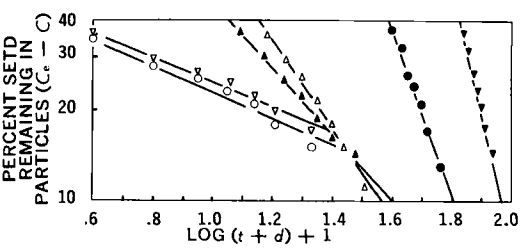

Fig. 6—Experimental data for percent SETD released from SETD-carnauba wax particles in acid pepsin medium, plotted on lines predicted from dissolution model. Key: ●, $N_8S_0W_3$; △, $N_8S_1W_3$; ○, $N_8S_5W_3$; ▼, $N_{10}S_0W_3$; ▲, $N_{10}S_1W_3$; ▽, $N_{10}S_5W_3$.

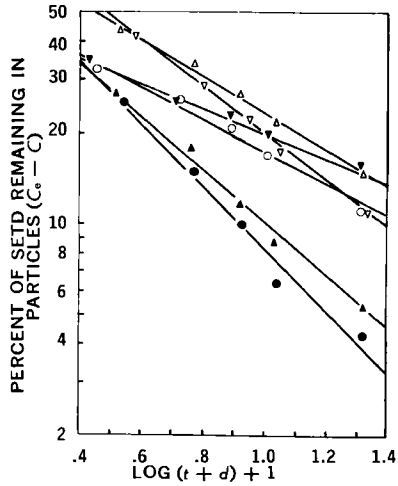

Fig. 7—Experimental data for percent SETD released from SETD-cetyl alcohol particles in alkaline pancreatin medium, plotted on lines predicted from dissolution model. Key: ●, $N_8S_0W_5$; Δ, $N_8S_1W_5$; ○, $N_8S_5W_5$; ▼, $N_{10}S_0W_5$; ▲, $N_{10}S_1W_5$; ▽, $N_{10}S_5W_5$.

particles. This would be the case particularly for those products that were somewhat tacky. Another factor is that many of the spray-congealed SETD-wax products were not easily wetted by the dissolution medium, at least initially. Some of the particles tended to agglomerate upon coming in contact with the dissolution medium, particularly in acid pepsin medium. As the dissolution process continued, these agglomerates were subsequently emulsified, disintegrated, or solubilized as were the individual particles.

Tumor-Inhibitory Activity of Pyrrolizidine Alkaloids

By C. C. J. CULVENOR

Eighteen pyrrolizidine alkaloids and several derivatives have been examined for tumor-inhibitory properties. Of these, 10 compounds show significant activity against one or more test tumors. Heliotrine, lasiocarpine, monocrotaline, spectabiline, and senecionine are highly active against the Walker 256 (intramuscular) system. The activity pattern is consistent with the tumor-inhibitory action being associated with the allylic ester function which imparts alkylating ability and is also responsible for hepatotoxicity.

PYRROLIZIDINE ALKALOIDS are found typically in species of *Senecio* (family *Compositae*, tribe *Senecioneae*), *Crotalaria* (family *Leguminosae*, tribe *Genistae*) and the subfamilies *Heliotropioideae* and *Boraginoideae* of the family *Boraginaceae* (1). They occur also in other genera of the tribes *Senecioneae* [*e.g.*, *Cacalia*, *Emilia* (2), *Erechtites*] and *Genistae* [*e.g.*, *Adenocarpus* (3), *Cytisus* (4)] as well as in the unrelated genera *Eupatorium* (*Compositae*) (5), *Thesium* (*Santalaceae*) (6), *Planchonella* (*Sapotaceae*) (7), *Lolium* (8), and *Festuca* (9) (*Gramineae*). The ability of some alkaloids of the group to cause an unusual chronic liver disease in animals (10) has promoted extensive study of their chemical and toxicological properties (*e.g.*, *References 1, 11, 12*). Platyphylline (I) (13) has no hepatotoxic action and has found use in the U.S.S.R. as an antispasmodic.

