THE PHARMACEUTICAL or cosmetic chemist, involved with the problems of topical formulations, is often concerned with the potential of his product for skin irritation and sensitivity and confused by the number of possible local toxicity tests. This review is an attempt to outline the nature of the topical toxicities and the principal test methods for irritation and sensitivity. The vital problems of systemic toxicities, such as acute and subacute studies, as well as special tests (*e.g.*, teratogenesis) are not the province of this review.

INCIDENCE OF SKIN REACTIONS

Considering the widespread use of toiletries and cosmetics the incidence of skin reactions is remarkably low (1–4). This is primarily due to the efforts of reputable manufacturers to detect potential hazards before a product is marketed and thus minimize the possibility of adverse side reactions in normal use. The ultimate goal of toxicity studies is to insure safety or harmlessness under the proposed use conditions (5). Calculated risk is sometimes necessary. This must be based on knowledge of compound sensitivities, such as the use of bromoacid dyes in lipsticks or certain resins in nail polishes. The potential toxicities of cosmetics and toiletries have been discussed in several excellent reviews (3, 6–12).

Statistics on the incidence of skin reactions from cosmetics and toiletries are mainly derived from studies by dermatologists on clinical patients (2, 6, 7, 13, 14). Yet dermatitic skin exhibits about 10–50 times the reaction incidence of intact skin (15, 16). Complaint letters to manufacturers vary from 0.2–1.2 per 100,000 units sold (2, 17, 18), while dermatologists report 2–4% reactions (3). It must be remembered that the data on complaint letters assume each unit sold represents a separate user. This is a fallacy since one consumer may actually use multiple packages (19), which would raise the complaints per user. The most valid procedure is to conduct consumer tests in which the product is placed with a relatively large number of users, and each subject is questioned as to irritation side effects as well as product performance.

Judgments of safety and size of human test panels are based on the prediction of 95% certainty of safety. There has been an assumption that the results with 200 test subjects will apply

Received from the Pharmaceutical Research and Development Department, Hoffmann-LaRoche, Inc., Nutley, NJ 07110

to the population at large (20). Yet if 200 subjects contained no reactors, this would denote 95% confidence that not more than 1.5% of the general public will become sensitized. Even in the absence of an adverse reaction on 30,000 persons tested, it is 95% certain that 1 in 10,000 would still be liable to skin reactions (21, 22). Thus, if there are 10 million users, 1,000 cases of dermatitis will probably arise. The prediction of 99.9% safety in a mass population would require an impossibly huge number of subjects (23). The degree and type of use is the cardinal factor. A 0.5% frequency of sensitization (1:200) might be tolerated if the material is in limited distribution and its efficacy is great. However, in a mass distribution cosmetic, 1 in 200 reactions would necessitate further prerelease studies. An incidence of 1 or less in 100,000 is the desirable goal for mass distributed products.

Primary irritation is rather unusual in a modern commercially available product, although new agents are of concern. Agents capable of inducing skin reactions in 1 in 100 or even 1 in 1,000 subjects are readily detected, but it becomes increasingly difficult to predict the irritation or sensitization potential of a preparation causing skin reactions in 1 in 10,000 or even 1 in 100,000. (This is particularly true for topical agents having weak photosensitizing properties.) It is this particular type of agent that concerns those who are responsible for passing on the safety of products that are used by millions of people.

TOPICAL TESTING

No ideal single test procedure exists which will adequately measure irritation and sensitivity potential. There is rather a spectrum of tests to be selected by the trained toxicologist who can secure data and translate it into probable effects in man, and balance these effects against the intended use and possible misuse of the product.

Simpler and less expensive tests are first performed to determine the range of the problems. Usually, animal eye and primary skin irritation tests must first prove favorable before more complex tests are undertaken. The further experimental design should be geared to indicate the possible type injury, the extent or seriousness of the injury, and the margin of safety that prevails under the most extreme conditions of use (24). Yet, even with these considerations it must be understood that tests which are absolutely predictive are, for the present, beyond practical accomplishment (20).

While opinions concerning the value of animal studies vary (25–27), no responsible person would dispense with animal skin tests. If properly judged, on the basis of degrees of variability and not on a "yes–no" basis, animal tests help predict dangers of severe human irritation and, to some degree, the concentrations that may safely be tolerated by man. The tests have their greatest value as comparative tools. The data, with adequate controls, are related to other substances whose hazards have been defined by time and experience. In addition, toxic doses provide an estimate of the margin of safety under normal usage (24). Additional animal studies may be necessary even after a product has been introduced into clinical usage. As the major effects of a preparation are characterized by studying it in detail in man, a more suitable laboratory model, to simulate more closely these actions in man, may be sought by rescreening a wide variety of animals.

Argument continues as to the great differences between human and animal skin. No one can doubt this. Yet it appears more profitable to be concerned with what, if any, correlations can be obtained between animal testing and human clinical experiences, than to be concerned with differences. The mounting costs of clinical tests virtually dictate initial animal tests as an aid in screening and predicting toxicity potential.

Whenever possible, the intended marketing product and package should be studied. If feasible, the program should include parallel studies of a similar product of known safety. If any question of an individual component's safety or "newness" is involved, it should be examined separately. Ultimately, tests must be performed on man under conditions of actual use. Kennon has discussed many of these usage tests in a recent review of toiletry technology (28).

IRRITATION REACTIONS

Primary irritants are substances which damage skin by direct cytotoxic action (134). Reactions are divided according to severity. A strong irritant has been defined as one which will cause 100% of subjects to react in 24 hr. at a definite reasonable concentration (29).

Mild primary irritants exert their reactions after repeated exposure or overexposure. These include soaps, detergents, and solvents that also present a more serious problem of possible sensitization. Mild irritation may become chronic or cumulative after a number of exposures resulting in "skin fatigue." Conversely, after daily exposure to mild irritants, the irritated skin often adapts to these changes, and recovers from and

becomes resistant to further irritation, resulting in "skin hardening" or "skin accommodation" (132).

Generally speaking, agents that cause primary irritation are not selective in their action and will ultimately affect any normal skin if allowed to act, in sufficient concentration, for a long enough period of time. A precise frame of reference is essential for valid assessments of safety. Unfortunately, there is no universal statement that can be made about the type of chemical which will irritate healthy skin. While the pH of normal skin is mildly acid, there is little reason to believe that mildly alkaline products are irritating to the skin. Excellent tests (30) have demonstrated that except for relatively high alkaline or acid materials, pH *per se* is an unreliable criterion for predicting irritancy to skin. Substances which are easily oxidized or reduced are usually more likely to irritate; *e.g.*, hair dyes with strong reducing agents or depilatories containing sulfides. The products most commonly associated with reactions of the primary irritant type are antiperspirants, depilatories, and permanent wave preparations. Many liquid "automatic" or "roll on" mascaras and an occasional cream-type mascara produce false positive primary irritant reactions when patch tested under occlusive coverings. These misleading irritant reactions are apparently caused by solvents and can be avoided by using nonocclusive patch tests (31).

IRRITATION TESTING

Eye Irritation—There are few materials that are unlikely to enter the eye accidentally. Consequently, investigation of animal eye irritancy is the starting point of virtually all safety evaluation programs. The most widely used procedure has been and is the "Draize" test and its modifications (32–53), intended to provide a measure of the irritancy of a product by exposing rabbits under conditions which would resemble an accidental human exposure, such as splashing a substance into the eye. Many descriptions, modifications, and critiques of the test have been published (26, 32, 53–60).

The Draize test (32) scores the effects on the cornea, iris, and conjunctiva of rinsed and unrinsed material after 24, 48, and 72 hr., and 4 and 7 days. The emphasis is on corneal and iris lesions. Eyes that do not clear by the seventh day are considered to have contained severe irritants. For substances covered under the Federal Hazardous Substances Act, a modified procedure has been proposed (61). To aid in interpretation, a colored set of photos are available from FDA (62).

Variabilities in Draize results may stem from personal error, sample size, time of release of an irritant from a formulation, or sample drainage (54). The most viscous samples tend to remain in the eye longer and are more likely to localize in one area, increasing the possibility of irritation. The competence of the trained observer is always the most important factor. While there is considerable variability between laboratories testing the same sample by the "same" Draize techniques (26, 60), the tests have served quite well in delineating moderate and severe irritants. Their main value may lie in comparing an unknown material with control substances whose potential for producing human eye injuries is known through experience. As with other tests, problems arise with nonirritating or mildly irritating substances, or comparison of related formulations in product development.

Variant scoring systems of the Draize test and modifications have yielded greater reliability for comparisons between products. Kay and Calandra (55) score the extent of irritation, its persistency, and the over-all consistency of the data. Test materials are given tentative ratings on the basis of the scores obtained from all 3 tissues (cornea, iris, and conjunctiva) within the first 96 hr. These tentative ratings are adjusted according to the mean total scores at various specified times. Gaunt and Harper (63) judge the conjunctival reaction that is accompanied by persistent and severe injury to the cornea and iris persisting for more than 5 days. The arbitrary scoring system ranges from 1 for a nonirritant to 5 for a severe irritant. S. P. Battista (54) varies exposure conditions to the irritant quantitatively between no-effect and maximum-effect levels. Interpretation and comparison of data are reduced to a single number which represents a time measurement for achieving a level of response. In addition, it enables an estimate of the maximum exposure time that will be tolerated for a given irritant. Time–response curves have been plotted to estimate the time required for a product to produce a given degree of opacity, iritis, or conjunctivitis. When the procedure is repeated with different sample concentrations, a comparative formulation study can have significance.

Several investigators have noted difficulty in correlating rabbit eye irritation with the experience found in humans (2, 26, 57, 60, 64). The rabbit eye is considered more sensitive than that of man. Nevertheless, Rieger and G. W. Battista (26), in their review of the correlation be-

tween animal and human tests, have cited the example of the hair neutralizer which was indicated to be safe according to the rabbit eye test, but which proved to be irritating in human usage.

Study of records of eye accidents in a liquid detergent factory provide a check against the predictive value of the standard rabbit eye irritation tests (21). The animal and human sources were compared on the basis of the number of days required for the eyes to recover completely. Irritation was more severe in the rabbit eyes than in the eyes of the factory workers subjected to actual accidental exposure. In rabbits there was a high incidence of corneal opacity, with some eyes requiring up to 91 days to recover. The effects in humans were limited to conjunctivitis, and all cases recovered within 2 days. The degree and type of irritation produced in the Rhesus monkey eye appeared to more closely approximate that which resulted from exposure of the workers' eyes. Buehler and Newmann (56) studied the response of rabbit and monkey eyes to surfactant solutions and recommend use of the monkey for eye irritancy tests.

In testing some shampoos consideration must be given to the nature of the active ingredients. They may act as anesthetics when placed in the eye. This is dangerous since the user may not be aware that the shampoo has entered the eye and damage may result before it is washed out. To test for anesthetic effects the guinea pig blinking test is used (65).

Aerosol sprays represent a difficult area in which there is lack of standardization for eye tests. Some laboratories apply sprays directly into the rabbit eye. The direct spray may cause eye damage due to the physical impingement of the particles as well as the cooling due to the propellant. This response may mask the eye damage which may be due to the active ingredients. Other workers allow the propellant to evaporate and instill the residue in the eye. This removes the possibility of damage that may be produced by pressure or chilling and allows the experimenter to test only the active ingredients.

The eye irritation test has become so important that further development of a prospective product with excellent sales potential is often arrested purely on the basis of conclusions drawn from eye irritation studies. In fact, some cosmetic firms use ophthalmic irritancy routinely as *the* principal evaluation criterion for checking all new products early in their developmental stages. Products should not be rejected solely on the basis of a questionable Draize, or any other eye test, unless gross injury is detected. The question is to resolve irritancy *versus* possible injury (59). If the product is desirable on a market basis, it would be well to try another species of animal, such as the dog or monkey. If the one or two other species show positive reactions, it is likely that human eye irritation would result.

Skin Irritation—Methods devised to measure skin irritancy are adequate for screening out stronger and moderate irritants, but are virtually insensitive in the low irritancy range. Materials are either placed in single contact with human or animal skin for varied time periods, at varied concentrations, or repeatedly used. These tests determine not only primary irritation but also "skin fatigue," when the skin reacts due to a succession of insults of a subthreshold intensity.

The skins of the mouse, rat, guinea pig, rabbit, miniature pig, and sheep have been used to screen compounds for primary irritant activity. Histologically, their skins do not closely resemble human skin, but from a responsive point of view, they all show changes when irritated. The rabbit and guinea pig are most frequently chosen (66). Materials which cause simple primary irritation of the skin of rabbits generally can be expected to cause a similar response in humans, but not necessarily in all humans. If appreciable edema occurs in rabbit skin, the material should be suspected as a possible vesicant to human skin.

Draize (32) has also proposed the most widely used skin irritation test. Patch tests are read of suspected irritants on the abraded and intact skin of rabbits. A "primary irritation index" is reached. An index of 0–2 indicates mild irritation potential; 2–6, moderate; and over 6 is rated severe, with 8 a maximum.

Roudabush (67) compared the dermal effects of a large number of diverse organic compounds in the guinea pig and rabbit. The results of primary irritation tests showed that the intact guinea pig skin test is as sensitive as, or more sensitive than, the rabbit skin test in eliciting skin reactions. Levenstein and Wolven (65) claim a close correlation between the response to graded patch tests in the rabbit and observations noted in man.

Carter and Griffith (21) point out the pitfalls in placing sole reliance on animal data for assessing primary irritant hazard. They compared a number of unrelated household products by the Draize rabbit irritation index and human patch tests. The products included toilet soap, a general purpose granular detergent, a light-duty liquid detergent, isopropyl alcohol, and a hair dressing. Agreement between the two methods was poor. The product that gave the least reaction in the

human test, the general purpose granular detergent, gave the most severe reaction on the rabbit, and would be classified as a severe irritant on the basis of the animal data.

The Draize rabbit test (32) or Roudabush guinea pig t[illegible](67) are adequate for screening out stronger ir[illegible]ts but are insensitive in the low irritancy range. To obtain responses to moderate or low irritants, exaggerated conditions of exposure of the skin are required to get an incidence of reaction which may be used as a base for extrapolation. These procedures are comparative to decide whether an irritancy is greater than, equal to, or less than some reference substance. The most practical product reference is one whose irritancy potential has become known through widespread use. The detection of moderate and low irritants usually involves increasing the visual sensitivity of the erythema response by injecting a dye substance, which concentrates in the injured areas as a result of increased vascular permeability. Trypan blue has been most widely used (64, 68–71). Recently, use of sulphan blue has been advocated for greater sensitivity (72, 73).

Finkelstein, Laden, and Miechowski (69) have combined the trypan blue technique with formaldehyde presensitization and occlusive patch testing of varied animal skin to give a fairly sensitive and reliable indicator of the irritancy of agents which fall in the low range of the Draize test. The test, omitting presensitization and dye injection, has been adapted for humans (64). Results of the tests indicate whether it is worthwhile to proceed to sensitivity studies and usage trials with a new formulation. With this technique and all similar procedures, selection of proper control formulation is important.

Kligman (29, 134) has critically discussed quantitative measurement of irritants on human skin. He has attempted to use statistical analysis to find the concentration of agent to reach an irritant response in 50% of subjects (ID_{50}). For strong irritants, this value is read directly from a curve of a percentage of reactors *versus* concentration. For weak irritants, patches are applied to the same site for a minimum of 10 days to reach a cumulative frequency plot which estimates the number of days required to cause 50% of the sampled population to develop a threshold irritant response. By inspecting the curves it is usually possible to judge whether 2 agents differ significantly.

Studies of very minor states of irritation or "mildness" use all available tests (21, 74–77). The procedures of Justice, Travers, and Vinson (76) use human arm immersion (HAI), human patch tests, repeat mouse patch tests (RAP), and water transmission through rat and rabbit excised skin. Both the RAP and HAI tests utilize the principle of eliciting a response by repeated exposures of the same area to the test material. In the HAI test, the quantitative difference between two products lies in the number of exposures necessary to achieve a prescribed level of irritation. In the RAP test, the number of exposures is kept fixed and a quantitative measure of the effect of these exposures is made by histological examinaion of the excised skin. The concentration of the test material can also be varied in the RAP test to obtain additional information about the effect of a product on the skin. The most sensitive test for revealing relatively small differences in mildness between the products appeared to be the HAI. The RAP test served best as a preliminary screening of topical products. Materials showing a significant irritation in the RAP test, at standard testing levels, are not given further consideration for use in products. Should the mildness ratings be favorable, studies are continued, employing the other tests. The water transmission test correlates well with the other mildness tests (120, 121). Opdyke and Burnett (77) immerse guinea pigs in products up to their axillae for 4 hr. on 3 successive days, grading mildness on a 0–10 scale.

SENSITIVITY REACTIONS

Allergic sensitization reactions form by far the largest proportion of toiletry and cosmetic reactions (3). An eczematous allergen has been defined as a substance that is not primarily irritating on first exposure but which, in animals or human beings of appropriate genetic constitution, causes the development of a sensitization. Subsequent contact with concentrations that are not irritating to unexposed or nonsensitized individuals produces a reaction (78). An individual may use a cosmetic for years without reacting and then suddenly acquire an allergenic hypersensitivity to the particular material (79). An antigen–antibody system is required for sensitization reactions.

Cross-sensitization is a special form of sensitization which occurs fairly frequently. People affected are not only sensitive to the substance to which their skin was originally exposed, but also to other substances that are chemically related. The closer the relationship and the longer the contact, the greater the incidence and degree of sensitization. Cross-sensitization may be provoked equally by substances which form a related compound as the result of metabolic changes in

the body (9). Kinmont (80) has compiled a list of varied products which are involved in cross-sensitization. Oxidation hair dye cross-sensitivity is fairly common in sensitive individuals (81, 82).

There is hardly a cosmetic or toiletry product to which someone has not become allergic at some time or other. The most frequent sensitizers are the paraphenylenediamine oxidation type of hair dye and the formaldehyde resin in nail lacquers. Perfumes, lipsticks, and sunscreening agents are also among the more frequent offenders. Artificial colorants, principally the halogenated fluoresceins (eosins) in lipsticks, are probably the most frequent single cause of allergic reactions to cosmetics (83). Paraphenylenediamine hair dyes are undoubtedly potent sensitizers to the majority of the population. Yet considerably fewer than 1% of women who dye their hair develop contact allergy. This is probably explained by the fact that the dye is mainly applied to the hair and not to the scalp. While perfumes are often strong sensitizers, the number of skin reactions is small. Perfumes composed of easily oxidizable aldehydes, phenols, and ketones are more liable to cause reactions than those with the more difficultly oxidizable alcohols and esters. With surface-active agents there is great variance in dermal toxicity. Yet, in general, their order of toxicity is cationic > anionic > nonionic (32, 33).

SENSITIVITY TESTING

Delayed type sensitivity reactions are rarely seen if an agent or product is applied to exposed intact skin. Patch tests in humans and animals and intradermal injections in animals aid in provoking the signs of sensitivity.

Animal testing is useful for preliminary screening before any human sensitization testing. Calnan (84) has reviewed the role of animals in contact sensitivity studies. The guinea pig has proved to be the most useful. The most widely accepted animal technique is that of Landsteiner (85), using the guinea pig. Instead of a patch technique, the material is injected intradermally every other day for 10 applications. Following a 2-week rest a challenging dose is injected and the resulting response is compared to the preceding reactions. Sensitization is present if the challenging dose causes a greater skin response than that evoked by any earlier injection. The major limitation of guinea pig testing is the range of sensitivity. Strong sensitizers may be picked up earlier in the guinea pig than in man, but the weak reactors may not be eliminated. These latter must be studied employing human patch test techniques. While humans can react to 1 p.p.m. of a potent sensitizer, such as dinitrochlorobenzene, it is not normally possible to make guinea pigs react to dilutions greater than 1:25,000 (84). However, with current guinea pig sensitization procedures, one may conclude that if a material produces a significant number of reactions, it is also likely to produce sensitizations in human testing (86, 87). Eczematous changes, similar to those occurring in man, have been produced in guinea pigs by first treating their skin with squalene, sodium lauryl sulfate, sorbitan monolaurate[1] (88), and polysorbate 80[2] (89), all of which stimulate acanthosis.

Patch tests, usually with occlusion, enhance sensitivity testing and are universally used, both with animals and humans (12, 16, 20, 26, 90–95). Human patch tests are the province of the dermatologist. Yet, virtually all products are tested by patch test, so it is important to be aware of the varied tests and their limitations. All predictive procedures are designed around the basic technique of insulting the skin of a group of test subjects one or more times and then, after a lapse of time to permit a reactive state to develop, challenging with another application of the material. Substantially increased reactivity to the challenge is taken as evidence of sensitization.

The Schwartz-Peck (S-P) test (96, 97) is the pioneer "prophetic patch test." New products are tested, using a closed patch, on at least 200 subjects. A control of an old formula with a known record of safety is used. If the new formula shows more reactions than the control, it is deemed unsafe. To secure usage data, a 4-week paired-comparison use test of the cosmetic on the same 200 subjects is recommended before trial sale. Trial sale, the final step by S-P definition, is the sale and use of 5,000–10,000 units in one community. The test has certain inherent defects. False positives may occur, since borderline primary irritants can sometimes produce reactions which can be confused with sensitizations when only a patch test reading is made. More important are the false negatives, which are due to the fact that the single application of a small amount of the product is often inadequate to produce sensitization except in the case of strong allergens. Most of the predictive burden is shifted to the use test, but this part of the procedure is probably numerically inadequate to reveal low reaction rates. Also, some products are used only once weekly, or every 4 to 6 weeks,

[1] Marketed as Span 20 by Atlas Chemical Industries, Wilmington, Del.
[2] Marketed as Tween 80 by Atlas Chemical Industries, Wilmington, Del.

and cannot be evaluated for sensitization in a 4-week use test.

The Traub-Tusing-Spoor (T-T-S) (98) and the Brunner-Smiljanic (B-S) (99) tests are extensions or completions of the S-P to widen usage, increase frequency of applications, and use of a larger area of contact with the test substance. Regardless, all these tests suffer in that trial periods are too short, since many chemicals do not cause sensitization until used for many months.

Draize (100) and Shelanski (101) independently published methods which have come to be known as the "repeated insult" test or the Draize-Shelanski test. The test substance is applied every other day for 10 or 15 exposures to 200 subjects. Two weeks after the last exposure the subjects are challenged at a new site. Draize randomizes the exposure. Shelanski applies the occlusive repetitive applications to the same site to give a higher yield of sensitized subjects but tends to magnify the irritant effects of the test formulation. The resulting so-called "skin fatigue," due to summation of irritations under the test conditions, may make the differentiation between sensitization and irritancy more difficult.

Neither the Draize nor the Shelanski procedures specifies the anatomical site to which the patch should be applied or uses a high enough concentration to allow prediction of sensitization in a small panel of volunteers. Maibach and W. Epstein (93) apply the patches to limbs, since the lymph nodes are crucial to development of allergic sensitization of the contact type. The highest nonirritating concentration is used. With these modifications it was possible to detect the marked sensitization and potential of tetrachlorosalicylanilide (TCSA), which would not be predicted with Draize use concentrations.

A judgment of the value of these tests can be made using agents whose sensitizing capacities have become rather well-defined through extensive use. Kligman (20) evaluated a large series of topical drugs and concluded that the S-P, T-T-S, and Draize procedures were all almost useless. The Shelanski test, while still inadequate, was somewhat better.

The basic problem with all the discussed predictive tests is the attempt at utilizing larger and larger numbers of subjects in lieu of a sensitive method of detection (84). The requirements of large numbers of subjects restricts evaluation to those investigators with access to such populations, so that fewer preparations can receive adequate testing. Furthermore, the same subjects are retested too often, which results in false positive reactions because of conditioned irritability (102). What is needed is to enhance the sensitizing capacity of weak allergens to the point where smaller groups of subjects yield more positive responses.

The judicious use of irritation will improve the sensitivity of any animal or human test. Simultaneous use of mild irritants, the allergen, and occlusion appear to aid penetration and enhance sensitization. These combined techniques are used in the triple-freeze (16) and maximization procedures (20, 91, 103, 133).

The triple-freeze technique consists of irritation of the patch test site by freezing for 3 sec. with dichlorodifluoromethane.[3] Occlusion is maintained for 48 hr. after application of a maximal nonirritating concentration of the test compound. The procedure is repeated an additional two times at 5-day intervals (for three exposures). The challenge or eliciting patch test is applied 10 days after the last freeze. While the triple-freeze method has considerable merit, yielding greater sensitivity results than the previously discussed prophetic methods, it does not give adequate reproducible results (84).

The "maximization" provocative patch test of Kligman (20, 91, 103, 133) was primarily designed to yield allergenicity ratings for individual substances, not complex mixtures, finished products, or formulations. It does not seek to predict the ultimate evidence of sensitization in the consuming public, but rather classifies substances according to the sensitization capabilities they exhibit under an arbitrarily defined set of experimental conditions. Essentially, the test consists of a course of five 48-hr. exposures of an allergen to a single skin site which has been previously inflamed by treatment with aqueous 5% sodium lauryl sulfate (SLS). Chemical irritants, such as SLS or dimethylsulfoxide (DMSO) appeared superior to physical agents such as ultraviolet radiation or Scotch tape. Potential sensitizers are divided into 5 grades ranging from weak to extreme allergenic potential (133). A failure to sensitize a single subject demonstrates almost with certainty that the compound is not a significant sensitizer.

The maximization procedure was used to test a large group of diverse substances including cosmetics, drugs, and industrial contactants. There was good correlation between usage and the maximization test results. Sensitization, within limits, was found to be proportional to the surface concentration of the allergen and not to the total amount of allergen. High concentrations are required for weak allergens. The optimal concen-

[3] Freon 12. E. I. du Pont de Nemours & Co., Wilmington, Del.

tration for the challenge patch testing is the highest nonirritating amount, up to a maximum of 10%. The vehicle was an important factor. Petrolatum was the most generally useful and effective. There is some concern that use of occlusion and other methods of facilitating skin damage, such as use of SLS, may create a false impression of allergenicity (95). There is little danger of this if proper judgment is used and further testing is done. Grief (109) utilized the maximization procedure to study a series of compounds used in fragrance formulation. A panel of 25 adult volunteers was tested with 5% sodium lauryl sulfate for 24 hr., and a 48-hr. occlusive patch was applied with high concentrations of the test material. No sensitization was noted.

Most screening series consist of numerous tests, since the greater the number the greater the likelihood of detecting the allergen. This on the whole renders patch testing expensive, tedious, and time consuming. Patch test screening could be simplified by using mixtures which permit screening for several allergens with a single patch. Mixtures sharply reduce the number of patches required in a screening series without curtailing the number of chemicals screened. E. Epstein (104) has demonstrated the usefulness of patch testing mixtures of topical medicaments, rubber additives, and antiseptic agents. Topical medicaments were most suitable for combination. In general, the irritancy of mixtures seems to be related to the sum of irritancy of their components.

Results of predictive tests, as now constituted, serve as guides rather than absolute criteria of sensitization and irritancy. The tests function best when the test substance is used on a comparative basis against control formulations, with known behavior, in actual usage. Positive reactions do not invariably signify sensitization and negative reactions do not rule it out. False positive reactions may be caused by substances which do not produce dermatitis under normal conditions of use but become primary irritants under closed patch test conditions. This is particularly true of depilatories, permanent wave preparations, shampoos, hair tonics, certain hair preparations, and cosmetics containing volatile solvents (11). These should be tested by the "open" method in which the compound is simply rubbed on a small area of the forearm. False negative reactions may also be encountered when the degree of sensitivity is low and when the area involved by the dermatitis is composed of thin skin, such as the eyelid. If the product in question produces a negative patch test result, it should be retested by actual use at the normal site of application.

Further study of the basic mechanisms of sensitization is required before the tests can be significantly improved. Alterations in current test procedures can increase or decrease the number of reactors but do not help in answering the crucial question of the relationship between sensitization results in laboratory test and in consumer usage. Properly supervised consumer use tests are still required to supplement the laboratory studies. The perfect predictive patch test for allergic sensitization has not been devised. This will ideally involve an *in vitro* test easily employed in the laboratory. Until there is additional information on the pathogenesis of delayed hypersensitivity, this approach is improbable. In the interim, predictive patch testing remains a useful tool. Hopefully, in the years to come, we will learn more about the molecular basis for allergic sensitization. It may then be possible to predict sensitizers on the basis of molecular structure (93).

PHOTOSENSITIVITY REACTIONS

Exposure to light of a particular wavelength will evoke allergic photosensitivity in a predisposed individual (39–51, 105, 106). The phototoxic reactions may be manifested as an exaggerated sunburn or as an eczematous response with pigmentation. The wavelength of light to set off a response closely corresponds to the absorption peak of the offending agent and is referred to as the "action spectrum." Most of the phototoxic materials have an action spectrum in the ultraviolet band between 2800 to 4300 Å. (3, 105). Once an individual becomes photoallergenic the reaction time becomes shorter with subsequent exposures. The eruption usually subsides in a few days leaving no residual pigmentation.

The mechanisms involved in photosensitivity are poorly understood (107). Photosensitizers probably act by virtue of photodynamic action or interaction of light and a photosensitizer in the presence of oxygen to cause a destructive photochemical reaction (39). They also may act as free radical reaction initiators. The free radicals produced can cause damage to the intracellular membrane (108). *In vitro* biochemical and biophysical studies strongly suggest that ultraviolet irradiation of halogenated salicylanilides leads to formation of free radicals.

If topically applied, the penetrability of the sensitizer is of decisive importance (110). A photosensitizer must be imbibed by the Malpighian layer of the skin before hypersensitivity

to light can occur (111). Lipid or aqueous solubility, or both, and the type of vehicle are important factors. The furocoumarins, anthracene, and benzpyrene are fat soluble, penetrate well, and are potent photosensitizers when applied topically (112, 113). Penetration of substances that are water soluble only (eosin, rose bengal, acridine preparations, and sulfanilamide) is slight, as is their phototoxic potentiality after external application (114). A number of drugs taken internally also evoke phototoxicity. The chief offenders are sulfonamides, sulfonylurea, diuretics, phenothiazines, chlorothiazides, tetracyclines, and griseofulvin (42).

The dyes used in lipsticks have been reported to cause an occasional photosensitization (38). Considering the vast number of lipsticks sold, the incidence of cheilitis is very low. An example of photosensitization associated with certain perfume ingredients or essential oils is the so-called Berloque dermatitis usually caused by oil of bergamot, which results in skin pigmentation after exposure to sunlight. The photosensitizing agent in oil of bergamot is not defined, although 5-methoxypsoralen may be responsible (115). In spite of the widespread use of such perfumes, few people have Berloque dermatitis because a number of other circumstances must coincide to produce the pigmentation (41).

The reports of photosensitivity to sunscreen agents would seem paradoxical. Yet, monoglyceryl *p*-aminobenzoate (116) and digalloyl oleate (48) have shown sensitivity effects. In these cases the subject patients were shown to have prior sensitizations to a number of related compounds, or were cross-photosensitized.

The halogenated salicylanilides and bithionol are examples of antibacterial compounds that can produce allergic photocontact reactions. Tetrachlorosalicylanilide, particularly, caused a serious flare-up several years ago in England, and to a lesser extent in the United States, and was withdrawn promptly from the market (118–120). Tribromosalicylanilide has been widely used in soap products for several years without any reported cases of photosensitization until quite recently (49, 121). Bithionol is a bacteriostatic agent related to hexachlorophene. It can produce not only ordinary allergic contact dermatitis but photoallergic reactions as well (80, 121–125). Cross reactions may occur between the polyhalogenated salicylanilides and bithionol. Hexachlorophene itself is apparently only a rare sensitizer.

The major sensitivity activity of the salicylanilides resides in the salicylic acid ring with a carboxyl and hydroxyl group being essential. At least one halogen atom is also required (126). The mechanism appears to be a photoactivation of the salicylanilide ring by 3600 Å. radiation, followed by free radical formation at the 3 or 5 carbon–halogen bond. Ensuing loss of free radical activity is associated with a chemical binding of the free radical (hapten) to protein (complete antigen formation).

PHOTOSENSITIVITY TESTING

Suspected agents are applied as photopatches in the same concentrations as used for ordinary patch tests (50). Tests are particularly indicated if an agent is present which has a chemical structure resembling known photosensitizers, such as chlorpromazine, promethazine HCl,[4] bithionol, tribromosalicylanilide, dibromosalicylanilide, and tetrachlorosalicylanilide.

Natural sunlight is the ideal source for photosensitization testing, but it is usually not regularly available at a given time. Artificial light sources are useful and have been advantageously substituted (35, 43, 46, 105).

Until recently, attempts to produce drug photosensitization in laboratory animals were generally unsuccessful. Guinea pigs (43, 72, 107, 127, 128), rabbits (32), rats (129), and mice (129, 135) have been reasonably satisfactory for some photosensitization substances. In some instances, it has not been possible to elicit photosensitization in animals to substances that regularly produce this response in man.

Vinson and Borselli (127) use stress conditions to elicit skin responses in guinea pigs to marginal sensitizers. If the results of this test and the Landsteiner-Jacobs test are both negative the test material can probably be tested on humans with good assurance that no photosensitization problem will develop. If an agent passes both tests, but shows cross-photosensitivity, additional tests on the preparation in the intended vehicle should be conducted. Wolven and Levenstein (72) used the Vinson-Borselli test, adding intraperitoneal injection of sulphan blue to better visualize the inflamed area and increase the sensitivity of the test. Sams and J. Epstein (107) use guinea pigs to test phototoxicity of systemic drugs. Sunlight, initially used, proved unreliable because the intensity of light varies and because the survival of guinea pigs exposed to sunlight is dependent on the temperate climate. The phototoxic reactions could be produced with either a bank of fluorescent lamps or a mercury vapor lamp (43, 130), but only when Mylar transparent plastic (duPont) was interposed between

[4] Phenergan. Wyeth Laboratories., Philadelphia, Pa.

the light source and the experimental animals. The plastic absorbs all wavelengths below 3100 Å. It prevents normal erythema from developing in control animals but has no effect on the phototoxic response. This represents a means of enhancing the contrast between the control and experimental animals. Using Mylar, phototoxicity of chlorpromazine (43) and demethylchlortetracycline (131) could be demonstrated. Recently, hairless mice have been used in a test which may have predictive phototoxic value, especially for new drugs (129).

The Curwen-Jillson (106) technique is in chief human use to differentiate photoallergic from phototoxic reactions. The ordinary patch test, using the suspected photosensitizer, is first performed in triplicate. Twenty-four hours later a sub MED (minimal erythema dose) is applied to one uncovered test site and a DED (delayed erythema dose), which is 8 times the MED, is applied to the second uncovered test site. The third patch site is a control. A phototoxic reaction is present when there is a sharply demarcated erythema at the sub MED irradiated patch test site. This is usually most marked 24 hr. after irradiation. A photoallergic reaction is present when there is an eczematous or papular response at the DED irradiated test site. This usually appears 48 hr. after irradiation (47).

Toxicological Studies on Certain Medical Grade Plastics Sterilized by Ethylene Oxide

By R. K. O'LEARY and W. L. GUESS

Ethylene oxide gas sterilization of plastics used in medical and pharmaceutical applications presents a toxicity problem which at the present time remains largely unsolved due to the increasing complexity of the plastic itself. A series of preliminary experiments was conducted to survey the problem and to present evidence of the toxic potential of plastics having a variety of chemical and physical properties. It was demonstrated that residual ethylene oxide caused extensive blood hemolysis and death to cells grown in culture.

ETHYLENE OXIDE appears to be an ideal sterilant for many heat sensitive items, but as a chemical agent it is recognized as being toxic in both its liquid and vapor phases or when prepared as a solution (1). In recent years ethylene oxide sterilization has become an important tool to biomedical personnel engaged in duties where sterilization by autoclaving is either impractical or, as in the case of many of the new plastic devices, is destructive to the product. The introduction of gas sterilization of plastics has raised questions as to the possible entrapment of ethylene oxide in a plastic, which may cause a toxic effect when placed in contact with living tissues, and the effect sorbed ethylene oxide will have on possible changes in the physical-chemical properties of the medical plastic. Certain aspects of these questions have been only partially answered in the medical literature.

Hirose *et al.* (2) and Clarke *et al.* (3) have found that plastic tubings which have been ethylene oxide sterilized can cause significant hemolysis when placed in contact with human blood. This condition was found not to exist if the materials were aerated for at least 5 days after sterilization. Similarly, Royce and Moore (4) have demonstrated that, on human volunteers, vesicular lesions occurred on the fingers, hands, and forearms when the ethylene oxide concentration in sterilized rubber gloves was greater than 2 mg./Gm. of rubber. It has been demonstrated (5) that higher concentrations of the epoxide can be taken up by polyethylene, gum rubber, and plasticized polyvinyl chloride (PVC) which reemphasizes the problem of gas entrapment in plastics. Bain and Lowenstein (6) in 1967 found that when mixed leukocyte cultures are incubated in disposable plastic tubes sterilized with ethylene oxide, the cell survival is severely affected by a toxic residue left on the plastics. The residue dissipated after 4 or 5 months' storage at room temperature, and the cell survival returned to the value obtained with ultraviolet sterilized control tubes. There have been other reports of the persistence of toxic effects after sterilization with ethylene oxide (7–12), as well as many references to the over-all procedures to be used in an effective sterilization of pharmaceutical and medical supplies (13).

This paper presents data on the ability of ethylene oxide to remain entrapped within a nonclosed system, such as a surgical tubing, gas washing bottle, plastic syringe, or plastic bottle at various temperatures above the boiling point, and also relates the hemolyzing ability of known amounts of ethylene oxide to that of freshly gas sterilized plastic pharmaceutical products. Some preliminary data on the effects of ester type plasticizers upon the sorption of ethylene oxide into PVC products are also introduced.

EXPERIMENTAL

The Effect of Plasticizer Concentration on the Uptake of Ethylene Oxide by Polyvinyl Chloride—Because literature references suggested that plasticized polymers were producing the greatest number of toxic responses following ethylene oxide sterilization, the following flexible PVC formulations were prepared for sterilization.

Received June 21, 1967, from the Drug-Plastic Research and Toxicology Laboratories, College of Pharmacy, University of Texas, Austin, TX 78712

Accepted for publication August 29, 1967.

This research was supported in part by grant CA-06120 from the National Cancer Institute, National Institutes of Health, U. S. Public Health Service, Bethesda, Md.

The authors are grateful to Mrs. Beverly C. Schmidt for valuable technical assistance with the blood hemolysis and cell culture toxicity studies.

Sample A—One hundred grams polyvinyl chloride,[1] 3 Gm. dibutyltin maleate heat stabilizer (M and T Chemical Co., Rahway, N. J.).

Sample B—One hundred grams PVC, 52 Gm. di-2-ethylhexyl phthalate plasticizer (Eastman Chemical Co., Bristol, Tenn), 5 Gm. epoxidized soya oil (Rohm & Haas, Philadelphia, Pa.), 2 Gm. calcium-zinc soap stabilizer (Advance Chemical Co., New Brunswick, N. J.).

Sample C—One hundred grams PVC, 20 Gm. di-2-ethylhexyl phthalate, 5 Gm. epoxidized soya oil, 2 Gm. calcium-zinc soap.

The above formulations were then processed in the following manner. The polymer and the additives (in the desired concentration) were placed into a 1-gal. laboratory Hobart mixer and mixed for 30 min. The films of the polymers were prepared by milling them on a Farrell-Birmingham mill with a chromium-plated, variable-speed roller. Prior to milling each film, the rollers were carefully cleaned with practical grade stearic acid. The temperature of the rollers was maintained at 175° C., and the duration of the milling was 5 min. During the final phase of the operation, the separation of the rollers was adjusted so as to furnish films having thicknesses in the range of 0.040–0.045 in. Cut samples $5^7/_8 \times 5^7/_8$ in. from the milled stock were then press polished on the Dake compression press. The molds containing the samples were then heated for 3.5 min. at 35,000 lb. of pressure and rapidly cooled to 120° before removing the test sample from the mold. All samples were finally allowed to condition at room temperature and 50% relative humidity for 48 hr. prior to their use. The 3 PVC plastics, containing 0, 15.8, and 32.7% di-2-ethylhexyl phthalate, were sterilized in a 10 × 16-in. Cryotherm experimental gas sterilizer.[2] The specific sterilization involved prehumidifying the test samples in the chamber at 50% relative humidity, 57° C., under 660 mm. of Hg vacuum for 1 hr. A mixture of 11.0% ethylene oxide, 78.3% trichlorofluoromethane[3] (CCl_3F), 10.7% dichlorodifluoromethane[4] (CCl_2F_2) was added to the chamber until a pressure of 16 p.s.i.g. was reached. The plastics used were then sterilized for 4 hr. At the end of this time interval, a vacuum of 660 mm. of Hg was placed on the system in order to remove the ethylene oxide–CCl_3F–CCl_2F_2 mixture. The samples were analyzed by a procedure previously described by Gunther (5). A plot of the concentration of ethylene oxide detected *versus* the concentration of plasticizer is presented in Fig. 1. These data were obtained on the plastics after they had been aerated at room temperature for 24 hr.

Ethylene Oxide Solubility Studies of a Series of Dialkyl Benzene Carboxylate Plasticizers—Because the experiments described in the preceding section suggested that the presence of an ester-type plasticizer in PVC permits a greater degree of ethylene oxide sorption to occur, an investigation of the solubility of this gas in a series of phthalic acid esters was undertaken. It was hoped that this information would help in the rationalization of the fact that plasticized PVC plastics produce a greater degree of toxicity following sterilization.

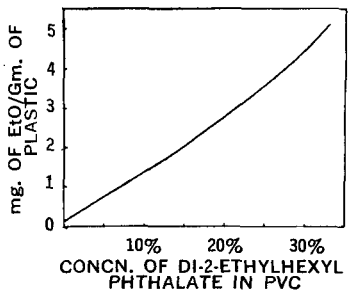

Fig. 1—A plot of di-2-ethylhexyl phthalate concentration in polyvinyl chloride versus *sorption of ethylene oxide after 24 hr. aeration.*

Description of Test System—Pure ethylene oxide vapor was distilled into a 125-ml. gas washing bottle containing an accurately weighed sample. The bottle was stoppered with a ground-glass cap which was provided with a venting tube connected to a desiccator. After approximately 5 ml. of liquid ethylene oxide had accumulated in the bottom of the container, it was removed from the ice bath and placed in a constant-temperature bath. Twenty minutes were allowed for the ethylene oxide–plasticizer mixture to reach equilibrium at the desired temperature. A glass-coated stirring bar provided agitation for the system. The bottle was then removed from the bath and titrated rapidly with a standardized HBr–glacial acetic acid reagent according to the method described by Gunther (5). The indicator was 0.1% crystal violet in glacial acetic acid. The concentration of ethylene oxide was calculated by:

$$\frac{\text{mg. of ethylene oxide}}{\text{Gm. of plasticizer}} = \frac{\text{ml. HBr} \times \text{normality} \times \text{equivalent wt.}}{\text{wt. of sample}}$$

Control Value for System—Before investigating the solubility of ethylene oxide in dimethyl, dipentyl, and dinonyl phthalate, it was necessary to determine if any ethylene oxide would remain in the test system in the absence of a sample. Five determinations were made at 45.5, 57.0, and 71.5° C. for the ethylene oxide which would remain in the gas washing bottle under the test conditions described above. Table I summarizes the data and presents the mean values obtained as well as the probable deviation of the mean (14).

Prior to testing the aforementioned plasticizers,

5.1	1.0	3.9	1.2	5.9	2.5

it was imperative to know that these esters would not interfere with the titration method of analysis. An evaluation of the amount of ethylene oxide which could be detected in the presence and absence of the esters showed that these plasticizers did not contribute to the titers.

Ethylene Oxide Solubility in Phthalates—Various amounts of dimethyl, dipentyl, and dinonyl phthalate were accurately weighed into the gas washing bottle previously described; they were then saturated with ethylene oxide prior to being placed in the constant temperature bath at 45.5° C. In this study only this one temperature (45.5° C.) was evaluated. Five replicate experiments were performed for each of the esters. The data obtained from the titration were corrected for the value of ethylene oxide obtained from the standard values in Table I. The corrected data appear in Table II, and are expressed both as Gm. of ethylene oxide per Gm. of ester and as Gm. per mole of ester. Probable deviations of the mean values were also calculated.

Application of Raoult's Law of Partial Pressure—Once an evaluation of the number of moles of ethylene oxide present in the phthalate plasticizers had been made, it was possible to evaluate the vapor pressure of ethylene oxide over this solution. Raoult's law states:

$$P = P_0 X_0$$

where P is the vapor pressure of the solvent or volatile solute over its solution, X_0 is the mole fraction, and P_0 is the vapor pressure of the pure solvent or the volatile solute at the same temperature as the solution. The mole fraction was obtained by dividing the number of moles of ethylene oxide in the plasticizer at 45.5° C. by the number of moles of plasticizer and ethylene oxide. Before carrying out this operation it was necessary to evaluate the vapor pressure of pure ethylene oxide with the Moor-Kanep formula which states that (15):

$$\text{EtO log vapor pressure [mm. Hg]} = 6.839 - \frac{1410}{T°\text{K.}}$$

DISCUSSION

For the sake of clarity and continuity, the discussion that follows will coincide with the sequence of topics covered under *Experimental*.

Ethylene Oxide Solubility Studies in Phthalate Esters—One of the most interesting observations made in the solubility experiments of ethylene oxide in phthalic acid esters was that this gaseous vapor has the ability to remain in a nonclosed system in high equilibrium concentrations at relatively high temperatures. Since ethylene oxide boils at 10.7° C., it was not anticipated that any significant amount of ethylene oxide would remain in the gas washing bottle system (previously described) at 71.5° C. However, at 7 times the boiling temperature, there was still almost 0.5 Gm. of residual sterilant (see Table I). If one considers the porous nature of certain plastic devices sterilized for medical use, it immediately becomes obvious that a thorough degassing technique must be employed following sterilization. It is not known at this time whether the ethylene oxide is sorbed in much the same manner as some tin compounds onto the surface of a glass system. In light of this observation, a possible explanation of the toxicity found in certain tubing systems following ethylene oxide sterilization might be better rationalized in terms of sorption processes into the polymeric matrices. One immediate example of where this residual ethylene oxide phenomenon could present a hazard would be in the sterilization of such devices as syringes. If the barrel and plunger of the syringe were engaged too soon after sterilization, the residual gas might produce a toxicity from the oxidation of the epoxide to a glycol, which in turn could be further oxidized to glyoxal, glyoxalic acid, glycolic acid, or even oxalic acid. All of these compounds could potentially produce a toxic response. As for the effect of the gas or its oxidation products upon the syringe contents, it is difficult to begin to even enumerate the many novel toxicities that could be produced.

In addition to the possibility of absorption of the ethylene oxide gas, it has been found that this relatively polar ether does have significant ability to solvate such nonpolar hydrocarbon esters as dinonyl phthalate. Considering that PVC tubing will contain approximately 35% of dioctyl phthalate, and that dinonyl phthalate has a solubility of 119.7 mg./Gm., as well as the fact that as the length of the hydrocarbon ester moiety decreases the EtO solubility increases (see Table II), it thus becomes possible that a flexible tubing weighing 1 Gm. might contain as much as 40 mg. of ethylene oxide. It has been shown that this is a sufficient amount to cause significant hemolysis in human blood. At the present time it is not known whether the plasticizer in the polymer will attain the same solubility limits for ethylene oxide as it does in the pure state. This information will be investigated in future studies.

The application of Raoult's law and the Moor-Kanep formula proves to be rewarding intuitively and practically. It was learned that the partial vapor pressure of ethylene oxide in the presence of dialkyl phthalates decreases as a linear function of the length of the dialkyl chain. This suggests

TABLE III—PARTIAL PRESSURES AND MOLE FRACTIONS OF ETHYLENE OXIDE IN A SERIES OF PHTHALATE ESTERS AT 45.5° C.

Plasticizer	Moles of EtO	Moles of Phthalate	Moles of EtO and Ester	Mole Fraction	Vapor Pressure, mm. Hg
Dimethyl phthalate	27.66	121.39	149.05	0.18558	490.3
Dipentyl phthalate	28.58	162.58	191.16	0.14951	395.0
Dinonyl phthalate	31 72	256.52	288.24	0.11005	290.75

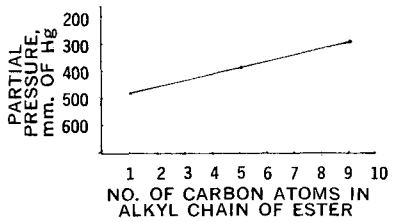

Fig. 2—Plot of the partial pressure of ethylene oxide in phthalic acid esters at 45.5°C. versus *length of alkyl moiety of the ester.*

that the lower esters would degas at a faster rate than their higher molecular weight congeners. (See Table III and Fig. 2.) However, as can be seen from Table II, it appears that this is not the only major consideration. The solubility of the ester in the epoxide also rises with the decrease of the number of carbon atoms in the hydrocarbon moiety. Thus one might rationalize that the higher alkyl esters of the phthalate type would be the preferred plasticizers for ethylene oxide sterilized plastics. If the solubility of the ester in the epoxide is to be the predominant consideration, then it can be said that for every four carbons added to the alkyl chain there will be a 25% decrease in the ethylene oxide solubility.

Table III presents the mole fractions, vapor pressure, and partial pressures just described. Figure 2 illustrates the linear function of the partial pressure of ethylene oxide to the length of the alkyl ester moiety.

A Dose Response Study of Ethylene Oxide Induced Hemolysis—Whole human blood, 27 days old, type O, Rh positive, was centrifuged and the plasma removed. The packed cells were washed with 0.85% saline and then recentrifuged and decanted. The procedure was repeated 8 times until the fragile cells and plasma had been thoroughly removed. A final 10% suspension of red blood cells was then prepared. This suspension was then added in varying volumes to a gas washing bottle which was known to contain the amount of ethylene oxide desired for the test. At 30, 60, and 120 min. after the red blood cell suspension was exposed to the ethylene oxide, the sample and the supernatant solutions were examined with the aid of a Spectronic 20 (Bausch & Lomb) spectrophotometer. The wavelength suggested for hemoglobin determinations is 540 mμ. The amount of hemoglobin as indicated by the percent absorption from the spectrophotometer was plotted against the time the suspension was exposed to the ethylene oxide. Figure 3 is a plot of the typical dose–hemolysis responses obtained for different concentrations of ethylene oxide at three time intervals of exposure.

An Evaluation of the Hemolysis Liability of Pharmaceutical Plastics Sterilized with Ethylene Oxide—Fourteen different plastic devices which may or may not be used to store blood were sterilized by a standard ethylene oxide sterilization technique which is presently used in many hospitals. The procedure involved exposing the devices to 7 p.s.i. (600 mg./L.) of ethylene oxide (12%) and CCl_3F–CCl_2F_2 (88%) for 4 hr. at 50% relative humidity and 57° C., followed by degassing the plastics 15 min. at 26 mm. of mercury vacuum at 57° C. The actual devices studied are given in Table IV, along with the percent absorption obtained on a Spectronic 20 from the development of hemolysis in a 10% red blood cell suspension. The devices were filled with the suspension immediately after sterilization and evaluated at varying time intervals. The controls were the same devices given the same treatment except that no ethylene oxide was allowed in the sterilization chamber. No attempt was made to control the surface-to-volume ratio.

Cell Culture Studies on the Toxicity of Ethylene Oxide Sterilized Polymers—Eighteen plastics (10-mil films) listed in Table V were sterilized by the procedure described in the previous section. The sterilized plastics were tested by a cell culture method which has been previously described (16, 17).

Table V presents the results obtained when the freshly sterilized plastics were placed on cell culture plates using the agar overlay techniques and observed 24 hr. later. It should be pointed out that all plastics listed in Table V were previously evaluated by the same cell culture technique and all were found to be nontoxic to the two cell systems utilized prior to sterilization.

TABLE IV—HEMOLYSIS LIABILITY OF SELECTED PHARMACEUTICAL PLASTICS STERILIZED WITH ETHYLENE OXIDE

Name of Device	Polymer Type	Time Blood Exposed to Plastic, min.	% Absorption at 540 mμ
Venopak disposable venoclysis set (Abbott lot No. 758-3518)	Flexible PVC	60 120	68 87
Blood administration set with plastic filter (Abbott, lot No. 740-3515)	Flexible PVC	60	22
Monoject 535S-C disposable syringe (Roehr Products Co.)	Polypropylene	40 140	18 18
Jelco disposable syringe (Jelco, lot No. 3165 JMB 130)	Polypropylene	45 130	2 8
Tomac disposable syringe (Amer. Hosp. Supply No. 4775 C2L106)	Polystyrene	85 195	15 18
Hemovial disposable blood collection unit (E. H. Wilburn Corp.)	Polyethylene	95 190	18 24
ACD—whole blood container (Pharmachem Corp.)	Polyethylene high density	75 135	33 33
Rilsan bottle (Wheaton Plastics)	Polyamide	80 150	3 14

Acrylic bottle (Wheaton Plastics)	Methacrylate	100 170	22 26
Bellow's bottle (Wheaton Plastics)	Polyethylene	50 180	4 15
Natural Droptainer (Alcon)	Polyethylene	115 170	16 20
Bottle 4 oz. (Alcon)	Polyethylene	100 175	10 16
Bottle 2 oz. (Wheaton Plastics)	Blend of polypropylene and linear polyethylene	100	8

TABLE V—CELL CULTURE TOXICITY RESULTS FOR 18 PHARMACEUTICAL PLASTICS STERILIZED WITH ETHYLENE OXIDE[a]

Plastic (10-mil Film)	"L" Cell Culture	Chick Cell Culture
Cellulose acetate	Cell death	Cell death
Polycarbonate	No effect evident	No effect evident
Polyethylene	Cell death	No effect evident
Teflon 7	No effect evident	No effect evident
PVC with 35% dioctyl phthalate	Cell death	Not tested
Nylon 6,6	No effect evident	No effect evident
Polyphenylene oxide	Cell death	Cell death
Polypropylene	No effect evident	No effect evident
PVC with 15% dioctyl phthalate	Cell death	Cell death
Rigid PVC	No effect evident	No effect evident
Cellulose triacetate	Cell death	Cell death
Rigid polyurethane	Cell death	No effect evident
Flexible polyurethane	Not tested	No effect evident
Cellulose acetate–butyrate	Cell death	No effect evident
Polymonochlorotrifluoroethylene	No effect evident	No effect evident
Polybutylene	No effect evident	No effect evident
Acrylonitrile–butadiene styrene	Cell death	No effect evident
Polyvinyl acetate	Cell death	Cell death

[a] Plastics were placed on the culture plates within 15 min. after the sterilization procedure was completed. Toxicity observations were made with the unaided eye, after 24 hr. exposure to the culture plates.

Toxicity Studies of Ethylene Oxide—The data submitted in Fig. 3 indicate that ethylene oxide is a rapid acting hemolytic agent. Independent of the dose involved, this gas will perform the major portion of its hemolyzing effect in the first 30 min. of exposure to blood. After this peak time is reached, the effect becomes asymptotically parallel with respect to the time axis. The importance of the plot in Fig. 3 is not as a direct read-out of the degree of percentage of hemolysis, but rather as a standard curve for the effect of a particular dose of ethylene oxide on human erythrocytes as compared to the same effect achieved with a sterilized plastic. For instance, in Table IV, it can be seen that Abbott's venoclysis set produced a hemolysis absorption read-out of 68% in 1 hr. According to the standard curve, it would take a concentration greater than 78.6 mg. of ethylene oxide per ml. of human blood cells (10% suspension) to produce this same hemolysis. The eye can detect this amount of hemolysis since it is so extensive. It is the opinion of the authors that the cause for the severe hemolysis liability of the Abbott devices is

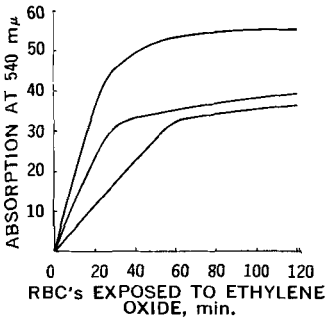

Fig. 3—Plot of ethylene oxide concentration in human blood versus *hemoglobin absorption at 540 mμ. Key: top, 78.6 mg. EtO/ml. RBC; middle, 47.2 mg. EtO/ml. RBC; bottom, 23.6 mg. EtO/ml. RBC.*

the result of the higher solubility of ethylene oxide in a plasticized PVC polymer as compared to other nonplasticized or crystalline polymers. This device also demonstrated the same phenomenon as was reported for the previously described gas washing bottle. This former device is a hollow tubular system in which residual gas pockets can develop as the ethylene oxide is desorbed from the polymer. Perhaps future studies of the effects of vacuum, temperature, and time upon the degassing of these plastics might reveal that no hemolysis liability does exist for these devices.

The different absorption readings obtained for the three syringes sterilized with Pennoxide (see Table IV) is not a reflection of the plastic used to make the barrel of the syringe, but rather the composition of the hub on the plunger. Once blood is drawn into the sterilized syringe it can be visually recorded that the hubs of the Monoject and Tomac syringes release bubbles of a gas. In the undisturbed syringe filled with the blood, hemolysis was extensive in the area next to the hub, but no noticeable difference was recorded in the rest of the barrel. The Jelco syringe did not produce this same effect and concomitantly less hemoglobin absorption was recorded.

It is difficult to pin down the differences in absorption readings obtained for the various polyethylene devices. It might be said that the narrow openings of the Pharmachem products might have permitted a greater residual ethylene oxide content and build-up as desorption occurred in the device. But the bottles with the wider openings allow for a lower final equilibrium concentration after the samples were removed from the sterilizer. The variation in the densities of the individual devices might also be reflected in the different absorption values because the higher density polyethylenes would be more impermeable to sorption and diffusion of the gas. It is felt that this same type of phenomenon was responsible for the delayed hemolyzing ability of the fluoroethylene propylene produced by du Pont. This product has a high degree of crystallinity and would resist the uptake of gas. However, some gas diffusion would occur into the polymer during the 4 hr. of sterilization under pressure. Once the pressure was released and temperature was dropped, the degassing would thus occur slowly over the 1.5-hr. period. The first 30 min. failed to show hemolysis because desorption had not progressed enough to produce a toxic dose.

The cell culture toxicity evaluation of the gas sterilized plastics gave somewhat erratic results, as noted in Table V. Certain explanations may be noted, however, to at least partially account for this variation. First, the mouse fibroblasts ("L" cells) are somewhat more sensitive to toxicants than are chick embryo cells in culture, and the toxic results shown in Table V reflect this difference in sensitivity. It should be noted that the more plasticized formulations caused cell death, again reflecting a higher degree of ethylene oxide solubility in the plasticizer and a more rapid release of the gas from this material. The cell deaths noted with the nonplasticized plastics are related to the complex desorption relationships resulting from different degrees of crystallinity, branching, and molecular weights of the polymers.

In conclusion, it appears that the blood saline suspension technique is a sensitive and effective

method for evaluating hemolysis liabilities of sterilized plastics. From the results of these tests, the polypropylene devices would have to be considered the best candidates for making a medical product which would undergo ethylene oxide sterilization. However, techniques must be evaluated to prove the effectiveness of longer degassing times, higher temperatures, and the effects of vacuum. It would appear from these results that further testing is necessary to establish the actual percentage of hemolysis that occurs for a particular concentration of ethylene oxide. In any event, it is sufficient to say that hemolysis liabilities do exist from the sterilization of medical plastics of many different types.

Surface Films of Soybean Lecithin II

Interactions Between Lecithin and Lipid Substances in Mixed Monomolecular Films

By G. TOROSIAN* and A. P. LEMBERGER

Mixed films of lecithin with the fatty acids (stearic, elaidic, and oleic) as well as with the glycerol esters of mono-, di-, and triglyceride have been investigated. Evaluation of these systems has been made utilizing two properties of surface films, their mean molecular areas and their collapse points. It would appear from this investigation that in mixed film systems, lecithin–stearic acid and lecithin–monoglyceride are miscible, but without a significant degree of interaction and as such, form ideal two-dimensional liquids. Lecithin–oleic and lecithin–elaidic acids have been shown to be miscible in mixed film systems but with a significant degree of interaction so that they may be considered to be nonideal two-dimensional liquids. The data for the lecithin–di- and triglyceride systems did not conclusively show whether these systems were ideal or nonideal two-dimensional liquids in mixed surface films.

THE IMPORTANCE of phospholipids in biological membranes has been discussed by Bangham (1). Among the phospholipids, lecithin is considered particularly important since it aggregates into sheet-like micelles which are capable of further accommodating lipids, phospholipids, and sterols (2, 3). The mixed film system of lecithin–cholesterol, first investigated by Dervichian (4), showed the ability of cholesterol to condense lecithin to a smaller cross-sectional area than it exhibits alone. Van Deenen (5) indicated the molecular proportions of cholesterol to phosphotides of animal red cell membranes

The mixed film system of lecithin–cholesterol, first investigated by Dervichian (4), showed the ability of cholesterol to condense lecithin to a smaller cross-sectional area than it exhibits alone. Van Deenen (5) indicated the molecular proportions of cholesterol to phosphotides of animal red cell membranes

to be 1:1, thus increasing the biological significance of Dervichian's lecithin–cholesterol mixed film observations. Van Deenen (5) verified the ability of cholesterol to condense lecithin using synthetic lecithin containing saturated fatty acid moieties alone and lecithin with unsaturated fatty acid moieties. The condensing effect of cholesterol was more pronounced when in a mixed film in conjunction with the synthetic lecithin containing unsaturated acyl groups.

Lipid materials with which lecithin may be associated in nature include fatty acids and glyceryl esters. Dervichian (6) and Desnuelle (7) have observed interactions between phospholipids and other lipid substances. Yeadon *et al.* (8) studied the emulsification properties of lecithin. They were able to show that purified lecithin alone was an inefficient emulsifier while purified lecithin in conjuction with other lipids in some cases led to improved emulsions. The implications of mixed film interactions between lecithin and these materials, both in nature and in pharmaceutical systems such as emulsions, are of broad interest. Hence this study was undertaken to examine carefully the nature and degree of lecithin interactions with several fatty materials.

EXPERIMENTAL

Materials—Lecithin used in this study was prepared from soybean concentrate[1] and purified after the method of Saunders and Perrin (9, 10). Stearic and oleic acids, obtained from Mann Research Laboratories, were chromatographically pure and were used without further treatment. The elaidic acid used in this study was obtained from K and K Laboratories and was further purified by recrystallization twice from ethanol–water mixture. The pure elaidic acid had a melting point range from 44–45°. The saturated (primarily stearoyl with some palmitoyl moieties) mono-, di-, and triglycerides were obtained from K and K Laboratories as a mixture and were purified and separated after the chromatographic method of Higuchi *et al.* (11).

Apparatus and Experimental Procedure—The surface balance employed was that developed by Poulsen and Lemberger (12). Concentrated solutions of the pure components for a particular mixed film series were prepared separately using dried redistilled reagent benzene as the solvent. Specific volumes of these stock solutions were combined, maintaining the final volume constant, so that the mole fraction of the second component, any compound mixed with lecithin, increased for each mixed film determination within a particular system. These solutions containing the specified mole fraction of each component were then layered on the surface of double-distilled water contained in the trough of the film balance by using a Hamilton syringe with a Chaney adapter. The volume of the injection was held constant throughout this study at 0.1 ml. Temperature was held constant throughout a particular compression and all runs were made at 25 ± 0.5°.

Layering of the material was performed slowly to avoid dissolution of the wax coating on the trough by the benzene. The resulting mixed film was compressed manually until the film collapsed, with readings taken at specific trough areas. This allowed the construction of the π–A isotherms, where π equals the film pressure and A equals the area occupied by the molecules. The time intervals between individual compressions were constant throughout the course of a single run, but did vary with different mixed films from 1–5 min., depending upon the components in the mixed films. Molecular cross-sectional areas for lecithin, obtained by extrapolation to $\pi = 0$, were reproducible within less than 2% for a given lot of lecithin. In general, the study of each system was completed with the same lot of lecithin. Molecular cross-sectional areas for mixed film systems were reproducible within 1–2 Å.^{2}. This allowed the construction of the π–A isotherms, where π = the film pressure, and A = the area occupied by the molecules.

RESULTS AND DISCUSSION

Construction of π–A Isotherms—Figures 1 and 2 are representative families of curves which graphically indicate what occurs as the mole fraction of lecithin is decreased while increasing that of the second component. While systems containing lecithin with stearic acid, oleic acid, elaidic acid, mono-, di-, and triglycerides were investigated, only representative isotherms for lecithin–stearic acid and lecithin–oleic acid are presented since they show what typically occurs in these systems.

In general, it can be seen that as the mole fraction of the second component increases, the curve for the mixed film shifts along the area/molecule axis. Reading the plots from right to left, each succeeding curve represents a further increase in the mole fraction of the second component, until on the extreme left is represented the pure second component. Films of pure natural lecithin exhibit an expanded liquid character, which when diluted

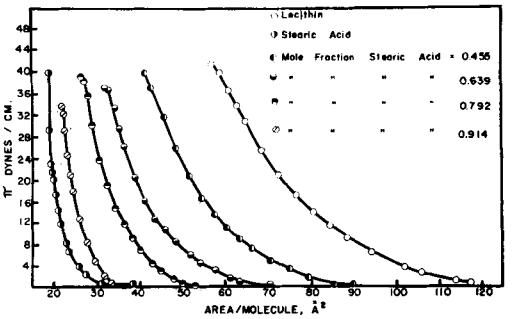

Fig. 1—Representative compression isotherms for lecithin–stearic acid systems. Area/molecule axis based on total number of molecules.

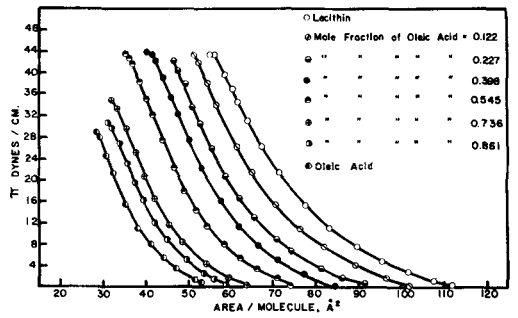

Fig. 2—Represenative compression isotherms for lecithin–oleic acid system. Area/molecule axis based on total number of molcules.

with a second component whose mono-molecular film exhibits a more condensed solid state, results in a mixed film which is a hybrid in its character with respect to the two pure components. The degree to which this hybridization occurs is dependent upon the mole fraction of the second component and on the specific characteristics of the second component. This is demonstrated in Fig. 1, which shows the lecithin–stearic acid system in which the gradual progression of the expanded liquid state of pure lecithin to the more condensed solid state of component 2, stearic acid, takes place. These rather general observations hold equally well for those other more condensed components when mixed with lecithin such as the mono-, di-, and triglycerides.

On the other hand, when 2 components are mixed, both of which when pure show an expanded liquid character, the resulting mixed film retains its expanded liquid characteristic from pure component 1 all the way to pure component 2. This can be seen in Fig. 2 for the lecithin–oleic acid system and is also true for lecithin–elaidic acid system.

In addition to the change in the shape of the curve and the progression of the curves toward smaller cross-sectional areas as the mole fraction of component 2 is increased, there is another property of these films which may change and that is the point at which the mixed film collapses. The collapse point is experimentally taken to be the highest film pressure attainable. In Fig. 1, the lecithin–stearic acid system shows little change of the collapse point, while Fig. 2 for lecithin–oleic acid system shows a gradual reduction in the collapse pressure from the high point exhibited by pure lecithin to the low collapse pressure indicated for pure oleic acid, particularly above the mole fraction of 0.55. This property is again observed in the systems containing elaidic acid, di-, and triglycerides. The pure monoglyceride, like pure stearic acid, has a collapse pressure as high as pure lecithin itself, and one observes little change in the collapse pressure for the mixed film systems of lecithin–stearic acid and lecithin–monoglyceride.

In an attempt to characterize the systems of lecithin with stearic acid, oleic acid, elaidic acid, mono-, di-, and triglycerides, plots of the extrapolated mean cross-sectional area *versus* mole fraction of the second component were constructed. The extrapolated mean cross-sectional areas were obtained by extrapolating the linear portions of the isotherms to $\pi = 0$ on the area/molecule axis. The extrapolated mean cross-sectional area obtained in this manner represents the average area occupied by the molecule in the particular system at zero pressure. The mean cross-sectional areas, on the other hand, were obtained by reading the area/molecule on the x-axis at the specified pressure. This results in a mean cross-sectional area for the molecule at the pressure specified and reflects the average area occupied by the molecules at that specific pressure for that specific system.

When these properties are plotted against the mole fraction of the second component, a linear relationship results if the cross-sectional areas are additive implying the existence of an ideal two-dimensional liquid. This is seen to be the case in Fig. 3 for the lecithin–stearic acid system. This relationship is shown to hold as well for the mean cross-sectional area at film pressures of 10–30 dynes/cm. as seen in Fig. 4. Figures 5 and 6 for the lecithin–monoglyceride system also seem to be linear and closely resemble the lecithin–stearic acid system. This is not, however, the case for the lecithin–oleic acid and the lecithin–elaidic acid systems. Figures 7 and 8 show that most of the points fall below the theoretical line. This is further demonstrated in Figs. 9 and 10 for the film pressures from 4 to 20 dynes/cm. This implies that the cross-sectional areas are less than additive for these systems.

Apparent Linearity of Lecithin–Di- and Triglyceride—The lecithin–di- and triglyceride

systems show a linear relationship between the extrapolated mean cross-sectional area and the mean cross-sectional area *versus* the mole fraction of the second component similar to that observed for the lecithin–monoglyceride system. This would seem to indicate that the mean molecular cross-sectional area for the lecithin–diglyceride and triglyceride mixed films are also additive. However, it will be shown that this evidence alone is insufficient to confirm this first impression.

According to Crisp (13), two components of a mixed film are immiscible if the components remain separate and distinct from each other, when they form as for example, surface micelles, then the following equation is obeyed:

$$A_T = A_1N_1 + A_2N_2 \qquad \text{(Eq. 1)}$$

where A_T = total area, A_1 = area of component 1, N_1 = the mole faction of component 1, A_2 = area of component 2, and N_2 = the mole faction of component 2. Molecular interaction and miscibility result when Eq. 1 is not obeyed, yet agreement with Eq. 1 does not absolutely indicate immiscibility since components may be miscible with each other yet have little or no interaction between them, and Eq. 1 may still be observed for these ideal two-dimensional solutions. Most mixed film systems may have some range of miscibility and according to Crisp (13) one may determine the limiting solubility of component 2 in component 1, as well as the partial molar area of component 2, the value of which serves to give some indication as to the ex-

tent of the interaction. Crisp (13) defines the partial molar area as:

$$\bar{A} = -RT \frac{d \ln N'_s}{d\pi'} - RT \frac{d \ln f_s'}{d\pi'} \quad \text{(Eq. 2)}$$

where $\bar{A}$ = partial molar area, R = gas constant, T = absolute temperature, N_s' = mole fraction of the second component being squeezed out of the films. π' = film pressure at which the second component is being squeezed, and f_s' = activity coefficient of the second component at the point of being squeezed out. If the activity coefficient is reasonably constant, one may plot $\ln N_s'$ *versus* π'. The partial molar area may be calculated from the slope of the line, and limiting solubility of component 2 in component 1 may be obtained from the point at which the linear portions at high N values, as reported by Crisp, intersect.

Evaluation of Partial Molar Areas—Figures 11–14 are examples of plots of the film pressure at the collapse point *versus* log N_2. These plots, made after the method of Crisp (13), do not show an immiscible region at high N_2 values. There is, however, a linear segment in these plots corresponding to the region in which collapse film pressure increases as N_2 decreases up to a limiting value. The slope of the first portion allows the calculation of the partial molar area, $\bar{A}$, of component 2 in the system. $\bar{A}$ values for the various additives are listed in Table I along with their extrapolated cross-sectional areas and the actual molecular area at the collapse pressure of these components obtained when their films were cast alone. There is a reduction in the partial molar areas with respect to the extrapolated values, indicating that the interaction between lecithin and these second components does occur, and hence the mixed films appear to be condensed with respect to the areas of either component alone. Crisp describes this region as the region where component 2 is miscible with component 1, consequently the film pressure at the collapse point increases. In the systems reported here the mole fraction of component 2 was observed to reach a critical value at which the enhancement of collapse pressure was altered. At N_2 levels below the critical value in oleic and elaidic acid systems the collapse point became essentially constant and was essentially the same as for pure lecithin. In the lecithin–triglyceride system, the collapse points seemed to increase gradually with a reduction of N_2 until the collapse point of lecithin was reached while the diglyceride system demonstrated a maximum collapse pressure at the critical value. Since, according to Gaines (14) Eq. 2 holds only in the region where

TABLE I—TABULATION OF PARTIAL MOLAR AREAS OF COMPONENT 2 IN MIXED LECITHIN FILMS

Mixed Film System	Molecular Areas of Component 2, Å.² Partial Molar Areas in Mixed Film	at Collapse[a]	Extrapolated[a] to π = 0
Lecithin–oleic acid	17	27.0	39
Lecithin–elaidic acid	8.7	26.0	35.6
Lecithin–diglyceride acid	19.8	39.5	47.5
Lecithin–triglyceride acid	33	59	65.8

[a] Averages of 2 or more values.

$N_2 \rightarrow 1$, the significance of these observations at low N_2 values remains clouded.

The lecithin–stearic acid and the lecithin–monoglyceride systems cannot be evaluated in the same manner, since the collapse pressures for stearic acid and monoglyceride films were both very similar to that of lecithin films. However, they do obey Eq. 1, which supports the hypothesis that these systems are either immiscible or miscible but devoid of any specific interaction.

GENERAL DISCUSSION

The linear relationships existing between the extrapolated mean molecular area, the mean molecular area at the various π values, and the collapse points *versus* the mole fraction of component 2 of the mixed films of the lecithin–stearic acid, the lecithin–monoglyceride systems—together with the fact that stearic acid, monoglyceride, and lecithin are similar types of compounds—would seem to indicate that these mixed films are miscible. However, they do not manifest a significant degree of interaction and as such may be considered to form ideal two-dimensional solutions.

The negative deviations from linearity seen in Figs. 7–10 for the lecithin–oleic acid and lecithin–elaidic acid would seem to indicate, along with the data in Table I, that these systems do form miscible films. They further show the existence of interactions between the lecithin molecules and those of oleic and elaidic acid. This is corroborated in the case of the lecithin–oleic acid system by Dervichian in a preliminary note (6), indicating that oleic acid condensed lecithin films of unknown purity by approximately 18%.

Interactions between film components similar to those seen at the air–water interface may also occur at the oil–water interface in emulsion systems. Where this is the case, we would expect better stabilizing effects for those film systems which manifest a significant degree of interaction. To some extent, this is supported by the work of Yeadon *et al.* (8), who found that purified lecithin mixed with oleic acid formed better emulsions than purified lecithin alone.

In the case of the lecithin–diglyceride and lecithin–triglyceride system, the plots of the extrapolated mean cross-sectional area and the mean cross-sectional area *versus* the mole fraction for component 2 appear to be linear indicating an ideal two-dimensional liquid. However, Figs. 13 and 14 would imply that di- and triglyceride both tend to cause a condensation of the lecithin film. Table I shows the partial molar areas for these compounds to be smaller than the extrapolated molecular cross-sectional area for either diglyceride or triglyceride alone, which indicates the presence of a significant amount of interaction between lecithin and the glycerides. Desnuelle (7), using phospholipids obtained by precipitation of their ether solutions into acetone and a crude extract of unsaturated triglyceride, showed that the unsaturated triglyceride caused a condensation of the phospholipid film. His work tends to corroborate the authors' findings with lecithin–triglyceride systems —although the triglyceride in our system contained saturated acyl groups.

Equilibrium Phenomena in Solid Dosage Forms

By J. THURØ CARSTENSEN*, J. B. JOHNSON, D. C. SPERA, and M. J. FRANK

Certain aspects of the mechanics of drug decay in solid dosage forms are discussed. Apparent equilibration often takes place in solid dosage forms. In order to obtain data that are amenable to detection of equilibria and can be subjected to mathematical analysis, it is necessary, in the case of fairly stable drugs, to assay for degradation products. Van't Hoff plots should be used in this case.

THE AUTHORS are presently engaged in the study of stability behavior in solid dosage forms.

Theoretical treatment of reaction through moisture interfaces should lead to zero-order behavior (1). To our knowledge only Leeson and Mattocks (2) and Lachman (3) have touched on this in a quantitative manner. Garrett (4, 5) has paved the way for use of extrapolatory procedures and Higuchi (6), Tardif (7), and Carstensen (8, 9) have reported on first- and zero-order behavior of vitamin A in solid dosage forms.

Nevertheless, the literature is poor in reports on this important aspect of stability evaluation, and some of the authors' findings are presented with special emphasis on (*a*) the occurrence of apparent equilibria and (*b*) the importance of following degradation product formation rather than evaluating only percent active drug retained.

THEORETICAL

It is a general practice to evaluate stability by percent active component retained.[1] For short term evaluation, however, it is more meaningful, and in general much more instructive, to gauge degradation by the amount of decomposition products formed.

In general, a good analytical procedure for the intact drug exists at the time pharmaceutical product development is initiated, but breakdown products may be either unknown or poorly quantitated.

It has been the authors' experience that application of TLC in evaluating compatibility (9) as well as stability, gives insight far beyond simply testing for percent intact drug retained, even though analytical procedures for the latter may be good to ± 2% and the former only to ± 20%.

[1] It is also popular practice to treat log linear relations by the method of least squares directly. This, however, is quite fallacious if the data are very scattered (10).

EXPERIMENTAL

Vitamin A tablets were made by mixing vitamin A acetate beadlets (17.5 mg. per tablet of 500 unit/mg. beadlets), spray-dried lactose (427.5 mg. per tablet), and calcium stearate (5 mg. per tablet), and compressing the tablets on a conventional tablet machine using a $^3/_8$-in. deep concave punch. The tablets were stored at 25, 37, 45, 55, 70, and 85° in sealed containers, and samples were removed at regular intervals. The tablets were assayed by a modified USP method[2] using Morton Stubbs correction factor.

Stability of isopropanolic solutions of vitamin A acetate were studied in the absence of air and oxygen in the following fashion.

A solution of vitamin A acetate in isopropanol was prepared under nitrogen and transferred to the vessel shown in Fig. 3. Nitrogen was bubbled through the vessel through stopcock B, with stopcock A open. Both stopcocks were then closed, and the vessel stored at 25°. Samples were taken at various intervals by opening stopcocks A and B, and applying nitrogen pressure at position A, and collecting the sample at position B.

Vitamin E succinate tablets were made in the same fashion as described for vitamin A acetate tablets. They contained 6 mg. vitamin E succinate, 192 mg. lactose, and 2 mg. magnesium stearate. Storage conditions and sampling procedure paralleled those for vitamin A acetate tablets.

The tablets inherently contain sufficient moisture for complete de-esterification. Even though this would imply a second or higher order reaction, it will be seen that the data lend themselves to first-order kinetics and that meaningful extrapolations can be made.

The melting point of vitamin E succinate is 68°, but addition of additives[3] (lactose, magnesium stearate) sufficiently lowers the melting point so that the physical state of the vitamin E succinate is the same at all temperatures studied.

Vitamin E succinate potency was determined spectrophotometrically by measurement of the absorbance at 285 mμ of an ethanol extract of the tablet mass. The absorptivity, at 285 mμ in 1-cm. cells, is 3.78 for *dl*-α-tocopherol succinate.

A portion of finely ground tablet mass equal to approximately 10 mg. of vitamin E succinate was accurately weighed, transferred to a 100-ml. volu-

[2] USP method employs four washings with ether, whereas the modified method (which in our hands gives identical results) employs two extractions with petroleum ether.

[3] If vitamin E succinate and magnesium stearate are melted together and cooled, the following congealing points may be observed: vitamin E succinate 99%–magnesium stearate 1%, 45°; vitamin E succinate 95%–magnesium stearate 5%, 30°; vitamin E succinate 90%–magnesium stearate 10%, 5°.

metric flask, and 50 ml. of 95% ethanol added. The liquid was shaken for 10 min. and then brought to volume with ethanol, filtered through Whatman No. 12 paper, and absorbance of this solution then was measured at 285 mμ on a suitable spectrophotometer.

The free tocopherol was determined by thin-layer chromatography. An amount of tablet mass equal to approximately 10 mg. of vitamin E succinate was triturated with 1 ml. of chloroform. Fifty microliters of this solution (equal to 500 mcg. of vitamin E succinate) was then applied to a Silica Gel G thin-layer chromatographic plate, and the following thin-layer chromatographic system was used: adsorbent, Silica Gel G; sample, 500 mcg. from chloroform solution; solvent, cyclohexane–diethyl ether (80:20); development, 15 cm. ascending; visualization, 20% phosphomolybdic acid in 95% ethanol.

RESULTS AND DISCUSSION

Sufficient information may be extracted by studying percent retained in the case of lactose tablets containing vitamin A, since in this case, losses are of fair magnitude. Figure 1 shows the percent retained of vitamin A in lactose–magnesium stearate base tablets as a function of time. The assay is modified USP with Morton Stubbs correction, and although data pertaining to degradation products are absent (except for the quantitative Morton Stubbs correction), they show that the assay will level off.

The vitamin A used was vitamin A acetate containing substantial amounts of antioxidants. In the absence of antioxidants the effect is noticeable only after long periods at room temperature. Three batches of vitamin A acetate, containing no antioxidants, when incorporated into uncoated multivitamin tablets, retained vitamin A potency at room temperature in the pattern shown in Fig. 2. Statistical evaluation, as well as visual observation, shows the potency to level off, but long periods at room temperature are necessary to observe the effect.

That equilibration should take place is not unreasonable, since isopropanolic solutions of vitamin A acetate show a similar behavior, if care is taken to exclude air, for example by use of a vessel such as shown in Fig. 3. Figure 4 shows the results of such a study.

The vitamin A beadlets may be viewed as an isolated system in the tablet matrix, and as long as compression of the tablet is kept reasonably gentle the fall-off of potency is fairly independent of the surrounding mass. The reason for introducing vitamin A at this point is to demonstrate that equilibrium conditions do occur in solid dosage forms, and that, if the equilibrium point is sufficiently in favor of the degradation product(s), it is possible to follow the pattern by determining percent retained as a function of time.

Since this is the exception rather than the rule in good tablet formulations, it would be more appropriate to study a compound which would be relatively stable.

It is obvious, however, that in such a case much longer storage times would be necessary to attain meaningful results, if assays of the intact molecule were followed. If individual assay tolerances were ±2%, either a great many assays would have to be

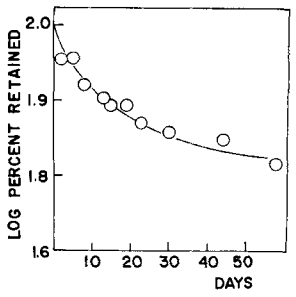

Fig. 1—Stability pattern at 45° of vitamin A acetate beadlets (containing antioxidants) in lactose base tablets.

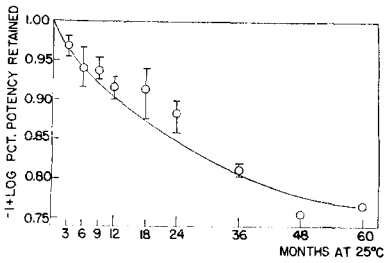

Fig. 2—Long term room temperature stability of vitamin A beadlets (without antioxidants) in a multivitamin tablet formulation.

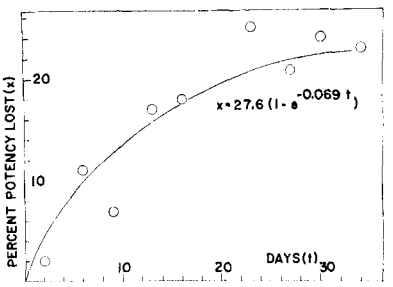

Fig. 4—Stability pattern at 25° of vitamin A acetate dissolved in isopropanol.

performed to distinguish between, *e.g.*, 100% and 99.5% content of active component, or sufficient time would have to elapse in storage to allow the content of active component to drop to a level which would be significantly different from initial content to allow differentiation by triplicate (or other reasonable multiplicate) assays. If the rate of degradation product formation is followed, however, even a crude assay will be more meaningful for this purpose. The example of vitamin E succinate tablets (6 mg.) shown in Table I demonstrates this.

TABLE I—VITAMIN E SUCCINATE DE-ESTERIFICATION AT 55°

Storage Time, 55°	mg./Tablet	% Free Tocopherol[a]
0 days	5.92	0
3 days	...	0.5–1.0
5 days	5.96	1.0
7 days	5.93	1.5
10 days	5.92	1.5
20 days	6.11	2.0

[a] As mentioned, the content of free tocopherol here was evaluated by comparing thin-layer chromatograms of the tablet with standard chromatograms of tocopherol with various amounts of tocopherol applied. In the amounts shown, the assay of "decomposition product" is good to ±25 relative percent in amounts above 1% decomposition product present.

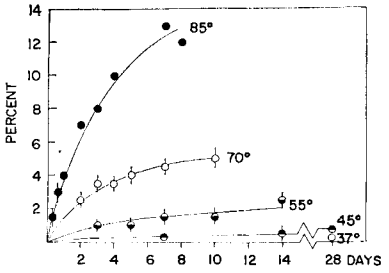

Fig. 5—Stability patterns at various temperatures of vitamin E succinate in lactose base tablet . For estimation of asymptotic values, see text.

It is obvious that the tablet and assay variance here does not allow stability evaluation by column 2 (intact molecule). The data regarding decomposition product formation as they stand are not impressive, but considering the fact that the data concerning percent retained can give no quantitative information at all, and viewed in light of the 85°-data described in the following, they lend themselves to mathematical analysis.

The product formation curve at 85° is shown in Fig. 5 and is indicative of equilibration. Considering the simplest form, $A \rightleftarrows B$, and denoting forward and backward rate constants by k_+ and k_-, and equilibrium concentration by X_e, would lead to the rate equation for content of decomposition product (X):

$$X = X_e[1 - e^{-(k_+ + k_-)t}] = X_e(1 - e^{-kt}) \quad \text{(Eq. 1)}$$

where $k = k_+ + k_-$. X then is the concentration of the component denoted by B above, and $(1 - X)$ is the content of intact molecule A.

Drawing a crude curve through the points of Fig. 5 and recording the X-values at time 2, 4, and 6 yield equations (*i*), (*ii*), and (*iii*) below. It will be noted, that for arithmetic handling any arithmetic series (*e.g.*, $t = 1, 2$, and 3 or $t = 3, 6$, and 9) could have been used equally well. However, the highest numbers, compatible with the data, give the best estimates.

k and X_e are then evaluated by the procedure shown:

$$(i) \quad X_2 = X_e - X_e \cdot e^{-2k}$$

$$(ii) \quad X_4 = X_e - X_e \cdot e^{-4k}$$

$$(iii) \quad X_6 = X_e - X_e \cdot e^{-6k}$$

Subtraction now yields:

$$(ii) - (i) \quad X_e(e^{-2k} - e^{-4k}) = X_4 - X_2$$

$$(iii) - (ii) \quad X_e(e^{-2k} - e^{-6k}) = X_6 - X_2$$

Division of $(ii) - (i)$ by $(iii) - (i)$ then eliminates X_e and yields:

$$(X_4 - X_2)e^{-6k} - (X_6 - X_2)e^{-4k} + \{(X_6 - X_2) - (X_4 - X_2)\}e^{-2k} = 0$$

or, providing that $(X_4 - X_2)$ is different from zero:

$$(iv) \quad (X_4 - X_2)e^{-2k} \times \left\{(e^{-2k})^2 - \frac{X_6 - X_2}{X_4 - X_2}(e^{-2k}) + \frac{X_6 - X_4}{X_4 - X_2}\right\} = 0$$

The equation is satisfied when the quadratic equation in brackets is zero, *i.e.*, when:

$$(v) \quad (e^{-2k})^2 - \frac{X_6 - X_2}{X_4 - X_2}(e^{-2k}) + \frac{X_6 - X_4}{X_4 - X_2} = 0$$

or

$$(vi) \quad (X_4 - X_2)(e^{-2k})^2 - (X_6 - X_2)(e^{-2k}) + (X_6 - X_4) = 0$$

One of the roots of the quadratic equation (*v*) is an estimate of e^{-2k} (and hence an estimate of k) and insertion of this value in, *e.g.*, (*i*), will yield X_e.

It will be noted that the factoring of $(X_4 - X_2)$ in (*iv*) requires it to be different from zero, but $X_4 - X_2 = 0$ only if $k = 0$. In this case $e^{-k} = 1$, and $e^{-kt} = 1$ for all t, and Eq. 1 degenerates to $X = 0$. For this case $e^{-2k} = 1$ and $X_6 = X_4 = X_2 = 0$, and the quadratic equation (*v*) is satisfied by this value.

The equation hence always has the superfluous root $e^{-2k} = 1$, and the other root is the value determining k. Since, in a quadratic equation the two roots ($e^{-2k'}$ and e^{-2k}) add up to the negative coefficient of the first power term, when the equation is normalized, and since, here, $e^{-2k'} = 1$, then:

$$e^{-2k'} + e^{-2k} = 1 + e^{-2k} = \frac{X_6 - X_2}{X_4 - X_2}$$

or

$$e^{-2k} = \frac{X_6 - X_2 - (X_4 - X_2)}{X_4 - X_2} = \frac{X_6 - X_4}{X_4 - X_2}$$

The 85°-data obtained with vitamin E succinate yield the following values (*iv*):

$$0.039\, e^{-2k}\{(e^{-2k})^2 - 1.54\, e^{-2k} + 0.537\} = 0$$

The sum rule gives: $1 + e^{-2k} = 1.54$ or $e^{-2k} = 0.54$. A check on how good the crude curve is, can be obtained by solving for e^{-2k} in conventional fashion and ascertaining that the one root is (or is close to) 1.

In the case above, the roots are $e^{-2k} = 0.523$ and $e^{-2k'} = 1.037$, *i.e.*, the latter is sufficiently close to 1.0 to justify the initial estimate of X_2, X_4, and X_6, and the ensuing k value. Having a first estimate, a best estimate can be found by computer, using Taylor series and iteration as described by Wylie (10).

Inserting $e^{-2k} = 0.54$ in (*i*) yields:

$$X_2 = 0.066 = X_e(1 - 0.54)$$

so

$$X_e = 0.143 \text{ or } X_e = 14.3\%$$

TABLE II—DEGRADATION OF VITAMIN E SUCCINATE IN TABLETS AT VARIOUS TEMPERATURES

Time, Days	Temp., °C.	Free Tocopherol, %

28	37	0.25

is indicated in this case, since equilibrium values, rather than rate constants are being studied. Stability prediction should indeed be done by this equation rather than by Arrhenius plotting, when equilibrium conditions prevail. The data are presented graphically in Fig. 6. The rate constants, in this case, may or may not follow an Arrhenius relationship. Figure 7, however, shows that they conform fairly well in this case to this type equation. However, for prediction of stability, the rate constants are of no importance if equilibrium is ultimately reached.

The important features then are (*a*) that it becomes apparent that equilibrium is reached and that Van't Hoff rather than Arrhenius plotting is indicated, and (*b*) that use of percent retained data is of no value for extrapolation when compounds have fair stability.

In such cases a crude assay of the degradation product is not only more meaningful, but also more informative and accurate.

TABLE III—VAN'T HOFF CORRELATION OF VITAMIN E SUCCINATE TABLETS

Temp., °C.	$10^3/T$ (°K^{-1})	X_e, %	K (Range)	$\ln_e K$ (Range)	k (Days^{-1}) (Range)	$\ln_e k$ (Range)
85	2.79	13.9–14.3	0.16 –0.17	(−1.83)–(−1.77)	0.27 –0.54	(−1.309)–(−0.616)
70	2.92	5.8– 8.0	0.062–0.087	(−2.78)–(−2.44)	0.15 –0.31	(−1.897)–(−1.171)

45	3.15	1.0– 1.4	0.010–0.014	(−4.61)–(−4.27)	0.049–0.067	(−3.016)–(−2.700)

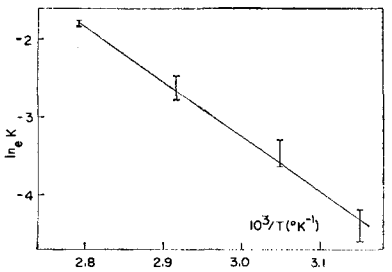

Fig. 6—Van't Hoff plot of apparent equilibrium values derived from asymptotes in Fig. 5.

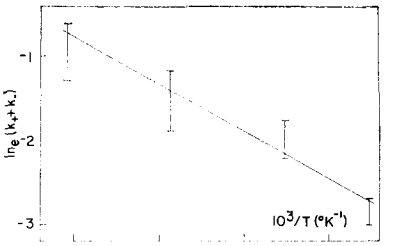

Fig. 7—Arrhenius type plot of the sum of rate constants of vitamin E succinate in lactose base tablets. Values are derived from the curves shown in Fig 5.

The theoretical curve then is $X = 0.143\ (1 - 0.735^t) = 0.143\ (1 - e^{-0.31t})$ as a first estimate.

The theoretical curve can then easily be constructed, and is shown in Fig. 5. Plots at 70° and 55° can similarly be run in a span of 20 days, and fairly good values of X_e may be obtained; longer periods are required for lower temperatures.

Results from storage at other temperatures are shown in Table II and graphically in Fig. 5. The ranges of k and X_e values, as well as of the apparent equilibrium values [$K = X_e/(100 - X_e)$] are shown in Table III. Van't Hoff plotting, *i.e.:*

$$\ln_e K = \frac{-\Delta H}{RT} + \alpha$$

SUMMARY

Cases of equilibrium in solid dosage forms are presented. Such cases should be handled by Van't Hoff plotting rather than Arrhenius plotting.

The virtues of following breakdown product formation as opposed to sole reliance on assays of intact drug are presented.

A rapid method for establishing crude estimates of sum of rate constants and equilibrium value is presented.

p-Methoxycinnamate and Its Metabolite in Rabbit Serum

By WON SICK WOO

A method of *p*-methoxycinnamate determination in serum is described. *p*-Methoxycinnamate, following intravenous injection, disappeared very rapidly from the serum with a half-life of 0.4 hr. due to metabolic alteration. When orally administered to fasted rabbits, it is rapidly absorbed and maximum concentration is reached within 1 hr. Maximum concentration proportionally increases with increasing dose. The metabolite of *p*-methoxycinnamate in serum was identified as *p*-methoxybenzoate.

SCHROPHULARIAE RADIX, a medicinal plant cultivated in Korea, has long been used as an antipyretic and anti-inflammatory drug. In this laboratory, *p*-methoxycinnamic acid (*p*-MCA) was isolated from this plant, and its antipyretic and analgesic properties have been reported (1, 2). It was also shown that *p*-MCA decreased the ascorbic acid contents of adrenals of rats (3) and in unpublished experiments it has been shown that it inhibits the edema formation by irritants such as yeast, formalin, croton oil, and dextran. When administered to a human and rabbits, it is oxidized to *p*-methoxybenzoic acid (*p*-MBA) which is excreted in the urine as conjugates of glycine and glucuronic acid (4).

The present paper describes the rate of decline of the serum *p*-MCA concentration in rabbits following a single dose, and its metabolite in serum. A rapid and convenient method for the measurement of *p*-MCA in serum is included.

EXPERIMENTAL

Estimation of p-Methoxycinnamate in Serum—The determination method of *p*-MCA has not yet been reported. The following UV spectrophotometry for measurement of *p*-MCA in serum was established.

Serum sample (0.2 ml.) was pipeted into a 5-ml. volumetric flask, brought to exactly 5 ml. by adding a 5% solution of $HClO_4$, and thoroughly mixed. After heating at 60–70° for 10 min., the mixture was cooled and centrifuged at 3000 r.p.m. for 5 min. The clear supernatant was poured into a 1-cm. silica cell and the absorbance was measured at a wavelength of 308 mμ in a Beckman DU spectrophotometer. The test solution was read against a 5% solution of $HClO_4$. The mean absorption of serum was subtracted from the absorbance readings. The mean absorption was determined on a series of sera from normal untreated animals.

Figure 1 shows the standard curve obtained by this method as applied to standard solution of sodium *p*-MCA. Linear function is clearly demonstrated over the range studied.

Table I illustrates the recovery of added amounts of sodium *p*-MCA to rabbit serum. The amounts recovered vary from 96 to 112%, averaging 100.5%.

When serum contained more than 20 mg. % sodium *p*-MCA, the analysis was carried out using a smaller aliquot of sample plus water, and diluting

8	6.375	6.425	100.78
9	6.375	6.325	99.22
10	6.375	6.150	96.47

supernatant with 5% $HClO_4$ if necessary, in order to make final concentration in $HClO_4$ solution less than 8 mcg./ml. The results were calculated from the following formula:

$$G \times V/v \times 0.1 = \text{mg. Na } p\text{-MCA/100 ml. serum}$$

where G = amount (mcg.) found in Fig. 1 (after subtraction of serum absorption); V = total volume of the solution after adding $HClO_4$; v = volume of serum used.

Experimental Animals—All rabbits, weighing 2.0–2.5 Kg., were maintained on a constant diet for 1 week prior to the experiments and randomly divided into groups of 4–6 rabbits each. The indicated amounts of sodium *p*-MCA in water solution were administered intravenously and orally to rabbits. In the case of oral administration, animals had been fasted overnight. No food was ingested by animals until at least 5 hr. after drug administration.

Extraction of Metabolites from Serum and Paper Chromatography—A portion of the serum, at a definite interval after drug administration, was adjusted to pH 1 by adding dilute HCl, and extracted with ether. The ether extract was shaken with saturated aqueous solution of $NaHCO_3$. The aqueous phase was made to pH 1 again, and extracted with ether. After drying over anhydrous Na_2SO_4, ether was evaporated under reduced pressure from the extracts. The UV absorption spectrum of the residue in a 5% solution of $HClO_4$ was quite similar to that of the unextracted deproteinized serum.

The residue was dissolved in ethanol to use as a sample for paper chromatography. R_f values of reference compounds are given in Table II.

TABLE II—CHROMATOGRAPHIC BEHAVIOR OF *p*-MCA AND RELATED SUBSTANCES[a]

p-Methoxybenzoic acid	0.58	Bl	...	...
p-Methoxycinnamoyl glycine	0.57	Bl	Br	Or
p-Methoxybenzoyl glycine	0.53	Bl	...	Or
p-Hydroxycinnamic acid	0.35	Bl	Br	...
p-Hydroxybenzoic acid	0.25	Bl	Br	...

[a] The ascending method was used with Whatman No. 4 paper at room temperature. Solvent mixture: isopropyl alcohol–NH_4OH–H_2O–toluene (80:5:15:20). Detecting reagents: *A*, 0.4% bromophenol blue; *B*, iodine vapor; *C*, 4% *p*-dimethylaminobenzaldehyde in acetic anhydride. Abbreviations: Bl, blue; Br, brown; Or, orange.

p-Methoxycinnamoyl glycine (*p*-MCG), m.p. 161°, and *p*-methoxybenzoyl glycine (*p*-MBG), m.p. 172°, were prepared by reaction of corresponding acid chlorides with glycine. *p*-MCA and *p*-hydroxycinnamic acid (*p*-HCA) were prepared according to Knoevenagel (5) and Zincke and Leisse (6), respectively, and *p*-MBA by oxidation of anisaldehyde. *p*-Hydroxybenzoic acid (*p*-HBA) was obtained commercially.