Received May 15, 1967, from the Division of Applied Chemistry, C.S.I.R.O. Chemical Research Laboratories, Melbourne, Australia.
Accepted for publication October 9, 1967.
This work has been carried out partly in collaboration with Cancer Chemotherapy National Service Center, Bethesda, Md., and partly in collaboration with Abbott Laboratories, North Chicago, Ill. Thanks are due to both organizations for permission to publish the screening results.

Platyphylline (I) (13) has no hepatotoxic action and has found use in the U.S.S.R. as an antispasmodic.

Received May 15, 1967, from the Division of Applied Chemistry, C.S.I.R.O. Chemical Research Laboratories, Melbourne, Australia.
Accepted for publication October 9, 1967.
This work has been carried out partly in collaboration with Cancer Chemotherapy National Service Center, Bethesda, Md., and partly in collaboration with Abbott Laboratories, North Chicago, Ill. Thanks are due to both organizations for permission to publish the screening results.

The hepatotoxic alkaloids have an irreversible, antimitotic effect on liver cells which leads to grossly enlarged cells and cell nuclei (megalocytosis). They cause chromosome breakage (14) and are mutagenic (15). These properties suggested possible antitumor activity, and in 1958, several alkaloids from this laboratory were screened by the Cancer Chemotherapy National Service Center against sarcoma 180, lymphoid leukemia L1210, and Ehrlich ascites cell culture. Weak activity against sarcoma 180 was observed with heliotrine, but heliotrine *N*-oxide, seneciphylline, sarracine *N*-oxide, jaconine hydrochloride, lasiocarpine, and retronecine hydrochloride were inactive. About the same time, Pukhal'skaya *et al.* (16) also investigated the action of heliotrine, viridiflorine, platyphylline, seneciphylline, lasiocarpine, and heliosupine on a transplanted hepatoma in mice, Ehrlich's adenocarcinoma, and sarcoma 45. The hepatoma was inhibited to the extent of 21% by lasiocarpine, 10% by seneciphylline, and 8% by heliotrine. The Ehrlich's tumor was inhibited 54% by heliosupine and 19% by seneciphylline. Sarcoma 45 was inhibited 28% by heliosupine and 17% by lasiocarpine.

More extensive testing has since been undertaken in response to two developments. First, it was recognized that the hepatotoxic alkaloids, which conform to the general formula (II), behave chemically as alkylating agents and that several of their biological properties are those of alkylating agents (17). This provided further rationale for possible antitumor action, and in particular, suggested testing against the Walker 256 tumor systems which are sensitive to alkylating agents (18). Second, a high level of activity was observed in monocrotaline (III), which was isolated as the tumor-inhibitory constituent of *Crotalaria spectabilis* (19). The main activity was against adenocarcinoma 755, the highest degree of inhibition achieved being 95% at a dose of 90 mg./Kg. Further testing by CCNSC disclosed activity against plasmacytoma, but in many other systems monocrotaline was inactive (20). This paper reports results of testing of 18 alkaloids, three alkaloid *N*-oxides, and two derivatives from this laboratory and discusses the structure-activity pattern within the series in relation to tumor-inhibitory activity.

EXPERIMENTAL

Alkaloids—The alkaloids examined were either available from other studies or were reisolated by the techniques previously employed. They are crispatine (21), echinatine (22), europine (23), fulvine (21), heleurine (23), heliotrine (24), jacobine (25), jaconine hydrochloride (25), lasiocarpine (24), 1-methylenepyrrolizidine (26), 1-methoxymethyl-1,2-epoxypyrrolizidine (27, 28), 1-methoxymethyl-7β-hydroxy-1,2-dehydropyrrolizidine (28), monocrotaline (29), senecionine (30), seneciphylline (25), spectabiline (31), and supinine (23).

Alkaloid N-Oxides—Sarracine *N*-oxide was isolated directly from *Senecio mikanioides* Otto (32). Heliotrine *N*-oxide and monocrotaline *N*-oxide were prepared by oxidation of the parent alkaloids as described previously (*References 24* and *29*, respectively).