RESULTS AND DISCUSSION

The Decline of Serum p-Methoxycinnamate Concentration After Intravenous Administration—Figure 2 shows the decline of the serum *p*-MCA concentration following intravenous administration at dose levels of 100 mg. and 200 mg./Kg. Serum *p*-MCA concentrations were about 41 mg. and 80 mg./100 ml. 3 min. after injection. It can be seen that *p*-MCA disappeared very rapidly from serum and this elimination was first order. Half-life time for excretion was about 0.4 hr. But this first-order process was preceded by an initial apparent lag phase.

Variation of the Serum p-Methoxycinnamate Concentration After Oral Administration—The results obtained in this study are given as plots of log concentration against time in Fig. 3. The peaks of serum concentration were obtained at around 30–60 min. after drug administration. This result indicates that *p*-MCA was rapidly absorbed. Since *p*-MCA could not be detected in feces excreted within 24 hr. after drug administration (7), it is suggested that *p*-MCA was almost completely absorbed from the digestive tract. The elimination of *p*-MCA from serum was found to proceed by first-order kinetics at a small dose (100 mg./Kg.). At higher doses, *p*-MCA elimination did not follow first-order kinetics (nor a zero-order process), until the amount remaining in the serum was decreased to about 17 mg./100 ml. When serum *p*-MCA concentration has fallen below this level, the first-order elimination seemed to occur. But the rate constants were essentially the same, regardless of

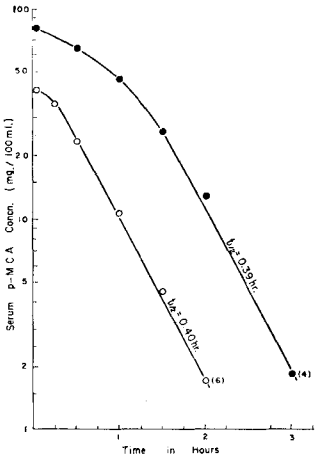

Fig. 2—Elimination of p-*MCA from serum following its intravenous injection of 100 mg./Kg.* (○) *and 200 mg./Kg.* (●). *Figure in parentheses at the right of each line is number of rabbits used.*

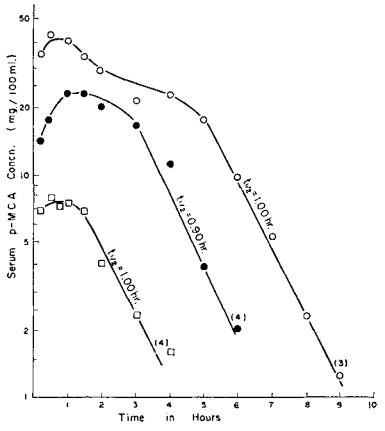

Fig. 3—Serum p-*MCA levels after its oral administration. Key:* □, *100 mg./Kg.;* ●, *300 mg./Kg.;* ○, *500 mg./Kg. Figure in parentheses at the right of each line is number of rabbits used.*

the amount of drug administered. This observed phenomenon is similar to that of salicylate elimination at higher doses (8).

It is of interest that half-life for first-order elimination when administered orally differed from that when administered intravenously. In the case of administration of 100 mg./Kg., the *p*-MCA level was higher (10.85 mg. ± 2.0/100 ml.) 1 hr. after intravenous treatment than when orally given (7.38 mg. ± 0.41/100 ml.). After 2 hr., the *p*-MCA level was higher (3.97 mg. ± 0.8/100 ml.) by oral administration than by intravenous (1.68 mg. ± 0.51/100 ml.).

Maximum Serum p-Methoxycinnamate Concentration as Function of Dose—By representing the average value of observed serum concentration at 30–60 min. after oral administration of drug as a mean maximum serum concentration, over-all results are given in Fig. 4, which indicate that there is a linear relationship between mean maximum concentration and dose.

Metabolite of p-Methoxycinnamate in Serum—Figure 5 shows the spectra of deproteinized serum with $HClO_4$ at various times after an intravenous injection of 100 mg./Kg. Absorption peak at 308 mμ might represent that of *p*-MCA. Although *p*-MCG and *p*-HCA have the absorption peaks at around 292 mμ and 306 mμ, respectively, as shown in Fig. 6, they were not detected in serum by paper chromatography. It is, therefore, evident that this peak was reflected neither by *p*-MCG nor by *p*-HCA. *p*-MBA, *p*-MBG, and *p*-HBA all have no absorbance above 300 mμ. These facts reconfirm that UV spectrophotometry of *p*-MCA is suitable for its determination in serum.

This absorption peak at 308 mμ decreased considerably as time passed. However, the secondary peak at around 258 mμ developed, which also decreased with advance of time. From this phenomenon it is clear that *p*-MCA was converted into another substance. The fact that *p*-MBA has an absorption peak at 258 mμ as shown in Fig. 6 and that *p*-MBA was detected in serum by paper chromatography while neither *p*-MBG nor *p*-HBA was detected indicates that the secondary peak might be identical with that of *p*-MBA. These results show that *p*-MCA is *in vivo* rapidly metabolized to *p*-MBA. This fact coincides with the previously reported communication (4).

SUMMARY

A rapid and convenient method was developed for the measurement of *p*-methoxycinnamate. With this method, the serum *p*-methoxycinnamate concentration has been measured after oral and intravenous administration to rabbits. *p*-Methoxycinnamate disappeared very rapidly from serum with a half-life of 0.4 hr. when injected intravenously. When orally administered, it was rapidly absorbed into the blood stream, and blood levels peaked within 1 hr. but then declined slowly. Average maximum concentrations were strictly proportional to the oral doses. Its elimination from serum was also first order, but the apparent half-life was more than 2 times that when administered intravenously. At higher doses, however, the elimination was not an exponential process in the initial stage. The metabolite of *p*-methoxycinnamate was identified as *p*-methoxybenzoate by ultraviolet spectrophotometry and paper chromatography.

Opium Alkaloids VI

Isolation of *N*-Methyl-14-*O*-desmethylepiporphyroxine

By E. BROCHMANN-HANSSEN, K. HIRAI, B. NIELSEN, S. PFEIFER, I. MANN, and L. KÜHN

The papaverrubine alkaloids and their *N*-methyl derivatives are widely distributed in the genus *Papaver*. They have a number of interesting structural and stereochemical characteristics. A new alkaloid of this general class has now been isolated from opium. It has been characterized by means of NMR and mass spectrometry and by chemical conversions to known compounds.

ALKALOIDS of the general structure (I) are widely distributed in the genus *Papaver* and actually constitute the principal alkaloids of several species (1–3). Many compounds of this type have been isolated from natural sources and differ with regard to their substitution pattern, their conformation, as well as the stereochemistry at the three asymmetric centers. Four opium alkaloids belonging to this group have been reported, namely porphyroxine = papaverrubine D (I; $R^1 = R^4 = CH_3$, $R^2 = R^3 = H$) (4–8), papaverrubine B = *O*-methylporphyroxine (I; $R^1 = R^2 = R^4 = CH_3$, $R^3 = H$) (6, 7, 9, 10), papaverrubine C = epiporphyroxine (I; $R^1 = R^4 = CH_3$, $R^2 = R^3 = H$) (12), and glaudine = *O,N*-dimethylporphyroxine (I; $R^1 = R^2 = R^3 = R^4 = CH_3$) (9, 11). They have a *trans*-

SUMMARY

A rapid and convenient method was developed for the measurement of *p*-methoxycinnamate. With this method, the serum *p*-methoxycinnamate concentration has been measured after oral and intravenous administration to rabbits. *p*-Methoxycinnamate disappeared very rapidly from serum with a half-life of 0.4 hr. when injected intravenously. When orally administered, it was rapidly absorbed into the blood stream, and blood levels peaked within 1 hr. but then declined slowly. Average maximum concentrations were strictly proportional to the oral doses. Its elimination from serum was also first order, but the apparent half-life was more than 2 times that when administered intravenously. At higher doses, however, the elimination was not an exponential process in the initial stage. The metabolite of *p*-methoxycinnamate was identified as *p*-methoxybenzoate by ultraviolet spectrophotometry and paper chromatography.

Opium Alkaloids VI

Isolation of *N*-Methyl-14-*O*-desmethylepiporphyroxine

By E. BROCHMANN-HANSSEN, K. HIRAI, B. NIELSEN, S. PFEIFER, I. MANN, and L. KÜHN

The papaverrubine alkaloids and their *N*-methyl derivatives are widely distributed in the genus *Papaver*. They have a number of interesting structural and stereochemical characteristics. A new alkaloid of this general class has now been isolated from opium. It has been characterized by means of NMR and mass spectrometry and by chemical conversions to known compounds.

ALKALOIDS of the general structure (I) are widely distributed in the genus *Papaver* and actually constitute the principal alkaloids of several species (1–3). Many compounds of this type have been isolated from natural sources and differ with regard to their substitution pattern, their conformation, as well as the stereochemistry at the three asymmetric centers. Four opium alkaloids belonging to this group have been reported, namely porphyroxine = papaverrubine D (I; $R^1 = R^4 = CH_3$, $R^2 = R^3 = H$) (4–8), papaverrubine B = *O*-methylporphyroxine (I; $R^1 = R^2 = R^4 = CH_3$, $R^3 = H$) (6, 7, 9, 10), papaverrubine C = epiporphyroxine (I; $R^1 = R^4 = CH_3$, $R^2 = R^3 = H$) (12), and glaudine = *O,N*-dimethylporphyroxine (I; $R^1 = R^2 = R^3 = R^4 = CH_3$) (9, 11). They have a *trans*-

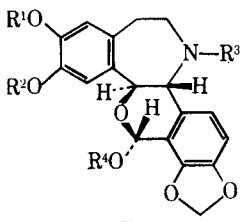
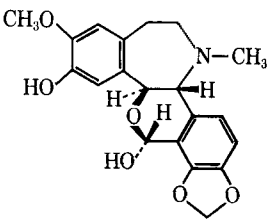
This investigation was supported in part by research grant MH-03487 from the National Institutes of Health, U. S. Public Health Service, Bethesda, Md.

Previous paper: Brochmann-Hanssen, E., and Hirai, K., *J Pharm. Sci.*, **56**, 1658(1967).

P. rhoeas (13) and oreodine from *P. oreophilum* (14, 15) have the C-1 and C-2 protons in *cis*-configuration. There is convincing evidence that the stereochemistry at the 14-position of porphyroxine, papaverrubine B, and glaudine is as shown in II (8). This configuration is thermodynamically unstable and refluxing with methanol containing trace amounts of acid will cause epimerization to III (12, 16). Papaverrubine C already has this configuration (12). However, it may be an artifact formed from porphyroxine during the extraction (12). Treatment with 1 *N* HCl will invert the *trans*-configuration at the B/D ring junction to *cis* (1, 16, 17). Gentle hydrolysis of the methyl acetal glaudine (II; $R^1 = R^2 = R^3 = R^4 = CH_3$) will give the hemiacetal glaucamine (III; $R^1 = R^2 = R^3 = CH_3$, $R^4 = H$) which has been isolated from *P. glaucum* (18). During this hydrolysis, epimerization occurs at the 14-position, and methylation of glaucamine does not produce glaudine but epiglaudine (1, 16) (III; $R^1 = R^2 = R^3 = R^4 = CH_3$).



III



IV

A new phenolic opium alkaloid related to glaucamine has now been isolated simultaneously by research groups at the University of California, San Francisco,[1] and Humboldt University, Berlin, Germany.[2] The present paper is a joint report of the isolation and structure elucidation of this substance. The mass spectrum and accurate mass determinations of the major fragments indicated that the alkaloid was a lactol of structure I in which $R^4 = H$. This was confirmed by NMR spectrometry which showed the presence of one *O*-Me group and a *N*-Me group. The coupling constant $J_{1,2}$ placed the alkaloid as a member of the B/D-*trans*-series. The position of the phenolic hydroxyl group was established by observing the changes in the chemical shifts of the C-6 and C-9 protons in going from the phenol to the phenolate ion. This made it possible to assign structure IV to the new compound. Confirmation of this structure was achieved by methylation of the hydroxyl group in the 14-position to give *N*-methylepiporphyroxine (III; $R^1 = R^3 = R^4 = CH_3$, $R^2 = H$). *O*-Methylation of the new alkaloid with diazomethane produced glaucamine which was further methylated with methanol and acid to epiglaudine. This substance was converted to epiglaudine methiodide with methyl iodide. Glaucamine obtained by methylation of the new alkaloid was refluxed with 1 *N* hydrochloric acid to give the *cis*-isomer (oreogenine) which on methylation produced oreodine. The various derivatives were identified by NMR spectrometry, thin-layer chromatography, melting points, and mixed melting points with authentic materials.

EXPERIMENTAL

Isolation—Dried and powdered opium (1,755 Gm.) of Indian origin was extracted and a separation of the major alkaloid groups carried out by liquid–liquid extraction techniques as described in an earlier publication (19). Preparative thin-layer chromatography of the phenolic alkaloid fraction on silica gel (20) revealed reticuline, isoboldine, scoulerine, and a broad band consisting of several alkaloids. This alkaloid mixture was eluted from the silica gel with warm methanol, the solution evaporated to dryness *in vacuo*, and the residue chromatographed on a column of neutral alumina (Merck, activity 4) with chloroform. Twenty-milliliter fractions were collected with an automatic fraction collector. The first fractions contained porphyroxine (8) followed by scoulerine and several unknown alkaloids. One of these (100 mg.) referred to in the following as A-4 crystallized from methanol as colorless prisms, m.p. 217–218° (micro m.p.K.), $[\alpha]_D^{20} = +340$ (c 0.2% in methanol). It gave a single spot by thin-layer chromatography in two different solvent systems (21) and a single, somewhat broad peak by gas chromatography on silicone rubber SE-30 (3.8%, 4 ft., 200°). When the thin-layer plate was sprayed with potassium iodoplatinate, the orange-brown spot turned to a stable red color after several hours.

Anal.[3]—Calcd. for $C_{20}H_{21}NO_6$: C, 64.73; H, 5.70; N, 3.78. Found: C, 64.32; H, 5.78; N, 4.00.

Elucidation of Structure—The IR spectrum[4] (in Nujol) showed broad bands at about 3270 and 3450 cm.$^{-1}$ due to hydroxyl groups The UV spectrum[5] (in 95% ethanol) had maxima at 238 and 288 mμ which shifted to 242 and 293 mμ on addition of sodium hydroxide, indicating the presence of a phenolic hydroxyl group. The mass spectrum[6] gave a molecular ion with mass 371 and major fragments at *m/e* 206, 192, and 163. The M-1 ion was very small while there was a significant M-18 peak. Metastable ions appeared at *m/e* 138.4 and 129. Accurate mass determinations[7] gave a molecular weight of 371.136908 for the molecular ion

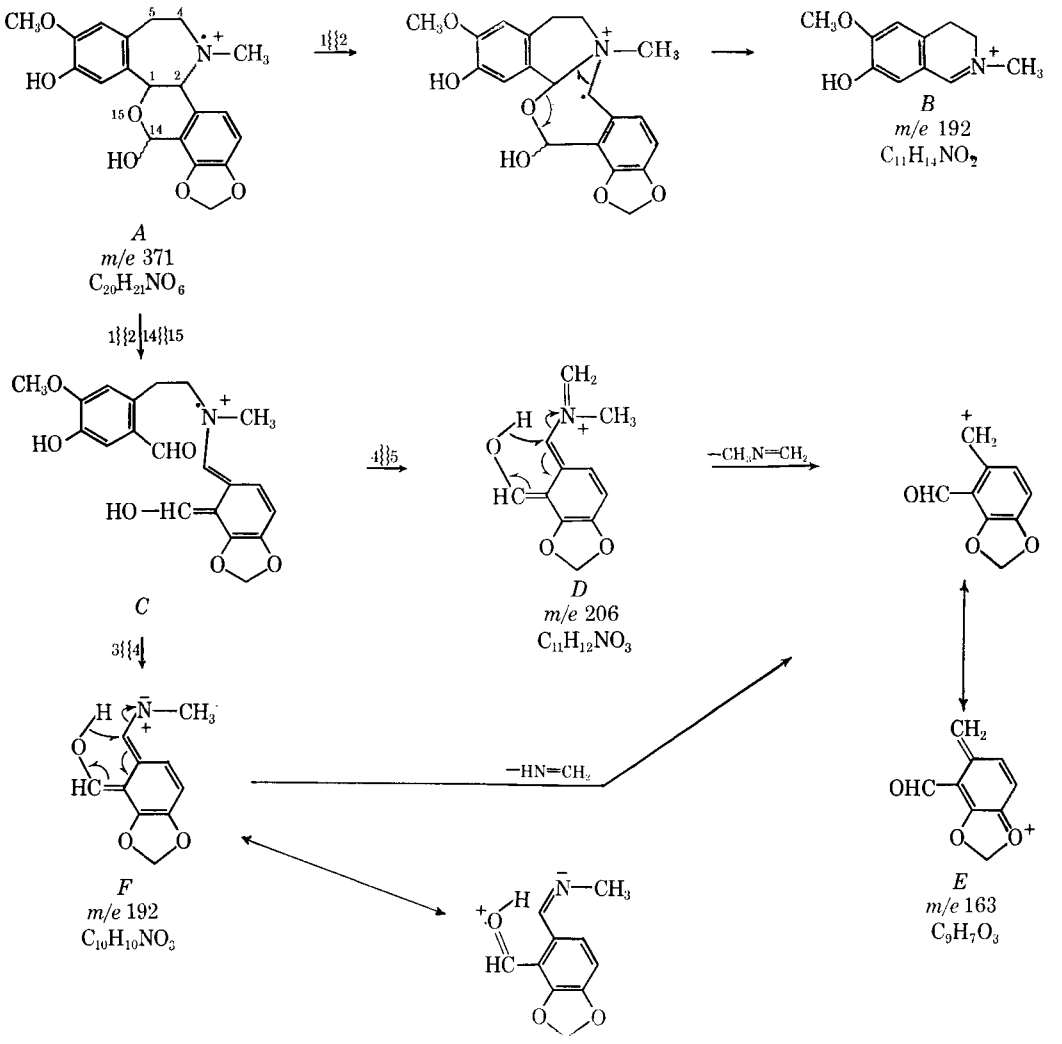
[7] The accurate mass determinations were made by the Robert Robinson Laboratories, University of Liverpool, England.



Scheme I

($C_{20}H_{21}NO_6$ = 371.136879). The *m/e* 206 peak gave a molecular weight of 206.081697 ($C_{11}H_{12}NO_3$ = 206.081712). The *m/e* 192 peak was a doublet: 192.065933 ($C_{10}H_{10}NO_3$ = 192.066063) and 192.101421 ($C_{11}H_{14}NO_2$ = 192.102447) with a 3:1 peak height ratio for the low and the high mass. The *m/e* 163 peak had a mass calculated to 163.039576 ($C_9H_7O_3$ = 163.039515). These results indicated that A-4 was a hemiacetal of the same general structure as glaucamine (22). There is a significant difference in the fragmentation pattern of the acetals (*i.e.*, glaudine and rhoeadine) and hemiacetals (*i.e.*, glaucamine and rhoeagenine). The acetals readily split off $CH_3\cdot$ and $CH_3O\cdot$ to give M-15 and M-31 peaks, whereas the hemiacetals give distinct M-18 ions by a pyrolytic removal of water. The proposed fragmentation of A-4 is illustrated in Scheme I (1, 6, 17, 22). The principal fragmentations occur according to the sequences $A \rightarrow C \rightarrow D \rightarrow E$ and $A \rightarrow C \rightarrow F \rightarrow E$, while the sequence $A \rightarrow B$ represents only a minor pathway. This is consistent with the results obtained by the accurate mass determinations as well as the appearance of metastable ions at *m/e* 138.4 and 129.

The NMR spectra[8] in deuterochloroform and hexadeuterodimethylsulfoxide (internal TMS standard) support the structure IV for A-4. The chemical shifts and the coupling constants are presented in Table I. The C-14 proton of the lactol ring gave a broad signal at 3.71 τ in $CDCl_3$, indicating coupling with an adjacent hydroxyl group. This was confirmed by the addition of D_2O which exchanged with the hydroxyl proton resulting in a sharp peak for the proton in position 14. In $(CD_3)_2SO$ this proton peak overlapped the methylenedioxy signal. The protons in positions 1 and 2 resonated as an AX-type quartet at 6.13 τ (2-H) and 4.26 τ (1-H) in $CDCl_3$ with a coupling constant J = 9 c.p.s. In $(CD_3)_2SO$ this quartet appeared at 6.23 τ and at 4.40 τ, J = 9 c.p.s. These results show that A-4 has a *trans*-configuration at the B/D junction

TABLE II—CHANGES IN THE CHEMICAL SHIFTS ON ADDITION OF SODIUM DEUTEROXIDE TO A SOLUTION OF A-4 IN $(CD_3)_2SO$ (τ)

	1	2	3	$\Delta\tau$
C-6	3.27	3.34	3.57	0.30 p.p.m.
C-9	2.96	3.06	3.37	0.41 p.p.m.
	phenol → phenolate			

because the coupling constant is in agreement with the values reported for glaucamine (23), isorhoeadine (13, 15), glaudine (15), and porphyroxine (8). A smaller coupling constant ($J_{1,2}$ = 2–2.5 c.p.s.) has been observed for the B/D *cis*-alkaloids (13, 15).

The position of the phenolic hydroxyl group in ring A was determined by measuring the chemical shifts of the aromatic protons as a function of pH as described previously for porphyroxine (8). Small amounts of sodium deuteroxide were added successively to a solution of A-4 in $(CD_3)_2SO$ until no further changes were observed in the chemical shifts of the C-6 and C-9 protons. The results are recorded in Table II. The C-6 proton shifted upfield 0.30 p.p.m. by conversion to the phenolate, and the C-9 proton shifted 0.41 p.p.m. in the same direction.

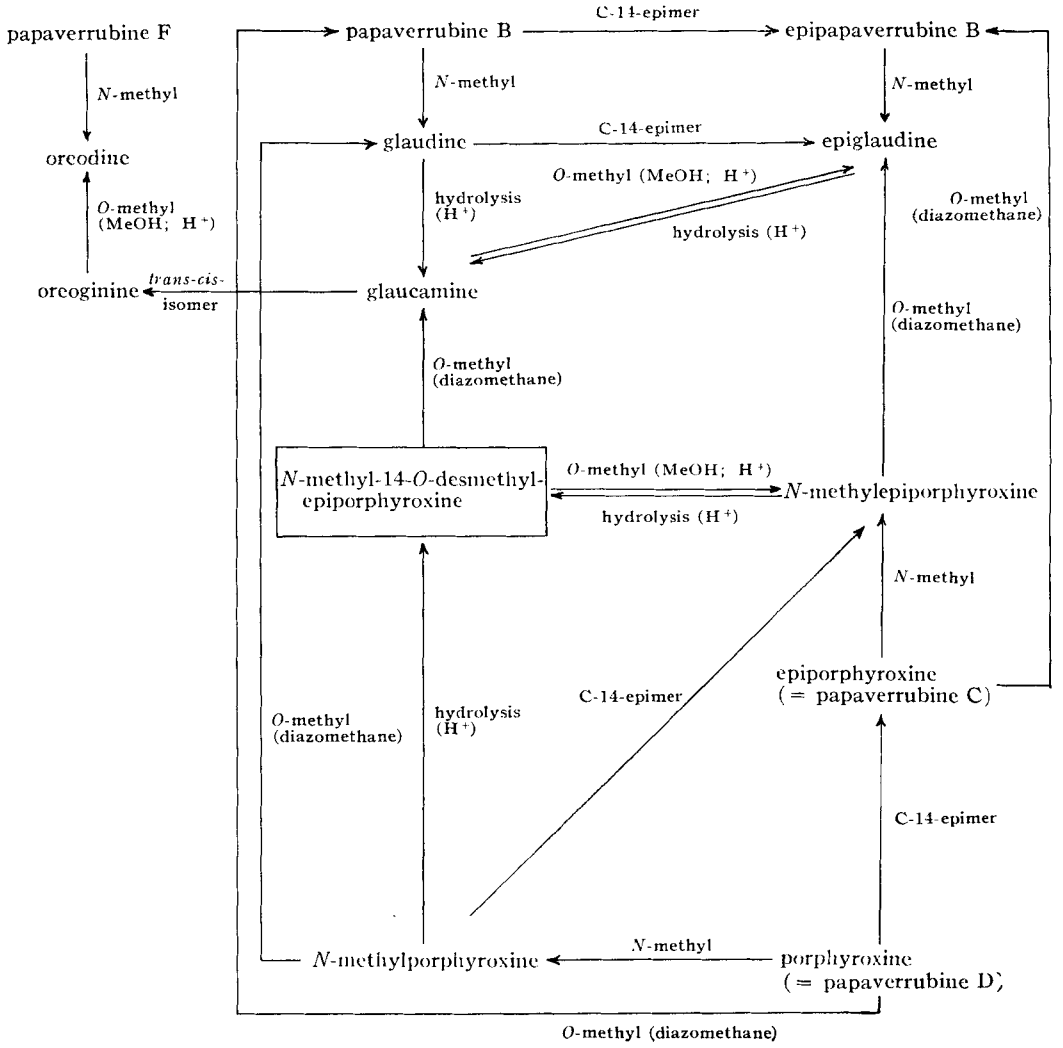
These values are in excellent agreement with those recorded for porphyroxine and show that these two alkaloids have the same substitution pattern in ring A, *i.e.*, the phenolic hydroxyl group is in position 8.

Synthesis of Derivatives

A—*14-O-Methyl-A-4*—Ten milligrams of A-4 was dissolved in 9 ml. of anhydrous methanol and 0.9 Gm. of dry hydrogen chloride was added at 0°. The mixture was allowed to stand at room temperature in the dark for 4 days. The solution was evaporated to dryness *in vacuo*, the residue dissolved in water, made alkaline with sodium bicarbonate, and extracted with chloroform. Evaporation of the chloroform gave an oil which was purified by preparative thin-layer chromatography on silica gel (20). An amorphous substance was obtained which gave a single spot by thin-layer chromatography on silica gel in two solvent systems (21). The R_f values of 14-*O*-methyl-A-4 were identical with those of authentic *N*-methylepiporphyroxine and slightly different from those of *N*-methylporphyroxine. The NMR spectrum of 14-*O*-Me-A-4 was very similar to that of epiglaudine, prepared as described previously (8), but it differed from that of *N*-methylporphyroxine (Table I). It may, therefore, be concluded that 14-*O*-Me-A-4 and *N*-methylporphyroxine only differ with respect to the configuration at the asymmetric center of position-14.

The acetal 14-*O*-methyl-A-4 was also prepared by refluxing for 5 hr. with methanolic hydrochloric acid (0.02 *N*).

B—*Preparation of Glaucamine from A-4*—To a solution of 15 mg. of A-4 in 2 ml. of methanol was added 3 ml. of diazomethane solution (from 0.1 mole of nitrosomethylurea in 100 ml. of ether), and the mixture was kept at 5° for 24 hr. The solution was evaporated to dryness *in vacuo* and the residue dissolved in ether. The solution was concentrated to 1 ml. and allowed to stand for several days to



Scheme II

crystallize. The crystals melted at 222–223° and gave no melting point depression in mixture with authentic glaucamine. The R_f values were identical with those of authentic glaucamine on Silica Gel G (benzene–acetone–methanol, 7:2:1) and on aluminum oxide (Merck) (heptane–chloroform–ether, 4:5:1 and 5:3:2).

C—*Preparation of Epiglaudine Methiodide from A-4*—Glaucamine prepared as described under *B* was refluxed for 5 hr. with methanolic hydrogen chloride (0.02 *N*). The solution was neutralized with ammonia and evaporated to dryness *in vacuo*. The residue was dissolved in a little 0.1 *N* sulfuric acid, immediately made basic with ammonia and extracted with ether. The ether extract was dried over anhydrous sodium sulfate and evaporated to dryness. The residue, which had the same R_f value as authentic epiglaudine, was converted to the methiodide with methyl iodide, m.p. 157–160°. [Lit. m.p. 159–161° (12).]

D—*Preparation of Oreodine from A-4*—Ten milligrams of glaucamine prepared from A-4 as described under *B* was dissolved in 3 ml. of 1 *N* hydrochloric acid and refluxed for 1 hr. After cooling to room temperature, the solution was made basic with ammonia and extracted several times with ether. The combined ether extracts were dried over anhydrous sodium sulfate and evaporated to dryness. The residue (= oreogenine) was dissolved in 5 ml. of methanol containing 0.1 ml. of 1 *N* hydrochloric acid and refluxed for 5 hr. After neutralization with ammonia, the solution was evaporated to dryness *in vacuo*. The residue was dissolved in a little 0.1 *N* sulfuric acid, made basic with ammonia, and extracted repeatedly with ether. The combined ether extracts were dried over anhydrous sodium sulfate and concentrated to 2 ml. The substance, which crystallized as colorless needles, melted at 184–186° and gave no melting point depression when mixed with authentic oreodine. It gave the same R_f values as oreodine by thin-layer chromatography on aluminum oxide (Merck) with two solvent systems prepared from heptane–chloroform–ether (4:5:1 and 5:3:2).

DISCUSSION

A new phenolic alkaloid has been isolated from opium and characterized as *N*-methyl-14-*O*-desmethylepiporphyroxine (IV) by mass and NMR spectroscopy and by chemical conversion to known compounds. It belongs to a group of plant bases of the general structure I which is widely distributed in the genus *Papaver*. *N*-Methyl-14-*O*-desmethylepiporphyroxine is the fifth such alkaloid isolated from opium. Like glaucamine, it is a lactol (hemiacetal) having a thermodynamically stable configuration at the 14-position, and a *trans*-configuration at the B/D ring junctions. The relationships of the new base to other compounds of this type have been verified experimentally and are illustrated in Scheme II. *N*-Methyl-14-*O*-desmethylepiporphyroxine may also be obtained by hydrolysis of *N*-methylporphyroxine. There is reason to believe that *N*-methylporphyroxine, having the less stable configuration at the 14-position (II) may occur in the opium poppy. It is, therefore, possible that *N*-methyl-14-*O*-desmethylepiporphyroxine may not exist as such in the fresh plant, but may be formed by acid hydrolysis and epimerization during the drying and storage of opium or in the course of the extraction and purification of the alkaloid fractions.

Human Urinary Excretion of Orally Administered Anisotropine Methylbromide

By MORRIS PFEFFER, JOSEPH M. SCHOR, NORMAN GLUCK, MARTIN G. SEMMEL, and SOLOMON GRIBOFF

A procedure is described for the quantitative determination of anisotropine methylbromide in undiluted human urine. It has been used to follow the urinary excretion of this compound after oral administration of 20 mg. to six humans. A sustained excretion has been found in human volunteer subjects, in one case lasting up to 104 hr.

AN INVESTIGATION of anisotropine methylbromide[1] (8-methyltropinium bromide 2-propylpentanoate), a quaternary antispasmodic, required the development of a method sufficiently sensitive for its estimation in materials of biological origin.

A modification of the picric acid assay of Chin and Lach (1), itself adapted from a method reported by Slonecker *et al.* (2), was found to have definite advantages over the previously reported method of Mitchell and Clark (3) in ease and speed of operation, with a resultant gain in accuracy and precision, as well as permitting the analysis of human excretion of the quaternary ammonium compound (QAC) in undiluted urine.

EXPERIMENTAL

Reagents—Anisotropine methylbromide, methyltropinium bromide, and homatropine methylbromide originated at Endo Laboratories. Atropine methylbromide was of Mann assayed grade. Choline chloride, acetylcholine chloride, and phosphocholine chloride were obtained from Calbiochem, the first two of commercial grade and the last of A grade. Thiamine hydrochloride was a USP supplied standard. Chloroform (J. T. Baker Chemical Co.) was of spectrophotometric reagent grade. All other chemicals were commercial products of reagent grade.

Analytical Procedures—The analytical method is an ion-pair extraction of methyl anisotropinium picrate from an alkaline aqueous solution into a nonpolar medium. A 5-ml. aqueous QAC-containing solution or 5 ml. of urine was made alkaline (pH >11) with 0.05 ml. of concentrated ammonia and 1 ml. of 0.1% aqueous picric acid solution added. After addition of 5 ml. of chloroform, the mixture was extracted by agitation on a Vortex Genie mixer for 15 sec. The upper aqueous layer was removed by aspiration, and the absorbance at 365 mμ (A_{365}) of the chloroform layer was determined in a Hitachi Perkin-Elmer 139 spectrophotometer using 10-mm. silica cells. The spectrophotometer was set to zero absorbance with the chloroform layer derived from a reagent blank. Chloroform–urine emulsions were broken by centrifuging 10 min. at 1000 r.p.m. at ambient temperature.

The sensitivity of the method was increased roughly threefold by limiting it to a single extraction, thereby avoiding dilution of the absorbing material. Replicate alkaline solutions were extracted, in duplicate, with, respectively, one, two, or three 5-ml. portions of chloroform, and it was determined that 92% of all the methyl anisotropinium picrate extractable in three successive extractions came out in the first extraction.

The characteristics of the picric acid assay system are similar to those reported by Chin and Lach (1). Absorption spectra of the chloroform extracts of the alkaline QAC–picric acid solutions were determined. The QAC's used are listed above in the reagent section. Standard curves were determined by plotting A_{365} of the chloroform extracts *versus* the concentrations of the aqueous QAC solutions which were subjected to analysis. The absorption spectrum of the chloroform extract derived from the anisotropine methylbromide–picric acid reaction mixture is essentially identical to the absorption spectra reported for benzalkonium picrate and cetylpyridinium picrate by Chin and Lach (1). Chloroform extracts of alkaline aqueous or urine solutions of choline chloride, acetylcholine chloride, phosphocholine chloride, thiamine hydrochloride, methyltropinium bromide, atropine methylbromide, or homatropine methylbromide mixed with picric acid yielded negligible absorption spectra; the naturally occurring quaternaries, choline, its deriva-

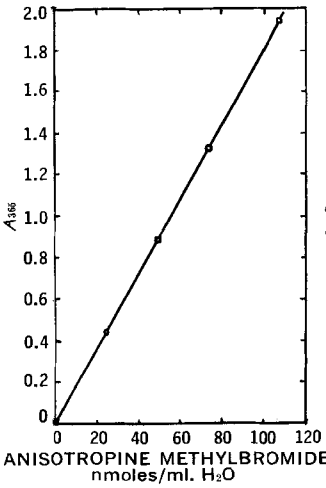

Fig. 1—Standard curve, methyl anisotropinium picrate in chloroform.

Received July 7, 1967, from the Department of Biochemistry and Department of Medicine, Endo Laboratories, Inc., Garden City, NY 11530
Accepted for publication August 21, 1967.
[1] Valpin, Endo Laboratories, Inc.

tives, or thiamine, will not interfere with the methyl anisotropinium assay when they are present in urine. Atropine methylbromide and homatropine methylbromide are several orders of magnitude more susceptible to alkaline hydrolysis than anisotropine methylbromide (4), both forming the unreactive quaternary alcohol, methyltropinium bromide. Presumably, thiamine hydrochloride produced no interaction due to prior destruction in the highly alkaline medium (5). At concentrations up to 110 nanomoles/ml. (nmoles/ml.), the only QAC which reacted to produce a standard curve was anisotropine methylbromide (Fig. 1).

When control, human urines from untreated individuals were compared to water blanks assayed at the same time, there was always a component of blank absorption. In addition, when human urines containing added anisotropine methylbromide were compared to water standards of the same concentrations, there was always an analytical loss. This loss could be due to the presence in urine of anions which have a greater affinity for methyl anisotropinium cation than does picrate. The blank absorptions and analytical losses were calculated by comparing quintuplicate samples of 0, 5, 10, and 15 nmoles/ml. anisotropine methylbromide in deionized water and in control urine, collected daily, over a period of 5 days. It was determined that the quantities recovered varied from one individual to another but were quite constant for the individual (Table I). The values for methyl anisotropinium ion in urine samples were determined by correcting the experimental A_{365} values for these factors.

Creatinine concentrations of urine specimens were determined by the method of Taussky (6) wherein ether removes reactive impurities while the creatinine is reacting with picric acid. The color of the picric acid–creatinine reaction product is developed with alkali. It was found that QAC's did not interfere with this assay in either aqueous solution or urine.

TABLE I—REPRODUCIBILITY OF BLANK VALUES AND ANALYTICAL RECOVERIES IN ANALYSIS OF URINE FOR ANISOTROPINE METHYLBROMIDE

Donor No.	Mean Blank A_{365} ± S.D.[a]	Mean Analytic Recovery,[b] % ± S.D.
1	0.019 ± 0.001	82.9 ± 5.5
2	0.024 ± 0.001	81.4 ± 3.5
3	0.021 ± 0.005	44.1 ± 7.2
4	0.018 ± 0.002	73.9 ± 7.4
5	0.041 ± 0.002	97.2 ± 1.7
6	0.014 ± 0.003	...
7	0.020 ± 0.002	...
8	0.043 ± 0.008	71.2 ± 5.8
9	0.038 ± 0.017	72.1 ± 5.2
10	0.018 ± 0.009	92.2 ± 5.3

[a] S.D. = standard deviation. [b] Losses are due to components normally present in urine. Expressed as percent of compound recovered after addition to urine from that donor.

TABLE II—CORRECTION VALUES AND DOSAGE FOR HUMANS

Subject	Mean Blank A_{365} ± S.D.	Mean Analytical Recovery, % ± S.D.	Anisotropine Methylbromide, Dose, mg./Kg.
A	0.015 ± 0.003	91.9 ± 6.7	0.264

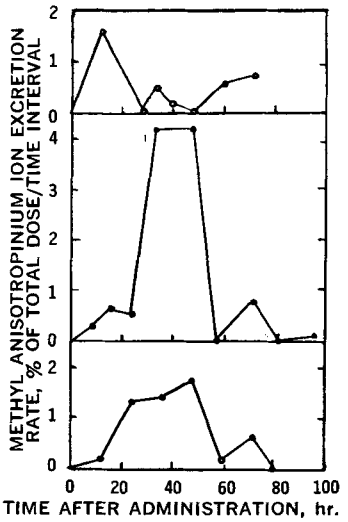

Fig. 2—Fractional urinary excretion of 20 mg. of anisotropine methylbromide administered as two 10-mg. tablets. Top, subject C; *middle, subject* B; *bottom, subject* A.

Excretion Study—After determining the blank value and the analytical loss in four separate 24-hr. urine samples per subject (Table II), six male subjects each took 20 mg. of anisotropine methylbromide (as two 10-mg. tablets) 0.5 hr. before breakfast. None of the subjects were taking any other medication at the time and none showed specific gravity abnormalities or any urine pathology; negative for blood, protein, and glucose and normal for pH as determined with Clinistix.[2] The mg./Kg. dosages of anisotropine methylbromide are listed in Table II. Urine collections from subjects *A*, *B*, and *C* were carried out for 80, 96, and 72 hr., respectively. Subjects *D*, *E*, and *F* were followed for 144 hr. The results for methyl anisotropinium ion excretion are presented in Table III and Figs. 2 and 3.

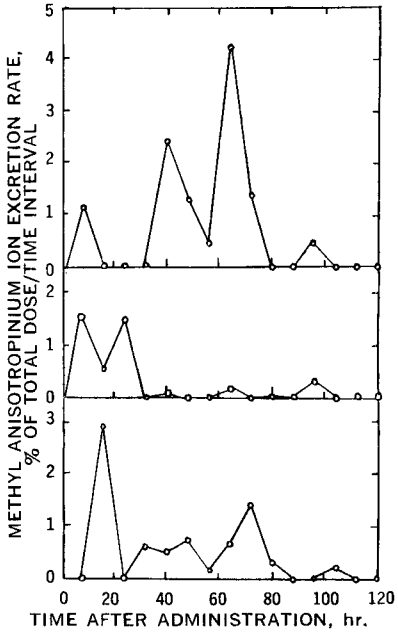

Fig. 3—Fractional urinary excretion of 20 mg. of anisotropine methylbromide administered as two 10-mg. tablets. Top, subject F; middle, subject E; bottom, subject D.

RESULTS AND DISCUSSION

Only methyl anisotropinium ion or nonhydrolyzed metabolic products would be likely to be detected by the picric acid assay method. If any such metabolites are present in urine, they are being included in the results reported as methyl anisotropinium ion excretion. Conversely, any drug broken down and being excreted as methyltropinium ion is being excluded.

The pattern indicated for methyl anisotropinium excreted by humans is most interesting. The data for fractional excretion (Figs. 2 and 3) indicate the presence of several excretion peaks over a period of 4 days. The magnitude of each of these peaks, and of the total cumulative excretion (Table III), varies with the subject. Previous studies of urinary excretion of QAC's after oral administration do not seem to have been carried out past 24 hr. (7–12). It is, as yet, unclear whether this sustained excretion is a common phenomenon in QAC excretion. The total excretions reported in Table III for anisotropine methylbromide show that anisotropine methylbromide, like previously studied quaternary compounds, is incompletely absorbed (7, 9, 11).

These results indicate not only absorption of anisotropine methylbromide, but also retention in the body of a portion of the absorbed material for an appreciable length of time. The compound may be stored for varying lengths of time in tissue depots, or perhaps recurring reabsorption of anisotropine methylbromide excreted in the bile has this effect. The periodicity of excretion would then be a function of the release of bile from the gall bladder. There are other explanations possible, but the present data do not permit definite conclusions to be drawn.

These results refer to only a limited number of human volunteers, and the variability which has previously been reported in QAC excretion (7–11) is also present here.

Synthesis and Antibacterial Activity of Certain 3-Substituted Benzoxazolinones

By RAJENDRA S. VARMA and W. LEWIS NOBLES

The preparation of a series of 3-substituted 2-benzoxazolinones is described. These compounds were screened for their antibacterial properties; most compounds have shown significant antibacterial activity.

BENZOXAZOLINONES have been associated with various types of biological properties; Lespagnol and co-workers prepared and tested a number of derivatives of 2-benzoxazolinones for their anticonvulsive, hypnotic, antipyretic, and analgesic effects (1). 2-Benzoxazolinone and its 3-methyl, 3-ethyl, and 3-hydroxyethyl derivatives elicited the greatest anticonvulsant activity, whereas the 3-acetamido, 3-dihydroxyethyl, and 3-diethylaminoethyl derivatives exhibited marked analgesic activity. 2-Benzoxazolinone has also been reported to inhibit the growth of *Pseudomonas aeruginosa* (2), whereas its quaternary ammonium complexes have shown bactericidal properties (3).

The pronounced biological activity of many benzoxazole derivatives (4, 5) and the medicinal value of 5-chloro-2-benzoxazolinone (6) prompted the investigation of 3-substituted-2-benzoxazolinones. In this article the preparation of a number of 3-substituted-2-benzoxazolinones and their antibacterial activity are reported.

DISCUSSION

The compounds listed in Table I were prepared by the condensation of 2-benzoxazolinone, formaldehyde, and the appropriate secondary amine. The reaction usually occurred in the cold, but, in certain cases, warming for a few minutes resulted in improved yields. The source of formaldehyde was either formalin or paraformaldehyde; both gave satisfactory products. The condensations were performed in both ethanol or *p*-dioxane. Ethanol was usually preferred to *p*-dioxane.

Condensation of 2,6-dimethylpiperidine, as might be expected due to steric factors, with 2-benzoxazolinone did not yield the 2,6-dimethylpiperidinomethyl derivative, but gave instead a product whose analytical data, melting point, mixed melting point, and infrared spectra were identical with 3-hydroxymethyl-2-benzoxazolinone (XXIV). Under identical conditions 5-chloro-2-benzoxazolinone gave 3-hydroxymethyl-5-chloro-2-benzoxazolinone (XXV). While using 5-chloro-2-benzoxazolinone, 2,6-dimethylmorpholine also did not yield 3-(2,6-dimethylmorpholinomethyl)-5-chloro-2-benzoxazoline, but gave instead compound XXV.

The NMR spectrum (CCl_4) of compound III (Table I) was in complete agreement with the proposed structure. A multiplet representing protons (4H) of the aromatic ring and a singlet due to the $-N-CH_2-N-$ protons were observed at 6.9–7.2 δ and 4.5 δ, respectively. Four protons of the two methylene groups adjacent to the nitrogen were attributed to a doublet centered at 2.6 δ. A broad singlet observed at 1.5 was assigned to the methylene protons (6H) remote from the nitrogen.

Treatment of 2-benzoxazolinone with formaldehyde in the absence of amine furnished compound XXIV. The infrared spectrum of compound XXIV showed a band of medium intensity at 3400 cm.$^{-1}$ (OH, stretching) and a broad strong band at 1750 cm.$^{-1}$ (C=O, stretching). 5-Chloro-2-benzoxazolinone under identical conditions yielded compound XXV. The infrared spectrum of compound XXV exhibited a band of medium intensity at 3380 cm.$^{-1}$ (OH, stretching) and a strong band at 1755 cm.$^{-1}$ (C=O, stretching). In its NMR spectrum (CD_3CN) a complex multiplet was observed at 7 δ and a singlet at 5.16 δ which might be attributed to aromatic (3H) and methylene (2H) protons, respectively. The spectrum also showed a singlet at 4.18 δ which was assigned to the hydroxyl protons. The peak due to the hydroxyl group disappeared on D_2O exchange.

3-Hydroxymethyl-5-chloro-2-benzoxazolinone (XXV), on treatment with acetic anhydride, gave 3-acetoxymethyl-5-chloro-2-benzoxazolinone (XXVI). The infrared spectrum of this compound exhibited a doublet at 1785 cm.$^{-1}$ (ring carbonyl) and 1720 cm.$^{-1}$ (ester carbonyl). Compound XXV reacted with phosphorous tribromide to yield compound XXVII. Its infrared spectrum showed a strong band at 1780 cm.$^{-1}$ (C=O, stretching). The spectrum did not show hydroxyl absorption, thus indicating that the reaction has taken place. The NMR spectrum (CCl_4) of compound XXVII demonstrated singlets at 6.96 δ and 5.45 δ; these were assigned to aromatic (3H) and methylene (2H) protons, respectively.

The reaction of compound XXIV with 2-nitrophenylisocyanate furnished compound XXVIII. Its infrared spectrum showed characteristic absorptions at 3390 cm.$^{-1}$ (–NH–), 1790 cm.$^{-1}$ (ring carbonyl), and 1770 cm.$^{-1}$ (–C(=O)–NH–). Likewise compound XXV gave compound XXIX on treatment with 2-nitrophensyliocyanate. Its infrared

(*Continued on next page.*)

spectrum exhibited absorption bands at 3300 cm.$^{-1}$ (–NH–), 1790 cm.$^{-1}$ (ring carbonyl), and 1740 cm.$^{-1}$ (–C(=O)–NH–). Aniline in the presence of formaldehyde reacted with 5-chloro-2-benzoxazolinone to give compound XXX. Characteristic absorption bands were observed at 3380 cm.$^{-1}$ (–NH–) and 1750 cm.$^{-1}$ (C=O). 3,4,5-Trimethoxybenzoyl chloride in benzene solution successfully reacted with compound XXIV to yield compound XXXI. Its infrared spectrum showed a doublet at 1790 cm.$^{-1}$ (ring carbonyl) and 1720 cm.$^{-1}$ (ester carbonyl). Similarly, compound XXV yielded compound XXXII on treatment with 3,4,5-trimethoxybenzoyl chloride. A doublet was observed at 1800 cm.$^{-1}$ (ring carbonyl) and 1730 cm.$^{-1}$ (ester carbonyl) in the infrared spectrum of compound XXXII. The sequence of these reactions is described in Scheme I.

BIOLOGICAL DATA

All compounds reported here were subjected to preliminary antibacterial screening procedures except compounds XXIV, XXV, and XXVII. Filter paper disks (6.35 mm.), saturated with 2 drops of the solution or suspension of the test compound (20 mg./ml. in ethanol), were placed on the agar. The microbial spectrum consisted of four organisms: *Pseudomonas aeruginosa*, *Staphylococcus aureus* K257, *Mycobacterium smegmatis*, and *Klebsiella pneumoniae* ATCC8052. After 4 days of incubation, the zones of inhibition around the disks were measured. Out of the 29 compounds screened, 20 compounds inhibited the growth of *Ps. aeruginosa*, 19 compounds inhibited the growth of *S. aureus*

[a] Hexamethyleneimino. [b] Yields are of the products obtained from first crystallization. [c] Prepared by method *A*. [d] Prepared by method *B*. [e] Prepared by method *C*. [f] Lit. (7) reports m.p. for II, III, VI, 126°, 110°, 148°, respectively.

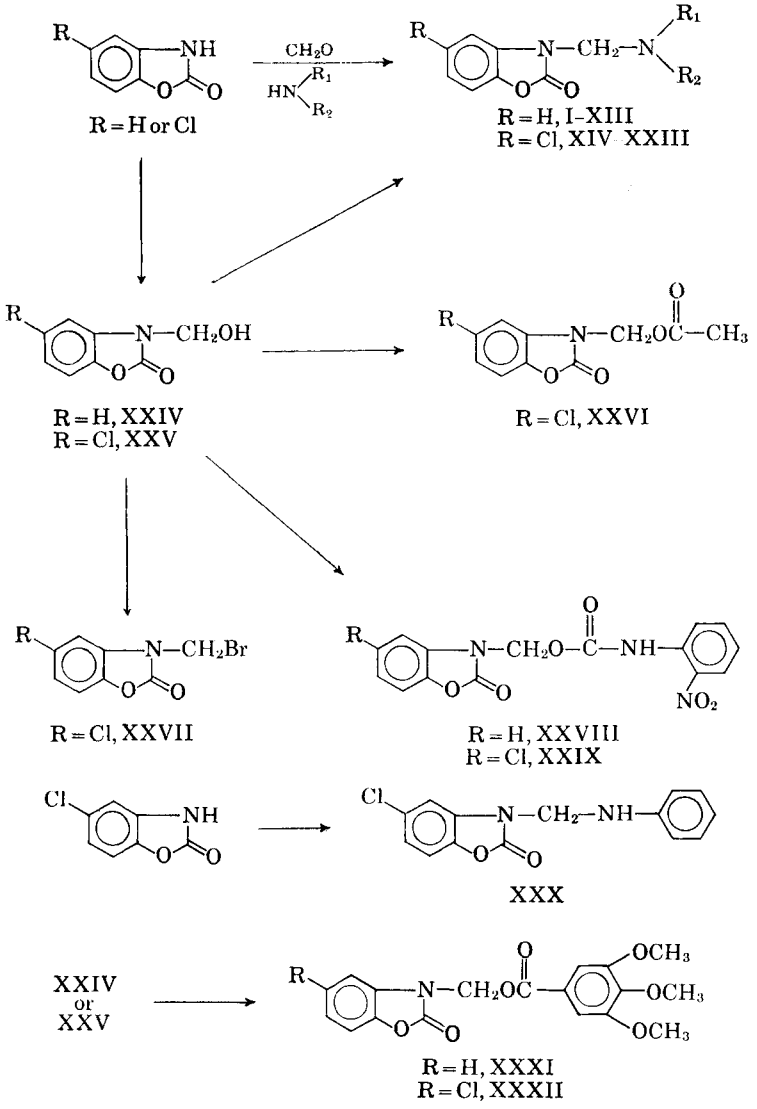
K257, 9 inhibited the growth of *M. smegmatis*, and 21 inhibited the growth of *K. pneumoniae* ATCC-8052. Zone sizes smaller than 6.35 mm. were considered to provide no inhibition of the growth of the organisms. A blank space indicates no activity.

The width of the zone of inhibition around a disk containing the compound depends to some extent on the rate of diffusion of the compound through the medium. A compound that diffuses very slowly through the agar may show a smaller zone of inhibition, but it might demonstrate a greater effect *in vivo* than another compound that showed a greater zone of inhibition *in vitro* because of the greater diffusion rate. This has been shown to be true with certain commercially available antibiotics. Because of this effect, even a narrow zone of inhibition *in vitro* may indicate a compound with potential usefulness. (See Table II.)

EXPERIMENTAL

Melting points were determined on a Thomas-Hoover apparatus and are uncorrected. Infrared spectra were determined on a Perkin-Elmer model 137 Infracord spectrophotometer in Nujol mull. NMR spectra were charted on a Varian A-60 spectrometer using tetramethylsilane as the internal standard. Microanalyses were performed by Galbraith Microanalytical Laboratories, Knoxville, Tenn.

N-Dialkylaminomethyl-2-benzoxazolinones (I–XXIII, Table I)—*Method A*—2-Benzoxazolinone



Scheme I

(0.05 mole), paraformaldehyde (2.25 Gm.), ethanol (25 ml.), and appropriate secondary amine (0.05 mole) were mixed thoroughly in a 100-ml. round-bottom flask. The reaction mixture was refluxed for 4 hr. At the end of this time, the contents were cooled in a refrigerator, and the product thus separated was collected on a filter.

Method B—To a suspension of 2-benzoxazolinone (0.05 mole) in 20 ml. of ethanol, were added 7.5 ml. of 37% formalin and appropriate secondary amine (0.05 mole). During addition of amine, the reaction mixture became warm. It was kept at room temperature for 30 min. and then heated for another 30 min. on a water bath. The reaction mixture upon cooling furnished the desired product.

Method C—A mixture of 3-hydroxymethyl-2-benzoxazolinone (0.02 mole), amine (0.02 mole), and ethanol (50 ml.) was refluxed for 4 hr. The reaction mixture was cooled, and the product thus separated was recrystallized from a suitable solvent.

Dimethylamine was used as a 25% aqueous solution. When a compound was prepared by more than one method, its identity was always established by comparison of melting points, mixed melting points, and infrared spectra.

3-Hydroxymethyl-2-benzoxazolinone (XXIV)—2-Benzoxazolinone (6.75 Gm., 0.05 mole) was suspended in 100 ml. of hot distilled water. To this suspension 7.5 ml. of aqueous 37% formaldehyde solution was added, and the reaction mixture was set aside for 24 hr. The product thus separated was recrystallized from chloroform–petroleum ether (60–80°), m.p. 135–136°. [Lit. (7), m.p. 110°.] Mixed melting point with 2-benzoxazolinone, 108–110°; IR: 3400 (OH), 1750 cm.$^{-1}$ (carbonyl).

Anal.—Calcd. for $C_8H_7NO_3$: C, 58.18; H, 4.27; N, 8.48. Found: C, 58.36; H, 4.46; N, 8.58.

3-Hydroxymethyl-5-chloro-2-benzoxazolinone (XXV)—Formalin (9 ml.) was added to a suspension of 10.17 Gm. (0.06 mole) of 5-chloro-2-benzoxazolinone in 100 ml. of hot water. The reaction mixture after keeping at room temperature overnight yields

3 - Acetoxymethyl - 5 - chloro - 2 - benzoxazolinone (XXVI)—Acetic anhydride (6 Gm.) was refluxed with 2 Gm. (0.01 mole) of 3-hydroxymethyl-5-chloro-2-benzoxazolinone for 3 hr. and then the whole was poured on crushed ice while stirring. The product thus obtained was crystallized from ethanol, m.p. 76–80°. IR: 1785 (ring carbonyl), 1720 cm.$^{-1}$ (ester carbonyl).

Anal.—Calcd. for $C_{10}H_8ClNO_4$: C, 49.70; H, 3.34; N, 5.80. Found: C, 49.48; H, 3.18; N, 6.02.

3 - Bromomethyl - 5 - chloro - 2 - benzoxazolinone (XXVII)—3 - Hydroxymethyl - 5 - chloro - 2 - benzoxazolinone (3.99 Gm., 0.02 mole) was suspended in 150 ml. of dry ether and allowed to cool in ice. Three milliliters of phosphorous tribromide was then added to it dropwise while stirring. The reaction mixture was stirred for 1 hr. in cold and another 1 hr. at room temperature. During this time the hydroxy compound dissolved and the reaction mixture became clear. Ether was removed under vacuum. The product was crystallized from benzene, m.p. 108–110°, yield 4 Gm. (76%). IR: 1780 cm.$^{-1}$ (C=O); NMR: 6.96 δ (aromatic, 3H), 5.45 δ (-CH_2-).

Anal.—Calcd. for $C_8H_5BrClNO_2$: C, 36.61; H, 1.91; Br, 30.44. Found: C, 36.82; H, 2.09; Br, 30.24.

3 - (2 - Nitrophenylcarbamylmethyl) - 2 - benzoxazolinone (XXVIII)—2 - Nitrophenylisocyanate (1.64 Gm., 0.01 mole) was added to 1.64 Gm. (0.01 mole) of 3-hydroxymethyl-2-benzoxazolinone in 25 ml. of anhydrous benzene. The reaction mixture was heated under reflux for 8 hr. At the end of this time, the reaction mixture was diluted with 50 ml. of petroleum ether (b.p. 60–80°) and refrigerated overnight. The solid product thus obtained was filtered and recrystallized from benzene, m.p. 142–143° (softens at 123°); yield, 2 Gm. (60%). IR: 3390 cm.$^{-1}$ (-NH-); 1790 cm.$^{-1}$ (ring carbonyl); 1770 cm.$^{-1}$ (-C(=O)-NH-).

Anal.—Calcd. for $C_{15}H_{11}N_3O_6$: C, 54.72; H, 3.37; N, 12.76. Found: C, 54.94; H, 3.51; N, 12.59.

3 - (2 - Nitrophenylcarbamylmethyl) - 5 - chloro-2-benzoxazolinone (XXIX)—3-Hydroxymethyl-5-chloro-2-benzoxazolinone (2 Gm., 0.01 mole) and 2-nitrophenylisocyanate (1.64 Gm., 0.01 mole) were refluxed overnight in 50 ml. of dry benzene. Benzene was removed under vacuum and the product was recrystallized from benzene, m.p. 177–178° yield, 1.8 Gm. (50%). IR: 3300 cm.$^{-1}$ (-NH-), 1790 cm.$^{-1}$ (ring carbonyl), 1740 cm.$^{-1}$ (-C(=O)-NH-).

Anal.—Calcd. for $C_{15}H_{10}ClN_3O_6$: C, 49.56; H, 2.77; N, 11.55. Found: C, 50.55; H, 2.85; N, 11.31.

3 - Anilinomethyl - 5 - chloro - 2 - benzoxazolinone (XXX)—Aniline (1.86 Gm., 0.02 mole) was added with stirring to 5-chloro-2-benzoxazolinone (3.39 Gm., 0.02 mole) suspended in 10 ml. of ethanol containing 3 ml. of 37% formalin. The reaction mixture was stirred for 1 hr. and allowed to remain at room temperature overnight. The product thus obtained was recrystallized from ethanol–acetone, m.p. 174–175°, yield, 4.2 Gm. (68%). IR: 3380 cm.$^{-1}$ (-NH-), 1750 cm^{-1} (carbonyl).

Anal.—Calcd. for $C_{14}H_{11}ClN_2O_2$: C, 61.20; H, 4.04; N, 10.20. Found: C, 60.92; H, 4.03; N, 10.09.

3 - (3,4,5 - Trimethoxybenzoyloxymethyl) - 2 - benzoxazolinone (XXXI)—Freshly prepared 3,4,5-trimethoxybenzoyl chloride (4.6 Gm., 0.02 mole) and 3-hydroxymethyl-2-benzoxazolinone (2.47 Gm., 0.015 mole) were refluxed in 50 ml. of dry benzene for 4 hr. At the end of this time, benzene was distilled off and residual semisolid was washed repeatedly with 10% aqueous sodium bicarbonate solution. The product on crystallization from acetone gave 2 Gm. (37%) of the ester, m.p. 171°. IR: 1790 cm.$^{-1}$ (ring carbonyl), 1720 cm.$^{-1}$ (ester carbonyl).

Anal.—Calcd. for $C_{18}H_{17}NO_7$: C, 60.17; H, 4.77; N, 3.90. Found: C, 60.31; H, 4.90; N, 3.88.

3 - (3,4,5 - Trimethoxybenzoyloxymethyl) - 5 - chlorobenzoxazolinone (XXXII)—This compound was prepared in a manner similar to XXXI from 2 Gm. (0.01 mole) of 3-hydroxymethyl-2-benzoxazolinone and 3.45 Gm. (0.015 mole) of 3,4,5-trimethoxybenzoyl chloride. Recrystallization from ethanol–acetone gave 2 Gm. (50%) of the product melting at 159°. IR: 1800 cm.$^{-1}$ (ring carbonyl), 1730 cm.$^{-1}$ (ester carbonyl).

Anal.—Calcd. for $C_{18}H_{16}ClNO_7$: C, 54.90; H, 4.10; N, 3.56. Found: C, 55.06; H, 4.25; N, 3.43.

Amine Exchange Reaction—3-Dimethylaminomethyl-2-benzoxazolinone (1.02 Gm., 0.01 mole), 3-methylpiperidine (0.99 Gm., 0.01 mole), and 2 ml. of ethanol were heated on a water bath for 3 hr. The product obtained after cooling the reaction

mixture was recrystallized from ethanol, m.p. 150°, mixed melting point with compound IV, 150°. Infrared spectrum, of this product was identical with IV.

Influence of Cyclodextrins on Ester Hydrolysis

By TING-FONG CHIN, PING-HONG CHUNG, and JOHN L. LACH

The hydrolysis of various ethyl esters of aminobenzoic acids, acetylsalicylic acid, and atropine in alkaline solution was shown to be either accelerated or decelerated in the presence of α and β-cyclodextrin. It is also shown that the stereochemistry of binding and the degree of ionization of cyclodextrin are primarily responsible for these catalytic and inhibitory effects observed.

THE FACT that the cycloamyloses (cyclodextrins) are capable of forming inclusion complexes with various compounds in solution especially with molecules containing aliphatic and aromatic groups has been known for some time and was recently reviewed by Thoma and Stewart (1). Although this aspect of inclusion formation has received considerable study, the present interest in cycloamylose chemistry has been in the kinetic aspect, since these cycloamyloses or cyclodextrins also have been shown to impose both rate accelerations and decelerations on various organic reactions.

Cramer and co-workers (2–4) have studied the cyclodextrin catalyzed decarboxylation of various organic acids and the fission of pyrophosphate. With respect to carboxylic acids, Cramer assumes that the carboxylic acids, after inclusion in the cavity of cyclodextrin, are activated by nucleophilic attack of the ether and hydroxyl O atoms at the carboxyl C atom and that their decarboxylation is consequently accelerated.

Bender and co-workers (5–8) reported that the cyclodextrins accelerated the hydrolysis of the various esters studied and that the accelerations are often large and are markedly substituent dependent. They also stated that this acceleration effect was due primarily to nucleophilic attack on the included ester by alkoxide ion of the cyclodextrin.

Lach and Chin (9) in their study dealing with hydrolysis of ethyl *p*-aminobenzoate in the presence of cyclodextrin, on the other hand, reported a deceleration effect. They attributed this deceleration in rate to a complete occlusion of the total ester in the void space of the cyclodextrin molecule and therefore shielding the ester linkage from hydroxyl ion attack and from alkoxide ion attack in the cyclodextrin molecules. They also stated that in this system the hydrolysis is due only to the free ester in solution resulting from the dissociation of the inclusion

complex. Such a mechanism, however, cannot be applied to a reaction which exhibits a catalytic effect in that both the complexed ester and free ester in solution undergo hydrolysis. Since no detailed kinetic data or mathematic expressions have been reported dealing with this acceleration and deceleration reaction, the present study was undertaken in order that these two different mechanisms be better understood. Acetylsalicylic acid and the various ethyl esters of aminobenzoic acids were studied with respect to this cyclodextrin effect in alkaline solution.

EXPERIMENTAL

Reagents—Ethyl - *p* - aminobenzoate, recrystallized, m.p. 87–88°; ethyl-*o*-aminobenzoate, b.p. 266–268°; ethyl-*m*-aminobenzoate, b.p. 292–294°; acetylsalicylic acid, recrystallized, m.p. 135°; atropine, recrystallized, m.p. 114–115°; α-cyclodextrin, $[\alpha]_D^{25}$ in water = 150.5 ± .5°; β-cyclodextrin, $[\alpha]_D^{25}$ in water = 162.5 ± .5°.

Buffer Systems—pH range: 1.0–2.2, 5.8–7.8, 8.0–10.0 in HCl–KCl, KH_2PO_4–NaOH, and H_3BO_3–NaOH, respectively.

Analytical Procedure—The ethyl-*p*-aminobenzoate, ethyl-*o*-aminobenzoate, ethyl-*m*-aminobenzoate, and atropine are separated from their degradation product by extracting with chloroform in basic solution. The unhydrolyzed benzoates and atropine were then determined spectrophotometrically at the wavelengths of 285 mμ, 330 mμ, 316 mμ, and 257 mμ, respectively. Acetylsalicylic acid was determined by using two-component analysis determining the absorbance at wavelengths of 278 mμ and 308 mμ spectrophotometrically. The absorptivity of acetylsalicylic acid and salicylic acid at 278 mμ and 308 mμ were previously determined in different pH buffered solutions which were used in these studies. The presence of cyclodextrin in these solutions did not interfere with the spectrophotometric procedure in the concentrations employed for the analysis.

Kinetic Studies—Kinetic studies were carried out at specified temperatures and constant pH buffered solutions in a system with or without cyclodextrin. The reaction course was followed by measuring the absorbance at the given wavelength utilizing a Beckman DU spectrophotometer after proper dilution. An accurate weight of the ester was dissolved in 5 ml. of ethanol and an accurate amount of cyclodextrin was added in a system containing cyclodextrin and brought to exactly 100 ml. with buffer, separated into 10-ml. amber vials, sealed, and placed in the water bath. All these procedures were conducted under nitrogen. The hydrolysis was carried out in a Haake-Thermostate Unitherm constant-temperature water bath at a given temperature. Aliquots were withdrawn periodically from each vial and analyzed for the unhydrolyzed ester. In all cases first-order rate constants were observed at constant pH and constant temperature.

RESULTS AND DISCUSSION

For purpose of discussion some of the data dealing with the deceleration of the hydrolytic rate of ethyl-*p*-aminobenzoate in the presence of cyclodextrin and previously reported (9) are presented here. In this study it is shown that β-cyclodextrin and ethyl-*p*-aminobenzoate formed a 1:1 complex in aqueous solution and that the hydrolysis was due to the free or uncomplexed ester in solution resulting from the dissociation of the inclusion complex. This was verified mathematically and is presented, in part, in Scheme I,

$$(\text{BCD} \ldots \text{BZA}) \underset{K_F}{\overset{K_D}{\rightleftharpoons}} (\text{BZA})_f + (\text{BCD})_f, \quad (\text{BZA})_f \xrightarrow{k_h} \text{PABA} + \text{EtOH}$$

Scheme I

where K_D is the dissociation constant, K_F is the formation constant, k_h is the hydrolysis constant, $(\text{BZA})_f$ is the free ethyl-*p*-aminobenzoate, $(\text{BZA})_t$ is the total ethyl-*p*-aminobenzoate, $(\text{BCD})_f$ is the free β-cyclodextrin, (BCD . . . BZA) is the complex, PABA is the *p*-aminobenzoic acid.

$$K_D = \frac{(\text{BZA})_f \cdot (\text{BCD})_f}{(\text{BCD} \ldots \text{BZA})} \qquad \text{(Eq. 1)}$$

$$(\text{BZA})_f = \frac{K_D \cdot (\text{BCD} \ldots \text{BZA})}{(\text{BCD})_f} \qquad \text{(Eq. 2)}$$

Since in solution $(\text{BCD} \ldots \text{BZA}) = (\text{BZA})_t - (\text{BZA})_f$ therefore:

$$(\text{BZA})_f = \frac{K_D \cdot [(\text{BZA})_t - (\text{BZA})_f]}{(\text{BCD})_f} \qquad \text{(Eq. 3)}$$

Simplified Eq. 3 gives:

$$(\text{BZA})_f = \frac{K_D}{K_D + (\text{BCD})_f} (\text{BZA})_t \qquad \text{(Eq. 4)}$$

The rate equation for ethyl-*p*-aminobenzoate hydrolysis at constant pH is:

$$-d(\text{BZA})_f/dt = k_h(\text{BZA})_f \qquad \text{(Eq. 5)}$$

The rate equation for ethyl-*p*-aminobenzoate hydrolysis in solution containing β-cyclodextrin should be:

$$-d(\text{BZA})_t/dt = k_h(\text{BZA})_f = k_h \frac{K_D}{K_D + (\text{BCD})_f} (\text{BZA})_t \qquad \text{(Eq. 6)}$$

$$k_{\text{app.}} = k_h \frac{K_D}{K_D + (\text{BCD})_f} \qquad \text{(Eq. 7)}$$

$$k_h/k_{\text{app.}} = 1 + \frac{(\text{BCD})_f}{K_D} \qquad \text{(Eq. 8)}$$

From experimental data, K_D has been determined to be 2.34×10^{-3}. The apparent rate constants, evaluated for the reaction in a system containing β-cyclodextrin are thus related to the true rate constant by Eqs. 7 and 8. From Eq. 7 the apparent rate constants can be calculated and can be compared with the experimental rate constant data obtained in a system containing β-cyclodextrin. These comparisons are given in Table I.

The close agreement of the calculated and experimental apparent rate constants gives additional support to the assumptions that were made. Equation 8 shows a linear relationship between the ratio of $k_h/k_{\text{app.}}$ and the concentration of free β-

Table I—Comparison of Calculated and Experimental Apparent Rate Constants of Ethyl-*p*-aminobenzoate Hydrolysis in a System Containing β-Cyclodextrin in 0.04 *N* $Ba(OH)_2$ Solution at 30°

% of BCD	Apparent Rate Constants, hr.$^{-1}$/*M* Exptl.	Calcd.

1.00	0.129	0.139

cyclodextrin. This linear relationship is shown in Fig. 1 which further substantiates our hypothesis.

The rate of hydrolysis of acetylsalicylic acid (ASA) in alkaline solution in the presence of cyclodextrin was accelerated indicating that the cyclodextrin exerted a catalytic effect. Previous study (10) has shown ASA and β-cyclodextrin interact in aqueous solution to form a 1:1 complex. It is believed that ASA and cyclodextrin undergo only partial inclusion with the phenyl portion of the organic acid occupying the void space of the cyclodextrin molecule, and being sterically fixed in this position, thus allowing a favorable approach of the carbonyl group to the hydroxyl group of the cyclodextrin. This catalytic effect then is due to the interaction of the ester with hydroxyl group of the cyclodextrin. The data also indicated that this catalytic effect only occurred at a pH where the hydroxyl group of the cyclodextrin existed as an alkoxide ion. The hydrolysis of ASA in alkaline medium and in the presence of cyclodextrin is due to the hydrolysis of the free ASA in solution resulting from the dissociation of this complex and to the hydrolysis of the ASA in the complex resulting from the catalytic effect due to the cyclodextrin, both of these reactions occurring simultaneously. A mechanistic scheme and the mathematical relationship for this hypothesis describing these reactions are shown in Scheme II,

$$\begin{array}{ccc} (BCD)_f + (ASA)_f & \overset{K_F}{\rightleftharpoons} & (BCD \ldots ASA) \\ \downarrow k_h & K_D & k_c \downarrow \\ SA + ACA & & (BCD)_f + SA + ACA \end{array}$$

Scheme II

where $(ASA)_f$ is the free acetylsalicylic acid, SA is the salicylic acid, ACA is the acetic acid, k_c is the constant of cyclodextrin catalysis, (BCD . . . ASA) is the complex.

$$K_F = \frac{(BCD \ldots ASA)}{(BCD)_f \cdot (ASA)_f} \quad \text{(Eq. 9)}$$

$$(BCD \ldots ASA) = K_F \cdot (BCD)_f \cdot (ASA)_f \quad \text{(Eq. 10)}$$

Rate of hydrolysis of ASA in alkaline solution containing cyclodextrin at constant pH should be:

$$\begin{aligned} -d(ASA)_t/dt &= k_h \cdot (ASA)_f + k_c \cdot (BCD \ldots ASA) \\ &= k_h \cdot (ASA)_f + k_c \cdot K_F (BCD)_f (ASA)_f \\ &= k_h[1 + k_c/k_h \cdot K_F (BCD)_f](ASA)_f \end{aligned} \quad \text{(Eq. 11)}$$

$$k_{app.} = k_h[1 + k_c/k_h \cdot K_F (BCD)_f] \quad \text{(Eq. 12)}$$

$$k_{app.}/k_h = 1 + k_c/k_h \cdot K_F (BCD)_f \quad \text{(Eq. 13)}$$

From experimental data, K_F has been determined to be 1.7×10^2; k_c to be 0.74 at pH 10 and at 35°.

From Eq. 12, one can then calculate the rate constants in systems containing cyclodextrin. Experimental rate constants and those calculated are given in Table II.

It is interesting to note here the close agreement obtained for these constants, indicating that the assumptions made are reasonable. Further verification of the assumptions is shown in Fig. 2, a plot of $k_{app.}/k_h$ against the concentration of free cyclodextrin should result in a straight line as indicated in Eq. 13.

Since the hydrolysis of ASA was carried out at pH = 10, it was felt that additional information with respect to this catalytic effect would be obtained if this reaction was carried out at various pH's.

An examination of Table III which lists these data indicated that this catalytic effect exhibited by the cyclodextrin is not operative at acid pH, and that this catalytic effect increased substantially with an increase in pH in the alkaline range. This suggested that the hydroxyl groups of the cyclodextrin must be in the ionized form in order that they act as a

Ethyl-*m*-aminobenzoate[a]	7.00	4.06	8.40
Atropine[b]	9.65	6.05	15.37
Acetylsalicylic acid[b]	2.67	0.956	0.855

[a] pH = 10.0, T = 70°. [b] pH = 10.0, T = 35°. [c] No CD = no cyclodextrin. [d] ACD = α-cyclodextrin. [e] BCD = β-cyclodextrin.

nucleophile. Cramer (3) also speculated as to this effect. For this reason a study was undertaken to investigate the ionization of cyclodextrin at different pH's. The pK value of β-cyclodextrin was found to be 12.2 which was in agreement with the previous reported value (6) and the percent of ionization was calculated using the following equation:

$$\% \text{ ionization} = \frac{100}{1 + \text{antilog}\,(pK_a - pH)} \quad \text{(Eq. 14)}$$

According to Eq. 14, the percent of ionization of β-cyclodextrin at different pH's is listed below:

pH	% of Ionization of BCD
12.2	50.000
11.0	5.940
10.0	0.627
9.0	0.063

Figure 3, which shows a plot of log percent of hydrolytic rate increase against pH and also a plot of log percent of ionization of β-cyclodextrin against pH, indicated that a direct relationship exists between the ionization of β-cyclodextrin and the rate increase of ASA hydrolysis in a system containing cyclodextrin. It seems reasonable therefore that the ASA undergoes only partial inclusion with cyclodextrin, is rigidly fixed with the void, and is catalyzed by the ionized hydroxyl groups of the cyclodextrin molecule and that this catalytic effect depends on the degree of ionization of these hydroxyl groups. In the case of deceleration effect noticed in the ethyl-*p*-aminobenzoate—β-cyclodextrin system, the ester linkage is totally shielded and therefore not subject to this nucleophilic attack. This was readily seen when Stuart models were prepared of these two systems. It should also

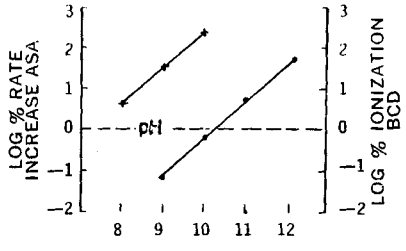

Fig. 3—A plot of log percent of hydrolytic rate increase of acetylsalicylic acid (+) hydrolysis in the system containing β-cyclodextrin against pH and log percent of ionization of β-cyclodextrin (●) against pH at 35°.

be pointed out here, that the cyclodextrin molecule exists in the C_1 conformation (11) with the hydroxyl groups existing on the outside of the cyclic structure. Since the pK value of some organic acids is decreased in the presence of cyclodextrin, and Henglein (12) also suggested that the catalytic effect may be due to this phenomenon, however, our own data with respect to this pK decrease or increase of various acids (acetic acid, hexanoic acid, benzoic acid, salicylic acid, acetylsalicylic acid, *p*-hydroxybenzoic acid, *p*-aminobenzoic acid, *m*-aminobenzoic acid, and *p*-nitrobenzoic acid) and the small pK change observed in the presence of cyclodextrin would not account for the large change in this hydrolytic rate and will be discussed later.

Additional information concerning the nature of the acceleration and deceleration effect was obtained in a study of the hydrolysis of various ethyl esters of aminobenzoic acids and atropine in the presence of α and β-cyclodextrin. Results of this study are given in Table IV.

These compounds were chosen in order to show that the rate of alkaline hydrolysis is determined primarily by the stereochemistry of the fit between guest and host in the relatively rigid cyclodextrin system. An examination of Table IV shows that the rates of hydrolysis of ethyl aminobenzoates (*para-*, *meta-*, and *ortho-*) were inhibited in the presence of β-cyclodextrin. This suggests that these molecules undergo total inclusion with the β-cyclodextrin and are shielded from nucleophilic attack by the alkoxide ion of the cyclodextrin and also by hydroxyl ion from solution. In the case of atropine due to its large size, total inclusion is not possible; however, it is highly likely that the phenyl and ester portion of the molecule is enclosed in the void space of the cyclodextrin and thus is shielded from attack. In these two cases the hydrolysis is due primarily to the free ester in solution resulting from the dissociation of the complexes. On the other hand, compounds, which do not totally fit into the void space of the cyclodextrin molecules and undergo only partial inclusion, exhibit an increase in hydrolytic rates due to the catalytic effect of the cyclodextrin in alkaline solution. For example, ASA which undergoes only partial inclusion with both α and β-cyclodextrin as seen in Table IV shows an increase in the rate of hydrolysis. Atropine, ethyl-*o*-aminobenzoate, and ethyl-*m*-aminobenzoate with α-cyclodextrin also show this catalytic reaction. Since the void space of β-cyclodextrin (8 Å.) is larger than the alpha void (6 Å.), it is readily seen by constructed molecular models that all of the ethyl esters of aminobenzoic acid can readily fit into the

void of β-cyclodextrin. On the other hand, only the *para* derivative readily fits into the void the of α-cyclodextrin molecule. The *meta* and *ortho* derivatives do not totally fit into the void of the α-cyclodextrin due to steric hindrance resulting from the amino group and thus are accelerated with respect to the rate of hydrolysis. With respect to ASA the large carbonyl group in the *ortho* position next to the leaving group prevents a total fit in both of the α and β-cyclodextrins and consequently it undergoes a catalytic reaction. In such cases the over-all hydrolytic rate is due not only to the free ester in solution but due also to the degradation of the ester in the complexed form.

CONCLUSION

The effect of cyclodextrins on the alkaline hydrolysis of various esters has been shown to be one of acceleration or deceleration depending on the nature of the complexes formed. Compounds which form a true inclusion compound or a compound in which the active center is included in the void of cyclodextrin exhibit a deceleration effect, and the hydrolytic rate is dependent primarily on the amount of free ester in solution resulting from dissociation of the complex. Compounds which do not totally fit into the void or are only partially included leaving the active center sterically fixed in close proximity to the hydroxyl group of cyclodextrin undergo an acceleration effect. In this case the hydrolytic rate is due not only to the free ester in solution resulting from the dissociation of the complex but also to nucleophilic attack of the ester linkage by the alkoxide ion of the cyclodextrin molecules. This catalytic effect is related to degree of ionization of these hydroxyl groups in the cyclodextrin molecule. Although it has been suggested that this catalytic effect may be due to a decrease in pK_a in the presence of cyclodextrin, the present data do substantiate this. For example, both α and β-cyclodextrin increase the pK_a value of *m*-aminobenzoic acid by approximately 0.1 unit, yet in the hydrolytic rate study, α-cyclodextrin exhibits an acceleration effect with respect to the hydrolysis of ethyl-*m*-aminobenzoate, whereas β-cyclodextrin has an opposite effect. This suggested that the stereochemistry of binding and the degree of the ionization of cyclodextrin are primarily responsible for the catalytic effect. This catalytic effect is absent when the hydroxyl groups are in the unionized form as in acid solution even though the ester is present in the complexed form.

The interest (13) in the kinetic aspect of these cyclodextrins has been due to the fact that these cyclodextrins have been used as models in the study of enzyme catalysis. Although such a model cannot explain completely the mechanism of enzyme action, kinetic data present in this investigation do illustrate some of the physical-chemical aspects involved in enzyme catalysis.

Sulfaethylthiadiazole (SETD) Release from Synthetic Wax Prolonged-Release Particles I

Effect of Dispersant Concentration

By IRA C. ROBINSON* and CHARLES H. BECKER

Synthetic wax particles containing sulfaethylthiadiazole (SETD) dispersed throughout and on the surface were made by a method of aqueous dispersion using various concentrations of polysorbate 80 USP and sorbitan monooleate each alone and in combination as dispersants. The *in vitro* release of SETD from 50–70 mesh wax particles was investigated with a rotating bottle dissolution apparatus, using simulated gastric and intestinal fluids. The dispersant factor was found to affect both the release rate and the proportion of total drug apparently constituting the prolonged-release fraction.

THE LITERATURE contains numerous examples of investigations of factors affecting the dissolution of drugs from both dosage forms and ideal experimental matrices effecting retarded drug release. Most of these studies were conducted on granules, pellets, or beads prepared by conventional means, by spray-drying, or by spray-congealing, or on dosage forms comprised of such particles.

In studies of drug release from various dosage forms Wagner (1) and Wiegand and Taylor (2) reported that the percent released time data followed apparent first-order rates. Lazarus *et al.* (3) observed the influence of drug particle size, drug concentration, and granule size on the *in vitro* release rate of drug from a compressed waxy granular tablet matrix and reported that drug concentration and crystal size exerted greater effects on the rate than matrix granule size.

Apparent first-order release rates for drug were found to be inversely proportional to drug–wax particle size in one investigation by Draper and Becker (4).

Higuchi attempted to relate the rate of drug release from one surface of sustained action solid matrices to physical constants based on simple laws of diffusion and obtained the following mathematical relation for the case where drug particles are incorporated into a granular matrix from which release is by a leaching action of penetrating solvent (5):

$$Q = \sqrt{\frac{D\epsilon}{\tau}(2A - \epsilon C_s)C_s t} \qquad \text{(Eq. 1)}$$

where Q is the amount of drug released after time, t, per unit exposed area; D, the diffusivity of the drug in the permeating fluid; τ, the tortuosity factor; A, the total amount of drug present in the matrix per unit volume; C, the solubility of the drug in the permeating fluid; and ϵ, the porosity of the matrix.

Desai *et al.* (6) showed the applicability of the Higuchi theory in a study of drug release from planar surfaces of plastic matrices.

The effects of concentration of drug and water solubility on release rates were investigated by Sjorgren and Fryklof (7) with tablets prepared from granules. The use of water-soluble substances to increase the rate of release of water-soluble drugs from a compressed plastic tablet was suggested in a patent by Endicott (8).

Saski and Shah (9) studied the effects of three oxyethylene oxypropylene polymers on the availability of hexetidine and observed enhancement of activity with concentrations below the CMC's for two and a decrease in activity at the CMC for all three. Desai *et al.* (6) reported that the addition of benzalkonium chloride and sodium lauryl sulfate increased the rate of release of sodium salicylate from tablets, presumably by an increase in the effective porosity of the tablets.

In the present investigation, the authors prepared synthetic wax particles containing dispersed sulfaethylthiadiazole and dispersant, if used, by a method of aqueous dispersion and considered the effects of two nonionic surfactants, polysorbate 80 USP[1] and sorbitan monooleate,[2] when used singly and in combination as dispers-

ing agents, on the *in vitro* rates of drug release from the wax matrices. The procedure was to manufacture the particles under controlled conditions, characterize or examine, classify, and assay, and to use such particles in *in vitro* release studies.

DISCUSSION

The general method of aqueous dispersion consists of blending subdivided drug in a melted waxy material and dispersing this mixture by controlled agitation in either a heated or cooled aqueous bath, with or without the aid of a surface-active agent. The end product may be spherical or irregularly shaped particles, all containing drug over the surface as well as dispersed throughout the wax matrix. Drug dispersed on the surface would be expected to enter into the dissolution medium more rapidly than drug dispersed within the matrix since solvent must first penetrate the matrix and dissolve the medicament therein before diffusion from within can take place.

Factors which may affect matrix particle size and/or geometry include type and concentration of dispersant, temperature to which the initial melt and aqueous bath are heated, rate of cooling, and rate and type of agitation. Particle size and geometry and dispersant type and concentration would be expected to affect the drug release rate.

If the Higuchi relation (Eq. 1) applies to the systems under study, drug release data when plotted *versus* the square root of time should produce linearity for that portion of drug dispersed within the wax matrix. However, the fact that these percent released square root of time data plots are linear does not in itself prove that the equation applies to this study. Such proof is obtainable only from controlled studies specifically designed to test the effect of variables in Eq. 1.

It was theorized that altering the concentration of surfactant used as dispersing agent would result in altered release rates for SETD from within the synthetic wax–drug particles when tested in simulated digestive fluids. This result would presumably be due to a combination of the wetting effect of the dispersant and the consequent increase in availability of more channels to permit leaching to take place. Further, the linear portion of the release curve should not go through the origin when extrapolated to zero time.

EXPERIMENTAL

Official drug, or reagent grade materials were used throughout this work. Sulfaethylthiadiazole was obtained from American Cyanamid Co. Glyceryl tristearate[3] was supplied by Glyco Chemicals. The term SETD–glyceryl tristearate is employed to designate an approximate ratio of 1 part sulfaethylthiadiazole to 3 parts of glyceryl tristearate in completed products. Where reference is made to a mesh size range, it indicates that the particles passed through the lower-numbered sieve but were retained on the higher-numbered sieve.

9	...	0.47[f]
10	...	0.16[g]

[a] Used per 24 Gm. glyceryl tristearate and 8 Gm. SETD: [b] 3.0 ml. [c] 2.0 ml. [d] 1.0 ml. [e] 0.25 ml. [f] 0.15 ml. [g] 0.05 ml.

The USP XVII method of determining uniformity of fineness (10) was employed in a particle size analysis of the SETD powder reserved for this study, the mean diameter of which was determined to be 47 μ.

Preparation of SETD–Glyceryl Tristearate Particles—The basic formula for products manufactured was: glyceryl tristearate, 3 parts; SETD, 1 part; dispersing agent, a predetermined quantity (Table I); and distilled water, 50 parts. The glyceryl tristearate was melted in a glass beaker on a water bath and heated to a temperature of 75°. The SETD was uniformly dispersed in the melted glyceryl tristearate. In order to minimize loss, distilled water, generally containing a dispersant, was heated to 80° and added slowly to the SETD–wax dispersion with stirring provided by a "Lightnin" mixer, laboratory type, model F. Stirring was continued at an optimum rate until the temperature reached 45°. The SETD–glyceryl tristearate particles were separated from the aqueous phase by filtration and washing with three 250-ml. portions of distilled water to remove free SETD. These products were then air dried. A 50–70 mesh fraction was separated on a Ro-Tap sieve shaker by the official USP method (10) to represent a mean diameter of 203 μ, assuming spherical shape. Visual and microscopic examination of the particles was made. Bulk densities of the SETD–glyceryl tristearate particles were determined by the method of Butler and Ramsey (11) using the relationship:

$$\rho_b = W/V \qquad \text{(Eq. 2)}$$

where V is the volume in ml., W is the quantity of Gm. of material in the cylinder, and ρ_b, the bulk density expressed as Gm./ml. with the modification that the graduate was dropped 20 times/min. for better uniformity of results.

In the preparation of all drug–wax particles, it was desired that as many variables as possible be held constant. Therefore, the ratio of drug to wax (1:3), the volume of aqueous phase, the rate of addition of aqueous phase to melted wax–drug mixture, the temperature to which the wax–drug and the aqueous phases were initially heated, mixing container type and size, method of mixing, and position of stirrer in container were held constant throughout the manufacturing operations. Opti-

mum rates of stirring were determined and kept constant thereafter.

Assay for SETD Content—Duplicate samples of exactly 0.5000 Gm. of each air-dried product were placed in 25-ml. portions of chloroform heated on a water bath. These were then extracted with several 30-ml. portions of warmed 3.5% HCl using a separator. The combined extracts were made up to volume and an aliquot portion was assayed by the Bratton and Marshall colorimetric procedure (12). A Klett-Summerson colorimeter equipped with a No. 54 filter was employed.

In Vitro Release Studies—A rotating bottle dissolution apparatus[4] similar to that described by Souder and Ellenbogen (13) and constructed by the Bioelectronic and Instrument Department, J. Hillis Miller Health Center, was employed in release studies. It consisted of a rotating machine with spring clamps for holding sixteen 90-ml. screw-capped bottles in alternately perpendicular pairs along the rotating axis. A speed of rotation of 40 r.p.m. and a constant-temperature water bath were used.

The two dissolution fluids used were simulated gastric fluid (0.1 *N* HCl, pH 1.1) and simulated intestinal fluid (alkaline pancreatin solution, pH 8.3). For studies in the simulated gastric fluid, duplicate samples of each product equivalent to 120.0 mg. of SETD and one sample of an equivalent amount of blank glyceryl tristearate particles prepared in the same manner as the product were provided for each time interval and withdrawn for analysis after 15, 30, 45, 60, 90, and 120 min., and at appropriate intervals thereafter to determine when equilibrium of release was achieved. A similar procedure was followed with simulated intestinal fluid except that samples equivalent to 600.0 mg. of SETD were used and intervals after which withdrawals were made were 15, 30, 45, 60, 120, 180, 240, 360, 480, and 720 min., and additional ones to determine when equilibrium of release had been attained. With all samples, at withdrawal the contents of each bottle was filtered and 0.5 or 1 ml. of the filtrate was diluted to an appropriate volume with distilled water in a volumetric flask. One milliliter of the dilution was assayed for SETD by the colorimetric procedure previously mentioned.

RESULTS

Production of SETD–Wax Particles—Preliminary investigations showed the maximum workable ratio of sorbitan monooleate to wax to be 1:8 and higher proportions resulted in excessively soft masses. It was also found that a small proportion of polysorbate 80 USP to sorbitan monooleate gave particles with more desirable surface properties than particles prepared with larger proportions. Increasing the concentration of either dispersant when used singly or in combination with the other facilitated the production of finer particles.

In the preparation of particles from the dispersant mixtures employing the smallest amount of sorbitan monooleate along with polysorbate 80 USP, water-in-oil emulsions developed during the early stages of mixing. With cooling and further addition of aqueous phase containing dispersant, inversion took place. Resultant particles were less smoothly surfaced than were products made from formulas employing sorbitan monooleate alone in all proportions under investigation. Particles prepared with polysorbate 80 USP alone as dispersant had more irregular surfaces than those prepared with sorbitan monooleate alone. It was apparent from these results that the spherical and surface smoothness properties of completed products should be properly attributed to the surface activity of sorbitan monooleate. Observations by visual and microscopic examination of particles prepared and studied are presented in Table II along with the bulk densities for these products.

Increasing the concentration of sorbitan monooleate in combination with a constant amount of polysorbate 80 USP resulted in slightly increased bulk densities of the drug–wax particles. Products made with varying concentrations of each surfactant alone showed no trend with respect to bulk density differences. However, the bulk densities for these latter products were greater than for either product made with a combination of surfactants as dispersant.

SETD Release Rate Comparison—From plots of percent SETD released in alkaline pancreatin solution *versus* the square root of time (in min.), the slopes for the linear portions of the curves were calculated and compared for the various products. Most of the following discussion pertains to these results.

It was found that from 50–60% of the total SETD provided in the wax matrices was released in the simulated gastric fluid at equilibrium, and this amount was released quite rapidly during the first 15 min. as can be seen in Table III. The percentages of SETD released in the alkaline pancreatin solution during the first 15 min. was of the same relative order except for products 3 and 4 where the lowest percentage of sorbitan monooleate was used with polysorbate 80 USP. In the alkaline pancreatin solution, however, drug continued to be extracted from the wax particle after this initial period due not only to diffusion but also in part to a gradual disintegration of the wax matrix in this test fluid. Thus it appears that the SETD released in the simulated gastric fluid during the initial period (and at equilibrium) was drug from the particle surface, indicating negligible diffusion of drug from within the wax matrix. During dissolution studies in alkaline pancreatin solution, both the porosity and tortuosity factors were constantly changing. Nevertheless, the release data plots as square root of time results were reasonably well approximated.

Increasing the concentration of sorbitan monooleate approximately twofold in combination with constant amount of polysorbate 80 USP decreased the rate at which SETD was released in alkaline pancreatin solution by a factor of 4 (Fig. 1). The additional increase in sorbitan monooleate in a third product caused no further reduction in the SETD release slope, indicating that a minimum had been attained. Figure 2 shows that increases in sorbitan monooleate as singular dispersant promoted the release of SETD after the initial period. Rates are presented in Table III. Increased

[4] Subsequent to this work, this type of apparatus was made official in NF XII, 2nd supplement, March 1, 1967, p. 15.

SETD release rates were observed with each raise in polysorbate 80 USP concentration when this dispersant was used both singly and in combination with constant amount of sorbitan monooleate (Figs. 1 and 3).

In addition to their effects on drug release rate and in the observable physical characteristics of the drug–wax particles, zero intercept values calculated from the linear portion of the dissolution curve for SETD in alkaline pancreatin solution suggest that variation in both the type and amount

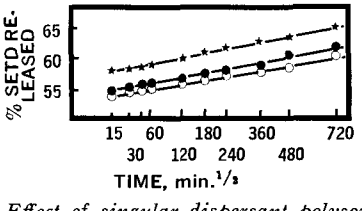

Fig. 3—Effect of singular dispersant polysorbate 80 USP on SETD release in simulated intestinal fluid from SETD–wax particles. Key: ★, 0.78%; ●, 0.47%; ○, 0.16%.

of dispersant influenced the amount of drug concentrating on or near the wax particle surface. A glance at the zero intercept values presented in Table III will show that more drug was apparently present on or near the surface of the drug–wax particles produced with the aid of sorbitan monooleate alone than on those prepared with polysorbate 80 USP alone; that increasing the concentration of sorbitan monooleate twofold with constant amount of polysorbate 80 USP gave a marked increase in this portion of drug rapidly released in the alkaline pancreatin solution; and that increasing the concentration of polysorbate 80 USP, while holding constant the amount of sorbitan monooleate in the formula, caused a marked decrease in the amount of SETD representing this value.

For all products except those prepared with use of polysorbate 80 USP singly as dispersant, where a larger portion of the total drug was apparently embedded within the wax matrix (total drug minus apparent surface drug), an increased rate of SETD release in the simulated intestinal fluid was observed.

SUMMARY

SETD–glyceryl tristearate particles were manufactured by a method of aqueous dispersion for prolonged-release application using various concentrations of polysorbate 80 USP and sorbitan monooleate singly and in combination as dispersants. The effects of variation in the type and concentration of surfactant used as dispersant were studied by *in vitro* release tests, physical testing, and visual and microscopic examination. Rates of release of SETD constituting the prolonged dissolution portion were calculated for results in simulated intestinal fluid using square root of time relationships and compared. Percent released square root of time plots gave reasonable linear approximations of prolonged-release SETD dissolution data.

Complexation of Sodium Fluorescein with Polyvinylpyrrolidone

By RUSSELL E. PHARES, JR.

The complexation of sodium fluorescein (NaFluor) with polyvinylpyrrolidone (PVP) was studied at four pH values using a method similar to that of Benesi and Hildebrand. It was found that fluorescein can exist in four forms, each of which is capable of complexing. The results tend to indicate that at low pH values PVP exists in more than one form and that not all forms of the PVP are capable of complexing with NaFluor. When the ratio of NaFluor to PVP is small, a 1 : 1 complex is favored; but as the ratio increases, higher complexes predominate. The stability of the 1 : 1 complex seems to increase as the negative charge on the fluorescein decreases.

IT WAS recently discovered that polyvinylpyrrolidone (PVP), which for a long time has been known to complex with many substances, would form a sodium fluorescein complex possessing some interesting properties (1). By utilizing the unique properties of this complex, Krezanoski (1) has been able to formulate a stable and effective applanation tonometry diagnostic aid[1] con-

of dispersant influenced the amount of drug concentrating on or near the wax particle surface. A glance at the zero intercept values presented in Table III will show that more drug was apparently present on or near the surface of the drug–wax particles produced with the aid of sorbitan monooleate alone than on those prepared with polysorbate 80 USP alone; that increasing the concentration of sorbitan monooleate twofold with constant amount of polysorbate 80 USP gave a marked increase in this portion of drug rapidly released in the alkaline pancreatin solution; and that increasing the concentration of polysorbate 80 USP, while holding constant the amount of sorbitan monooleate in the formula, caused a marked decrease in the amount of SETD representing this value.

For all products except those prepared with use of polysorbate 80 USP singly as dispersant, where a larger portion of the total drug was apparently embedded within the wax matrix (total drug minus apparent surface drug), an increased rate of SETD release in the simulated intestinal fluid was observed.

SUMMARY

SETD–glyceryl tristearate particles were manufactured by a method of aqueous dispersion for prolonged-release application using various concentrations of polysorbate 80 USP and sorbitan monooleate singly and in combination as dispersants. The effects of variation in the type and concentration of surfactant used as dispersant were studied by *in vitro* release tests, physical testing, and visual and microscopic examination. Rates of release of SETD constituting the prolonged dissolution portion were calculated for results in simulated intestinal fluid using square root of time relationships and compared. Percent released square root of time plots gave reasonable linear approximations of prolonged-release SETD dissolution data.

Complexation of Sodium Fluorescein with Polyvinylpyrrolidone

By RUSSELL E. PHARES, JR.

The complexation of sodium fluorescein (NaFluor) with polyvinylpyrrolidone (PVP) was studied at four pH values using a method similar to that of Benesi and Hildebrand. It was found that fluorescein can exist in four forms, each of which is capable of complexing. The results tend to indicate that at low pH values PVP exists in more than one form and that not all forms of the PVP are capable of complexing with NaFluor. When the ratio of NaFluor to PVP is small, a 1 : 1 complex is favored; but as the ratio increases, higher complexes predominate. The stability of the 1 : 1 complex seems to increase as the negative charge on the fluorescein decreases.

IT WAS recently discovered that polyvinylpyrrolidone (PVP), which for a long time has been known to complex with many substances, would form a sodium fluorescein complex possessing some interesting properties (1). By utilizing the unique properties of this complex, Krezanoski (1) has been able to formulate a stable and effective applanation tonometry diagnostic aid[1] con-

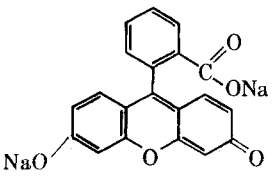
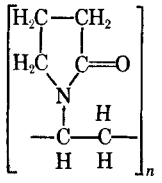
taining chlorobutanol, benoxinate HCl, and 0.25% sodium fluorescein in an isotonic boric acid buffer. It seemed desirable to collect more information about this complex in view of its practical applications and the fact that sodium fluorescein is a relatively simple molecule possessing the same basic structure found in many dyes which might be complexed with PVP to give other useful products. The structures of PVP and sodium fluorescein are given in I and II.