Derivatives—Retronecine hydrochloride was obtained by hydrolysis of monocrotaline using the procedure described by Culvenor and Smith (31). 1 - Chloromethyl - 7α - hydroxy - 1,2 - dehydropyrrolizidine was prepared by reaction of heliotridine with thionyl chloride as described previously (33).

Testing Procedure—Testing was carried out in accordance with the Cancer Chemotherapy National Service Center protocols (34). The dosing regimens are as follows: adenocarcinoma 755, in mice, one dose daily for 11 days; lymphoid leukemia L1210, in mice, one dose daily until death; sarcoma 180, in mice, one dose daily for 7 days; Walker 256 (intramuscular), in rats, one dose daily for 4 days; Walker 256 (subcutaneous), in rats, one dose daily for 5 days, by dose response at 4 doses; and plasmacytoma 1, in hamsters, one dose daily for 15 days. The criterion for significant activity accepted by CCNSC is at least 58% decrease in tumor size compared with controls for solid tumors, and 25% increase in survival time for leukemia 1210 and 50% inhibition of KB cell culture at a concentration of 1 mcg./ml.

Results—The results obtained are summarized in Table I, in which plus and minus signs indicate whether the level of inhibition in the particular tumor system meets the criteria given in the preceding paragraph. Detailed results are given for the active compounds in Table II, replicates being omitted except where it seemed advisable to indicate a variability or reproducibility in the level of action.

DISCUSSION

It is apparent from Table I that tumor-inhibitory activity is widely exhibited among pyrrolizidine alkaloids, 10 of 23 compounds tested being active at a significant level against one or more tumor systems. The tumors most frequently inhibited were the Walker 256 (intramuscular) and adenocarcinoma 755, the level of activity against the former being in some cases very high. Thus complete or nearly complete destruction of this tumor was observed with heliotrine (IV) at a dose level of 125 mg./Kg., and T/C values[1] below 30 were attained at fairly low dose levels with fulvine (V), heliotrine *N*-oxide (VI), lasiocarpine (VII), monocrotaline (III), spectabiline (VIII), and senecionine (IX).

Against adenocarcinoma 755, the strongest activity is found in the bases of monocrotaline type, monocrotaline, spectabiline, and fulvine, and in the chloro-derivative (X); crispatine (XI), heliotrine, and supinine (XII) exhibit weak activity. Heliotrine, lasiocarpine, monocrotaline, and the chloro-

[1] T/C is the ratio of tumor weight or survival time of test animals to control animals, expressed as percent.

X

derivative were active against sarcoma 180, and lasiocarpine, spectabiline, and fulvine were active (the last two only weakly) against the Walker 256 (subcutaneous) system. Activity was essentially confined to the solid tumors, all compounds being inactive against leukemia 1210 and KB cell culture, except that heliotrine, lasiocarpine, europine (XIII) and heleurine (XIV), evinced weak activity against the latter (ED_{50} 15–23 mcg./ml.) at a level lower than the CCNSC minimum standard (ED_{50} 1 mcg./ml.).

The active alkaloids are all of the allylic ester type which have a potential for alkylation (17). Of the bases of monocrotaline type (11-membered ring diesters), monocrotaline and spectabiline are highly active against WM and CA, fulvine of moderate activity, and crispatine of weak activity overshadowed by a high toxicity. The alkaloids of senecionine type (12-membered ring diesters) also appear to be generally of too high toxicity to the host to permit expression of activity against the