Sodium Fluorescein
I



PVP
II

EXPERIMENTAL

The sodium fluorescein (NaFluor) used was USP grade, and the PVP was pharmaceutical grade[2] having an average molecular weight of 30,000. All absorbance values were determined using a Beckman DK-2 spectrophotometer. A preliminary experiment was done to determine the spectral absorbance curves of a 1×10^{-5} *M* sodium fluorescein solution at pH values of 0.6 to 12.0. These curves are shown in Figs. 1 and 2. Another preliminary investigation was made using Job's method of continuous variation (2). A 3.7×10^{-5} *M* solution of PVP was mixed in various ratios with a 3.7×10^{-5} *M* solution of sodium fluorescein. Each solution was made in a pH 5.0 buffer adjusted to have an over-all ionic strength of 0.1. The absorbance of each mixture, as well as the absorbances of various concentrations of sodium fluorescein without PVP, was determined at 475 mμ. Figure 3 shows a plot of the differences between the expected and the observed absorbances for the various volume ratios of the PVP and sodium fluorescein solutions.

It was decided, based upon the results of the preliminary experiments, to study the complexation process at pH values of 1.5, 3, 5, and 8, using a method similar to that of Benesi and Hildebrand (3). The experiments conducted were as follows:

pH 1.5:

Sodium fluorescein held constant at 5×10^{-5} *M*, and the PVP varied from 1.66 to 13.28 $\times 10^{-4}$ *M*. Buffer system was HCl and KCl.

pH 3.0:

Sodium fluorescein held constant at 5×10^{-5} *M*, and the PVP varied from 1.66 to 13.28 $\times 10^{-4}$ *M*. Buffer system was phthalate.

PVP held constant at 1.8×10^{-5} *M*, and the sodium fluorescein varied from 1 to 36 $\times 10^{-5}$ *M*.

pH 5.0:

Sodium fluorescein held constant at 5, 25, and 50 $\times 10^{-6}$ *M*, and the PVP varied from 8.3 $\times 10^{-5}$ to 1.33 $\times 10^{-3}$ *M*. Buffer system was neutralized phthalate.

PVP held constant at 6.5×10^{-6} and 1.3×10^{-5} *M*, and the sodium fluorescein varied from 2.0×10^{-4} to 1.4×10^{-3} *M*.

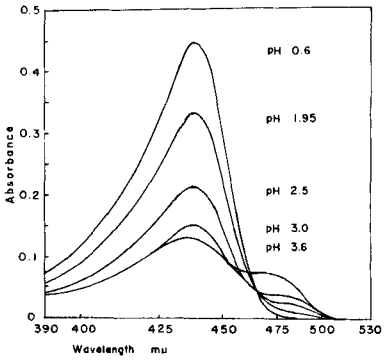

Fig. 1—Effect of pH on the spectral absorbance curve of sodium fluorescein.

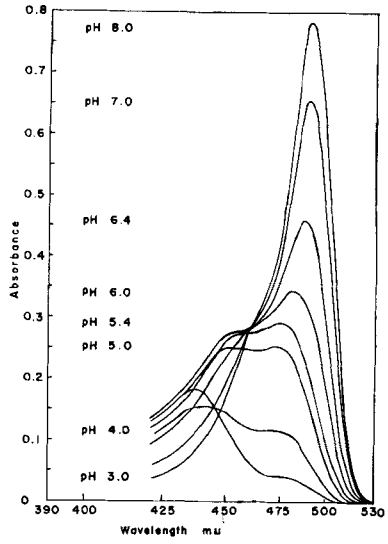

Fig. 2—Effect of pH on the spectral absorbance curve of sodium fluorescein.

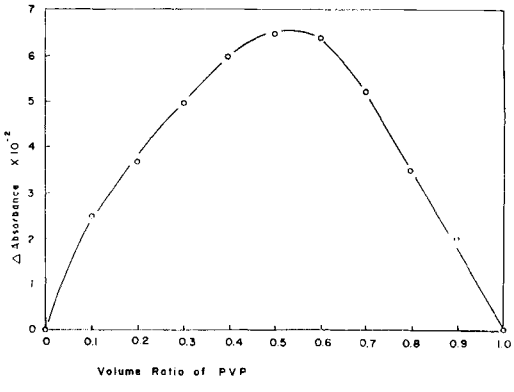

Fig. 3—Job plot of the NaFluor–PVP complex.

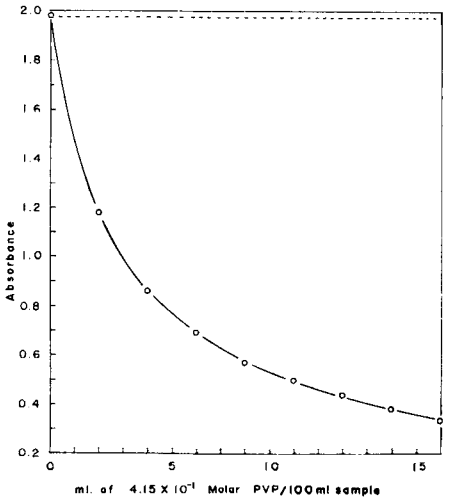

Fig. 4—Effect of PVP concentration on the absorbance of 5 × 10⁻⁶ M sodium fluorescein at pH 1.5.

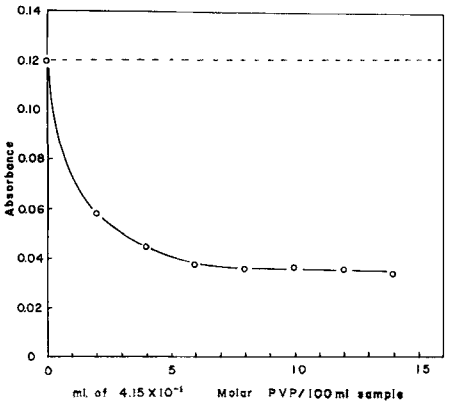

Fig. 5—Effect of PVP concentration on the absorbance of 5 × 10⁻⁶ M sodium fluorescein at pH 5.0.

pH 8.0:

Sodium fluorescein held constant at 5×10^{-5} *M*, and the PVP varied from 1.66 to 13.28 × 10^{-4} *M*. Buffer system was phosphate.
PVP held constant at 1.3×10^{-5} *M*, and the sodium fluorescein varied from 2×10^{-4} to 3.2×10^{-3} *M*.

The absorbances of the above solutions were measured at their spectral peaks, which were 437.5 mμ at pH values of 1.5 and 3.0, 475 mμ at pH 5.0, and 490 mμ at pH 8.0. Figures 4 and 5 are typical of the results obtained from the above experiments, and show the expected absorbances if no complexes were formed and the absorbances which were actually obtained.

DISCUSSION

The data summarized in Figs. 1 and 2 indicate that sodium fluorescein exists in several forms, much the same as phenolphthalein, which is quite similar structurally. Based upon the observed fact that the solubility of sodium fluorescein is much greater at the very low pH values than it is at a pH of about 2.5 to 3.0, and based upon the behavior of phenolphthalein at low pH values, it seems that the absorbance peak at 437.5 mμ is associated with a protonated form of the fluorescein. This form has a pKa of approximately 2.2. At about 465 mμ, there appears to be an isobestic point which is also associated with the protonation. The changes which take place between this isobestic point and the next one, which is also at 465 mμ, are probably associated with the singly charged anion, which appears to have a pKa of about 4.4. The peak at 490 mμ can be attributed to the doubly charged anion, which has a pKa of about 6.7. There were no indications of the formation of a triply charged anion such as is formed by phenolphthalein, even when the pH was raised to 12.0.

The Job plot shown in Fig. 3 has a maximum at about 0.5 parts of PVP by volume, which indicates the preferential formation of a 1:1 complex. It is interesting to note that the side of the curve representing relatively high concentrations of PVP is straight, as would be expected, while the side of the curve representing high concentrations of sodium fluorescein is curved. This curving is presumed to be a result of the formation of higher complexes which give way to the more stable 1:1 complex upon the addition of more PVP.

Assuming a 1:1 complex in dilute solutions of sodium fluorescein and recognizing the fact that any and possibly all forms of sodium fluorescein might be complexing with the PVP, the following equations were derived to describe the deviations of absorbances from those that would be predicted if no complexation were taking place.

The following equilibria are assumed:

$$\frac{[H^+][Fluor^-]}{[H\ Fluor^-]} = K_3 \text{ and } [H\ Fluor^-] = \frac{[H^+]}{K_3}[Fluor^-] \quad \text{(Eq. 1}a\text{)}$$

$$\frac{[H^+][H\ Fluor^-]}{H_2\ Fluor} = K_2 \text{ and } [H_2\ Fluor] = \frac{[H^+]^2}{K_3 K_2}[Fluor^-] \quad \text{(Eq. 1}b\text{)}$$

$$\frac{[H^+][H_2\ Fluor]}{H_3\ Fluor^+} = K_1 \text{ and } [H_3\ Fluor^+] = \frac{[H^+]^3}{K_3 K_2 K_1}[Fluor^-] \quad \text{(Eq. 1}c\text{)}$$

$$\frac{[C_1]}{[PVP][H_3\ Fluor^+]} = k_1 \text{ and } [C_1] = [PVP]k_1[H_3\ Fluor^+] \quad \text{(Eq. 2}a\text{)}$$

$$\frac{[C_2]}{[PVP][H_2\ Fluor]} = k_2 \text{ and } [C_2] = [PVP]k_2[H_2\ Fluor] \quad \text{(Eq. 2}b\text{)}$$

$$\frac{[C_3]}{[PVP][H\ Fluor^-]} = k_3 \text{ and } [C_3] = [PVP]k_3[H\ Fluor^-] \quad \text{(Eq. 2}c\text{)}$$

$$\frac{[C_4]}{[PVP][Fluor^-]} = k_4 \text{ and } [C_4] = [PVP]k_4[Fluor^-] \quad \text{(Eq. 2}d\text{)}$$

The following equation describes the measured absorbance (A_M) obtained when the sodium fluorescein is held constant and the absorbance due to PVP is negligible.

$$A_M = [C]_T Q_1 + [\text{Na}_2\text{ Fluor}]_{TF} Q_2 \quad \text{(Eq. 3)}$$

Q_1 and Q_2, defined in Eqs. 5 and 6, are constants for a given pH. The absorbance which would be expected (A_E) if no complex was formed should be:

$$A_E = [\text{Na}_2\text{ Fluor}]_T Q_2 \quad \text{(Eq. 4)}$$

The subscript TF stands for total free, T stands for total, and C stands for complex.

$$Q_1 = \frac{\epsilon_1 k_1[H^+]^3 + \epsilon_2 k_2 K_1[H^+]^2 + \epsilon_3 k_3 K_1 K_2[H^+] + \epsilon_4 k_4 K_1 K_2 K_3}{k_1[H^+]^3 + k_2 K_1[H^+]^2 + k_3 K_1 K_2[H^+] + k_4 K_1 K_2 K_3} \quad \text{(Eq. 5)}$$

$$Q_2 = \frac{\epsilon_5 K_1 K_2 K_3 + \epsilon_6 K_1 K_2[H^+] + \epsilon_7 K_1[H^+]^2 + \epsilon_8[H^+]^3}{K_1 K_2 K_3 + K_1 K_2[H^+] + K_1[H^+]^2 + [H^+]^3} \quad \text{(Eq. 6)}$$

where ϵ_1, ϵ_2, ϵ_3, ϵ_4, ϵ_5, ϵ_6, ϵ_7, and ϵ_8 are the absorptivity coefficients for C_1, C_2, C_3, C_4, H_3 Fluor$^+$, H_2 Fluor, H Fluor$^-$, and Fluor$^=$, respectively.

It can also be shown that when the above assumptions are true:

$$[A_E - A_M] = \Delta A = [C]_T(Q_2 - Q_1) \quad \text{(Eq. 7)}$$

and

$$\Delta A_{\max.} = [C]_{T\max.}(Q_2 - Q_1) = [\text{Na}_2\text{ Fluor}]_T(Q_2 - Q_1) \quad \text{(Eq. 8)}$$

An apparent stability constant (K_a) can be calculated as follows:

$$K_a = \frac{[C]_T}{[\text{PVP}][\text{Na}_2\text{ Fluor}]_{TF}} = \frac{\Delta A}{[\text{PVP}]_{TF}(\Delta A_{\max.} - \Delta A)} \quad \text{(Eq. 9)}$$

Equation 9 can be rearranged to give Eq. 10, which is more convenient for plotting. In plotting Eq. 10, it is assumed that $[\text{PVP}]_{TF} \simeq [\text{PVP}]_T$.

$$\frac{[\text{PVP}]_T}{\Delta A} = \left(\frac{1}{K_a\,\Delta A_{\max.}}\right) + \left(\frac{1}{\Delta A_{\max.}}\right)\left([\text{PVP}]_T\right) \quad \text{(Eq. 10)}$$

The data for each experiment in which sodium fluorescein was held constant are plotted in Figs. 6–9. The calculated K_a and the $\Delta A_{\max.}$ for each experiment are given in Table I. Although it appears that the stability constant for the complex at pH 5.0 may change as the amount of substrate changes, the variation may actually be a result of the inaccuracy associated with determining the absorbance values of small amounts of substrate. It is interesting to note that when the expected absorbance for each level of substrate is plotted *versus* the predicted $\Delta A_{\max.}$ a straight line which goes through zero, as would be expected, is obtained.

It can be shown that:

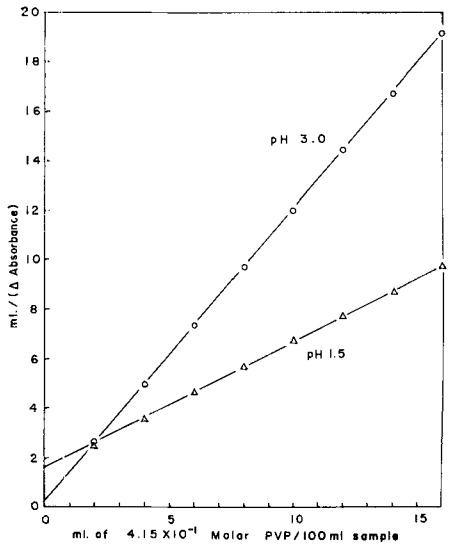

Fig. 6—The pH 1.5 and 3.0 data plotted according to Eq. 10.

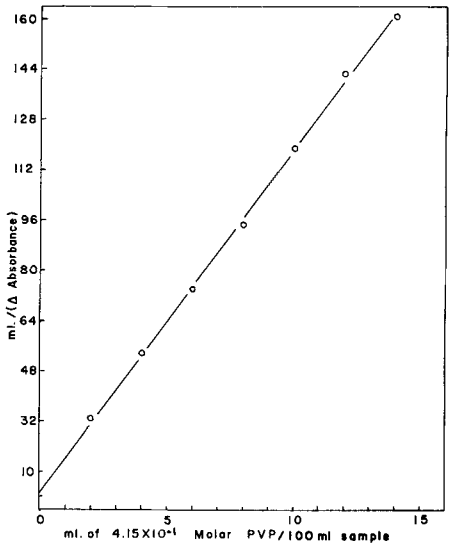

Fig. 7—The pH 5.0 data for 5 × 10^{-6} M substrate plotted according to Eq. 10.

$$K_a = \frac{k_1[H^+]^3 + k_2 K_1[H^+]^2 + k_3 K_1 K_2[H^+] + k_4 K_1 K_2 K_3}{[H^+]^3 + K_1[H^+]^2 + K_1 K_2[H^+] + K_1 K_2 K_3} \quad \text{(Eq. 11)}$$

By knowing the individual dissociation constants for sodium fluorescein and the apparent stability constants calculated at four different pH values, it should be possible to calculate the stability constant for the complex produced by each form of fluorescein. A large negative value was obtained for k_1 when the K_a values in Table I and the approximate dissociation constants for sodium fluorescein of 2.2,

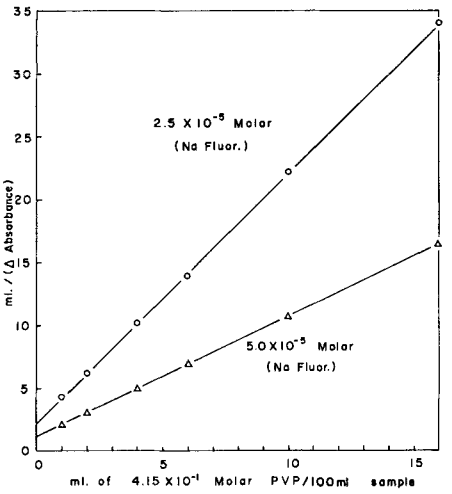

Fig. 8—The pH 5.0 data for 2.5 and 5.0 × 10^{-5} M substrate plotted according to Eq. 10.

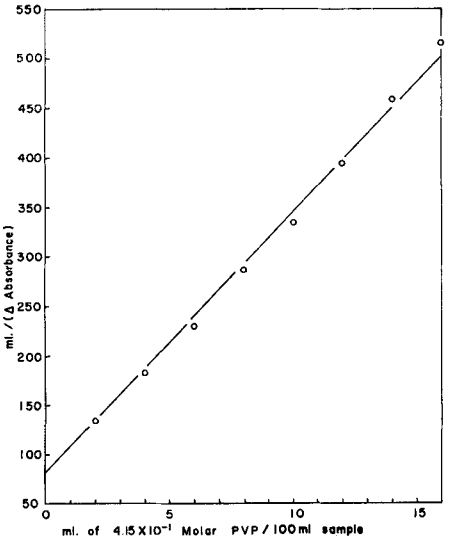

Fig. 9—The pH 8.0 data plotted according to Eq. 10.

TABLE I—SUMMARY OF BINDING DATA

pH	K_a × 10^{-4}	$\Delta A_{max.}$	ΔA_∞[a]	Concn. of Substrate × 10^{+5}
1.5	0.377	1.940	0.048	5.0
3.0	5.37	0.848	0.038	5.0
5.0	1.51	0.095	0.025	0.5
5.0	1.08	0.502	0.102	2.5
5.0	1.04	1.039	0.176	5.0
8.0	0.384	0.038	0.293	5.0

[a] ΔA_∞ is the measured absorbance at infinitely high concentrations of PVP and is obtained when all of the sodium fluorescein is complexed.

4.4, and 6.7 were used to calculate k_1, k_2, k_3, and k_4. This negative value was a result of the unusually

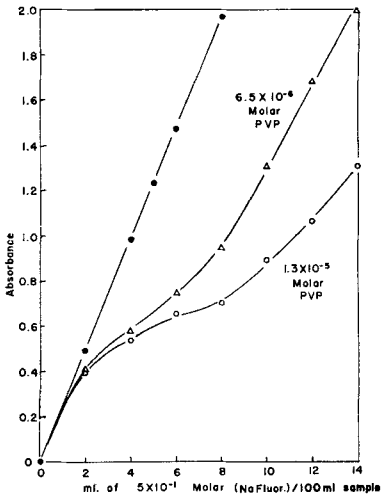

Fig. 10—Effect of sodium fluorescein concentration on the absorbance of 6.5 × 10^{-6} M PVP at pH 5.0.

small K_a observed at pH 1.5. A low value for K_a would result if the concentration of PVP free to complex were lower than expected. This would be the case at pH 1.5 if the complexing form of PVP was in equilibrium with a significant amount of a noncomplexing form of PVP. The literature states (4) that a PVP solution has its minimum viscosity at a pH of about 1.5, a statement which suggests that the PVP is in more than one physical form at this pH.

It was found that higher than 1:1 complexes were formed when the PVP was held constant and the sodium fluorescein varied. Although the stoichiometry and the stability constant of the higher complexes could not be determined, there was no doubt about their existence. The minimum number of moles of complexed sodium fluorescein required to produce the observed ΔA values were much larger than the number of moles of PVP which were present. The results at all three pH values were essentially the same as those shown in Fig. 10 for pH 5.0. None of the systems could be properly evaluated because of solubility problems, extremely high absorbances, or the need to make assumptions with questionable validity.

CONCLUSIONS

Based upon spectrophotometric data and qualitative solubility results, it appears that fluorescein can exist as a singly charged anion, a noncharged molecule, and a singly charged or doubly charged anion. Although each form of fluorescein has characteristic absorption properties, all four forms have a similar yellow color in solution. Each form of fluorescein can complex with PVP, but with varying strengths. This is probably a charged transfer type of complex. It appears that the higher the positive charge on the fluorescein, the weaker is the complex. When the ratio of fluorescein to PVP is about equal, a 1:1 complex is formed, but as the amount of fluorescein is increased, the order of the complex also increases. At low pH values anomal-

ous results are obtained which might well be due to an interaction of PVP with itself.

Unusual Interaction of Bishydroxycoumarin with Plasma Proteins—Development of a New Assay

By RENPEI NAGASHIMA, GERHARD LEVY*, and EINO NELSON†

A widely used method for the determination of bishydroxycoumarin (BHC) in plasma, which involves extraction of BHC from acidified plasma (pH <1) into an organic solvent, fails at high concentrations of BHC. Evidence is presented to show that this is not due to a limited solubility of the drug in the organic phase but rather to a concentration- and pH-dependent interaction of plasma protein with BHC. Complete extraction of BHC from the blood plasma of rats, guinea pigs, dogs, monkeys, and man is obtained readily only in the narrow pH range of 3.0 to 3.5. A new method of analysis for BHC in plasma has been developed on the basis of these findings and its specificity is demonstrated. It is shown that the development of analytical methods for drugs in plasma or serum, which involve extraction of the drug into an organic phase, cannot be based solely upon a consideration of the effect of pH on the distribution of the drug between the organic and aqueous phases. It is necessary also to consider the effect of pH (and possibly of other factors, such as the type of organic solvent, the buffer system, and ionic strength) on the physical-chemical properties of plasma proteins as they affect the type and magnitude of interaction of these proteins with the drug.

THE PHARMACOKINETICS of the coumarin anticoagulants has been and is the subject of intensive investigation in many laboratories (1–24). Studies have been concerned with the kinetics of elimination of various coumarin anticoagulants in several animal species (2–11) and in man (12–17), as well as with the interaction of these anticoagulants with various other drugs (*e.g.*, 18–23) and with plasma proteins (24). Of particular interest is the unusual, dose-dependent pharmacokinetics of bishydroxycoumarin (BHC) elimination in man, as well as the biologic fate of this drug which so far has eluded adequate characterization (25, 26).

The most widely used method for the determination of BHC is that of Axelrod and his associates (27), which involves extraction of the drug from plasma acidified with 3 *N* hydrochloric acid to pH <1 into *n*-heptane, followed by re-extraction into 2.5 *N* aqueous sodium hydroxide solution, and spectrophotometric measurement of BHC in the latter phase. In the course of studies in this laboratory on the comparative pharmacokinetics of BHC elimination, which will be described in subsequent reports (28, 29), it was noted that the assay method of Axelrod and his associates fails at relatively high concentrations of BHC. Therefore, a new analytical method for the determination of BHC in plasma or serum has been developed. This method and studies concerning its specificity are described in detail in view of the extensive interest in and continuing research related to the pharmacokinetics of the coumarin anticoagulants.

It will be shown that the recovery of BHC from plasma of various species, including man, is un-

† Deceased.

usually pH- and concentration-dependent. This phenomenon has wider implications in that it might be found also with other highly protein-bound drugs. It is evident on the basis of findings to be described here that the extractability of a drug from plasma is related not only to the degree of ionization and the intrinsic partition coefficient of the drug itself, but also to the physical-chemical state of plasma protein at a given pH and the degree and nature of the interaction of the drug with such protein(s) under given conditions.

EXPERIMENTAL

Materials—Heparinized blood was obtained from rats (Sprague-Dawley) and guinea pigs (Hartley) by cardiac puncture, and from dogs, rhesus monkeys, and humans by venipuncture. Plasma was obtained by centrifugation, pooled within the same species, and stored at −15° (for no longer than 1 month) until used. Bishydroxycoumarin[1] [m.p. 288–290°, uncorrected; lit. (30) m.p. 287–293°] was obtained from Nutritional Biochemicals Co., Cleveland, Ohio.

Preparation of Plasma Samples Containing Known Concentrations of BHC—A series of plasma samples containing various concentrations of BHC was prepared in the following manner. One-half milliliter of BHC solution, prepared by dissolving one part of bishydroxycoumarin and 10 parts of tris(hydroxymethyl)aminomethane (Nutritional Biochemicals Co.) in distilled water, was added to 2 ml. of plasma. The samples were maintained at 36–37° for 2 hr. and then stored at −15° (for no longer than 2 weeks) until used.

Micro-Adaptation of Axelrod's Method for the Determination of BHC (27)—Depending on the concentration of BHC, about 0.06 to 0.25 Gm. of plasma was pipetted into a tared 15-ml. capacity centrifuge tube (with a screw cap lined with polyethylene) which was then weighed. The sample was acidified with 0.03 ml. 3 *N* HCl, and the total volume of the aqueous phase was adjusted to approximately 0.35 ml. with distilled water. At this point the pH of the aqueous phase was found to be less than 1. Three milliliters of heptane was added and the tube was shaken vigorously for 10 min. by hand[2] and centrifuged. Two milliliters of the organic phase was transferred to another centrifuge tube, an exact volume of 2.5 *N* NaOH (0.5 to 2 ml.)[3] was added, and the tube was shaken for 5 min., by hand and centrifuged. The absorbances of the aqueous phase at 314 and 360 mμ were determined in a fused silica microcell, 10-mm. light path, with a Beckman DU spectrophotometer using a 0.3-mm. pinhole slit with 2.5 *N* NaOH in the reference cell. The absorptivity was determined with standard solutions of BHC in 2.5 *N* NaOH. Measurements at two wavelengths were necessary for plasma blank corrections, as described in a subsequent paragraph. Some studies were done using 0.5 ml. of suitably diluted plasma, in which case the following volumes of reagents were used: 0.2 ml. of distilled water, 0.06 ml. of 3 *N* HCl, and 6 ml. of heptane. All glassware was cleaned by immersion in an acid dichromate bath for at least 12 hr.

Extraction Efficiency as a Function of pH—BHC was extracted from plasma into *n*-heptane and assayed as described under *New Assay Method for BHC* except that the plasma was adjusted to various pH values by means of specified types and concentrations of buffering agents.

Determination of Rate of Extraction—Two and one-half milliliters of suitably diluted[4] BHC-containing rat plasma and 1 ml. of buffer solution were placed in a 60-ml. bottle furnished with a polyethylene cap. After a specified time, 20 ml. of heptane was layered over the aqueous phase. The bottle was then capped and agitated in an upright position on a reciprocating shaker (280 strokes per min., 5.9-cm. stroke travel). Three-milliliter aliquots of the organic phase were withdrawn 15, 30, 60, and 120 min. after the beginning of agitation, and an equal volume of *n*-heptane was added after each withdrawal. The BHC concentration in each 3-ml. aliquot of the heptane phase was determined by extraction of the drug into 2.5 *N* NaOH and spectrophotometric measurement at 314 mμ. The pH-adjusting agents used were 1.5 *N* HCl (for pH 0.6), 1.5 *M* citrate–phosphate buffers (for pH 3.0 and 4.9), and 1.5 *M* acetate buffer (for pH 4.9).

New Assay Method for BHC—*Small Scale Assay*—One-tenth milliliter of citrate–phosphate buffer (0.99 and 0.51 *M*, pH 3.0) and an appropriate volume of distilled water were added to 0.06 to 0.25 Gm. of plasma to yield a total volume of 0.35 ml. of sample with a pH of between 3.0 and 3.2. The same procedure as described for the micro-adaptation of Axelrod's method was then followed.

Large Scale Assay—This method was employed in the case of dog, monkey, and human plasma, where it is possible to obtain 0.6 ml. or more of plasma repeatedly from any one animal. Six-tenths milliliter suitably diluted plasma, 0.2 ml. citrate–phosphate buffer (1.5 *M*, pH 3.0), and 6 ml. of heptane were placed in a 15-ml. centrifuge tube, shaken for 10 min., and centrifuged. Four milliliters of the organic phase was transferred to another centrifuge tube and extracted with 1 to 5 ml. of 2.5 *N* NaOH, and the BHC concentration of the aqueous phase was determined at 314 and 360 mμ, using 2.5 *N* NaOH in the reference cell.

The lower limit of the sensitivity of the assay procedure is a function mainly of the contribution of the plasma blank to the total absorbance. One microgram of BHC/ml. of plasma can be determined readily in a plasma sample of 0.5 ml., but the plasma blank will be equivalent to almost one-third of the drug alone. The upper limit of the assay is determined by the solubility of BHC in heptane (approximately 14 mcg./ml. at room temperature). Thus, undiluted plasma containing up to 100 mcg./ml. can be assayed readily by the large scale assay method, although the volume of NaOH phase may

[1] The material showed a single spot when visualized with diazotized *p*-nitroaniline or under ultraviolet light, on a thin-layer chromatogram (Silica Gel G) developed with a solvent mixture of chloroform–heptane–acetic acid (10:15:4).

[2] This resulted in more rapid extraction than mechanical agitation as used by Axelrod *et al.* (27).

[3] One part of 2.5 *N* NaOH can quantitatively extract the drug from 4 parts of heptane.

[4] Dilution of plasma containing high concentration of BHC is necessary prior to extraction with *n*-heptane due to the limited solubility of BHC in the organic solvent.

have to be increased. Higher concentrations of BHC in the plasma require that the plasma sample be diluted prior to extraction. The Beer-Lambert law holds for BHC concentrations as high as 20 mcg./ml. in 2.5 *N* NaOH.

Correction for Plasma Blanks—The contribution of plasma blanks is negligible at BHC concentrations of 50 mcg./ml. and above. The blank contribution is, however, appreciable when BHC concentrations are quite low. In the small scale assay, when the drug is extracted from the organic phase into 0.5 ml. of 2.5 *N* NaOH, blank values ranged from 0.15 mcg./ml. to 0.30 mcg./ml. apparent BHC. This includes the contribution of plasma as well as organic solvent. While plasma blank values obtained from different animals vary appreciably, it was found that the ratio of the absorbances at 314 mμ (A_{314}) and 360 mμ (A_{360}) are quite constant. The average ratios, A_{314} to A_{360}, were 0.9 for the rat, 1.4 for the guinea pig, 1.0 for the dog, 0.6 for the monkey, and 0.9 for man. The plasma blanks for the large scale assay were approximately 0.15 mcg./ml. for the dog and monkey, and 0.35 mcg./ml. for man, in terms of apparent BHC.

For the determination of BHC in plasma, the absorbances of the sodium hydroxide extract are determined at 314 mμ and 360 mμ. The plasma blank value at 314 mμ is calculated from the absorbance of sample at 360 mμ and the known ratio of absorbance of plasma blanks at 314 and 360 mμ (R). The absorbance of BHC at 360 mμ is very small (about 1/110 of its absorbance at 314 mμ) and thus contributes only negligibly to the apparent plasma blank value. It may however be incorporated in the calculations in the following manner:

$$\text{plasma blank } A_{314} = R(A_{360} - 0.009 \times A_{314})$$

when A_{314} due to BHC plus blank $\gg A_{314}$ due to blank alone.

Specificity of the New Assay Method for BHC—The specificity of the new assay method for the determination of BHC, as opposed to metabolites of this drug, was determined by a partitioning method similar to that of Axelrod *et al.* (27). For this purpose, heparinized plasma samples were obtained from animals which had received BHC intraperitoneally at least 7 hr. earlier. Samples were also obtained from BHC-containing blood which had been perfused through an isolated rat liver since this was considered to be an effective means of obtaining plasma which contains both BHC and its metabolites. The procedures used in the partitioning study are outlined schematically in Fig. 1. In essence, the plasma was extracted with *n*-heptane, the organic phase was removed, and an appropriate volume of isoamyl alcohol was added to it.[5] This latter solution was then equilibrated with buffer solutions of pH 4.0 (0.5 *M* citrate-phosphate), 6.5, 7.0, 7.5, 8.0, 8.5, and 9.0 [tris-(hydroxymethyl)aminomethane–HCl; ionic strength, 0.1]. The amount of BHC remaining in the organic phase was determined by extracting the latter with 2.5 *N* NaOH, followed by spectrophotometry of that extract.

For purpose of comparison, other plasma samples were extracted with ethyl acetate following addition of solid sodium chloride. This is known to extract not only BHC but also its metabolites (7). The ethyl acetate extract was evaporated under reduced pressure, the residue was dissolved in *n*-heptane–isoamyl alcohol mixture,[6] and this solution was equilibrated with buffers of various pH values as described above. The results of the partitioning experiments are described in terms of the fraction of BHC (or apparent BHC) remaining in the organic phase.

RESULTS

Determination of BHC in Plasma by the Method of Axelrod et al. (27)—Known amounts of BHC were added to plasma samples obtained from rats, guinea pigs, dogs, and man to yield BHC concentrations ranging from 2 to 200 mcg. per ml. or Gm. of plasma. These plasma samples were analyzed by the micro-adaptation of the method of Axelrod *et al.* (27). The results, depicted in Fig. 2, show that all of the assay values were appreciably lower than theory at BHC concentrations above 50 mcg./ml.[7] The logarithmic scales of Fig. 2 tend to de-emphasize the magnitude of the deviation of the analytical results from theory; note that the assay results at BHC concentrations of 100 and 200 mcg./ml. were in some instances only 25 to 50% of theory. It was also found that there was appreciable intersubject variation in the results of an analysis of BHC in plasma of different healthy humans (Table I). Several modifications of the method of Axelrod and associates (27) were tried (Table II), but these did not result in any appreciable improvement in the recovery of BHC. The results listed in Table II rule out the possibility that the incomplete extraction is due to a possible saturation of the organic phase with BHC. It was noted in general that the recovery of BHC was more a function of the ratio of the concentration of BHC to that of plasma than of the concentration of BHC in the plasma *phase*.[8] This becomes apparent upon comparison of the results obtained by the unmodified assay method and the assay method which involves a thirteenfold dilution of the plasma prior to extraction. This degree of dilution produced a substantial decrease in the concentration of plasma proteins in the aqueous phase. Yet, neither the dilution of plasma proteins nor the decrease in the concentration of BHC produced a significant increase in the recovery of the drug.

Extraction Efficiency as a Function of pH—Figure 3 shows the effect of pH on BHC extraction efficiency, using rat plasma containing 200 mcg./ml., which was diluted to 2.5 times its volume with water, and *n*-heptane as the extracting solvent.

---

[5] Note that isoamyl alcohol was added *after* the extraction The use of isoamyl alcohol was necessary because it was desired to compare the partitioning profiles of BHC and its metabolites. These metabolites do not dissolve in *n*-heptane alone.

[6] This is where the addition of isoamyl alcohol became necessary in order to dissolve the BHC metabolites.

[7] Note, however, that Axelrod *et al.* (27) made no claim for the usefulness of their method above this concentration. Therefore, nothing in our results or discussion should be interpreted as a criticism of the contribution made by these investigators.

[8] The plasma *phase* consists of plasma and aqueous diluent (*i.e.*, water, buffer, and/or HCl solution) in a ratio appropriate for effective extraction of the drug into the organic solvent; the terms "concentration in plasma phase" and "concentration in plasma" must be distinguished accordingly.

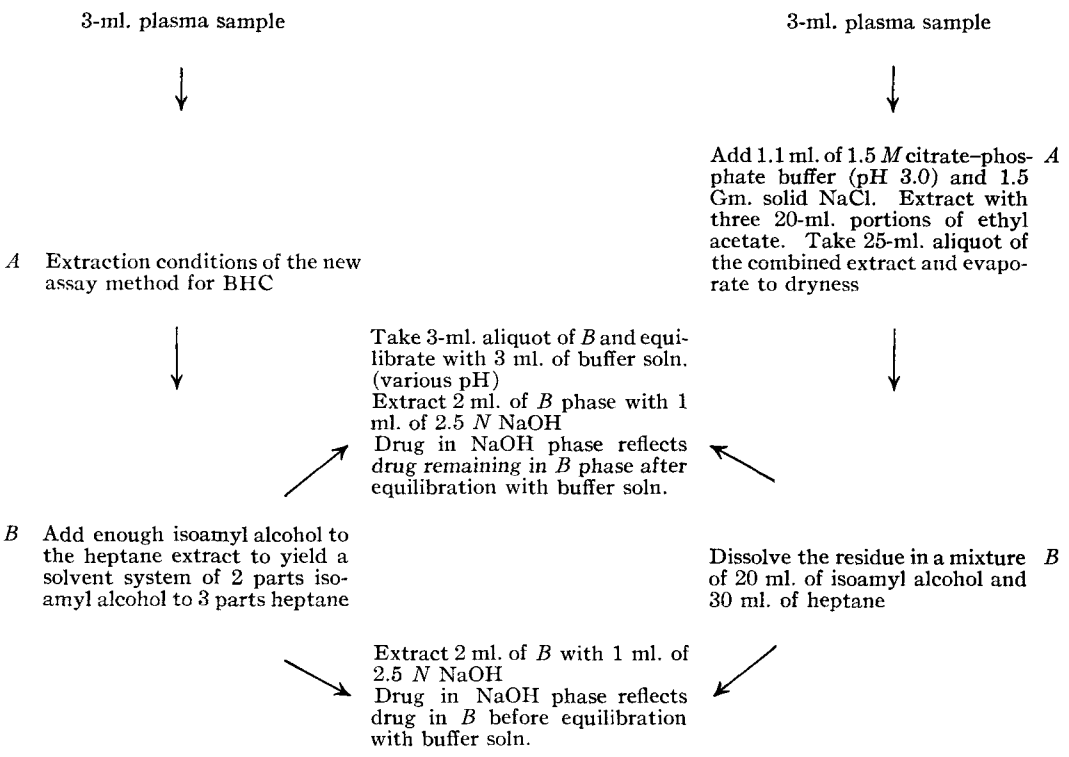

Fig. 1—Schematic diagram of the pH-partitioning procedure used to determine the specificity of the assay method for BHC. For further details see Experimental.

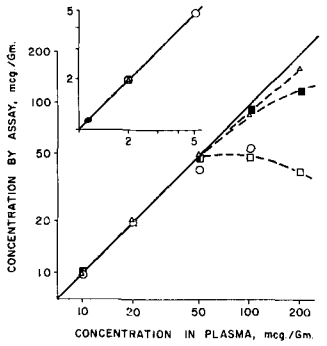

Fig. 2—Apparent concentration of BHC, as determined by the method of Axelrod et al., *plotted against the actual concentration of BHC in the plasma of rats* (■), *guinea pigs* (○), *dogs* (□), *and man* (△). *Average of at least 3 determinations for plasma from rat and guinea pig, and at least 2 determinations for plasma from dog and man. The inset represents the results obtained at concentrations lower than 10 mcg./Gm. In plasma from dog and man, the concentrations shown are expressed as mcg./ml. rather than mcg./Gm.*

F	26	58, 44

[a] 200 mcg. of BHC/ml. of plasma. [b] All subjects were males. [c] Results of two separate analyses.

It can be seen that complete extraction of BHC is obtained only in a narrow pH range of pH 3.0 to 3.5. At pH <3 and >4.5 there is a precipitous decrease in the extractability of BHC from plasma. These effects are not due to specific buffers or differences in ionic strength. Complete extraction at pH 3 was obtained when the pH adjustment was made with either citrate–phosphate buffer or monochloroacetate buffer; a pronounced decrease in extraction efficiency was observed at pH 2.5 and below with monochloroacetate buffer as well as when hydrochloric acid was used to adjust pH. Similarly, though the ionic strength increased from 0.047 at pH 2.4 to 0.32 at pH 0.8 when HCl was used to adjust pH, the ionic strength decreased from 0.25 at pH 3.1 to 0.03 at pH 1.9 when monochloroacetate served as the buffer system. Nevertheless, the decrease in extraction efficiency at the lower pH was observed with both systems. It is possible that the magnitude of this decrease is affected by ionic strength. Variability of extraction efficiency in duplicate experiments at a given pH was very small

TABLE II—RECOVERY OF BHC FROM RAT PLASMA BY VARIOUS MODIFICATIONS OF AXELROD'S METHOD

Conditions	BHC Concn., mcg./ml. →	Recovery, mcg./ml.[a] 100	150	200
Axelrod's method, unmodified[b]		93	110	111
Thirteenfold dilution of plasma before extraction		100	121	118
Five repetitive extractions each with 3 ml. heptane		89	...	150
Single extraction with 3 ml. ethylene dichloride		85	...	106

[a] Average of 3 determinations except for the repetitive extractions where 2 determinations were made. [b] Additional data shown in Fig. 2.

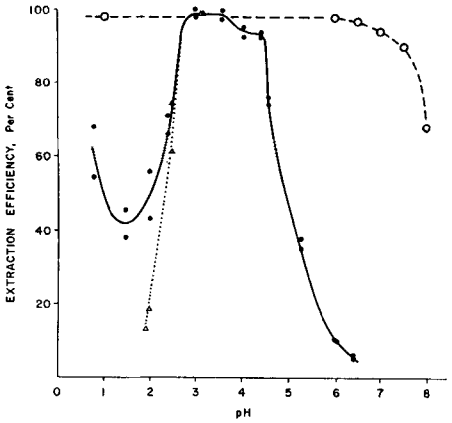

Fig. 3—Effect of pH on the efficiency of BHC extraction from rat plasma containing 200 mcg. of BHC/ml. Five-tenths milliliter of 2.5-fold diluted plasma was adjusted with 0.25–3 N HCl to pH <2.5 (●), with 1.5 M monochloroacetate buffers to pH ≤3.0 (△), and with 1.5 M citrate-phosphate buffers to pH ≥3.0 (●) prior to extraction with 7.5 volumes of n-*heptane. The concentration of buffers in the plasma phase was approximately 0.4 M. The data points represent individual values. Key: ---○---, BHC extraction efficiency from simple aqueous BHC solution as calculated from the partitioning data of Axelrod* et al. *(27).*

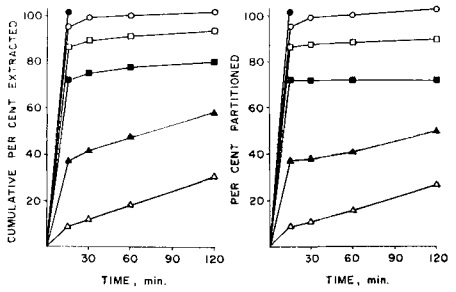

Fig. 4—Effect of pH and BHC concentration on kinetics of BHC extraction from rat plasma. Symbols are defined in Table III. (Further details under Experimental.)

in the pH range of 3.0 to 6.5, and rather pronounced at pH <2.5. This can be related to the kinetics of BHC extraction, as will be shown subsequently. The extraction efficiency *versus* pH profile of BHC from plasma differs appreciably from that of BHC from water (Fig. 3). The extraction of BHC from simple aqueous solution is practically complete at pH 6 and below.[9]

Kinetics of BHC Extraction from Plasma—The rate of BHC extraction from rat plasma was determined as a function of BHC concentration, pH of the plasma phase, and time interval between pH adjustment of the plasma and extraction with heptane. The various experimental conditions are listed in Table III and the results are shown in Fig. 4. In the case of plasma samples containing a low concentration (10 mcg./ml.) of BHC, complete extraction was obtained within 15 min., regardless of pH (<1 to 3.0) and time between pH adjustment and extraction. On the other hand, complete extraction of BHC from plasma containing 200 mcg./ml. was obtained within 15 min. only when the plasma pH was 3.0 and extraction was carried out immediately after pH adjustment. The increase in extraction of BHC with time, as shown in the lefthand graph of Fig. 4 for all other experiments involving 200 mcg. BHC/ml. plasma, could reflect either a slow rate of extraction of BHC or could be due to the fresh solvent which was added to replace that portion of organic phase which had been removed for assay (see under *Experimental*). A distinction between these two mechanisms can be made by expressing the amount of BHC in the heptane phase at any given time as a percent of the total amount of the drug in the system at that time (*i.e.*, sum of BHC in heptane phase and in plasma phase). This is shown in the righthand graph of Fig. 4 in terms of "percent partitioned" as a function of time.[10] At pH 4.9, the extraction of BHC from plasma containing 200 mcg./ml. was at its maximum within 15 min. and subsequent increases in the cumulative percent extraction as a function of time were due to addition of fresh organic solvent. The constancy of "percent partitioned" with time at a value of about 70% reflects the effect of plasma protein binding on the apparent partition coefficient of BHC at pH 4.9 since, in the absence of plasma proteins, extraction of BHC is complete within 15 min.

At low pH's (0.6 and 3.0) it is evident that the incomplete extraction of BHC at any given time

[9] The pKa_1 of BHC appears to be about 6.5 on the basis of Axelrod's partitioning data which have been verified in this laboratory. Other workers have reported a pKa_1 value of 5.7 based on potentiometric titration (31).

[10] The reader is cautioned to distinguish between "partition coefficient" (which is an equilibrium constant) and "percent partitioned." No assumption is made as to whether the latter reflects an equilibrium or a kinetic situation.

TABLE III—EXPERIMENTAL CONDITIONS FOR THE DETERMINATION OF THE KINETICS OF BHC EXTRACTION FROM PLASMA

Symbol in Fig. 4	BHC Concn., mcg./ml.	pH	Buffer System	Time Between pH Adjustment and Extraction, hr.
●	10	0.6	HCl 0.4 *N*	0 and 1
●	10	3.0	Citrate–phosphate, 0.4 *M*	0 and 1
●	200[a]	3.0	Citrate–phosphate, 0.4 *M*	0
○	200[a]	3.0	Citrate–phosphate, 0.4 *M*	1
□	200[a]	3.0	Citrate–phosphate, 0.4 *M*	3

▲	200[a]	0.6	HCl, 0.4 *N*	0
△	200[a]	0.6	HCl, 0.4 *N*	0.5 and 1

[a] Diluted fourfold with distilled water (1 part plasma and 3 parts water) prior to pH adjustment.

is due to a kinetic effect. The rate of extraction decreased with decreasing pH, and decreased also at a given pH as the time interval between pH adjustment and extraction was increased. A detailed consideration of factors affecting the rate of extraction will not be undertaken here, but it should be pointed out that these factors include the time between pH adjustment and extraction, sampling interval, agitation intensity, volume of organic phase, and volumes of the aliquots removed for assay. In general, the time course of extraction consisted of an initial rapid phase followed by a slower exponential phase. Representative rate constants of the latter are 0.33 hr.$^{-1}$ at pH 3.0 after 3 hr. standing, and 0.14 hr.$^{-1}$ at pH 0.6 after 1 hr. standing. Thus the extraction efficiency *versus* pH profile shown in Fig. 3 reflects an equilibrium phenomenon at pH's above the optimum, and kinetic phenomena at pH's below the optimum pH for extraction. In fact, complete extraction of BHC may be attained at pH <3.0 by prolonged agitation. However, this would, for example, require more than 20 hr. in the case of plasma adjusted to pH 0.6 when the interval between pH adjustment and extraction is 1 hr. The adverse effect of low pH on BHC extraction from plasma is reversible as shown in Table IV.

New Assay Method for BHC in Plasma—The new assay method for BHC in plasma, which involves extraction of the drug with heptane from plasma adjusted to about pH 3.2, was used to determine the concentration of BHC in blood plasma obtained from rats, guinea pigs, dogs, monkeys, and man. These plasma samples were prepared by adding appropriate amounts of BHC to plasma obtained from unmedicated animals to yield BHC concentrations from 0.8 to 400 mcg./ml. The results, listed in Table V, show essentially complete recovery of the drug in all instances. The standard deviation of the analytical data was 1 to 2% except in the case of monkey plasma, where the possibility of a small and practically insignificant concentration-dependency of BHC recovery precluded the use of the combined data (*i.e.*, all concentrations of BHC) for the determination of a percent standard deviation.

TABLE IV—REVERSIBILITY OF ADVERSE pH EFFECT ON BHC EXTRACTION FROM RAT PLASMA

Conditions[a]	Extraction Efficiency,[b] %
Plasma adjusted to pH 3.0 and extracted immediately	99,99
Plasma adjusted to pH <1 and extracted after 30 min.	14,14
Plasma adjusted to pH <1 and extracted after 90 min.	10,12
Plasma at pH <1 for 30 min. then at pH 3.0 for 60 min.	61,70
Plasma at pH <1 for 30 min. and at pH ≃7 for 30 min. then adjusted to pH 3.0 and extracted immediately	99,101

[a] Plasma samples contained 200 mcg. BHC/ml. and were diluted 2.5-fold with distilled water prior to pH adjustment. [b] One ml. plasma phase was extracted for 10 min. with 8 ml. *n*-heptane. Results of two separate analyses.

Specificity of the New Assay Method for BHC—The specificity of the new assay method for BHC, particularly with respect to the lack of interference by biotransformation products of that drug, was investigated by means of the pH-partition profile (27). For this purpose, 20 mg. of BHC/Kg. of body weight was administered intraperitoneally to rats and guinea pigs, blood was withdrawn 7 to 8 hr. later [equivalent to about 1.5 biologic half-lives of BHC (28)] and the plasma thus obtained from animals of each species was pooled. The pH-partition profile for apparent BHC from rat plasma is shown in Fig. 5 and from guinea pig plasma in Fig. 6. There is excellent agreement between these profiles and that obtained by use of pure BHC in water. On the other hand, the use of an initial extraction procedure which is known to extract not only BHC but also some of its metabolites yields a quite different partition profile (stippled line in Figs. 5 and 6) and shows also that BHC metabolites are more polar than the parent drug. An even more rigorous determination of assay specificity was made by using plasma containing BHC which had been perfused for 3 hr. through an isolated rat liver (29). During the period of perfusion, the BHC concentration in the plasma decreased to less than one-third of its initial concentration. Thus, this sample is likely to have contained relatively high concentrations of BHC metabolites (except for the unlikely possibility that these metabolites were trapped totally in the liver and/or excreted completely in the bile).[11] The results of the partitioning experiment are shown in

[11] Christensen (7) has shown that the plasma of rats contains appreciable concentrations of BHC metabolites 6 and 24 hr. after intravenous administration of BHC.