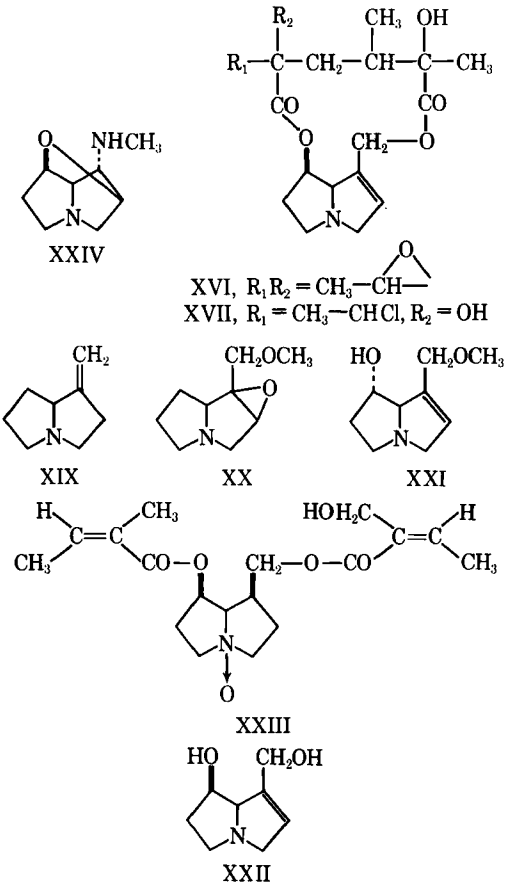
[a] The tumor systems are CA, adenocarcinoma 755; LE, lymphoid leukemia L1210; SA, sarcoma 180; WM, Walker 256 intramuscular; WA, Walker 256 subcutaneous; KB, cell culture; EA, Ehrlich ascites; Pl, plasmacytoma 1. [b] T/C is the ratio of tumor weight or survival time of test animals to control animals, expressed as percent. [c] A denotes testing by Dr. R. J. Stein, Abbott Laboratories, North Chicago. C denotes testing by Cancer Chemotherapy National Service Center, Bethesda, Md. [d] ED_{50} in mcg./ml.

tumors, although senecionine itself has shown high activity against WM at low dose levels. Senecionine (XV) almost meets the criterion for activity against WM at a dose of 50 mg./Kg., while jacobine (XVI) and jaconine (XVII) are inactive at nontoxic levels. Of the bases of heliotrine type (esters of monocarboxylic acids) heliotrine is strongly active against WM, lasiocarpine moderately active, and echinatine (XVIII), supinine, and heleurine essentially inactive.

On the whole, these results suggest that there is for tumor-inhibitory activity, an optimum level or set of levels for one or more of the interrelated properties, water solubility, lipid-water partition coefficient, and base strength. High hepatotoxicity is correlated with low water solubility and low base strength (2) as found for example in lasiocarpine and the macrocyclic diester alkaloids, excepting monocrotaline which has a moderate water solubility occasioned by two hydroxyl groups. Echinatine is very highly soluble in water and weakly hepatotoxic; it might be expected to have only poor access to the target cells. Supinine and heleurine are more highly basic than the other alkaloids [pK_a 9.6, compared with heliotrine, 8.5, and lasiocarpine, 7.8 (35)] and are so highly ionized at physiological pH that they partition only very slightly into a lipid phase (2). Thus monocrotaline and heliotrine appear to come closest to the optimum in properties although spectabiline and lasiocarpine, both more lipid-soluble, are almost as active. The restriction of even weak KB activity to the esters of monocarboxylic acids and the fact that europine (highly soluble in water) and heleurine (high base strength) are among the weakly inhibitory bases is probably a reflection of the different environment of the cell culture. High water solubility is apparently less damaging to activity in this system than high lipid solubility. Alternatively, there is the intriguing possibility that the macrocyclic alkaloids are too bulky to pass the cell membranes.