TABLE V—RECOVERY OF BHC FROM PLASMA OF VARIOUS ANIMAL SPECIES BY THE NEW ASSAY METHOD

[a] Average of 2–4 determinations. [b] Single determinations. [c] Mean and S.D. of individual values irrespective of concentration. [d] Data from the 2 mcg./ml. samples were excluded due to pronounced variations within group (3 samples). [e] The value for the 0.8 mcg./ml. sample was excluded due to pronounced difference from those for the other concentrations. [f] Not calculated because relative recovery appears to be concentration dependent.

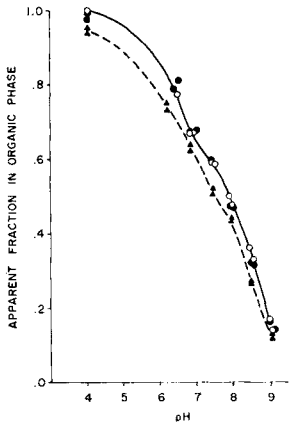

Fig. 5—Specificity of the new assay method for BHC in rat plasma, as determined by pH-partitioning. The plasma obtained from two rats 7 hr. after an i.p. dose of 20 mg. of BHC/Kg. was subjected to the new assay method (heptane extraction at pH 3) and to ethyl acetate extraction, and the pH-partition profiles of the substance(s) in each extract were determined. (See under Experimental *for details.) Pure BHC added directly to the organic phase used in the partitioning experiment* (○), *heptane extract (new assay method)* (●), *ethyl acetate extract* (▲).

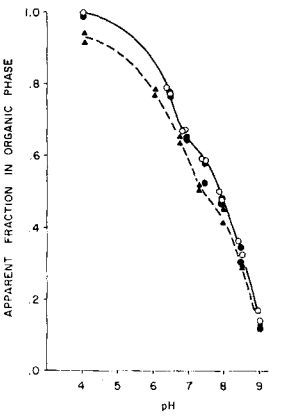

Fig. 6—Specificity of the new assay method for BHC in guinea pig plasma, as determined by pH-partitioning. The plasma was obtained from two guinea pigs 8 hr after an i.p. dose of 20 mg. BHC/Kg. (See Fig. 5 for other details.)

Table VI and indicate a very good agreement between results obtained with the plasma and with an aqueous solution of BHC. There was no noticeable interference by BHC metabolites in the assay.

DISCUSSION

Evaluation of the Method of Axelrod et al. (27) for the Determination of BHC in Plasma—The recovery of BHC from the plasma of rats, dogs, and man by the method of Axelrod *et al.* (27) is essentially quantitative at BHC concentrations up to 50 mcg./ml., but becomes incomplete and markedly concentration-dependent at BHC concentrations exceeding 50 mcg./ml. (Fig. 2). In guinea pig plasma, the recovery of added BHC was quantitative at 10 mcg./ml. but already incomplete at 50 mcg./ml. These results are not due to a limited solubility of BHC in *n*-heptane, nor to the precipitation of BHC in the acidified aqueous phase, since extraction of BHC from aqueous solution does not show the concentration dependence found with plasma. In addition to its incompleteness, the recovery of BHC in high concentrations from plasma shows poor reproducibility and appears to vary in

TABLE VI—SPECIFICITY OF THE NEW ASSAY METHOD FOR BHC AS TESTED BY pH-PARTITIONING USING PLASMA CONTAINING BHC AND METABOLITES DERIVED FROM PERFUSION OF ISOLATED RAT LIVER

6.4	0.79	0.76
6.8	0.68	0.70
7.4	0.58	0.56

the plasma samples obtained from different subjects (Table I).

The incomplete recovery of BHC from plasma at high concentrations can easily be overlooked. While it is standard practice to ascertain the adequacy of an analytical method for a drug in plasma at concentrations in the range suitable for instrumental analysis, it is usually taken for granted that plasma samples containing higher concentrations of drug may be diluted appropriately and that they can then be analyzed as readily as plasma samples containing lower concentrations of drug. Such is not the case with BHC (Table II). Apparently the extractability of this drug from plasma depends more on the BHC:plasma protein concentration ratio than on the absolute concentration of BHC. This phenomenon has some interesting implications and can lead to unusual artifacts resulting in the possibility of serious errors in pharmacokinetic interpretations. This is illustrated in the results obtained after intravenous administration of BHC in doses of 2 mg./Kg. and 20 mg./Kg. to guinea pigs, where the plasma concentrations of BHC were determined either by the method of Axelrod *et al.* (27) or by the new method which assures complete recovery of the drug (Figs. 7 and 8). The plasma concentrations determined by the method of Axelrod *et al.*, when plotted semilogarithmically, show a downward curvature with time. When plotted on linear coordinates, the data obtained with the 20 mg./Kg. dose yield essentially a straight line. It might be concluded, therefore, that the elimination of BHC is an apparent zero-order process, as had been suggested previously (12). [Note, however, that this hypothesis was rejected upon further investigation (17).] However, it is clearly evident from the results obtained with the new assay method (Fig. 8) that such conclusions are the result of an artifact due to the decreasing extraction efficiency of the method of Axelrod *et al.* at higher BHC concentrations.[12] In fact, BHC elimination follows apparent first-order kinetics in the guinea pig at doses of 2 and 20 mg./Kg. (Fig. 8). These observations led to a re-examination of published data on BHC elimination with the purpose of determining if pharmacokinetic analyses of others,

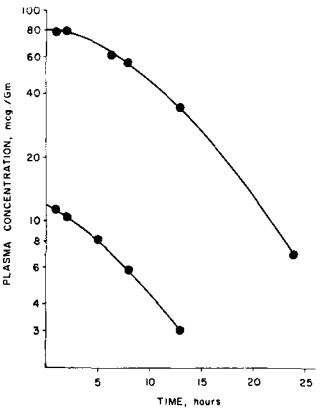

Fig. 7—Apparent plasma concentrations of BHC, as determined by the method of Axelrod et al., *in a guinea pig receiving intravenous doses of 2 mg./Kg. (lower curve) and 20 mg./Kg. (upper curve) of the drug. One-week interval between tests.*

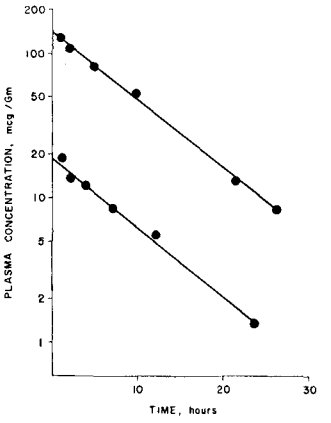

Fig. 8—Plasma concentrations of BHC, as determined by the new assay method, in a guinea pig receiving intravenous doses of 2 mg./Kg. (lower curve) and 20 mg./Kg. (upper curve) of the drug. One-week interval between tests.

and particularly the reported dose dependence of BHC elimination in man (12, 15), could be explained by the assay problems described in this report. It appears that this possibility can be excluded since published data are in a concentration range where assay problems are unlikely. Such problems will be encountered mainly in pharmacokinetic investigations with rather high doses of BHC (28, 29).

The Effect of pH on BHC Extraction from Plasma—The problems encountered in the determination of BHC in plasma by the method of Axelrod *et al.* led to an examination of the effect of pH on the extraction of BHC from plasma. It was found that complete extraction of the drug from plasma containing high concentrations of BHC was achieved only in a relatively narrow pH range of 3.0 to 3.5 (Fig. 3). The lower recovery in the pH range of 4 to 6 appears to be primarily due to a decreased apparent partition coefficient of BHC as a consequence of protein binding (Fig. 4). At higher pH

[12] The apparently incomplete recovery of BHC from plasma by the method of Axelrod *et al.* following the 2 mg./Kg. dose (Fig. 7) might appear to be quantitatively inconsistent with the recovery data shown in Fig. 2. However, this is due to the pronounced variability of BHC recovery at low pH as shown in Fig. 3. When, in another animal, BHC plasma levels were determined simultaneously by the method of Axelrod *et al.* and by our new method, similar differences in results were obtained, but the data derived from the Axelrod assay were not describable by either first- or zero-order kinetics.

the decrease in extraction efficiency is due to ionization of BHC (Fig. 3). The decreased extraction efficiency at pH's below 3 is a rate, rather than an equilibrium, phenomenon (Fig. 4 and Table IV). Quantitative extraction of BHC at pH <1 from plasma containing high concentrations of this drug would require almost 1 day. The slow rate of extraction at the low pH leads to poor reproducibility of results obtained by procedures involving a short extraction period and yielding incomplete recoveries (Fig. 3). This is probably why the data listed in Table I show poor reproducibility. While there apparently has not been a systematic study of the effect of pH on the extraction of BHC from plasma and other biologic tissues to date, it is of interest that Christensen (40) reported recently that the recovery of BHC from rat liver and muscle tissue was more complete at pH 4 and 5 than at pH <2 and >7. This is reasonably consistent with the findings of this study. The results described here may also have some relation to observations of others that the gastrointestinal absorption of BHC is very slow and prolonged in man, particularly at higher doses (12, 15). For example, O'Reilly *et al.* (15) noted that absorption of orally administered BHC in man occurred over about 65 hr. with a dose of 300 mg., 95 hr. with 600 mg., and 210 hr. after administration of 1200 mg. While the dissolution rate of BHC in gastrointestinal fluid will be very low due to the poor water solubility of the drug, it appears unlikely that undissolved particles could be retained in the gastrointestinal tract for a week or longer. What appears to be an unusually slow gastrointestinal absorption of BHC, when calculated by means of a single-compartment pharmacokinetic model, could actually be an unusual distribution phenomenon requiring the use of a multiple-compartment model. However, the pronounced affinity of BHC at high concentrations and low pH to plasma proteins, as observed in this study, suggests the possibility of a similar phenomenon in the gastrointestinal tract. BHC might be bound in the gastrointestinal mucosa for a prolonged period of time, as has been suggested by O'Reilly *et al.* (15). This could be the case particularly if the pH optimum for binding of BHC to mucosal protein is in the physiologic range.

Factors Affecting Drug–Albumin Interactions—BHC in the plasma is bound mainly, if not exclusively, to albumin (12, 15). An interpretation of the results obtained in this study requires, therefore, a consideration of factors affecting the interaction of drugs with plasma albumin. This in turn requires a consideration of the effect of pH on the conformation and physical-chemical properties of albumin. Plasma albumin undergoes a largely reversible structural alteration at pH $\simeq$4 (32). This involves a structural expansion at the low pH which is driven by electrostatic forces and which leads to formation of a species with greater electrophoretic mobility and higher viscosity (33). This expanded form of albumin is known as the F form as opposed to the more compact N form at neutral pH. A similar electrostatic expansion of albumin occurs above pH 9 (32). The N to F transition of albumin is accompanied by a pronounced decrease in the ability for hydrophobic binding of substances such as alkanes (33). It is believed that apolar binding sites are located in the interior of the albumin molecule and that they are therefore not in contact with polar solvent. N to F transition is thought to cause disruption of apolar clusters in the albumin molecule, resulting in the exposure of these regions to the aqueous solvent. This is accompanied by a drastic decrease in the capacity to bind alkanes such as butane and pentane (33) and drugs such as the xanthines (34). The N–F equilibrium is affected by ionic strength and specific counter ions and by interacting substances such as detergents (32, 35) and organic solvents used in extractions, including heptane (36). Detailed physical-chemical studies of bovine and human plasma albumin suggest that the N to F change actually involves a double transition, one at pH 3.6 and the other at pH 3.0 (39). Significantly, this coincides with the region of optimum pH for extraction of BHC from plasma (Fig. 3). It is evident, therefore, that the high extraction efficiency of BHC at pH's slightly below 4 as compared to higher pH's is due to the N to F transition of albumin at pH $\simeq$ 4 and the decreased binding of neutral molecules such as BHC by the F form of albumin. At pH 2.5, the positive charge on the protein is at its maximum and further lowering of pH appears to reduce the expansion of albumin molecules due to the increased ionic strength of the environment (37). There is evidence for slow aggregation of albumin below pH 3.2 (32), reflected among others by a slow increase in the viscosity of albumin solutions (38). The viscosity increase proceeds more rapidly at lower pH (38). The reversibility of this aggregation decreases with increased duration of exposure of albumin to low pH (32). The decreased extraction efficiency below pH 3 is apparently due to the conformational change of albumin at the low pH involving partial refolding of the expanded molecule (37) and/or aggregation (32). The decreased extractability of BHC with time at low pH (Fig. 4) is consistent with the relatively slow structural change of albumin at low pH. Specifically, the more rapid decrease in extractability of BHC at pH <1 as compared to pH 3 (Fig. 4) is paralleled by the more rapid increase in viscosity of albumin solutions at the lower as compared to the higher pH's (38). These effects are reversible by pH adjustment, as is evident from the data in Table IV.

Last, an explanation must be sought for the unusual concentration dependence of BHC extraction at low pH. O'Reilly (24), who studied the interaction of warfarin with human plasma albumin, concluded that the albumin molecule undergoes a reversible configurational alteration in the process of binding the drug, thereby yielding additional binding sites. It is likely that the same is true for BHC in view of its structural similarity to warfarin. One may then conceive of a series of events whereby BHC in low concentrations is bound to readily accessible peripheral binding sites on the albumin molecule, with increasing concentrations of BHC bringing about a partial unfolding of the albumin molecule and thereby causing the exposure of additional binding sites in the internal region of the macromolecule. If, during extraction at low pH, the peripherally bound BHC dissociates first, it is conceivable that the albumin molecules will contract and aggregate, and thus make it difficult for BHC molecules bound to internal sites in the albumin molecule to be extracted. Foster has recognized

the possibility of such a mechanism by suggesting that "A variety of substances, both ionic and nonionic, but particularly substances with considerable hydrophobic character, could become trapped within the postulated hydrophobic interfaces and be released only when the protein reaches an ionic environment favoring conversion to the F form" (32). In summary, BHC in high concentrations can be extracted readily from plasma only in a pH range where the interaction between albumin molecules (*i.e.*, aggregation) is minimal and where these molecules are maximally expanded.

New Assay Method for BHC in Plasma—The method of Axelrod *et al.* has been modified by changing the pH adjustment of the plasma from less than 1 to about 3.2 to assure maximum extraction efficiency. Essentially quantitative recovery of BHC in concentrations ranging from 2 to 400 mcg./ml. was obtained with plasma from rats, guinea pigs, dogs, monkeys, and man (Table V), and this assay method has been used successfully in a comparative pharmacokinetic study of BHC elimination in these species (28). The specificity of the new method, particularly in terms of distinguishing between BHC and its biotransformation products, has been demonstrated (Figs. 5 and 6; Table VI).

Conclusions—The findings of this study go clearly beyond the discovery of an unusual concentration dependence of a widely used method for the determination of BHC in plasma, the identification of the consequent possibility of interesting pharmacokinetic artifacts, and the development of a new assay method which is not subject to these shortcomings. Guttman and Gadzala (34), who studied the interaction of xanthine derivatives with bovine serum albumin, considered as their most interesting observation the sensitivity of the binding behavior of albumin to pH-dependent changes in its structure. This observation can now be extended to include the sensitivity in the extractability of a strongly albumin-bound drug to pH-dependent conformational changes of the albumin molecule. It is not unlikely that similar effects will be encountered with other strongly protein-bound drugs. The optimum pH for extraction of such drugs from plasma or other biologic materials may depend not solely on the pKa of the drug (as it affects the distribution of the drug between an organic phase and an aqueous phase of given pH), but also on the effect of pH on the physical-chemical properties of plasma proteins as they affect the type and magnitude of interaction of these proteins with the drug. The pH-extraction efficiency profile may be affected in some instances also by ionic strength and by the nature of the buffer system and organic solvent used in the extraction.

Comparative Pharmacokinetics of Coumarin Anticoagulants II

Pharmacokinetics of Bishydroxycoumarin Elimination in the Rat, Guinea Pig, Dog, and Rhesus Monkey

By RENPEI NAGASHIMA, GERHARD LEVY*, and NATHAN BACK†

Low (1–2 mg./Kg.) and high (8–20 mg./Kg.) doses of bishydroxycoumarin (BHC) were administered intravenously in cross-over fashion to rats (Sprague-Dawley, male), guinea pigs (Hartley, male), dogs (beagle and mongrel, male and female), and monkeys (rhesus, male). BHC levels in the plasma declined exponentially with time in each species. The size of the dose had no significant effect on half-life in rats and guinea pigs. The half-life was variable in the dog and increased with increasing dose in the monkey. There was no pronounced change in the apparent volumes of distribution of BHC with dose in any of the animal species studied. The rat, guinea pig, and monkey eliminate BHC considerably more rapidly, while the dog eliminates the drug more slowly than man.

THE PHARMACOKINETICS of bishydroxycoumarin (BHC) in man are unusual in that the biologic half-life of the drug increases markedly with increasing dose, although plasma concentrations appear to decline exponentially at all dose levels (1, 2). It also has been suggested that the apparent volume of distribution of BHC in man decreases with increasing dose (2). These pharmacokinetic characteristics are encountered only infrequently, and a detailed study of the mechanism responsible for them is highly desirable. In view of the potential hazards associated with the use of BHC in man a search was instituted for a suitable animal species showing the same characteristics of BHC distribution and elimination as man. While there have been some studies of BHC elimination kinetics in the mouse (3–5), rat (6–8), rabbit (3–5, 9), and dog (4, 10), these investigations were carried out at only a single dose level of BHC and, therefore, provide no information concerning a possible dose dependency in the distribution and elimination kinetics of this drug. The distribution and elimination of BHC at several dose levels in rats, guinea pigs, dogs, and monkeys have been studied in this laboratory, and the results of this investigation are described in the present communication.

EXPERIMENTAL

Bishydroxycoumarin Solution for Injection—Bishydroxycoumarin was purchased from Nutritional Biochemicals Co., Cleveland, Ohio. One part by weight of the drug and 10 parts by weight of tris(hydroxymethylamino) methane (Nutritional Biochemicals Co.) were dissolved in a sufficient volume of freshly distilled water to yield a 0.5 or 1.0% (w/v) solution of BHC. The pH of the solutions was 9.2–9.3. They were stored in a refrigerator and were used within 12 hr. after preparation.

Animals—The following is a list of animal species, strain or its equivalent, sex, body weight, and the diet fed before and during the experiments: rat, Sprague-Dawley, male, 400–500 Gm., Big Red rat mouse diet;[1] guinea pig, Hartley, male, 400–500 Gm., Big Red guinea pig diet;[1] dog, mongrel male or female or beagle male, 10–25 Kg., Big Red dog foods expanded;[1] monkey, rhesus, male, 5–7 Kg., primate diet expanded.[2] The animals had unrestricted access to water and food before and during the experiments.

Drug Administration and Collection of Plasma Samples—The drug was administered intravenously in the morning and blood samples were withdrawn at appropriate intervals. Rats and guinea pigs were placed under light ether anesthesia, and blood was collected into a heparinized centrifuge tube[3] by retro-orbital puncture using a glass capillary tube (1.6–1.8 mm. o.d.). Blood withdrawal from the cephalic vein of dogs and the saphenous vein of monkeys was done without anesthesia, using a heparinized syringe.[4] After centrifugation of the blood at 1800 × g for 10 min., the plasma was separated and stored at −15° until assayed. Blank plasma was obtained from each animal immediately before every experiment. The volume of blood withdrawn from rats and guinea pigs did not exceed 0.6 ml. per sample and 3.0 ml. in 24 hr. Two-milliliter blood samples were obtained from dogs and monkeys.

Assay Method—BHC in the plasma was determined by a modification of the method of Axelrod *et al.* (11). The assay consists essentially of adjustment of plasma to pH 3.2, extraction with heptane, transfer of the drug into 2.5 *N* NaOH, and spectrophotometry at 314 mμ. BHC metabolites in the plasma do not interfere in the assay (12).

Determination of Apparent Volume of Distribution and Biologic Half-Life—The apparent volume of distribution (V_d) was calculated by dividing the intravenous dose by the apparent initial concentration of BHC in the plasma. The latter was determined by extrapolating the linear portion of a log BHC concentration *versus* time plot to zero time. The biologic half-life ($t_{1/2}$) was determined graphically from the linear portion of the semilogarithmic plot. The small volume of the plasma samples

obtained from rats and guinea pigs made it necessary to use weighed rather than measured aliquots for analysis. Consequently, plasma concentration and V_d values for rats and guinea pigs are expressed in terms of mcg./Gm. and Gm./Kg., respectively. The specific gravity of the plasma averaged about 1.02.

RESULTS AND DISCUSSION

Figure 1 illustrates the elimination of BHC from the plasma in rats. Plasma concentrations of BHC declined exponentially and there was no pronounced difference in the apparent volume of distribution of BHC at the two dose levels. Unlike man, the rat did not show an increase in the biologic half-life of BHC with increasing dose.

[a] Rat, Sprague-Dawley, males; guinea pig, Hartley, males. [b] The drug was administered intravenously. [c] Apparent volume of distribution.

The elimination of BHC in the guinea pig followed a pattern similar to that found in the rat (Fig. 2). Drug elimination was exponential with the half-life slightly longer than in the rat. There was no apparent change in the half-life of BHC with increasing dose. The individual pharmacokinetic constants for BHC elimination in the rats and guinea pigs are listed in Table I.

The results of the study of BHC elimination in dogs are shown in Figs. 3, 4, and 5, and in Table II. The elimination followed apparent first-order kinetics, except for a small deviation from day 3 to day 7 after administration of the higher dose in dog *2*. The reason for this deviation is not known. There were appreciable differences in the plasma half-life of BHC between dogs. It appears that the half-life increased with increasing dose, but a definitive conclusion with respect to this apparent dose-dependency is not possible because of the occasional and unexplained pronounced changes in the half-life observed in dogs *4* and *5* (stippled lines in Figs. 4 and 5). These changes could not be ascribed to previous drug administration. There was no significant change in the apparent volume of distribution of BHC as a function of dose (Table II). Initial intensive blood sampling in one dog (No. *1*) during the first 2 hr. after BHC administration yielded an

apparent first-order distribution rate constant of 1.1 hr.$^{-1}$. Dog *3* expired due to massive internal hemorrhage on the 9th day after receiving a 10 mg./Kg. dose of BHC which had been administered 54 days after a 1 mg./Kg. dose. It is of interest that this dog exhibited the longest half-life for BHC (130 hr. at a 1 mg./Kg. dose) observed in all of the experiments (Table II).[5] Dog *1* had a considerably larger apparent volume of distribution for BHC than any of the other dogs; unfortunately, this animal was lost for reasons unrelated to BHC administration before additional experiments could be carried out.

The elimination of BHC by the monkeys showed consistent dose-dependency in that half-life increased with increasing dose (Figs. 6 and 7, Table II). There was no significant change in the apparent volume of distribution as a function of dose. An initial downward curvature in the elimination of BHC observed in monkey *1* after the first 1 mg./Kg. dose prompted a repetition of this experiment about 1 month later. Exactly the same phenomenon was observed in the second experiment. While a single occurrence of this type might be ascribed to an accidental extravascular injection of part of the dose, the exact reproduction of the plasma level curve in

[5] The $t_{1/2}$ and V_d for the 10 mg./Kg. dose were essentially the same as for the 1 mg./Kg. dose based on data collected up to the time of death.

the subsequent experiment makes this extremely unlikely.

Monkey *2* showed an interesting and reproducible discontinuity in the plasma concentration decline of BHC after administration of the lower dose (Fig. 7). Again, no explanation can be offered for this phenomenon other than to suggest the possibility of a postural effect, such as described recently by Levy (13). Diurnal variations were observed occasionally also in the dogs (see Fig. 4), although the long half-life of BHC in the latter makes these variations difficult to recognize. The value of intensive sampling and repetitive experiments is evident from the results of this study in that they illustrate the occurrence of interesting and apparently reproducible changes in individual elimination kinetics. A search for the mechanisms of such changes may lead to a better understanding of the effect of certain physiologic variables on drug elimination.

The findings of this study are summarized in Table III. The rat, guinea pig, and monkey showed similar half-lives for BHC elimination. The half-life of BHC in the dog is considerably longer. This is consistent with the previously observed unusually long half-life of another coumarin anticoagulant, biscoumacetate, in the dog (14). The limited number of animals studied in each group does not permit recognition of possible genetic or strain differences; the possibility of such effects should be recognized, particularly since a pronounced genetic effect has been noted in the rabbit (4, 5). Of the four species studied, only the rhesus monkey showed definite evidence of a dose dependency in the elimination kinetics of BHC, similar to that found in man. Differences in apparent volume of distribution as a function of dose were relatively minor in each species. In particular, there was no indication of a decreased volume of distribution for BHC with increasing dose, as reported for man (2). The possible reasons for this apparent difference are presently being studied.

In Vitro Action of Mescaline

Possible Mode of Action

By EMMETT CLEMENTE and VINCENT DE PAUL LYNCH

Mescaline (TMPEA) elicited a motor response (dependent upon segment and concentration) from isolated guinea pig, rat, and cat ileum. It did not alter inotropic or chronotropic activity of isolated mammalian atria. Estrogen dominated uteri responded similarly. TMPEA antagonized serotonin-induced motor responses of rat and guinea pig uteri. High concentrations of ganglionic blocking agents potentiated TMPEA motor effects. Evidence suggests that TMPEA does not act *via* a cholinergic mechanism, but rather through catecholamine mechanisms. The end result varies in definite situations. The primary site of action of TMPEA appears to be at the α-adrenergic receptor site.

THE LITERATURE contains few reports concerning the effects of mescaline (trimethoxyphenylethylamine: TMPEA) on peripheral systems. This is especially true of investigations involving *in vitro* systems. Most of the available data seem to have been compiled from studies in which TMPEA was compared to other psychotomimetic compounds, rather than from research into the effects of TMPEA *per se.*

It was observed by Grace (1) that duodenal preparations from the cat and rabbit, as well as uteri obtained from the rat, rabbit, and guinea pig, did not respond to TMPEA. On the other hand, that investigator reported that TMPEA produced powerful contractions in the rabbit intestine *in situ* and that this effect could be abolished by intravenously administered atropine. Subsequently, Costa (2) demonstrated in *in vitro* studies that atropine did not block the effect of TMPEA on rat uteri. Costa (2) also reported that very low concentrations of lysergic acid diethylamide (LSD) and TMPEA synergized the effects of serotonin on uterine tissue from estrogen-primed rats.

There appears to be a consensus that TMPEA does not antagonize the response of rat uteri to serotonin. However, a number of investigators have reported the antiserotonin activity of LSD (2–5).

Serotonin produces contraction of umbilical vessels of human placenta, and TMPEA has been shown to cause constriction of the same preparation (4). The latter reported also that while LSD and tryptamine antagonized the effect of serotonin, TMPEA usually did not alter the response to either serotonin or epinephrine.

Received January 30, 1967, from the Department of Pharmacognosy, Pharmacology and Allied Sciences, College of Pharmacy, St. John's University, Jamaica, NY 11432

Accepted for publication August 15, 1967.

Abstracted in part from a thesis submitted by Emmett Clemente to the Graduate School, St. John's University, in partial fulfillment of Doctor of Philosophy degree requirements.

Grateful acknowledgment is made to the American Medical Association Education and Research Foundation for support of a major portion of this work.

In *in vivo* systems, Parker and Hildebrand (6) found TMPEA to cause a rapid rise in blood pressure when it was administered intravenously to anesthetized cats, and that this response could be blocked by dibenamine. Speck (7) reported similar vasoactive properties for TMPEA in the rat, but that investigator observed antagonism between TMPEA and epinephrine.

The structural similarity between TMPEA and epinephrine has been an important factor in the elaboration of theories which tend to explain psychotomimetic action as involving the catecholamines in some fashion. Nevertheless, studies of the interaction of TMPEA and the neurohormones are relatively rare. Thus, Giarman and Freedman (8) cited the work of Waser *et al.* (9) in stating that serotonin, norepinephrine, and histamine were affected similarly in blood and brain by both TMPEA and LSD. In view of reports of cross-tolerance between TMPEA and LSD in both humans and animals, these findings have been interpreted as suggesting a receptor site common to TMPEA and LSD.

Schopp and his co-workers (10) presented further evidence which demonstrates an interaction between TMPEA, epinephrine, and acetylcholine in peripheral nerve transmission.

In distribution studies of TMPEA in the dog, Cochin *et al.* (11) recovered that compound from ventricular tissue. This finding is especially interesting in light of reports that TMPEA has a variable effect on pulse and blood pressure (12, 13).

In view of the above findings, *in vitro* studies were undertaken to determine the effect of TMPEA on isolated structures from different species and to assess those effects by the use of agents which might aid in the elucidation of those activities. In addition, TMPEA was compared to drugs of known similar and dissimilar activities. In this way, it was expected that some knowledge of the mechanism of action would be

obtained, so far as peripheral effects were concerned.

EXPERIMENTAL

Various smooth muscle tissue from different species was used to observe the activity of TMPEA. Adult male and female guinea pigs weighing between 800 and 1000 Gm. were utilized. The animals were sacrificed by exsanguination. The selected tissue was removed (ileum, esophagus, aorta, trachea, duodenum, jejunum, and atria) and placed in a 20-ml. tissue bath containing Tyrode's solution.[1] When uterine tissue was used, De Jalon's solution[2] was employed as the bathing medium. The bath was aerated with a mixture of 5% CO_2 and 95% O_2 at a flow rate of 30 ml./min., for all tissues except the atria. In the latter case, flow rate was maintained at 60 ml./min.[3] The bath was thermostatically controlled at 37.5° (±0.5°). The tissue was connected to a light magnesium lever and the activity of the tissue was recorded on a slow-moving, smoked paper kymograph (0.791 or 5.18 cm./min.). Fasted and unfasted guinea pigs were used when uterine tissue was studied.

Guinea pig tracheal tissue was prepared by cutting the tissue into spirals. The responses to TMPEA and other compounds were recorded after a pilocarpine-induced spasm had reached a stable plateau (14), unless otherwise stated.

Uterine tissue from unfasted albino rats weighing between 200 and 250 Gm. (inbred strain, Food and Drug Research Laboratories, Maspeth, N. Y.) was challenged similarly to the tissue from guinea pigs. Tissue from rats previously mated and determined to be in estrus was used. It had been observed that tissue from these animals was able to withstand more challenges than virgin tissue. Determination of estrus was made according to Papanicolaou's method (15). The nictitating membrane, right atria, and ileum from fasted kittens (500–850 Gm.) were similarly challenged. Removal of these tissues was accomplished while the animal was anesthetized with sodium pentobarbital (35 mg./Kg.). Nictitating membrane and atrial tissue was allowed an adaptation period of 1 hr. prior to drug challenge. It was noted that atrial tissue required this period of time for stability. Challenges were performed at 15-min. intervals or when control activity was reestablished. Animals from which ileum or other intestinal tissue was removed had been fasted for approximately 16 hr. Some animals (guinea pigs in particular) were fasted for prolonged periods (36–48–60 hr.) in order to evaluate the effect of long periods of fast on the response to TMPEA. All intestinal tissue was allowed to equilibrate in the bath at least 30 min. before commencement of any challenge. In some experiments, guinea pig ileum from fasted animals was removed, quick frozen (dry ice and acetone), and placed in the cold (5°) for periods of 24 to 60 hr. before being challenged with TMPEA. Tissue which had been frozen was allowed to equilibrate for 2 hr. prior to experimentation. The object of these experiments was to observe the effect of TMPEA on denervated smooth muscle. The doses of all compounds are expressed as their salts. The drugs and their range of concentration (mcg./ml.), in terms of base, are given in Table I.

TABLE I—RANGE OF CONCENTRATION OF COMPOUNDS *In Vitro*

Compd.	Range of Dose Employed (Base mcg./ml.)
Mescaline sulfate	0.017–140.0
Phenoxybenzamine·HCl	2.2–8.8
Isopropylmethoxamine·HCl	0.86–43.0
Hexamethonium chloride	0.92–3.70
Tetraethylammonium chloride	4.35–43.5
Serotonin creatinine sulfate	0.0004–2.1
Nicotine (pure)	1.0
Ergotamine tartrate	0.44–2.20
l-Epinephrine-*d*-bitartrate	0.014–2.75
l-Phenylephrine·HCl	0.010–4.10
Acetylcholine chloride	0.009–0.045
Atropine sulfate	0.0083–4.15
Hydralazine·HCl	4.05–8.10
Reserpine	1.0–12.5
Isoproterenol·HCl	0.0043–0.043
Dichloroisoproterenol	0.0087–8.7
Pilocarpine·HCl	8.5–10.6
Histamine diphosphate	0.18
Lidocaine·HCl	43.5–261.0
l-Arterenol-bitartrate	0.013–2.65
Procaine·HCl	43.5–261.0
Diphenhydramine·HCl	0.08–0.44

RESULTS

Effect of TMPEA on the Intestinal Tissue of Several Species—During the course of this research, it became apparent that the action of TMPEA on the terminal section of ileum was concentration, species, and tissue dependent. Over a wide range of concentration, the effect of TMPEA on guinea pig and cat ileum was consistently motor in nature, while concentrations approaching the upper limit were necessary for responses of equal magnitude for the rat ileum. In general, in all species concerned, the lowermost portions of the ileum were more responsive to the motor stimulatory property of TMPEA than were portions adjacent to the jejunum. In fact, the terminal portion of the ileum was the segment of intestinal tissue most sensitive to the effects of TMPEA. It was noted that the motor response to TMPEA roughly paralleled the motor response to norepinephrine, epinephrine, and serotonin. The response to TMPEA of other intestinal tissue (*e.g.*, duodenum, jejunum, and upper portion of ileum) was considerably less than that observed for the terminal segment of the ileum in all species employed. The effect of TMPEA on isolated tissue from various sources, including the present study, is presented in Table II.

Effect of Diphenhydramine Pretreatment on the Response to Mescaline—Diphenhydramine, in concentration sufficient to block the motor response to histamine on guinea pig ileum, was ineffective against TMPEA. Similar results were obtained during an *in vivo* phase of this work (38).

Effect of Mescaline on Cholinergic Mechanisms—In order to demonstrate whether TMPEA could be

[a] Concentration of compounds expressed as their salts. [b] Perfusion. [c] Key: A = antagonism, I = inhibition, V = variable, SA = slight antagonism, NA = no antagonism, SE = synergism (excitatory effect), SR = synergism (relaxatory effect), R = response reversal.

blocked by atropine, the tissue (guinea pig ileum) was first challenged with a submaximal concentration of acetylcholine (ACH), and when the response was maximal, atropine was added. After 2 or 3 min., another challenge to ACH was performed and if no response was elicited TMPEA was added to the system. On 30 occasions the characteristic motor response to TMPEA was observed. It has been reported (10) that TMPEA possesses a curare-like action. A series of experiments was performed to observe the action of TMPEA on ACH induced contractions. Tissue which did not actively respond to mescaline (25–50 mcg./ml.) did not block ACH contractions on the guinea pig ileum. If a tissue contracted in the presence of TMPEA, ACH produced a response which was less than control. However, if the heights of the induced TMPEA and ACH contractions were added; it equaled control response. The same phenomenon was observed with the catecholamines. Therefore, the specificity of the reaction is questionable.

Effect of Local Anesthetics, Lidocaine and Procaine, on the Activity of Mescaline—Concentrations of the above local anesthetics (50 to 250 mcg./ml.) not sufficient to entirely inhibit the action of ACH did not affect the response to TMPEA on the guinea pig ileum. Higher concentrations (300 mcg./ml.) were not observed to curtail the action of TMPEA, although these concentrations did block the action of ACH.

Effect of the Depolarizing Ganglionic Blocking Agent, Nicotine, on the Response to Mescaline in the Guinea Pig Ileum—Nicotine (1 mcg./ml.) did not antagonize the action of TMPEA (25 mcg./ml.) on the guinea pig ileum. Reversal of the procedure yielded the same results. In the majority of trials, nicotine was allowed a 3-min. contact period prior to the challenge with TMPEA.

Effect of TMPEA on the Adrenergic Receptor—Studies were initiated to observe the possible interaction between TMPEA and adrenergic receptors. Ergotamine, in sufficient concentrations (2.5–5.0 mcg./ml.) to block the motor response to a catecholamine (norepinephrine or epinephrine) was not observed to inhibit the motor response to TMPEA on guinea pig ileum and rat uterine tissue. It was noted that epinephrine and norepinephrine caused a greater degree of relaxation in the presence of *both* ergotamine and TMPEA, than in the presence of ergotamine only. Subsequently, it was observed that TMPEA *alone* could not only block the motor action of a catecholamine but also allow the relaxatory action to be manifested. In general, if the catecholamines produced weak to moderate motor responses, TMPEA was capable of antagonizing these responses. However, if a catecholamine caused a marked motor effect and TMPEA did not generate its characteristic action, the antagonism was diminished. It was apparent that sufficient incubation time and the concentration of TMPEA

was essential to its ability to effectively antagonize the catecholamines. An incubation period of 5 min. was found to be necessary for reproducible responses; however, other factors, such as the responsiveness of the tissue to both the catecholamines and TMPEA, were of equal importance. If shorter incubation periods were employed, the antagonism was proportionally diminished. Furthermore, it was demonstrated that when TMPEA was added after a "critical" period of time had elapsed following a stimulatory dose of norepinephrine, epinephrine, or phenylephrine (5 min.) an additional increase in tone was produced. If TMPEA was added before 5 min. had elapsed (1–3 min.) a decrease in tension was produced.

Interaction Between TMPEA and Serotonin, on Guinea Pig Ileum and Rat and Guinea Pig Uteri—TMPEA in very low concentration has been reported to synergize the motor action of serotonin on the rat uterus (2). Higher concentrations have been reported to have little effect on the activity of serotonin on rat uterus. The apparent synergistic action of low concentrations of TMPEA (0.1–0.4 mcg./ml.) observed during the present study on estrogen dominated uterus appeared questionable. Slightly higher concentrations of TMPEA (2.5 mcg./ml.) did antagonize the effect of serotonin. TMPEA was also observed to antagonize the effect of serotonin (100 trials) on guinea pig ileum. The degree of antagonism depended upon the sensitivity of the tissue to both compounds. Moderately stimulatory doses of serotonin could be almost completely blocked with very high concentrations of TMPEA. Ergotamine and TMPEA acted synergistically to antagonize the action of serotonin. In addition, moderate doses of TEA (15 mcg./ml.) plus TMPEA acted synergistically to antagonize the motor response to serotonin. TMPEA (25 mcg./ml.), after a 3-min. incubation period, was observed to block the motor response of guinea pig uterus to serotonin (0.25 mcg./ml.). Additional challenges were effectively antagonized.

Effect of TMPEA on Guinea Pig Tracheal Tissue—TMPEA alone (50–200 mcg./ml.) or following a pilocarpine (10 mcg./ml.)-induced spasm caused contraction. Epinephrine provoked relaxation alone or after either of the above procedures. The relaxation due to epinephrine appeared to be greater following mescaline than when the tissue was not pretreated. Unfortunately, a great deal of variability was encountered with this tissue, obviating definite conclusions.

The Interaction of TMPEA with Various Adrenergic Blocking Agents—A number of experiments were conducted to observe the possible interaction between hydralazine, isopropylmethoxamine, dichloroisoproterenol, and mescaline in various tissue. Concentrations of dichloroisoproterenol (10 mcg./ml.) were observed to inhibit or reduce the motor activity produced by TMPEA, while lower concentrations (0.5 mcg./ml.) had little effect. All tissue tested (guinea pig ileum and uterus and rat ileum and uterus) with the exception of cat atria reacted similarly. Hydralazine and isopropylmethoxamine had little modifying action on tissue response to TMPEA. However, it was noted that concentrations of TMPEA which were usually ineffective would produce a pronounced action on guinea pig uterus if the tissue were pretreated with either hydralazine or isopropylmethoxamine. In general, the results of the above procedures were difficult to assess because of the strong motor activities inherent to hydralazine and isopropylmethoxamine.

Concentration of DCI (10 mcg./ml.) and TMPEA (25–50 mcg./ml.) were effective in blocking the action of the catecholamine on rat uterine tissue. These results indicated that both α- and β-receptor sites were blocked. A more potent α-adrenergic blocking agent, phenoxybenzamine (10–20 mcg./ml.), was observed to completely block the motor activity due to TMPEA (25–50 mcg./ml.) on cat and guinea pig ileum. These results would suggest that TMPEA exerts its effect on the α-adrenergic receptor site.

In order to substantiate these results and to demonstrate the action of TMPEA on the β-adrenergic receptor site, cat atria (right atria) were selected as the test structure. TMPEA (12.5–50 mcg./ml.) had no demonstrable chronotropic or inotropic effect on this tissue, even after a 10-min. incubation period. Nevertheless, the tissue remained responsive to various catecholamines, isoproterenol, epinephrine, and norepinephrine. Pretreatment of the tissue with TMPEA (25–50 mcg./ml.) caused an apparent synergistic effect to the catecholamines. Phenoxybenzamine (10 mcg./ml.), incubated for the same period of time as TMPEA (3 min.), also seemed to synergize the action of the catecholamines. In contrast, DCI (10 mcg./ml.) completely blocked the action of isoproterenol, and to a lesser extent, epinephrine and norepinepheine. The synergistic effect of TMPEA was best observed if the water bath temperature was reduced from 37.5° to 32.0°.

It was of interest to observe the effect of TMPEA on ACH blockade of the right atria, in view of a report that TMPEA possesses a curare-like action. The effect of complete or partial blockade of normal rhythmicity of atrial tissue by ACH (0.25–0.5 mcg./ml.) was not affected by pretreatment with TMPEA (25–50 mcg./ml.). When slight antagonism was observed, the tissue usually responded in a different fashion to ACH following the washout of TMPEA. The very slight antagonism encountered in this series might be explained more logically as due to a change in response of the tissue to ACH, rather than specific antagonism by TMPEA.

DISCUSSION

Diphenhydramine, in sufficient concentration to block histamine, did not effectively antagonize TMPEA. There is some doubt as to how antihistamines actually antagonize histamine (16). This fact precludes a definitive conclusion that mescaline does not exert its effect *via* histaminic receptors. However, graded responses caused by TMPEA in the presence of diphenhydramine were not observed. These findings would suggest that a noncompetitive reaction due to the effect of TMPEA prevailed and the response elicited was distinct from the histamine effect.

Costa (2) reported that atropine *in vitro*, in sufficient concentration to block ACH, did not antagonize the effect of TMPEA in rat uterus. Grace (1) reported that atropine, *in vivo*, was capable of blocking the effect of TMPEA in the cat. The results obtained in this study using guinea pig

ileum are in agreement with those of Costa (2). Atropine in sufficient concentration to block submaximal stimulatory effects of ACH did not inhibit the motor response induced by TMPEA. Thus, TMPEA apparently does not produce its motor effects *via* a muscarinic action.

In order to determine if TMPEA stimulated nervous elements, local anesthetics were employed in concentrations which block ACH. The dose for both procaine and lidocaine, necessary to block ACH, caused a marked increase in the activity of the ileum. TMPEA was able to exert its effect in the presence of those compounds. These findings, in conjunction with those above, support the concept that TMPEA does not exert its effect on cholinergic receptors.

Ganglionic blocking agents (hexamethonium and TEA) did not antagonize the effect of TMPEA on guinea pig ileum. In the presence of both a ganglionic blocking agent and atropine, mescaline was observed to produce its characteristic effect. Thus it appears that TMPEA does not exert its action on ganglia. Moreover, large concentrations of TEA seemed to synergize the motor response exerted by TMPEA and serotonin. The latter findings are in agreement with those reported by Day and Vane (17) for hexamethonium.

Gaddum *et al.* (3), in an attempt to explain the antagonizing action of LSD on serotonin, postulated two distinct types of receptors in ganglia cells in the intestine. One of these was stimulated by ACH or nicotine and inhibited by excess nicotine or hexamethonium, while the other type was stimulated by serotonin and inhibited by excess serotonin. It is also possible that there exists two types of cells; one stimulated by nicotine, the other by serotonin. In light of this theory, TMPEA might conceivably be stimulating serotonin-sensitive receptors. However, serotonin was not observed to alter the action of TMPEA on guinea pig ileum. It is possible that the concentrations employed in these experiments were not sufficient to antagonize serotonin receptor sites.

Gaddum *et al.* (3) further differentiated between the response of smooth muscle of the ileum and rat uterus to serotonin. They stated that the receptors in the rat uterus are easily paralyzed by excessive serotonin, whereas those in the ganglia of the guinea pig ileum are not. They explained the antagonistic action of LSD on rat uterine tissue on the above hypothesis. TMPEA was not observed, in their studies, to antagonize the effect of serotonin on rat uterus. Costa (2) reported that mescaline acted synergistically with serotonin in causing increased activity on rat uterine tissue. Savini (18) reported that LSD was antagonistic to serotonin-induced constriction on perfused rabbit ear. Prior to Gaddum's theory concerning the site of action of serotonin, Rocha e Silva *et al.* (19) postulated the site to be the postganglionic cholinergic nerve fiber of the ganglia. Cocaine has been observed to effectively antagonize serotonin on isolated ileum, a finding which supports the proposal of Rocha e Silva and his collaborators.

Day *et al.* (17) have presented evidence demonstrating that serotonin is also capable of stimulating smooth muscle directly. However, they consider the blockade of the action of serotonin by phenoxybenzamine to be nonspecific and concluded that serotonin primarily exerts its effect indirectly through stimulation of cholinergic nerve fibers in guinea pig ileum.

The findings in this study involving the interaction between serotonin and TMPEA on guinea pig ileum and uterus and rat uterus are in agreement with the theory proposed by Gaddum *et al.* (3) and the findings of Day *et al.* (17). In the majority of experiments, there appeared to be some antagonism exerted by mescaline on the motor response to serotonin on the guinea pig ileum. These observations would indicate that the ganglionic component involved in the action of serotonin was not effectively antagonized, while the smooth muscle was affected.

Experiments conducted on rat and guinea pig uteri clearly demonstrated that TMPEA effectively antagonized the action of serotonin. These results are not in agreement with those reported by Gaddum *et al.* (3) and Astrom *et al.* (4). The latter authors stated that TMPEA had "no certain action against serotonin on human placental vessels." The findings in the present investigation would support the variation in receptor sites in different tissues sensitive to serotonin. They would also support the concept that TMPEA was primarily exerting its effect on the smooth muscle cell. These results support the clinical and experimental findings involving animals demonstrating cross-tolerance between LSD and TMPEA.

Costa (2) and Astrom (4) reported that low concentrations of TMPEA synergized the effect of serotonin on rat uterus and human placental preparations, respectively. Costa's (2) experiments were repeated precisely as he reported them during this investigation. After reproducible responses were obtained from challenges with serotonin by the method of Rocha e Silva (19), the tissue was challenged with TMPEA. When serotonin was added to this system, a synergistic effect was apparent. However, if this experiment was repeated without the addition of TMPEA, the same effect was observed. Thus the augmented response due to serotonin in the presence of TMPEA, in this investigation, appears to have been a function of variability in response to serotonin and not to a synergistic action of TMPEA.

Nicotine was not observed to antagonize the effect of TMPEA. It is generally agreed that nicotine depolarizes the postsynaptic neuron in ganglia, making it insensitive to acetylcholine (20, 21). Emmelin and Feldberg (22) demonstrated that nicotine also depressed smooth muscle directly. Evans and Schild (23) demonstrated that nerve-free preparations of intestine reacted to nicotine by contraction. This effect could be abolished by pretreatment with hexamethonium. The latter substance was reported to be the most specific ganglionic blocking agent known (24). The ganglionic blocking agents, *i.e.*, the depolarizing and nondepolarizing competitive types have, therefore, been shown to possess a number of properties which could have influenced the activity of TMPEA. However, if their major activities are considered, one would necessarily conclude that TMPEA does not possess characteristics of a substance which excites intramural ganglia cells responsive to ACH. Grace (1) reported that TMPEA caused an increase in tonic activity of uteri, *in situ*, from various species. The

effect was not abolished after pretreatment with nicotine.

TMPEA has been noted, in this study and others (1–3), to induce rhythmic movements in intestinal and uterine tissue. Various investigators have attributed the rate of spontaneous activity of uterine tissue to the level of catecholamine content (25, 26). Rudzik *et al.* (25) stated that the initial rate of spontaneous uterine contractions *in vitro* was inversely proportional to the quantity of epinephrine in the uterus. When the uterus from a rat in estrus was challenged with epinephrine, relaxation occurred—TMPEA caused contraction. The possibility exists that TMPEA produces uterine contraction by causing a release of endogenous epinephrine or directly stimulating excitatory sites, while epinephrine may relax the tissue by raising the endogenous level of epinephrine content or directly stimulating inhibitory sites.

The terminal segment of the ileum in a variety of species has been observed to contract in response to splanchnic nerve stimulation or to exogenous epinephrine (27–30). Dale (27) utilized this effect to demonstrate that the ergot alkaloids blocked the contracting properties of epinephrine on the terminal segment of the cat ileum. Munro (28) reevaluated this phenomenon and showed that various catecholamines were capable of causing similar responses (29). This motor effect produced by epinephrine on the intestinal tissue was not in accord with the theory proposed by Ahlquist (31). At that time α activity on intestinal tissue was classified as relaxatory. Some changes in this classification were proposed by Lands (32). He demonstrated that inhibitory and excitatory receptors were present in the terminal segment of the ileum and the response obtained was probably a function of the relative number and sensitivity of each type of receptor present. Furchgott (33) expanded upon the above classification and introduced the term "delta receptor" to explain intestinal inhibition mediated by a sympathomimetic amine. The subject, at present, is still unsettled (34).

In the present investigation, it was observed that when the terminal section of ileum was relaxed by a catecholamine, TMPEA had little or no effect. If a contraction was elicited in the presence of a catecholamine, TMPEA alone was also observed to produce a similar response. Moreover, the more sensitive the tissue appeared to be toward the motor effect of the catecholamines (contraction), the more sensitive it was to the effects of TMPEA. The above actions were interpreted as demonstrating that both receptors (α and β) or A_c (excitatory) and A_r (relaxatory) were present in the terminal segment of the guinea pig ileum. If a contraction was elicited, the α responses predominated, or if inhibition resulted, the β responses were manifested.

Ergotamine in sufficient concentration to antagonize the motor responses to epinephrine and norepinephrine did not inhibit the motor response to TMPEA on guinea pig ileum and rat uterine tissue. Phenoxybenzamine was capable of blocking the motor response of TMPEA on guinea pig and cat ileum as well as reversing a former stimulatory action of the catecholamines to a purely relaxatory one. The apparent ability of phenoxybenzamine and not ergotamine to effectively antagonize TMPEA may be attributed to the lower concentrations employed with the latter compound. Ergotamine and TMPEA appeared to possess synergistic properties in antagonizing motor responses to the catecholamines. The results would indicate that TMPEA was stimulating excitatory receptors in the terminal section of guinea pig ileum. Abolishment of this effect by phenoxybenzamine and the apparent synergistic effects of ergotamine and TMPEA on the blockade of motor responses to the catecholamines strongly suggest that TMPEA exerts its effect on α-adrenergic receptor sites.

Supporting this concept are the findings that TMPEA alone is capable of antagonizing the motor response to catecholamines in guinea pig ileum, rat ileum, and uterine tissue. Furthermore, simultaneous administration of dichloroisoproterenol (a β-adrenergic blocking agent) and TMPEA abolished the effect of epinephrine on rat uterus, thus demonstrating that both α- and β-adrenergic receptor sites were blocked. If TMPEA was stimulating α-adrenergic receptor sites, it should theoretically be possible to demonstrate competition between these compounds. This competitive phenomenon was observed to occur when TMPEA was added to a preparation which had reacted (motor response) to a catecholamine. It was also observed that TMPEA had to be introduced within a critical period of time, otherwise competition was not observed. These findings are in agreement with those reported by Speck (7) on the competitive nature existing between epinephrine and TMPEA on various parameters in the rat.

Experiments were conducted to observe a possible augmentation of the effect of mescaline with the use of β-adrenergic blocking agents. Of the three agents employed, isopropylmethoxamine, hydralazine, and dichloroisoproterenol, the latter was the most specific. The former compounds are also known to possess α-adrenergic stimulatory actions (34). The results would indicate that the β-adrenergic blocking agent, dichloroisoproterenol, did augment the action of TMPEA on guinea pig uterus. If isopropylmethoxamine was administered after TMPEA produced an excitatory response in rat uterus and ileum or guinea pig ileum, a marked reduction in tone was noted. These results would indicate that the former compound was exerting its effect on β-adrenergic sites, if the assumption is made that TMPEA had occupied the α-adrenergic sites. The variability encountered in these experiments, however, does not justify definitive conclusions. Powell and Slager (14) demonstrated that dichloroisoproterenol blocked the relaxatory response of epinephrine on tracheal tissue. Substituting TMPEA in place of dichloroisoproterenol did not alter the relaxatory response of epinephrine. These findings further substantiate the concept that TMPEA is not exerting an appreciable effect on β-adrenergic receptor sites. The fact that TMPEA increased the tone of the tracheal chain affords additional evidence that its activity is primarily on α-adrenergic receptor sites.

Reserpine, in low concentrations, was not observed to antagonize the action of mescaline on guinea pig ileum. Higher concentrations did effectively antagonize the motor activity of mescaline on guinea pig ileum and uterine tissue. The latter effect might be due to a direct action on the smooth muscle. The higher concentrations employed in

these studies have been observed to markedly reduce the response of guinea pig ileum to ACH and histamine (35). Reserpine is known to release catecholamines from isolated tissue (36). These effects might nonspecifically antagonize the action of TMPEA.

Chronotropic and inotropic changes were not observed to occur in isolated right atria (cat) in the presence of TMPEA. Similar results were obtained with phenoxybenzamine. The latter findings are in agreement with those of Nickerson and Chan (37). Changes in rate and force of contraction have been attributed to β-adrenergic stimulation (33, 34). Dichloroisoproterenol was observed, in this study and by Nickerson *et al.* (37), to antagonize the effect of various catecholamines on cardiac tissue. TMPEA did not, however, reduce catecholamine activity. There also appeared to have been some augmentation to the simulatory effects of epinephrine, norepinephrine, and isoproterenol in the presence of TMPEA. These results are supportive of the findings with TMPEA on other tissue used in this study; that is, TMPEA exerts its primary action on α-adrenergic receptor sites.

TMPEA has been reported to possess a curare-like action (10). In this study, TMPEA was observed to apparently antagonize the effect of ACH on smooth muscle of the guinea pig ileum and cat atria. The latter experiments were too variable to draw any conclusions. However, epinephrine and norepinephrine were also observed to diminish the response of smooth muscle to ACH. These results would indicate that the antagonizing effect of TMPEA on ACH-induced contractions was nonspecific. The fact that Schopp *et al.* (10) reported that epinephrine and prostigmine oppose the paralyzing action of TMPEA supports this concept.

CONCLUSIONS

Evidence is presented which demonstrates the ability of TMPEA to stimulate α-adrenergic receptor sites in various peripheral tissue. The fact that TMPEA alone can antagonize α-stimulatory agents, and in combination with specific β-blocking agents can annul the effects of epinephrine, strongly suggest that it possesses α-adrenergic blocking properties. Furthermore, since it is capable of contracting smooth muscle preparations containing excitatory receptors, and because its actions were inhibited by α-adrenergic blocking agents, the concept that TMPEA possesses α-stimulatory properties is demonstrated. Competition between TMPEA and various catecholamines provides additional evidence that TMPEA possesses agonistic and antagonistic properties. The β activity of TMPEA appeared to be slight. To clarify this action, TMPEA should be studied on target structures which possess a preponderance of β-adrenergic receptors.

Evidence is presented that TMPEA does not stimulate cholinergic receptors. Clarification of the action of TMPEA on receptors in the ganglia should be carried out with more specific ganglionic blocking agents and with techniques reported to reduce ganglionic sensitivity. TMPEA has been shown to antagonize effectively the action of serotonin on guinea pig and rat uteri, but not in guinea pig ileum. It is concluded that in the latter tissue serotonin exerts an effect on ganglionic receptors which cannot be blocked by TMPEA.

Effect of Temperature Upon Solubilization by a Series of Nonionic Surfactants

By K. J. HUMPHREYS and C. T. RHODES

The solubilization of benzoic acid by four *n*-alkylpolyoxyethylene surfactants as a function of temperature has been examined by the dialysis and solubility techniques. In addition to their use in formulation work, it is shown that evaluation of the equilibrium constants controlling the solubilization process can be of use in elucidating micellar properties. The calculation of the thermodynamic parameters controlling the solubilization process is discussed and some difficulties indicated.

MICELLAR SOLUBILIZATION has been studied extensively in recent decades. To the pharmacist the topic is of particular interest because many pharmaceutical formulations utilize surfactants to enhance the solubility of sparingly soluble components.

One of the most important and illuminating ways of treating micellar solutions of surfactants is to regard the micelles as forming a definite phase which is at the same time dispersed throughout the system in submicroscopic particles of definite size, the micelles. The concentration of surfactant in the aqueous or continuous phase may be equated with the CMC. In systems where the CMC is very low, *e.g.*, aqueous solutions of many nonionic surfactants, the system is divisible into two essentially single-component phases, disregarding any solvent water bound to the micelles. If a third component, termed the "cosolute," is added to the system, it will be distributed between the 2 phases. When the distribution is in favor of the micellar pseudophase, the phenomenon is referred to as solubilization (1). When such surfactant solutions are brought into equilibrium with pure solid or liquid cosolutes, the system takes up appreciably more than an equivalent amount of pure water. Micellar solubilization is characterized by the enhanced solubility of cosolute only being apparent above the CMC of the ternary system. If the CMC itself is low, then the initial region of zero solubilization is not readily detectable.

In any L_1, isotropic aqueous liquid, surfactant system an equilibrium exists between micellar and nonmicellar cosolute.

$$(S_w) \overset{K}{\rightleftharpoons} (S_m) \qquad \text{(Eq. 1)}$$

where (S_w) and (S_m) represent the equilibrium activities of the nonmicellar and micellar species of cosolute and K is the equilibrium constant.

There is considerable evidence which suggests that the pharmacological activity of a drug in micellar systems is a function of (S_w), the micellar material being regarded as an inactive reserve of drug (1, 2). Two techniques are available for evaluating (S_w) and (S_m), equilibrium dialysis (3) and potentiometry (4). Unfortunately, comparatively little data have been collected using these methods. The results of most studies have been obtained by use of the conventional solubility technique which, of itself, does not allow differentiation between (S_w) and (S_m) except at saturation values. However, it is apparent from the results of those systems for which information about (S_w) and (S_m) is available that micellar solubilization can be accomplished by more than one mechanism (5). It is important to realize that, using the two-phase approach, since the micelles occupy a part of the total volume of the system, the over-all concentration of free cosolute may not necessarily be equated with the actual free concentration in the aqueous phase. However, considerable theoretical difficulties arise when attempts are made to estimate the volume of the micellar pseudophase. The phase could be considered to consist of (*a*) the hydrocarbon core of the micelle, (*b*) the whole micelle, or (*c*) the whole micelle plus bound and trapped water. At present insufficient evidence is available for a rational choice to be made.

The effect of temperature upon the properties of binary surfactant systems has been studied by many workers. Such measurements are particularly useful in that they allow evaluation of the thermodynamic parameters controlling the equilibrium in such systems (6, 7). Fewer studies of the effect of temperature upon equilibria in ternary surfactant systems have been reported, and little work has been done on the evaluation of the thermodynamic parameters controlling such equilibria. In the present

paper some studies of the effect of temperature upon the solubilization of benzoic acid by a series of *n*-alkylpolyoxyethylene surfactants are reported and their practical and theoretical significance discussed.

EXPERIMENTAL

Materials—Analar benzoic acid,[1] four *n*-alkylpolyoxyethylene surfactants[2] all of the general formula C_nOE_mOH where n is the number of carbon atoms in the alkyl chain and m the number of polyoxyethylene groups. The mean molecular weights of these compounds have been previously determined by nuclear magnetic resonance spectroscopy (8).

Methods—Dialysis studies were performed using dialysis cells similar in design to those described by Patel and Foss (9). The cells were thermostatically controlled to ±0.1° of the required temperature. Each cell, compartment capacity 10 ml., contained a glass bead to ensure continuous mixing of contents. Nylon membranes[3] were shown by preliminary tests to be impermeable to the surfactants but to allow diffusion of the benzoic acid. The solvent used in the dialysis and solubility studies was 0.01 *N* hydrochloric acid, to depress ionization of the benzoic acid. The cells were shaken for 4 days, a time found to be sufficient for equilibrium to be reached. Samples from both sides of the membrane were removed by pipet, calibrated gravimetrically at the appropriate temperature, and after suitable dilution, the benzoic acid concentrations were determined by spectrophotometric assay at 273 mm. using a Uvispek.[4] The molar absorptivity of benzoic acid, 966, compares closely to the literature value of 970 (10).

Solubility determinations were made by shaking excess benzoic acid in various concentrations of surfactant solution for 4 days. Samples for assay were filtered through No. 3 filter sticks, and the benzoic acid content determined as described above.

Determinations of weight/ml. were made by use of pycnometers, calibrated gravimetrically at the appropriate temperature. The apparatus was thermostatically controlled to within ±0.1° of the required value.

RESULTS AND DISCUSSION

Figure 1 is typical of the results obtained from the dialysis studies. HA_m represents the amount of benzoic acid solubilized by the surfactant and $[HA_w]$ the concentration of nonbound acid. The linear nature of such plots indicates that the solubilization process in such systems is governed by a distribution coefficient, correlation coefficients calculated for all systems being above 0.95. Thus for these systems the solubilization mechanism is most readily interpreted in terms of distribution between an aqueous continuous phase and a micellar pseudophase.

$$K_d = [HA_m]/[HA_w] \qquad \text{(Eq. 2)}$$

unity, and provided the activity coefficient of the micellar species also approximates to unity, the K_d values as defined in Eq. 2 will represent the thermodynamic equilibrium constant.

Figures 2 through 5 show the effect of temperature and surfactant concentration upon the solubilization of benzoic acid. In all cases the concentration of benzoic acid was calculated in molal terms by use of the appropriate weight/ml. value, though in fact the difference between molar and molal values was very small since in all cases the weight/ml. values were close to unity. The intercept values on the ordinates represent the solubility of benzoic acid in 0.01 *N* hydrochloric acid, $[HA_w^0]$. In all the systems examined the relationship between the total amount of benzoic acid present and surfactant concentration was found to be linear. This type of solubilization behavior is common, though in some systems both negative and positive changes of slope in such plots have been observed (11). Extrapolation of the graph in Figs. 2–5 to 100% w/w surfactant allows estimation of the solubility of benzoic acid in a "bulk micellar" surfactant phase, with properties exhibited by the surfactant when in 0–5% w/w aqueous solution. This value represents the solubility of benzoic acid in the micellar pseudophase. The K_d values for the various systems investigated in this work have been calculated by use of Eq. 3 and are listed in Table I.

$$K_d = [HA_m^0]/[HA_w^0] \qquad \text{(Eq. 3)}$$

This particular method of calculation of the K_d value is of considerable use since it does not involve estimation of micellar or nonmicellar phase volumes and thus avoids the difficulties described earlier. It is, of course, only applicable to systems in which it has been demonstrated that the solubilization process is governed by a form of the distribution law.

The effect of temperature upon the bactericidal activity of a preservative in a surfactant solution depends upon the temperature coefficient of the bactericide and the variation of the K_d value with temperature (12). Bean and his co-workers have emphasized that two-phase preparations containing bactericides must be formulated from a viewpoint that considers both the physical and microbiological properties of the system.

Using an extension of the two-phase model of micellar systems, it has been suggested that solubilization by surfactant micelles is due to the volume of the hydrocarbon core of the micelle, and that the solubilization process is directly comparable to solution in an organic bulk phase (13). If this hypothesis is valid, it may be predicted that the $[HA_m^0]$ values for the various surfactants studied in this investigation will be linear functions of the percentage of hydrocarbon, *i.e.*, alkyl chain H.

$$H = 225 \times 100/M \qquad \text{(Eq. 4)}$$

where M is the surfactant molecular weight, and 225 is the contribution to the molecular weight made by the cetyl chain. Thus the value $[HA_m']$, as defined in Eq. 5, should for any given temperature be the same for all the surfactants studied:

$$[HA_m'] = [HA_m^0] \times 100/H \qquad \text{(Eq. 5)}$$

Further, the values of $d[HA_m']/dT$ should be constant for the various surfactants. From the plots of $[HA_m']$ against temperature shown in Fig. 6, it can be seen that not only are the $[HA_m']$ values

Table I—Solubilization Parameters as a Function of Temperature

Surfactant Formula	H	K_d Temp., °K. 291.0	298.0	304.0	310.0	318.0

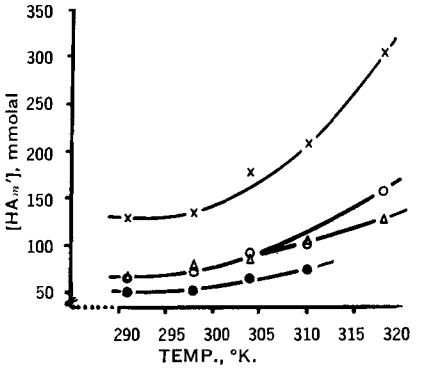

Fig. 6—Plot of [HA_m'] *as a function of temperature for four* n*-alkyl polyoxyethylene surfactants. Key:* ×, $C_{16}E_{96}$; ○, $C_{16}E_{40}$; △, $C_{16}E_{30}$; ●, $C_{16}E_{16}$.

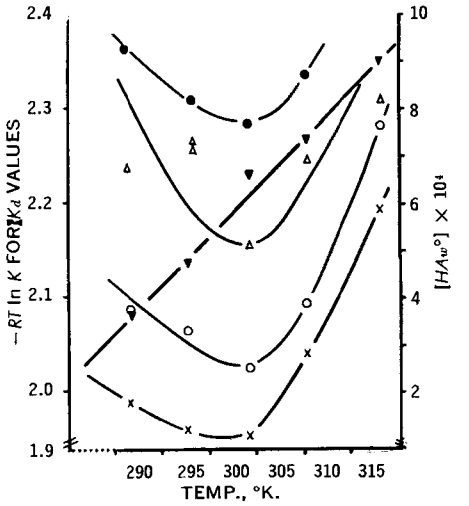

Fig. 7—Plot of −RT *ln* K *against temperature. Key:* ●, $C_{16}E_{16}$; △, $C_{16}E_{30}$; ○, $C_{16}E_{40}$; ×, $C_{16}E_{96}$; ▼, *benzoic acid, aqueous solubility.*

different for the various surfactants but also the rate of change of [HA_m'] with temperature varies. Thus the simple two-phase model appears insufficient to rationalize the solubilization phenomena in a quantitative manner. This failure may well be attributed to steric aspects of the solubilization process. Although the surfactant micelle is believed to be a loosely organized structure of transient existence, there are elements of rigidity not present in a hydrocarbon bulk phase. It has been suggested that benzoic acid and similar cosolutes are located at the junction of the hydrocarbon core and palisade layer of the micelle (14). Such an orientation provides a unique environment for the solubilized species; the hydrocarbon "tail" surrounded by the alkyl chains of the surfactant, and the carboxylic acid head group hydrogen bonded to either water molecules or polyoxyethylene groups in the palisade layer. This process cannot be envisaged entirely as a simple solution mechanism but rather as an interaction between surfactant and cosolute, *i.e.*, comicellization.

Although techniques for the calculation of the thermodynamic parameters controlling the micellization process in binary surfactant systems are well established, little attention has been directed to thermodynamic aspects of solubilization. When thermodynamic equilibrium constants for the solubilization process are available, it is possible to evaluate the free energy change of the process by use of Eq. 6:

$$\Delta G = -RT \ln K \qquad \text{(Eq. 6)}$$

Free energy changes may be resolved into two components, enthalpic and entropic values by means of Eq. 7:

$$\Delta G = \Delta H - T\Delta S \qquad \text{(Eq. 7)}$$

Thus a plot of $-RT \ln K$ against T should be linear with a slope of $-\Delta S$ and an intercept at 0°K. of ΔH. However, in order to substitute relevant ΔG values in Eq. 7, it is essential that the equilibrium being considered should exist between the same standard states. In the case of micellar solubilization it is doubtful if this criterion is fulfilled. As has been indicated previously, the uptake of solubilized material by the micelle must to some extent be a function of the micellar architecture. Since it is known that the aggregation number of surfactants, in both binary and ternary systems, varies with temperature (7), it may be concluded that micellar structure is temperature dependent and thus Eq. 7 may not be validly applied to such systems. Figure 7 shows the variation of $-RT \ln K$ as a function of T for the solubilization of benzoic acid by the four surfactants studied in this project. For comparison purposes the [HA_w°] values, solubility of benzoic acid in 0.01 N hydrochloric acid, expressed in terms of mole fraction are plotted in Fig. 7. However, plots of $-RT \ln K$, derived from the K_d values, against T show considerable curvature, all curves having a minimum at about 300°K. Though this curvature could be simply explained for equilibrium between the same standard states in terms of variation of ΔH or ΔS with temperature, it is felt that a more likely explanation is in terms of the variation of micellar structure as outlined above.

Relatively few attempts appear to have been made previously to estimate ΔH and ΔS for the micellar solubilization process from studies of the effect of temperature. Examination of the literature shows that studies of the effect of temperature upon solubilization processes made at several temperatures and over a considerable temperature range are comparatively rare. However, Bahal and Kostenbauder (15), who studied the interaction of chlorobutanol with polyvinylpyrrolidone, have shown that Eqs. 6 and 7 are obeyed by such a system.

Clearly, further studies of micellar solubilization, in particular the effect of cosolutes upon micelle size and shape, are required before a detailed theory rationalizing such interaction can be formulated.

Synthesis and Properties of the Antileukemic Agent 5(or 4)-[3,3-Bis(2-chloroethyl)-1-triazeno]imidazole-4(or 5)-carboxamide

By Y. FULMER SHEALY, CHARLES A. KRAUTH*, LEE B. HOLUM, and WILLIAM E. FITZGIBBON

The antileukemic agent 5(or 4)-[3,3-bis(2-chloroethyl)-1-triazeno]imidazole-4(or 5)-carboxamide (II, NSC-82196) is an unstable compound that is easily convertible to an isomeric transformation product. By taking appropriate precautions, however, the triazene may be prepared in good yield, with very little of the transformation product as contaminant, and may be stored for long periods at low temperatures. The quality of specimens of II may be estimated from its infrared spectrum and that of its transformation product.

In the mouse lymphoid leukemia L1210 test system (1), 5(or 4)-[3,3-bis(2-chloroethyl)-1-triazeno]imidazole-4(or 5)-carboxamide (II) has demonstrated excellent activity. Some of the animals treated with large single doses of this compound survived until the experiments were terminated 4–8 months after treatment. From the cell-kill kinetic studies of Skipper, Schabel, and Wilcox (2, 3), it may be concluded that complete eradication of leukemic cells must have occurred in these survivors. Compound II is unstable and is readily converted to an isomeric product that is not active against leukemia L1210. In a preliminary communication (1) the authors reported, without experimental details, the preparation of II from 5-diazoimidazole-4-carboxamide (I) and bis(2-chloroethyl)amine (III). In this report complete details are recorded on the preparation of II, including improvements; and some of its properties and the precautions that must be observed during the preparation, storage, and use of this compound are described more fully.

I II

$(ClCH_2CH_2)_2NH$ $[C_8H_{12}N_6OCl^+]Cl^-$

III IV

Bis(2-chloroethyl)amine free base (III) was extracted from an alkaline solution into either ethyl acetate or dichloromethane. In the procedure mentioned in the preliminary report (1) an ethyl acetate solution of III was diluted with methanol, the reaction of I and III was carried out in a 2 : 1 mixture of ethyl acetate and methanol, and the product was precipitated by the addition of a very large volume of petroleum ether (b.p. 30–60°). The preparative procedure has subsequently been improved by employing only methanol as the reaction medium (after removal of the extraction solvent from III) and by establishing an optimum temperature of about 15–20°. Compound II crystallizes directly from the reaction mixture and is obtained in higher yield (65–75%) and in improved quality without the need for large volumes of petroleum ether. Since dichloromethane is more easily volatilized, it is the preferred solvent for extracting III.

Although compound II is only slightly soluble in water and is sparingly soluble in methanol, prolonged stirring of a suspension of II in either solvent gives a solution from which a new compound is isolated. This transformation product (IV) has the same composition as II, but half of the chlorine is ionic as was shown by titration with silver nitrate. A suspension of the triazene (II) in a solution of the Bratton-Marshall reagent (4) gives a positive test upon acidification; under comparable conditions IV does not give a positive Bratton-Marshall test. Possible structures for the transformation product (IV) include aziridinium, *v*-triazolinium, and piperazinium salts formed by internal alkylation. The change of II to IV also occurs in dimethylsulfoxide solution and even in the solid state at room temperature. Infrared spectra showed, as explained below, that a considerable amount of IV had formed in a specimen of II kept at room temperature for 16 days and that II is, however, stable for at least 22 months at −15° to −20°.

Since IV has the same composition as II, elemental analyses are of value only for indicating gross contamination; however, infrared spectra of II and its potential contaminants constitute a reliable guide to the quality of the triazene product. If unreacted I is present, it can be detected by the diazo absorption band (which is very strong in pure specimens of I) at 2190 cm.$^{-1}$ (5). If the diazo band is absent but absorption is evident near 1700 cm.$^{-1}$, the product may contain 2-azahypoxanthine, a potential by-product that may be formed either directly from I (5) or from II by a light-catalyzed reaction (6). The most prominent differences between the infrared spectra of II (Fig. 1) and its transformation product (IV, Fig. 2) are as follows: the spectrum of IV shows strong bands at 1515, 1680 (C=O), and 3455–3460 (NH) cm.$^{-1}$; the spectrum of II has strong bands at 1655 (C=O) and 3380 (NH) cm.$^{-1}$. Other obvious differences are shifts of 10–15 cm.$^{-1}$ in the positions of 2 bands in the 1600–1540 cm.$^{-1}$ region, a medium band present at 742 cm.$^{-1}$ in the spectrum of II and absent from that of IV, a medium-strong doublet at 1145 and 1138 cm.$^{-1}$ in the spectrum of II, and a medium band at 768 cm.$^{-1}$ in the spectrum of IV.[1] Of these bands the first listed (1515 cm.$^{-1}$) is the most important for estimating the quality of II. Spectra of the best samples of II show very little, or no, absorption at 1510–1520 cm.$^{-1}$ (Fig. 1). In the spectra of specimens judged to contain only a very few percent of the transformation product, the 1515 cm.$^{-1}$ band can be observed as a very weak band or shoulder, whereas the 1680 cm.$^{-1}$ and 3460 cm.$^{-1}$ bands

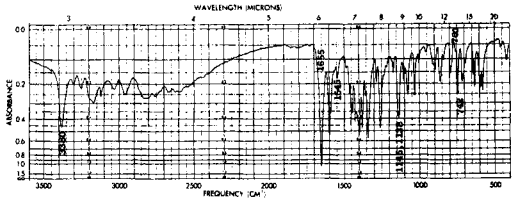

Fig. 1—Infrared spectrum of 5(or 4)-[3,3-bis(2-chloroethyl)-1-triazeno]imidazole-4(or 5)-carboxamide (II). Flattening of the curve in the 1520–1500 cm.$^{-1}$ region may indicate slight contamination with IV.

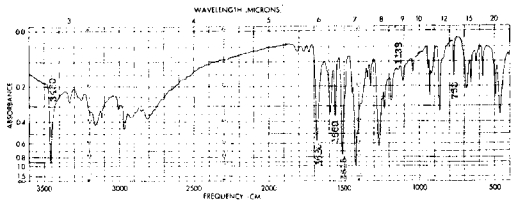

Fig. 2—Infrared spectrum of the transformation product (IV).

[1] However, weak bands at 1138 and 760 cm.$^{-1}$ in the spectra of IV and II, respectively, decrease the value of bands in these regions for detecting either IV or II in samples of the other.

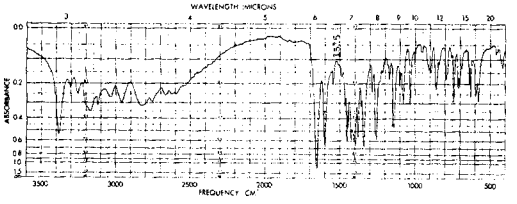

Fig. 3—Infrared spectrum of a specimen of II typical of those used for biological evaluation. The shoulder at 1515 cm.$^{-1}$ shows that a small amount of IV is present.

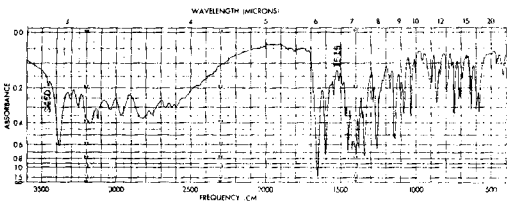

Fig. 4—Infrared spectrum of II showing further contamination with IV. The 3460 cm.$^{-1}$ band of IV appears after the 1515 cm.$^{-1}$ can be detected (cf. *Fig. 3*) *and before the carbonyl band of IV is perceptible. In this spectrum the 1545 cm.$^{-1}$ band of II has also begun to shift to the 1560 cm.$^{-1}$ band of IV.*

are not apparent. Most of the antitumor tests have been performed with samples of this type (Fig. 3). With increasing contamination, the 3460 cm.$^{-1}$ band appears on the side of the 3380 cm.$^{-1}$ band (Fig. 4). Shifting of the band near 1550 cm.$^{-1}$ and splitting of the carbonyl band are readily apparent only when considerable amounts of the transformation product are present.

Infrared spectra of crude products obtained from the ethyl acetate–methanol procedure showed that IV was usually present, the diazo compound was frequently present, and 2-azahypoxanthine was probably sometimes present. Brief and careful washing of these crude products (or of any specimens containing IV) with water at pH 7.3–7.5 reduced the amount of IV to a low concentration, as indicated by very slight absorption at 1515 cm.$^{-1}$, and removed the diazo compound (I) and 2-azahypoxanthine. This procedure may also be used, if necessary, to purify II obtained from the improved procedure. However, specimens from the improved procedure have not contained I detectable by infrared spectra, and, generally, IV has either not been detectable or has been present in quantities that produced only a slight shoulder at 1515 cm.$^{-1}$.

Specimens of II are routinely stored in brown jars that are kept in closed jars or desiccators containing a drying agent, and these containers are stored in a freezer at −15° to −20°. When specimens are to be transferred or weighed, the containers are allowed to come to room temperature before a specimen is removed in order to minimize condensation of atmospheric moisture, which might cause the formation of some of the transformation product on the surface. The infrared spectrum of a specimen stored in this way was essentially unchanged after 22 months. Solutions or suspensions for biological evaluation are prepared immediately before injection and are injected within 5 min., or less, after their preparation.

EXPERIMENTAL

Infrared spectra were recorded with a Perkin-Elmer model 521 spectrophotometer using samples in potassium bromide disks. Ultraviolet spectra were recorded with a Cary model 14 recording spectrophotometer.

5(or 4)-[3,3-Bis(2-chloroethyl)-1-triazeno]imidazole-4(or 5)-carboxamide (II)—*A. Preparation*—Compound II is protected, insofar as possible, from light and moisture during all operations involved in the preparation, handling, and storage. The starting material (I) is also protected from light and moisture (5).

A solution consisting of 625 Gm. of sodium chloride, 2.5 L. of distilled water, and 290 Gm., of bis(2-chloroethyl)amine hydrochloride in a 5-L. Morton flask was chilled in a salt–ice bath. Dichloromethane (1.25 L.) was added, and the mixture was stirred vigorously with a mechanical stirrer while a 50% aqueous sodium hydroxide solution was added until the pH of the mixture reached and became stable at 7.5–7.6. The sodium hydroxide solution was added at a rate that kept the temperature of the mixture below 4°. The mixture was stirred vigorously for 5–10 min., the dichloromethane layer was separated, and the water layer was extracted at the ice-bath temperature with a second 1.25-L. portion of dichloromethane. The two cold dichloromethane extracts were combined, washed quickly with 1 L. of cold saturated salt solution, and given a preliminary drying by stirring with magnesium sulfate in an ice bath for 15 min. The desiccant was removed by filtration, and the solution was dried further by stirring with calcium sulfate[2] for 1 hr. in an ice bath. Smaller additions of desiccant were made at 15-min. intervals. After the drying agent had been removed by filtration, the solvent was evaporated immediately under reduced pressure at 25–30°.

A solution of the bis(2-chloroethyl)amine free base in 1.25 L. of anhydrous methanol (which had been dried 24 hr. over calcium sulfate) was cooled to 15° in a 3-L. round-bottom flask wrapped with aluminum foil and equipped with a mechanical stirrer, a nitrogen inlet tube, and a drying tube. 5-Diazoimidazole-4-carboxamide (49.4 Gm.) was added slowly in small portions in a dry nitrogen atmosphere during 30 min., and the suspension was stirred vigorously for 3 hr. at 15–20°. The product was collected by

[2] Drierite.

filtration under a current of nitrogen, washed under nitrogen with 100 ml. of methanol and with two 100-ml. portions of acetone, and dried *in vacuo* at room temperature over phosphorous pentoxide: yield, 71 Gm. (71%). The absence of discernible absorption bands at 1515 and 2190 cm.$^{-1}$ indicated that the product contained very little, if any, transformation product (IV) or starting material (I).

Anal.—Calcd. for $C_8H_{12}Cl_2N_6O$:[3] C, 34.42; H, 4.33; N, 30.10 Found: C, 34.45; H, 4.30; N, 30.14.

The yields obtained from several experiments in which either dichloromethane or ethyl acetate was used to extract III were 65–75%. Usually absorption due to IV at 1515 cm.$^{-1}$ either was not observed or was very weak.

B. Purification—Specimens of II containing IV, the starting material (I), or 2-azahypoxanthine may be purified by washing the impure material with water adjusted to pH 7.5 with sodium hydroxide, provided that care is exercised to minimize the formation of additional IV. A mixture of the slightly basic solution and II (approximately 10 ml./Gm.) is stirred for 5–10 min. in the absence of light, and the triazene is then removed by filtration, washed with water and with 2 portions of acetone, and dried *in vacuo* over phosphorous pentoxide at room temperature. The purpose of washing with acetone is to hasten the removal of water, but most of the adhering water should be removed during the filtration because II appears to be more soluble in a mixture of acetone and water than in either solvent alone. Since the triazene is only slightly soluble in water, it is recovered in high yield from the washing operation.

Preparation of IV—A mixture of 2.5 Gm. of the triazene(II) and 250 ml. of absolute methanol was stirred in the dark for 44 hr. The mixture became homogeneous, and thin-layer chromatography (silica gel, chloroform–methanol, 1:1 by vol.) indicated that only a trace amount of II remained after 24 hr. (In this TLC system IV remains at the origin; II moves, but shows streaking owing to the formation of IV.) Although the total product from an earlier similar experiment gave satisfactory analytical data without recrystallization (1), the solution was treated with activated carbon, concentrated to about 125 ml., and diluted with an equal volume of chloroform. The yellow precipitate was recrystallized a second time from chloroform–methanol; it melted with decomposition at temperatures that varied with the determination procedure, *e.g.*, 197–199° dec., when inserted at 180° in a Mel-Temp apparatus.

Anal.—Calcd. for $C_8H_{12}Cl_2N_6O$: C, 34.42; H, 4.32; N, 30.10; total Cl, 25.4; ionic Cl, 12.7. Found: C, 34.41; H, 4.44; N, 30.02; total Cl, 25.3; ionic Cl, 12.6.

[3] Analysis of the product of an earlier experiment gave a satisfactory value for chlorine (Calcd.: 25.5%, found: 25.4%), as well as satisfactory data for carbon, hydrogen, and nitrogen (1).

Analysis of Data on Drug Release from Emulsions II

Pyridine Release from Water-in-Oil Emulsions as a Function of pH

By TAMOTSU KOIZUMI* and W. I. HIGUCHI

The practically important case of the release from an amine–amine hydrochloride solute mixture in a water-in-oil emulsion into an aqueous sink has been studied experimentally and theoretically. All of the parameters entering into the theory have been independently measured and put into the theory. The theoretically predicted release behavior was then determined employing the IBM 7090 computer. These results were then compared to the experimental data obtained over a wide range of conditions. The agreement between the experiments and the physical model was extremely good. These procedures should have extensive application in the future when complex solute–solute, solute–solvent, and solvent–solvent interactions are involved.

IN THE PREVIOUS paper (1), Fick's law of diffusion (Eq. 1) was used to predict medicament release from ointments:

$$\frac{\partial c}{\partial t} = \frac{\partial^2 c}{\partial x^2} \qquad \begin{matrix} t = 0 \text{ and } x > 0,\ c = C_0 \\ t > 0 \text{ and } x = 0,\ c = 0 \end{matrix} \qquad \text{(Eq. 1)}$$

Here C is the drug concentration, D is the diffusion coefficient, t is time, and x is the coordinate. Its solution (Eq. 2) was shown to agree with the experimental data in a satisfactory manner:

$$q = 2C_0\sqrt{\frac{Dt}{\pi}} \qquad \text{(Eq. 2)}$$

where q is the amount of drug released per unit area.

Among other assumptions involved in these equations is that D must be constant with respect to both time and position. This is a serious limitation, because in many situations involving emulsions the diffusion coefficient is not constant but varies with concentration.

This report deals with such cases, and an attempt is made to predict the drug release from emulsions in which the diffusion coefficient of the drug is a function of concentration. Studies such as this should be helpful in drug formulation practices.

THEORY

The Effective Diffusion Coefficient—It was reported (2) that approximate relationships between the effective permeability constant of a heterogeneous system and the permeability constants and the volume fractions of the individual phases can be obtained by considering the analogous electrostatic problem. The Wagner-Wiener equation (Eq. 3) and the Bruggeman equation (Eq. 4), which were derived originally to express the dielectric behavior of heterogeneous systems, may be employed to evaluate the effective diffusion coefficient:

$$\frac{P_e - P_c}{P_e + 2P_c} = \frac{P_i - P_c}{P_i + 2P_c} v_i \qquad \text{(Eq. 3)}$$

$$\frac{P_e - P_i}{P_c - P_i}\left(\frac{P_c}{P_e}\right)^{1/3} = v_c \qquad \text{(Eq. 4)}$$

and

$$P_j = K_j \times D_j \ (j = e, i, c) \qquad \text{(Eq. 5)}$$

where P is a permeability constant, K is a partition coefficient, D is a diffusion coefficient, and v is a volume fraction. The subscripts e, i, and c represent "effective," "internal phase," and "continuous phase," respectively. And K_e is given by Eq. 6:

$$K_e = K_i v_i + K_c v_c \qquad \text{(Eq. 6)}$$

where K_c is unity.

Solving Eqs. 3 or 4 for P_e and dividing by K_e, one obtains an expression for the effective diffusion coefficient, D_e, in the form of Eq. 7:

$$D_e = f(K_i, v_i, v_c, D_i, D_c) \qquad \text{(Eq. 7)}$$

where v_i and v_c are constants for a given system. Even when D_i and D_c are constant, D_e is a function of K_i, which may be concentration dependent.

The Partition Coefficient—K_i may change with drug concentration in various ways such as dissociation of the drug, dimerization, complex formation, *etc.* Let us now examine a situation where dissociation of the drug is involved.

It is assumed that (*a*) the drug molecule dissociates in the internal phase, (*b*) only the nonionized species dissolves in the continuous phase, and (*c*) equilibrium of nonionized species always exists between the internal and the continuous phases. The water-in-oil emulsion of pyridine hydrochloride is an example of this case. The concentration relationships among the various species for this system are: (*a*) in the internal phase:

$$K_a = \frac{(A)\,(H^+)}{(AH^+)}$$

$$C_i = (AH^+) + (A)$$

$$K_w = (H^+)\,(OH^-)$$

Received April 14, 1967, from the College of Pharmacy, University of Michigan, Ann Arbor, MI 48104

Accepted for publication August 9, 1967.

Presented to the Basic Pharmaceutics Section, APhA Academy of Pharmaceutical Sciences, Las Vegas meeting, April 1967.

This investigation was supported by a grant from Smith Kline & French Laboratories, Philadelphia, Pa., and by grant GM13368 from the National Institute of General Medical Sciences, U. S. Public Health Service, Bethesda, Md.

* Leave of absence from: Faculty of Pharmaceutical Sciences, Kyoto University, Kyoto, Japan.

$$(H^+) + (AH^+) = CA + (OH^-)$$

(*b*) in the continuous phase:

$$C_c = (A)_c$$

(*c*) at the interface:

$$\frac{(A)_i}{(A)_c} = \frac{1}{P_0}$$

where K_a is the acid dissociation constant of drug, and C_1 and C_i are the drug concentrations in the internal phase and the continuous phase, respectively. CA is the hydrochloric acid concentration in internal phase, P_0 is the true partition coefficient of the drug (partition coefficient of the nonionized species), and K_w is the ion product for water.

Solving these equations simultaneously, one can get Eq. 8.

$$K_i = \frac{C_i}{C_c} = \frac{1}{P_0} + \frac{CA + \sqrt{CA^2 + \frac{4K_w}{P_0K_a}(C_c + P_0K_a)}}{2(C_c + P_0K_a)} \quad \text{(Eq. 8)}$$

The total drug concentration is given by Eq. 9:

$$C_e = v_c \cdot C_c + v_i \cdot C_i = (v_c + v_iK_i) \cdot C_c \quad \text{(Eq. 9)}$$

From Eqs. 8 and 9, it is clear that the partition coefficient, K_i, is a function of concentration, C_e.

The Time Dependence of the Amount of Drug Released—When the diffusion coefficient, D, is a function of concentration, C (the subscript e is dropped from D_e and C_e), the equation for one-dimensional diffusion is given by Eq. 10, instead of Eq. 1.

$$\frac{\partial C}{\partial t} = \frac{\partial}{\partial x}\left(D\frac{\partial C}{\partial x}\right) \qquad \begin{matrix} t = 0 \text{ and } 0 < x, C = C_0 \\ t > 0 \text{ and } x = 0, C = 0 \end{matrix} \quad \text{(Eq. 10)}$$

Applying Boltzman's method (3), one can obtain Eq. 11:

$$C = a\int_0^\lambda \frac{1}{D}\exp.\left(-\int_0^\lambda \frac{\lambda}{2D}\,d\lambda\right)d\lambda \quad \text{(Eq. 11)}$$

$$a = \frac{C_0}{\int_0^\infty \frac{1}{D}\exp.\left(-\int_0^\lambda \frac{\lambda}{2D}\,d\lambda\right)d\lambda} \quad \text{(Eq. 12)}$$

where $\lambda = x/\sqrt{t}$.

Then the nonsteady state drug release rate per unit area, G, is given by:

$$G = \left(D\frac{\partial C}{\partial x}\right)_{x=0} \quad \text{(Eq. 13)}$$

Integration of Eq. 13, using Eqs. 11 and 14, gives:

$$\left(D\frac{\partial C}{\partial x}\right)_{x=0} = \frac{1}{\sqrt{t}}\left(D\frac{\partial C}{\partial \lambda}\right)_{\lambda=0} \quad \text{(Eq. 14)}$$

$$q = 2a\sqrt{t} \quad \text{(Eq. 15)}$$

where q is the amount of drug released per unit area, and a is the same constant defined by Eq. 12.

These results show that, even if D is concentration dependent, the release pattern is exactly the same as the constant D case. *"Square root" relationship still holds.*

Computation of a—It is quite difficult to solve Eq. 12 and evaluate a, analytically, even though D is a known function of C. Therefore, a numerical calculation method is expedient.

If the region ($0 \sim C_0$) is divided into N equal parts, the following relationships hold:

$$C_j = a\int_0^{\lambda_j}\frac{1}{D}\exp.\left(-\int_0^\lambda \frac{\lambda}{2D}\,d\lambda\right)d\lambda \quad (j = 1, 2, \ldots N) \quad \text{(Eq. 16)}$$

$$C_N = C_0,\ \lambda_N = \infty$$

$$C_j - C_{j-1} = \frac{C_0}{N} = a\int_0^{\lambda_j}\frac{1}{D}\exp.\left(-\int_0^\lambda \frac{\lambda}{2D}\,d\lambda\right)d\lambda - a\int_0^{\lambda_{j-1}}\frac{1}{D}\exp.\left(-\int_0^\lambda \frac{\lambda}{2D}\,d\lambda\right)d\lambda \quad \text{(Eq. 17)}$$

$$(j = 1, 2, \ldots N)$$

therefore

$$\int_{\lambda_{j-1}}^{\lambda_j}\frac{1}{D}\exp.\left(-\int_0^\lambda \frac{\lambda}{2D}\,d\lambda\right)d\lambda = \frac{C_0}{aN} = \text{constant} \quad \text{(Eq. 18)}$$

$$(j = 1, 2, \ldots N)$$

The constant a is computable from these relationships. The procedure is as follows.

(*a*) Divide C_0 into N equal parts, C_j,

$$C_j = C_0 \times \frac{j}{N} \quad (j = 1, 2, \ldots N) \quad \text{(Eq. 19)}$$

(*b*) Calculate D_j, which is a known function of C_j, from C_j obtained by the previous step.

(*c*) Choose arbitrary value for λ_1, and evaluate M_1, given by Eq. 20, applying the proper numerical integration method:

$$M_1 = \int_0^{\lambda_1}\frac{1}{D}\exp.\left(-\int_0^\lambda \frac{\lambda}{2D}\,d\lambda\right)d\lambda \quad \text{(Eq. 20)}$$

With the trapezoidal rule, M_1 is given by:

$$M_1 \simeq \frac{\lambda_1}{2}\left[\frac{1}{D_0} + \frac{1}{D_1}\exp.\left(-\frac{\lambda_1^2}{4D_1}\right)\right] \quad \text{(Eq. 21)}$$

(*d*) Look for the value of λ_2 which satisfies:

$$\int_{\lambda_1}^{\lambda_2}\frac{1}{D}\exp.\left(-\int_0^\lambda \frac{\lambda}{2D}\,d\lambda\right)d\lambda = M_1 \quad \text{(Eq. 22)}$$

(*e*) Repeat the similar procedure and calculate $\lambda_3, \lambda_4 \ldots \lambda_{N-1}$ which satisfies:

$$\int_{\lambda_{j-1}}^{\lambda_j}\frac{1}{D}\exp.\left(-\int_0^\lambda \frac{\lambda}{2D}\,d\lambda\right)d\lambda = M_1 \quad \text{(Eq. 23)}$$

Applying the trapezoidal rule, integration of Eq. 23 becomes calculable:

$$\int_{\lambda_{j-1}}^{\lambda_j}\frac{1}{D}\exp.\left(-\int_0^\lambda \frac{\lambda}{2D}\,d\lambda\right)d\lambda \simeq \left(\frac{\lambda_j - \lambda_{j-1}}{2}\right)(T_j + T_{j-1})$$

$$T_j = \frac{1}{D_j}\exp.\left\{-\frac{\lambda_j^2}{4D_j} - \sum_{k=2}^{j}\frac{\lambda_{k-1}\cdot\lambda_k\cdot(D_k - D_{k-1})}{4\cdot D_k\cdot D_{k-1}}\right\} \quad \text{(Eq. 24)}$$

(f) Calculate the integration from λ_{N-1} to infinity. Assuming D is constant, D_{N-1}, between λ_{N-1} and infinity, and by applying the infinite series for the error function, one obtains Eq. 25:

$$\int_{\lambda_{N-1}}^{\infty} \frac{1}{D} \exp.\left(-\int_0^{\lambda} \frac{\lambda}{2D}\, d\lambda\right) d\lambda \simeq \frac{\sqrt{\pi}}{\sqrt{D_{N-1}}}\left(1 - \sum_{n=0}^{\infty} \frac{(-1)^n X^{2n-1}}{(2n+1)n!}\right) \exp.\left(-\sum_{n=2}^{N-1} \frac{\lambda_{n-1}\lambda_n(D_n - D_{n-1})}{4 \cdot D_{n-1} \cdot D_n}\right) \quad \text{(Eq. 25)}$$

where $X = \lambda_{N-1}/2\sqrt{D_{N-1}}$

(g) If the value obtained at (f) is equal to M_1 within the allowable accuracy, a is calculated by:

$$a = \frac{C_0}{NM_1} \quad \text{(Eq. 26)}$$

(h) If (g) is not true, modify λ_1 according to the result of the comparison, *i.e.*, when the value of (f) is greater than M_1, increase λ_1. Repeat the whole procedure from (c) to (f) until (g) becomes true.

EXPERIMENTS

In order to test the validity of the theory, the release rates of pyridine from w/o emulsions were determined.

Apparatus—The apparatus used to determine drug release from emulsions is shown in Fig. 1. Compartments A and B are made of glass. Compartment B contains 345 ml. of water (or hydrochloric acid) and behaves as a sink for releasing drug. Solution samples are taken through C with a pipet. The emulsion is placed in compartment A at zero time. M is a cellophane membrane[1] separating the emulsion from the aqueous sink. The whole set-up is immersed in a constant-temperature water bath at 30°.

Emulsion—Water-in-oil emulsions of pyridine hydrochloride were made using sorbitan sesquioleate, HLB 3.7,[2] as emulsifier and hexadecane as the oil phase. Fifteen milliliters of a 2% solution of pyridine in water or in hydrochloric acid (0.063 N, 0.084 N, 0.126 N, 0.189 N, and 0.252 N) was added to a 50-ml. test tube containing 5 ml. of hexadecane and the weighed amount of sorbitan sesquioleate (0.64 Gm.). Stoppered tightly, the test tube was shaken vigorously for 20 min. This procedure gave a thick, stable emulsion, and the type of the emulsion was determined to be w/o by electric conductivity.

Ten milliliters of the emulsion was put into compartment A of the cell, and the release of pyridine was determined as a function of time. To make the sink more effective, the same concentrations of hydrochloric acid as the internal phase of emulsions were used in the B compartment of the cell. Samples of the solution were taken at predetermined periods. Drug content was determined by UV absorbance measurement (at 255 mμ). Amount of drug released, Q, was plotted against the square root of time. Results are shown in Fig. 2.

Diffusion Coefficient of Pyridine in Homogeneous System—Diffusion coefficients of pyridine in hexadecane, D_c, and in water, D_i, were determined with the apparatus (above) applying Eq. 2 for calculation. A small amount of glass wool was used in compartment A in order to prevent convection currents setting up (when the emulsions were used, the viscosities were high enough to prevent convection and such precautions were unnecessary). The amount of drug released, Q, was plotted against square root of time. Results are shown in Fig. 3. Diffusion coefficients were calculated from the slope of the straight line of Fig. 3 by Eq. 27:

$$D = \left(\frac{\text{slope}}{2 \cdot C_0 \cdot A}\right)^2 \pi \quad \text{(Eq. 27)}$$

where A is the cross-sectional area (cm.²) of the diffusion compartment and a constant for a given cell. A was determined from the release rate of 0.05 N hydrochloric acid for which the diffusion coefficient is known to be 2.93×10^{-5} cm.²/sec. at 25° and 3.61×10^{-5} cm.²/sec. at 35° (4). A value of 1.42×10^{-5} cm.²/sec. was obtained for the diffusion coefficient of pyridine in hexadecane, D_c, at 30°, and 1.19×10^{-5} cm.²/sec. was obtained for pyridine in water or in 0.252 N HCl (1% pyridine), D_i, at 30°.