The structure-activity pattern and the high activity against the intramuscular Walker 256 system both support the idea that activity is connected with the alkylating ability of the allylic ester system (II). It is also significant that the chloro-derivative (X), which has the ester grouping replaced by a halogen atom and has strong *in vitro* alkylating reactivity, is active against two test tumors. Insofar as they have been tested, the other nonester alkaloids (XIX, XX, and XXI), as well as retronecine (XXII) and sarracine *N*-oxide (XXIII), the ester of a saturated pyrrolizidine aminoalcohol, have no inhibitory action. Thus antitumor activity seems quite definitely to be associated with the same functional region in the molecule as hepatotoxicity (17). A recent report by Aizenman *et al.* (36) that loline (XXIV) and *N*-methylloline have a weak inhibitory action against Ehrlich carcinoma suggests that it may become necessary to extend this concept of the structure-activity relationship, but this is scarcely warranted on the present evidence. It is possible that the shape of the pyrrolizidine ring, which is not unlike that of a purine, is another factor in promoting activity.

The *N*-oxides of monocrotaline and heliotrine were tested in the hope of achieving a more favorable ratio of desired activity to acute toxicity. Heliotrine *N*-oxide is active against the Walker 256



tumor but superiority over the tertiary base has not been demonstrated. Monocrotaline *N*-oxide is inactive against CA and LE but has not been tested against WM. From the same point of view, heleurine and supinine were also disappointing. Both are weakly hepatotoxic and thus presumably capable of biological alkylation, but do not appear to shorten the life span of rats (37). They were essentially inactive at the dose levels used.

The known acute and chronic effects of pyrrolizidine alkaloids militate against successful exploitation of the tumor-inhibitory activity which has been uncovered in this group of compounds. However, it may be possible to utilize the selective and apparently permanent and complete antimitotic action exerted by the alkaloids on parenchymal liver cells. If there is a similar effect on tumor cells derived from liver cells, it may be possible to achieve complete inhibition of hepatomas while leaving the liver capable of sustaining life for long periods.

Prediction of Stability in Pharmaceutical Preparations XV

Kinetics of Hydrolysis of 5-Trifluoromethyl-2′-deoxyuridine

By HANS J. NESTLER* and EDWARD R. GARRETT†

The antiviral 5-trifluoromethyl-2′-deoxyuridine, F_3TdR, is hydrolyzed by hydrogen ions and solvent to 5-trifluoromethyluracil, F_3T, and deoxyribose. The F_3T is readily hydrolyzed to 5-carboxyuracil by hydroxyl ion attack on the undissociated and anionic species. At elevated temperatures, 5-carboxyuracil is decarboxylated by hydroxyl ion catalysis to uracil. The F_3TdR is readily hydrolyzed to 5-carboxy-2′-deoxyuridine by hydroxyl ion attack on the undissociated and anion species through an observable kinetic intermediate at high alkalinity, probably 5-hydroxydifluoromethyl-2′-deoxyuridine. The optimum pH range for stabilization is 1–4 where the half-life at 30° is 280 days. The material is readily degraded at pH 7.4 where 1.5 days is the half-life at 30°.

THE KNOWN antitumor and antiviral activity of the 5-halogenated uracils and 5-halogenated pyrimidine nucleosides (1) initiated the synthesis of 5-trifluoromethyl-2′-deoxyuridine (trifluorothymidine, F_3TdR, I) (2). The structure I sterically resembles 5-iodo-2′-deoxyuridine, IDU, which is active against *Herpes simplex* in human keratitis (3). The van der Waals radius of iodine is 2.15 Å. and that of the trifluoromethyl group is 2.44 Å. (4). Since a degradation product of IDU, 5-iodouracil tends to antagonize its activity (5), complete studies of its kinetics of solvolysis were performed in order to determine optimum conditions for pharmaceutical stabilization (6–9).

Preliminary experiments with F_3TdR, I, have

Received January 22, 1968, from the College of Pharmacy, University of Florida, Gainesville, FL 32601
Accepted for publication March 15, 1968.

Keyphrases

Pyrrolizidine alkaloids
Tumor inhibition–pyrrolizidine alkaloids
Lipid solubility—antitumor activity
Alkylating ability—antitumor activity

Prediction of Stability in Pharmaceutical Preparations XV

Kinetics of Hydrolysis of 5-Trifluoromethyl-2′-deoxyuridine

By HANS J. NESTLER* and EDWARD R. GARRETT†