Partition Coefficient—*Absence of Surfactant*—Ten milliliters of the aqueous solution of pyridine was added to a 50-ml. centrifuge tube, containing 10 ml. of hexadecane, which was stoppered tightly and shaken vigorously until equilibrium was reached. The mixture was centrifuged and the aqueous phase was separated from the oil phase. The pyridine contents of both phases were determined as well as the pH of the water phase. The concentration of the nonionized species in the water phase was calculated from the pH and the acid dissociation constant. The partition coefficient of the nonionized species, P_0, was calculated from the results. The data are shown in Table I.

Presence of Surfactant (5)—When a surfactant which is necessary for making the emulsion is present, its effects have to be taken into account. However, it is difficult to define K_i exactly in this situation.

For the practical purpose, however, it is convenient and reasonable to assume that the surfactant changes P_0, but nothing else, by solubilizing more pyridine into the hexadecane phase. Therefore:

$$P_0^* = P_0 + K(S) \qquad \text{(Eq. 28)}$$

where P_0^* is the partition coefficient of nonionized species in the presence of a surfactant. Here (S) is the surfactant concentration and K is constant. Because of the low solubility of sorbitan sesquioleate in water, all of the sorbitan sesquioleate used to make the emulsion is assumed to exist in the hexadecane phase.

Ten milliliters of the aqueous solution of pyridine was added to a 50-ml. centrifuge tube containing 10 ml. of hexadecane and the weighed amount (0.64 Gm.) of sorbitan sesquioleate. Stoppered tightly, the tube was shaken until equilibrium was reached. When the surfactant was used, centrifugation (7,000 r.p.m., 5 hr.) separated the oil phase but did not clear the water phase. Consequently, the determination of pyridine in the water phase was difficult.

In Eq. 8 as $4K_w/P_0K_a$ $(C_c + P_0K_a)$ is less than 10^{-7} mole/L. and negligible compared to C_A, which is greater than 6.3×10^{-2} mole/L., Eq. 29 may be used instead of Eq. 8.

$$K_i = \frac{C_i}{C_c} = \frac{1}{P_0} + \frac{C_A}{C_c + P_0K_a} \qquad \text{(Eq. 29)}$$

Table I—Partition Coefficient, P_0, of Pyridine Between Hexadecane and Water in the Absence of Surfactant

	Pyridine Concn. in Water Phase, mole/L.	Pyridine Concn. in Hexadecane Phase, mole/L.	pH of Water Phase	Nonionized[b] Pyridine Concn. in Water Phase, mole/L.	P_0 Partition Coefficient of Nonionized Species
1[a]	0.1095	0.0141	5.10	0.0418	0.337
2[a]	0.1106	0.0142	5.10	0.0422	0.336
3	0.0188	0.0058	6.20	0.0163	0.356
4	0.0895	0.0287	6.66	0.0820	0.350
5	0.1799	0.0587	6.87	0.1765	0.333

[a] Water phase is 0.063 N HCl. [b] Nonionized concentration = total concn. in water × $[K_a/K_a + (H^+)]$, $K_a = 5.89 \times 10^{-6}$ mole/L.

TABLE II—PARTITION COEFFICIENT, P_0^*, OF PYRIDINE BETWEEN HEXADECANE AND WATER IN THE PRESENCE OF SURFACTANT

Sorbitan Sesquioleate Concn. (S) Gm./10 ml. Hexadecane	V_i	V_c	HCl Concn. in Water Phase CA mole/L.	Slope	$P_0^* V_i/$ Slope $- V_c$	$P_0^* - P_0$[a]	K
0.16	0.500	0.500	0.063	1.84	0.37	0.03	0.19
0.16	0.500	0.500	0.126	1.86	0.37	0.03	0.19
0.64	0.500	0.500	0	1.64	0.44	0.10	0.16
0.64	0.500	0.500	0.063	1.61	0.45	0.11	0.17
0.64	0.500	0.500	0.126	1.55	0.48	0.14	0.22
1.28	0.667	0.333	0.063	1.53	0.56	0.22	0.17

[a] 0.34 was used as the value of P_0 (*cf.* Table I).

Therefore:

$$C_e = \left(v_c + \frac{v_i}{P_0}\right) C_c + \frac{v_i C_c C_A}{C_c + P_0 K_a} \qquad \text{(Eq. 30)}$$

Equation 30 shows that when C_c is large enough compared to P_0K_a, the relationship between C_c and C_e is linear. The slope is $v_c + v_i/P_0$, and the intercept is v_iC_A.

The pyridine concentration in the hexadecane phase, C_c, was determined and plotted against the total concentration, C_e. Figure 4 shows the results. P_0^* was calculated from the slope of the straight line, namely:

$$P_0^* = \frac{v_i}{\text{slope} - v_c} \qquad \text{(Eq. 31)}$$

The P_0^* values at various surfactant concentrations are shown in Table II. K is fairly constant at the different concentrations of surfactant, and therefore Eq. 28 holds reasonably well in this situation. The average value of K, 0.18, was used for the theoretical computations of pyridine release rate from emulsion.

Computation of the Theoretical Slopes—The computations were executed by the IBM 7090 digital computer. The flow chart is shown in Fig. 5. Results are in Table III and are shown also in Fig. 2.

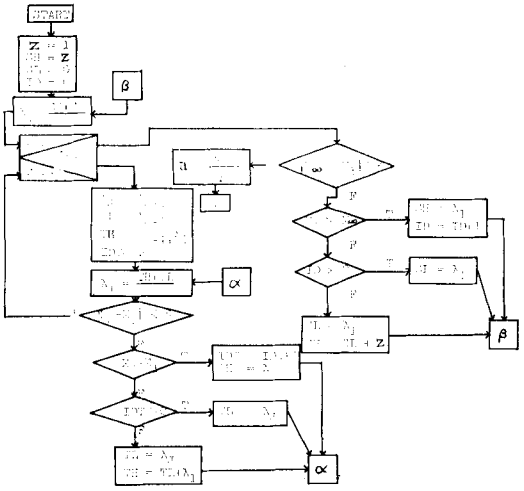

Fig. 5—Flow diagram showing the procedure for the computation of a. ϵ = *accuracy allowance (allowable error);* M_1 = *calculated value of Eq. 21;* M_J = *calculated value of Eq. 24;* M_∞ = *calculated value of Eq. 25.*

Discussion—The relatively good linearity of the data shown in Fig. 2 supports the validity of "square root" relationship for the variable diffusion coefficient case. Leveling off of the curve at large t is due to the finite thickness of emulsion in the diffusion compartment.

In Fig. 3, which shows the release of pyridine from homogeneous solution, the curve did not start from the origin but gave a short lag time. It is believed that this time lag of 0.6 min. was caused by the initial diffusion of pyridine in the membrane as well as by the initial absorption of pyridine by the membrane. Details of the lag time phenomenon are discussed under *Appendix*.

The Bruggeman equation (Eq. 4) appears to be better than the Wagner-Wiener equation (Eq. 3) for estimating effective diffusion coefficient in the present situation.

Considering the fact that the theoretical slope is computed from independently determined parameters, agreement of theoretical and experimental results is extremely satisfactory.

From these results, it is obvious that quantitative theory is quite useful and should have extensive applications in the future.

APPENDIX

One of the time-lag phenomena that is involved in the experimental situations of this report is the well-known lag time of Barrer (6) which is a measure of the period required for the absorption of the drug by the membrane.

TABLE III—THEORETICAL VALUES OF a[a]

CA mole/L.	N	60	80	100
0	B	0.022318	0.022321	0.022323
	W	0.022311	0.022313	0.022315

	W	0.015106	0.015132	0.015146
0.084	B	0.013720	0.013749	0.013760
	W	0.012978	0.013003	0.013014
0.126	B	0.0099014	0.0099215	0.0099319
	W	0.0089659	0.0089859	0.0089960
0.189	B	0.0046754	0.0046931	0.0047020
	W	0.0036538	0.0036719	0.0036809
0.252	B	0.0012180	0.0012220	0.0012244
	W	0.00048505	0.00048687	0.00048798

[a] The parameters are: $D_c = 1.42 \times 10^{-5}$ cm.²/sec., $C_0 = 0.189$ mole/L., $D_i = 1.19 \times 10^{-5}$ cm.²/sec., $K_a = 5.89 \times 10^{-6}$ mole/L., $P_0^* = 0.570$, B = Bruggeman equation, W = Wagner-Wiener equation.

Barrer's lag time is given by:

$$\tau_B = \frac{h^2}{6D} \qquad \text{(Eq. 32)}$$

where h is the thickness of the membrane and D is diffusion coefficient.

Another lag time is present because the diffusion coefficient of the drug in the membrane is smaller than that in the bulk.

Let D_1 be the diffusion coefficient in the membrane, the thickness of which is h, and D_2 that in the bulk. Also, let C_1 be the concentration in the membrane and C_2 in the bulk. Then assume that the diffusion is expressed by the following equations:

$$\text{at } t = 0 \qquad C_1 = C_0 \qquad -h \leq x \leq 0$$
$$C_2 = C_0 \qquad 0 \leq x$$
$$\text{at } t > 0 \qquad \frac{\partial C_1}{\partial t} = D_1 \frac{\partial^2 C_1}{\partial x^2} \qquad -h < x < 0$$
$$\frac{\partial C_2}{\partial t} = D_2 \frac{\partial^2 C_2}{\partial x^2} \qquad 0 < x$$
$$D_1 \frac{\partial C_1}{\partial x} = D_2 \frac{\partial C_2}{\partial x} \text{ and } C_1 = C_2$$
$$\text{at } x = 0 \text{ and } C_1 = 0 \text{ at } x = -h$$

Solutions to these equations with the indicated boundary conditions are given by Carslaw (7).

The amount of drug released from this system, q, is given by Eq. 33:

$$q = \int_0^t \left(D_1 \frac{\partial C_1}{\partial x}\right)_{x=-h} dt = \int_0^t \times \frac{C_0\sqrt{D_1}}{\sqrt{\pi t}} \left\{1 + 2 \sum_{n=1}^{\infty} \alpha^n \exp. -n^2h^2/D_1t\right\} dt \qquad \text{(Eq. 33)}$$

where $\alpha = \dfrac{\sqrt{D_2} - \sqrt{D_1}}{\sqrt{D_2} + \sqrt{D_1}}$

At large t, Eq. 34 is obtained:

$$q = \frac{2C_0\sqrt{D_2}}{\sqrt{\pi}} \left\{\sqrt{t} - \frac{h\sqrt{\pi}}{2\sqrt{D_2}} \left(\frac{D_2}{D_1} - 1\right)\right\} \qquad \text{(Eq. 34)}$$

Therefore the lag time due to slow membrane diffusion, τ_M, is expressed by:

$$\tau_M = \frac{h^2\pi}{4D_2} \left(\frac{D_2}{D_1} - 1\right)^2 \qquad \text{(Eq. 35)}$$

From steady-state diffusion experiments of pyridine through a cellophane membrane (other than those reported in this paper), a value of 3.43×10^{-4} cm./sec. was obtained for the value of D_1/h. If the thickness of the cellophane membrane is 0.015 cm., τ_B is calculated to be 3 sec., and τ_M to be 39 sec.

Analysis of Data on Drug Release from Emulsions III

Boundary Effect on Pyridine Release from Water-in-Oil Emulsions as a Function of pH

By TAMOTSU KOIZUMI* and W. I. HIGUCHI

The influence of a membrane separating an unstirred emulsion from a well-stirred sink upon the drug release rate has been studied experimentally and theoretically. Experimental data have been compared to theory. Numerical methods were employed in the analysis with the help of the IBM 7090 computer.

IN THE PREVIOUS paper (1) the release of drug from an amine–amine hydrochloride solute mixture in a water-in-oil emulsion into an aqueous sink was studied experimentally and theoretically. In the treatment of the theory it was assumed that the sink is perfect and that the drug concentration at the emulsion–sink interface is always maintained at zero. This model is shown in Fig. 1. While this assumption was reasonable for the experimental conditions of that study, it may not necessarily be always true when a membrane is used to separate an emulsion from an aqueous sink as is frequently done in studies of this kind.

Another model is proposed in this report. This is illustrated in Fig. 2. The region, $x < -h$, is the aqueous sink which is not perfect for the emulsion because of the membrane of thickness h, which acts as a barrier and separates the emulsion from the sink. Steady-state diffusion may be assumed in the region $-h < x < 0$ characterized by an effective diffusion coefficient, D_m. The region $0 \leq x \leq 1$ is the emulsion for which the effective diffusion coefficient may be calculated by either the Bruggeman or the Wagner-Wiener equation as was done previously (1).

The following appropriate partial differential equations for one-dimensional diffusion may be written:

at $x = 1$ and for all t,

$$\frac{\partial C_e}{\partial x} = 0 \qquad \text{(Eq. 1)}$$

At $0 \leq x \leq 1$ and for $t = 0$,

$$C_e = C_0 \qquad \text{(Eq. 2)}$$

and for $t > 0$,

$$\frac{\partial C_e}{\partial t} = \frac{\partial}{\partial x}\left(D_e \frac{\partial C_e}{\partial x}\right) \qquad \text{(Eq. 3)}$$

At $x = 0$ and for all t,

$$C_m = K_m \cdot C_e \qquad \text{(Eq. 4)}$$

and for $t > 0$,

$$D_e \frac{\partial C_e}{\partial x} = D_m \left\{\frac{(C_m)_{x=0} - (C_m)_{x=-h}}{h}\right\} \qquad \text{(Eq. 5)}$$

At $-h \leq x \leq 0$ and for all t,

$$\frac{\partial C_m}{\partial x} = \frac{(C_m)_{x=0} - (C_m)_{x=-h}}{h} \qquad \text{(Eq. 6)}$$

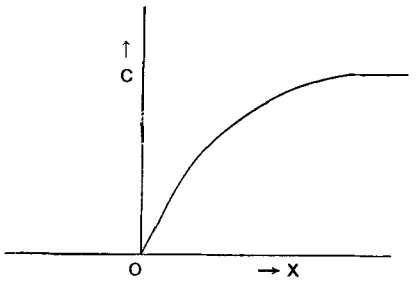

Fig. 1—Boundary conditions used in the previous report.

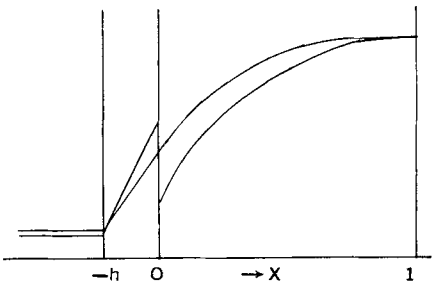

Fig. 2—Boundary conditions used in this report. Key: continuous curve represents the case where the partition coefficient between emulsion and membrane is unity; discontinuous curve is the case where the partition coefficient is not unity.

and for $t > 0$,

$$C_m = f(t) \qquad \text{(Eq. 8)}$$

Here C_e is the drug concentration in the emulsion, C_m is the drug concentration in the membrane, D_e is the effective diffusion coefficient which is a known function of C_e, and K_m is the apparent partition coefficient between the emulsion and the membrane. When the sink has a finite volume V_0, then $f(t)$ is given by:

$$f(t) = \frac{Q}{V_0} \qquad \text{(Eq. 9)}$$

where Q is the amount of drug released to the sink in time, t.

For obtaining numerical solutions, Crank (2) recommends the introduction of a new variable, S, when the diffusion coefficient is concentration dependent. This S is defined by Eq. 10:

$$S = \frac{\int_0^{C_e} D_e dC_e}{\int_0^{C_0} D_e dC_e} \qquad \text{(Eq. 10)}$$

With this new variable Eqs. 1 to 4 become Eqs. 11 to 14:

At $x = 1$, for all t,

$$\frac{\partial S}{\partial x} = 0 \qquad \text{(Eq. 11)}$$

At $o \leq x \leq 1$, for $t = 0$,

$$S = 1 \qquad \text{(Eq. 12)}$$

and for $t > 0$,

$$\frac{\partial S}{\partial t} = D_e \frac{\partial^2 S}{\partial x^2} \qquad \text{(Eq. 13)}$$

At $x = 0$, for $t > 0$,

$$\frac{\partial S}{\partial x} = \frac{D_m\{(C_m)_{x=0} - (C_m)_{x=-h}\}}{h \int_0^{C_0} D_e dC_e} \qquad \text{(Eq. 14)}$$

Applying the finite-difference method (3) to Eqs. 11 to 14, one can obtain the following equations:

At $x = 1$,

$$S_{n-1}{}^{+} = (S_n{}^{+} - S_n) \cdot \frac{2}{(D_n{}^{+} + D_n)\frac{\Delta t}{(\Delta x)^2}} + (S_n{}^{+} + S_n) - S_{n-1} \qquad \text{(Eq. 15)}$$

At $0 < x < 1$,

$$S_{i-1}{}^{+} = (S_i{}^{+} - S_i)\frac{2(\Delta x)^2}{(D_i{}^{+} + D_i)\Delta t} + 2(S_i{}^{+} + S_i) - (S_{i+1}{}^{+} + S_{i+1}) - S_{i-1} \qquad \text{(Eq. 16)}$$

At $x = 0$,

$$\frac{-S_2 + 4S_1 - 3S_0}{2(\Delta x)} = \frac{D_m\{(C_m)_{x=0} - (C_m)_{x=-h}\}}{h \int_0^{C_0} D_e dC_e} \qquad \text{(Eq. 17)}$$

Here the range 0 to 1 was divided into a number of equal intervals, Δx, and the time into intervals of Δt. S_{i-1}, S_i, S_{i+1} are the S values at $(i-1)\Delta x$, $i\Delta x$, $(i+1)\Delta x$, respectively, at $t = m\Delta t$, and $S_{i-1}{}^{+}$, $S_i{}^{+}$, $S_{i+1}{}^{+}$ are the corresponding values at $x = (i-1)\Delta x$, $i\Delta x$, $(i+1)\Delta x$ at time $(m+1)\Delta t$.

Similarly, $D_i{}^{+}$ and D_i are effective diffusion coefficients corresponding to the concentration at the point $i\Delta x$ at $t = (m+1)\Delta t$ and $t = m\Delta t$, respectively.

THE COMPUTATION PROCEDURE

The procedure for computation is as follows.

(*a*) Divide the emulsion thickness, 1, into n equal lengths of Δx and divide time into equal intervals of Δt.

(*b*) Set $S_i = 1$ (i = o to n)—initial condition.

(*c*) Choose an arbitrary value (between 0 and 1) of $S_n{}^{+}$.

(*d*) Calculate C_e corresponding to the value of $S_n{}^{+}$ chosen at (*c*). Equation 10 may be used for this calculation.

(*e*) Calculate the effective diffusion coefficient corresponding to the concentration, C_e, just calculated at (*d*). This is $D_n{}^{+}$.

(*f*) Calculate $S_{n-1}{}^{+}$ by Eq. 15.

(*g*) Calculate C_e corresponding to $S_{n-1}{}^{+}$, and then $D_{n-1}{}^{+}$.

(*h*) Calculate $S_{n-2}{}^{+}$ by Eq. 16.

(*i*) Repeat (*g*) and (*h*) until S_0 is calculated.

(*j*) Calculate C_e corresponding to S_0, *i.e.*, $(C_e)_{x=0}$. Calculate $(C_m)_{x=0}$ using Eq. (4), and also calculate $(C_m)_{x=h}$ using Eqs. 8 and 9, where:

$$Q = k \int_0^1 (C_0 - C_e)dx \qquad \text{(Eq. 18)}$$

k = cross-sectional area of the emulsion layer.

(*k*) Calculate separately the lefthand side and the righthand side of Eq. 17 and compare to see whether Eq. 17 holds.

(*l*) If the calculated values of the left and right sides of the equation are consistent within the range of error allowed, the value of Q obtained at (*j*) is the amount of drug released at $t = \Delta t$.

(*m*) If (*l*) is not the case, modify the value of $S_n{}^{+}$ depending on the results of (*k*). Then repeat steps from (*d*) to (*k*), until Eq. 17 holds. When Eq. 17 is obeyed, the most recent value of (Q) is the amount of drug released by $t - \Delta t$.

(*n*) Replace all values of S_i by the new values of $S_i{}^{+}$ obtained, and repeated procedure (*c*) to (*m*) until the desired time ($t = m\Delta t$) is reached. Here m is the number of times step (*n*) is repeated.

THE DETERMINATION OF D_m/h

Figure 3 is the schematic model of the apparatus which was used to determine the D_m/h value.

Compartments 1 and 2 were stirred, and diffusion took place inside the membrane only. At $t = 0$, $C_1 = C_0$ and $C_2 = 0$.

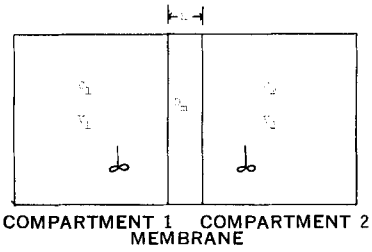

Fig. 3—Schematic model of apparatus for determination of D_m/h.

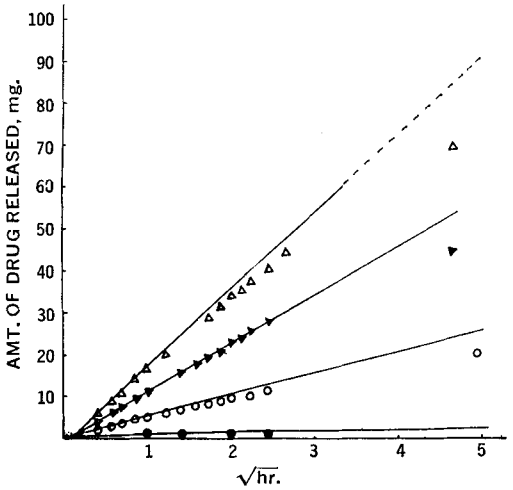

Fig. 4—Comparison of experimental data with theory. Amount of pyridine released from w/o emulsion vs square root of time. Sink is plain water, △, ▼, ○, and ● represent $C_A = 0.063, 0.126, 0.189,$ *and* 0.252 *mole/L., respectively. Solid lines are theoretical value computed by Bruggeman equation.* $V_c = 0.25$; $V_i = 0.75$; $P_o = 0.570$; $D_c = 1.42 \times 10^{-5}$ *cm.²/sec.*; $D_i = 1.19 \times 10^{-5}$ *cm.²/sec.*; $C_o = 0.189$ *mole/L.*; $K_a = 5.89 \times 10^{-6}$ *mole/L.*; $\Delta x = 0.1327$ *cm.*; $\Delta t = 360$ *sec.*; $D_m/h = 3.43 \times 10^{-4}$ *cm./sec.*

Conservation of mass gives Eq. 19 for this situation:

$$V_1C_1 + V_2C_2 = V_1C_0 = (V_1 + V_2)C_0' \quad \text{(Eq. 19)}$$

Assuming steady-state diffusion, Fick's first law gives:

$$\frac{d(V_2C_2)}{dt} = K\left(\frac{D_m}{h}\right)(C_1 - C_2) \quad \text{(Eq. 20)}$$

From Eqs. 19 and 20, Eq. 21 is obtained:

$$\log\left(\frac{C_0^1 - C_2}{C_0^1}\right) = -\frac{K(V_1 + V_2)}{2.303\ V_1 \cdot V_2}\left(\frac{D_m}{h}\right)t \quad \text{(Eq. 21)}$$

where C_1 and C_2 are the drug concentrations in compartments 1 and 2, respectively. V_1 and V_2 are the volumes of compartments 1 and 2, and K is area of the membrane.

When the logarithm of $(C_0^1 - C_2)/C_0^1$ is plotted against time, a straight line will be obtained. The value of D_m/h is then calculated from the slope of the line.

[a] Expressed as the fraction of total amount in the system. Sink is hydrochloric acid with concentration equal to C_A.

make the sink more ineffective, plain water was used instead of hydrochloric acid in the compartment B of the cell.

The amount of drug released, Q, was plotted against the square root of time. Results are shown in Fig. 4.

Determination of D_{mh}—The same apparatus as that used in the release experiments was used except both the inside of compartment B and compartment A were stirred, the latter by a screw-type stirrer attached to a motor driven glass rod. The following conditions were used: $C_0 = 5.643 \times 10^{-3}$ M, $V_1 = 100$ ml., $V_2 = 120$ ml., $K = 6.16$ cm.^{2}, and $C_0^1 = 2.565 \times 10^{-3}$ M.

Samples were taken from compartment 2 at predetermined intervals. Concentrations were

determined by UV absorbance. Results are shown in Table I. The logarithm of $(C_0^1 - C_2)/C_0^1$ was plotted against time, and Fig. 6 was obtained. The slope of the straight line was calculated to be 0.0605 hr.$^{-1}$, and D_m/h to be 1.234 cm./hr. or 3.43 $\times$ 10^{-4} cm./sec. This same value was also used under *Appendix* of the previous report (1).

The Computation of Theoretical Values—The computations were executed by the help of the IBM 7090 digital computer. The simplified flow chart is shown in Fig. 7. Results are in Tables II and III and shown in Figs. 4 and 5.

Discussion—The excellent agreement of computed values and experimental results can be seen in Figs. 4 and 5.

Chemically Defined Medium for the Production of *Fusarium graminearum*

By ROBERT D. IMHOLTE and L. C. SCHRAMM*

A chemically defined medium for production of *Fusarium graminearum* has been developed and modified. A series of carbon and nitrogen sources was studied, resulting in the selection of glucose and ammonium succinate as primary substrates. Using the economic coefficient as a criterion for efficiency, the optimum concentrations for glucose and succinic acid were 3 and 0.5 percent, respectively. Growth weight and pH changes as well as glucose, nitrogen, and succinic acid utilization were determined during a typical fermentation period.

FUSARIUM GRAMINEARUM is the imperfect stage of *Gibberella zea* [*G. saubinetti* (Mont.) Sacc.], a plant pathogen causing stalk, root, and ear rot of corn and scab disease on wheat and barley. This organism has been classified in the order Hypocreales of the class ascomycetes. Ingestion of scabbed grains by domestic animals having simple stomachs elicits digestive system disturbances, vomiting, and in extreme cases, death (1–3). Bread made from scabbed grains has been called "intoxicating bread." Recent work on the fungus has resulted in the isolation of an anabolic uterotrophic compound (4, 5). Most investigators concerned with *F. graminearum* metabolites have utilized natural or incompletely defined substances as growth media. These have included potato infusion enriched with dextrose, scabbed barley, and cracked corn (1–5). The present report is concerned with the development of a completely defined chemical medium for the production of the fungus and a study of the growth habits on this medium. With such a medium it is possible to control the total environment of the fungus in order to facilitate extraction, metabolic, and animal toxicity studies.

EXPERIMENTAL MATERIALS AND METHODS

A culture of *F. graminearum* was maintained by serial transfer on potato dextrose agar (PDA) slants. After initial growth for 1 week in an incubator at 28°, the cultures were stored at 4°. The liquid medium

used at the beginning of these experiments was derived from the PDA slant culture medium. It consisted of 20% potato infusion and 3% glucose, and was designated potato–dextrose broth (PDB).

Analytical determinations were accomplished in the following manner. A sufficient quantity of 500-ml. conical flasks, each containing 100 ml. of media, were plugged with disposable foam enclosures and autoclaved for 15 min. Inoculum was prepared by transferring a small portion of mycelium from a stock PDA slant to a flask of the same medium to be used for each experiment. This inoculum flask was incubated on a rotary shaker (1 in. diameter rotation, 300 r.p.m.) at 28° for 5–7 days. At the end of the incubation period, the contents of the flask were homogenized in a sterile Waring blender for 30 sec. The experimental flasks were inoculated by aseptically transferring a small loop of the well-stirred homogenized inoculum to each flask. The flasks were then incubated on the rotary shaker for a sufficient period of time. At arbitrarily specified intervals two flasks were harvested and treated as follows. The contents of each flask were filtered through a previously tared filter paper, the mycelium and filter paper frozen, then freeze-dried and weighed. The weight of the freeze-dried mycelium represented growth weight. The pH of the filtrate from the filtration described above was measured; a 15-ml. sample of the filtrate was preserved frozen. The quantity of glucose remaining in the filtrate was measured by the method of Shaffer and Somogyi (6). Nitrogen was measured by the method of Kala (7) and also by the Kjeldahl method.

RESULTS AND DISCUSSION

In an early investigation of the toxic metabolite of *F. graminearum* the PDB medium was devised to permit rapid production of large quantities of mycelium. When cultured in the PDB medium either in 500-ml. conical flasks on a shaker or in a 5-L. fermentor, the organism produced abundant growth and profuse quantities of red colored microconidia. Growth weight, pH, glucose, and nitrogen changes were determined during a typical incubation period of *F. graminearum* on this medium. The results are summarized in Fig. 1.

From this figure it can be ascertained that the maximum dry weight of mycelium obtained was

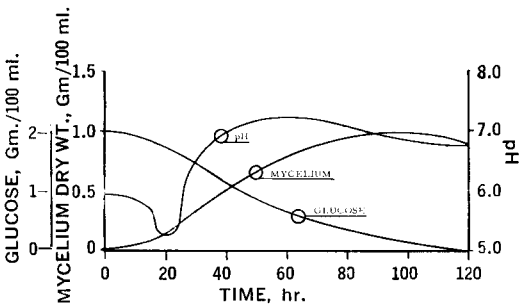

Fig. 1—Patterns of growth, pH changes, and glucose utilization of Fusarium graminearum *in potato–dextrose broth.*

0.94 Gm./100 ml., occurring approximately 100 hr. after inoculation. The pH of the medium varied from 5.25 to 7.25. The pH at the termination of the experiment (140 hr.) was 6.9. After an initial 15-hr. lag period, glucose was depleted in a logarithmic fashion during the logarithmic growth phase of the organism. (It is interesting to note that the minimum pH was recorded at the beginning of this logarithmic growth phase.) Glucose was apparently completely utilized at 110 hr. Maximum growth weight was reached before the glucose was depleted, indicating that glucose was not limiting growth. Nitrogen did not appear to be utilized since the slope of the nitrogen analysis regression line was −0.001. Because of the abundant production of the colored microconidia (about 8% of total dry weight) which hindered extraction studies, and because the mycelium produced in this medium was not acceptable to experimental animals as a food substitute in toxicity studies, it was necessary to investigate other media in anticipation that a completely defined synthetic medium might result from such further experimentation.

Semisynthetic media contain in part natural products and in part discrete chemical compounds. The absolute quantities of the chemical compounds may be varied between zero and the upper limits of solubility. Natural product constituents used in growth media are in many cases unknown. In addition, the reproducibility of the composition of a natural product is difficult due to the inherent variability of most biological systems. A synthetic medium would therefore be desirable if for no other reason than absolute control of all ingredients in the environment of the organism.

In order to evaluate and establish the limits of certain medium constituents capable of supporting growth, a number of semisynthetic media were constructed before attempting growth on a synthetic defined medium.

Glucose, mannitol, sucrose, and starch were screened singly and in combination, using neopeptone, yeast extract, and casein hydrolysate also singly and in combination as nitrogen sources. In these early screening experiments dry weight of mycelium after a 120-hr. incubation period was used as the criterion for efficiency. Although none of the media were as efficient as the original PDB medium, growth was supported by all media containing a nitrogen source; no growth was noted in media lacking nitrogen. Nitrogen was thus established as a requirement for growth.

Since *F. graminearum* did not appear to be a fastidious fungus, a chemically defined synthetic medium developed by Pacifici *et al.* (8) for the production of *Claviceps purpurea* was employed in the search for suitable substrates. This medium (see under *appendix*) not only supported growth, but was superior to PDB using terminal growth weight as criterion for efficiency.

The carbon and nitrogen modifications of Pacifici's medium are illustrated in Tables I and II.

Table I indicates that although Pacifici's original medium containing mannitol is capable of supporting growth of *G. zea*, either glucose or sucrose is more efficient in the combination with succinic acid. From the modifications made, it is apparent that a medium containing 3% glucose or sucrose and 0.1% to 1% succinic acid is most efficient. The criterion

[a] The basic medium consisted of 3% glucose, 3% succinic acid, and salts as listed in the Pacifici medium under *Appendix*. [b] Nitrogen sources were supplied in an amount equivalent to the nitrogen content of 3% ammonium succinate. [c] Average of three replicate flasks; 168 hr. fermentation. [d] Succinic acid was deleted from this modification.

for efficiency in this experiment was the economic coefficient; the greater numbers indicate greater utilization of carbon substrate. Succinic acid was considered as part of the carbon source in calculating the economic coefficient. For purposes of calculation, it was assumed that all sugar and succinic acid added to the medium was consumed.

The quantity of succinic acid does not appear to be critical between 0.1 and 1%. The economic coefficient drops sharply below 0.1% and above 1%. Using optimum succinic acid concentration, glucose appears to be the growth limiting factor at 3%; no further modifications of glucose concentration have been attempted.

Table II indicates that succinic acid, partially neutralized with ammonium hydroxide, is the most efficient nitrogen source. Although the nitrogen variations were accomplished before the optimum concentration of ammonium succinate was known, it is probable that similar results would be obtained using a nitrogen content equivalent to 0.1 to 1% ammonium succinate. Starting pH of the media was adjusted to 5.1–5.5 in all cases.

Variations in concentration of the major salts (magnesium sulfate and potassium hydrogen phosphate) indicated that the original quantities were in fact optimum.

No modifications of the micro elements have been attempted.

During the course of medium modification, a second analysis was accomplished. The medium used consisted of glucose 3%, succinic acid 3%, and salts as in Pacifici's original medium. Growth weight and pH changes as well as glucose utilization were determined. The results are summarized as Fig. 2.

Glucose was utilized in a logarithmic fashion, being depleted 80 hr. after inoculation. Growth weight did not reach a maximum until after glucose had been completely used, indicating utilization of succinic acid after glucose depletion. After an initial lag phase, the pH rose throughout the incubation period. The beginning of the rise coincided with the end of glucose utilization. The increase in pH could be explained on the basis of nonutilization of nitrogen (or only slight utilization) and metabolism of succinic acid after glucose had been almost completely depleted. This would account for the observed predominant ammonia odor in the medium, and the high ending pH (8.3). Maximum growth weight was 1.4 Gm./100 ml.

Decreasing the succinic acid to 5 Gm./L. (see under *Appendix*) resulted in still a different picture of metabolism. A fermentation similar to the previous ones was accomplished using the low succinic

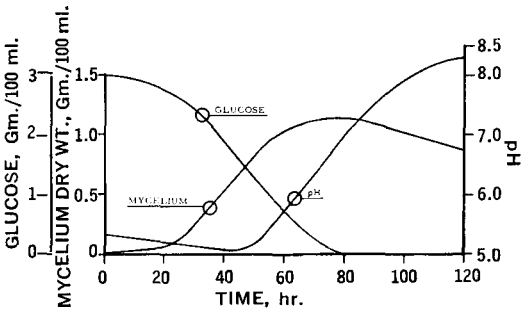

Fig. 2—Patterns of growth, pH changes, and glucose utilization of Fusarium graminearum *in the defined medium containing 3% succinic acid.*

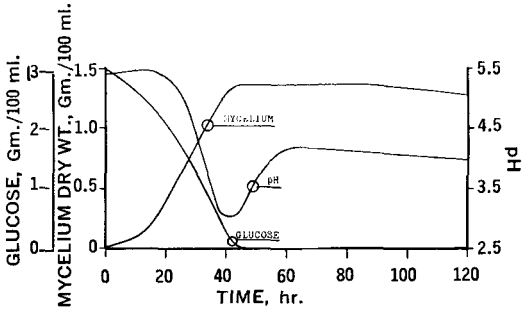

Fig. 3—Patterns of growth, pH changes, and glucose utilization of Fusarium graminearum *in the defined medium containing 0.5% succinic acid.*

acid concentration. The results are summarized in Fig. 3.

As in the previous experiment, glucose was utilized in a logarithmic fashion, being depleted in this case 45 hr. after inoculation. Growth weight, reached a maximum at the same time, indicating glucose as the growth weight limiting factor. After dropping from an initial pH of 5.4, the pH of the medium began to increase at the time glucose was depleted from the medium. It is probable that the succinic acid again was metabolized after glucose was depleted. In this fermentation, because of the low concentration of succinic acid, ammonia was also present in a much lower concentration. The final pH (4.0) was much lower than that encountered in other media. Maximum growth weight was 1.4 Gm.

SUMMARY

The experiments indicated above have resulted in the formulation of a completely defined medium for the production of *F. graminearum*. This medium was derived from one used for the production of another hypocrealic ascomycete, *Claviceps purpurea*. It appears that the optimal carbon sources are glucose (3%) and succinic acid (0.5%). Nitrogen is supplied in the form of ammonium hydroxide to adjust the pH of the medium to 5.1–5.5.

Effect of Complex Formation on Drug Absorption V

Studies on the Mechanism of the Secobarbital Absorption-Enhancing Effect of Polysorbate 80 in Goldfish

By GERHARD LEVY and JUDITH A. ANELLO

Polysorbate 80 in concentrations of 0.0005 to 0.01 percent increased significantly the absorption rate of secobarbital by goldfish. This absorption-enhancing effect was obtained also if the fish were immersed in polysorbate 80 solution, washed, and then placed in a solution of secobarbital without the surfactant. The ratio of rate constants for absorption of nonionized and ionized secobarbital, respectively, was not affected by polysorbate 80. The results of this study indicate that polysorbate 80 enhances the absorption of secobarbital by increasing the permeability of the biologic membrane to the drug, rather than by forming a more rapidly absorbed nonmicellar polysorbate–secobarbital complex in the bulk phase of the drug solution.

THE EFFECTS of surfactants on drug absorption are of considerable interest and have been investigated extensively (1, 2). Of particular pharmaceutical importance are the possible effects of surfactants at low concentrations, such as might be encountered when dosage forms containing surfactants are dissolved in or diluted with various body fluids following oral or parenteral admistration, or following application to mucous membranes. Unfortunately, appreciable technical difficulties may be encountered in studies of the effect of low concentrations of surfactants on drug absorption (3). The use of goldfish, as described in previous reports from this laboratory (4–6), obviates many of these problems (3). Good correlation has been noted between the results of drug absorption studies with goldfish and rats (5, 7), and similarly between results obtained in rats and in man (8).[1]

A recent study in this laboratory has shown that the absorption rate of secobarbital by goldfish was increased significantly in the presence of 0.01% polysorbate 80, and decreased significantly by high concentrations (1–2%) of the surfactant (3). On the other hand, polysorbate 80 had no effect on the absorption rate of ethanol[2] and certain other alcohols (3). It was noted by appropriate physicochemical studies and from a kinetic analysis of the biologic data that the modification of secobarbital absorption by high concentrations of polysorbate 80 represents the net effect of an enhanced intrinsic absorption rate constant in the presence of the surfactant and a decreased thermodynamic activity of secobarbital resulting from micellar complexation (3). The absorption-enhancing effect of polysorbate 80 was believed to be due either to a direct effect of the surfactant on the permeability of the biologic membrane, or to the formation of a nonmicellar drug–surfactant complex which is more rapidly absorbed than the free drug (3). The available data did not make it possible to distinguish between these possibilities. The purpose of this investigation to be described here was to study the mechanism of the absorption-enhancing effect of polysorbate 80 and to determine the basis for the selectivity of this effect.

EXPERIMENTAL

Goldfish, *Carassius auratus*, common variety, weighing 8–10 Gm., were used. All fish used in a given experiment (*i.e.*, listed in any one table) were from the same lot. The composition of drug solutions, methods for determination of absorption rate, and the method for the determination of surface tension were the same as described previously (3) except as noted in the next paragraph.

All absorption studies were carried out on groups of 5 fish immersed simultaneously in 1 L. of drug solution contained in a 2-L. capacity glass beaker placed in a water bath at 20 ± 0.5°. Pretreatment consisted of placing the 5 fish for the indicated time in 1 L. of 0.01% polysorbate 80 in 0.05 *M* THAM buffer (pH 5.9) or in THAM buffer without surfactant. The temperature of these solutions was maintained at 20 ± 0.5° by means of a water bath. After pretreatment, the fish were transferred with a fish net to a pan containing 3 L. distilled water at

[1] This statement refers to the relative absorption rates of a series of passively absorbed drugs in solution.

[2] Results of recent studies (12) raise the possibility that the mechanism of the pharmacologic effect of ethanol on goldfish differs at low and high concentrations. However, additional experiments conducted in this laboratory have shown that polysorbate 80 has no apparent effect on ethanol absorption even at a relatively low concentration (3.5%) of the latter.

room temperature where they remained for 4 min. The latter procedure was repeated twice for a total of 3 washes of 4 min. each. The fish were then placed in secobarbital solution as described above.

RESULTS AND DISCUSSION

The principal investigational approach used in this study was to determine the absorption rate of secobarbital in fish previously exposed to polysorbate 80 and in fish exposed only to buffer before being immersed in secobarbital solution. An initial concern was the possibility that sufficient surfactant may be transferred mechanically together with the polysorbate 80 treated fish to the secobarbital solution so that the latter would not really be free of surfactant. It was desirable therefore to determine the concentration range in which polysorbate 80, in the presence of secobarbital, will enhance significantly the rate of absorption of the latter. The data listed in Table I show that polysorbate 80 concentrations as low as 0.0005% have a pronounced absorption-enhancing effect. Polysorbate 80 as such, in the concentrations employed in this study, has no obvious deleterious effect on goldfish (3). It was noted that surface tension measurements provide a sensitive semiquantitative indication of surfactant concentration in the range employed in this study. There was only a small and possibly insignificant increase in the surface tension of the solutions at the end of the experiment; this suggests that only a small amount of the surfactant could have been adsorbed on the fish membranes.

Exposure of goldfish to 0.01% polysorbate 80 for 30 min., followed by three washings in water, resulted in a significantly enhanced absorption of secobarbital when the fish were placed in secobarbital solutions which did not contain polysorbate 80 (Table II). The magnitude of this effect was independent of the duration of exposure of the fish to surfactant; fish placed in polysorbate 80 solution for 1 min. subsequently absorbed secobarbital as rapidly as did fish maintained in polysorbate 80 solution for 60 min. before being placed in secobarbital solution (Table III). There was no detectable mechanical carry-over of polysorbate 80 to the secobarbital solution; the effectiveness of the three washings is evidenced by the fact that the secobarbital solutions used for surfactant-treated and control fish, respectively, had the same surface tension at the end of the experiment (Table II). Results obtained in control fish were not affected by duration of immersion in buffer solution (1 *versus* 60 min.) preceding their placement in secobarbital solution. Preliminary experiments had shown also that the response to secobarbital of fish

subjected to the several transfers required for pretreatment and subsequent washings did not differ from the response of fish placed directly in secobarbital solution. The times of death of control fish and pretreated fish in the experiments listed in Table II were somewhat longer than those in the experiments listed in Table III, but the relative magnitude of the surfactant effect was similar in each set of experiments. The absolute difference in death times of the control fish in the two sets of experiments is due to the use of different lots of fish. This lot to lot difference has been found previously and necessitates the use of appropriate controls in each set of experiments.

The experimental results listed in Tables II and III show that polysorbate 80 can increase the absorption rate of secobarbital in goldfish even if the two substances are not present together in the bulk phase of the solution. This leads to the conclusion that the absorption-enhancing effect of polysorbate 80 is due to a direct effect of the surfactant on the permeability characteristics of the fish membranes. The experimental results do not support an assumption that the enhanced absorption of secobarbital is due to the formation of a more rapidly absorbed nonmicellar drug–surfactant complex (9). In addition, no physicochemical evidence for such a complex in aqueous solutions containing up to 0.01% polysorbate 80 has been found in this laboratory (3).

The experimental data suggest that a small amount of polysorbate 80 is adsorbed rapidly on the absorbing membranes of fish, and that this in turn causes a more rapid absorption of secobarbital and certain other drugs. The fact that exposure of the fish to polysorbate 80 for 1 min. elicits the same effect as exposure for 60 min. shows not only that the surfactant acts rapidly, but also that the effect is relatively time independent. This is in agreement with the result of the previously reported kinetic analysis of the effect of polysorbate 80 on secobarbital absorption (3); the surfactant effect could be expressed in terms of a rate constant for the enhanced absorption and thus appeared to be essentially time independent. This would not be expected to occur if the surfactant acts by slowly removing lipoid constituents from the membrane or by causing the leaching out of some other membrane component. The rapid effect of polysorbate 80 is more consistent with a mechanism involving adsorption of surfactant molecules on the biologic membrane, thereby making the latter more permeable to certain drugs. Such a mechanism *could* involve interaction of adsorbed surfactant with the drug, thereby "augmenting the amount of drug on the surface of the biologic membranes" (9). Thus, a distinction between a membrane effect and a complexing effect as the basis for the absorption-enhancing mechanism of polysorbate 80 is a matter of semantics; the present study distinguishes between a membrane effect (including a possible complex formation between *membrane-bound* surfactant and drug) and an effect due to the formation of nonmicellar drug–surfactant complex in the *bulk phase* of the solution. It is apparent from the tabulated data that polysorbate 80 exerts a more pronounced effect on secobarbital absorption in the presence of the drug than when used as a pretreatment. This is probably due to partial desorption of surfactant from the fish membranes during the washings.

The failure of polysorbate 80 to enhance the absorption of low molecular weight alcohols and its effectiveness in increasing the absorption of two lipoid-soluble barbiturates of considerably higher molecular weight suggested that the surfactant might selectively increase absorption across the lipoid portion of biologic membranes without affecting the rate of drug permeation through membrane pores (3). These considerations (and a provisional assumption that secobarbital anion is absorbed solely or mainly by the pore route) led to an experiment to assess the relative effect of polysorbate 80 on the absorption rate of the nonionized and ionized forms of secobarbital, respectively. This involved determination of secobarbital absorption at pH 6.9 and 8.9 with and without surfactant (Table IV). Secobarbital has a pKa of 7.9 at 20° (10) and is about 90% nonionized at the low pH and 90% ionized at the higher pH. A more pronounced surfactant effect on the absorption of the nonionized form of secobarbital would be reflected by a greater overall effect at low pH than at higher pH where ionized secobarbital contributes appreciably to the total absorption. In fact, the surfactant affected the absorption of both species to an equal degree (Table IV).[3] This is evident not only from the respective ratios of times of death with and without surfactant, but also from the ratios of the rate constants for the absorption of nonionized and ionized secobarbital in the absence and presence of polysorbate 80. The ratios of these rate constants were calculated from two simultaneous equations of the form:

[3] Note also that the *relative* effect of 0.01% polysorbate 80 in the experiments listed in Table IV is exactly the same (50% decrease in time of death) as in the experiments listed in Table I.

$$L = k_n C_n T_L + k_i C_i T_L \qquad \text{(Eq. 1)}$$

where L is the lethal dose of secobarbital, k_n and k_i are the rate constants for the absorption of nonionized and ionized secobarbital, respectively, C_n is the concentration of nonionized secobarbital, C_i is the concentration of ionized secobarbital, and T_L is the time of death (4, 5). The experimental data obtained at pH 6.9 and 8.9 were used for each pair of equations, one for drug absorption in the absence of polysorbate 80, the other for absorption in the presence of the surfactant. The $k_n:k_i$ ratio was 16.5 in each case, showing that the absorption of ionized and nonionized secobarbital was enhanced equally by polysorbate 80. The experiments listed in Table IV were designed to yield a relatively constant T_L irrespective of pH by using an appropriately higher over-all concentration of secobarbital at pH 8.9 as determined from preliminary experiments. The $k_n:k_i$ ratio of 16.5 obtained in this manner is in relatively good agreement with the ratio of about 10 determined several years ago in this laboratory by an entirely different experimental approach where the over-all concentration of secobarbital was kept constant and T_L was variable (4).

The results of this study provide a better understanding of the nature of the absorption-enhancing effect of polysorbate 80 although the exact mechanism, and the basis for its specificity, must still remain speculative. One possibility is that surfactant molecules adsorbed to the surface of the biologic membrane interact with barbiturates [but not with the low molecular weight alcohols studied previously (3)] and thereby enhance to an equal degree the penetration of nonionized barbiturates across the lipoid portion of the membrane and the diffusion of barbiturate anions through pores in the membrane. This mechanism is difficult to accept on a rigorous basis, particularly since there is no evidence for nonmicellar complexation of secobarbital with polysorbate 80 at concentrations up to 0.01% of the latter. In addition, significant micellar complexation of secobarbital by polysorbate 80 occurs only with the nonionic form of secobarbital (11). It seems much more likely that secobarbital anion (mol. wt. >200) is absorbed solely or primarily across the lipoid portion of biologic membranes rather than through pores in the membrane, *i.e.*, by the same route as nonionized secobarbital. The similarity in the absorption-enhancing effect of polysorbate 80 on the ionized and nonionized forms of secobarbital, and the lack of effect on the absorption of low molecular weight alcohols, can then be explained by assuming that the surfactant affects drug absorption across the lipoid barrier portion of the biologic membrane but does not affect diffusion of drug through membrane pores.

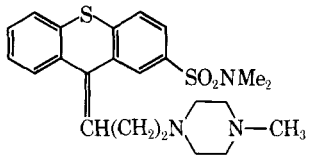
Metabolism of Thiothixene

By D. C. HOBBS

The metabolism of thiothixene, as shown by studies with rats and dogs employing ^{35}S-labeled drug, reflects the fundamental structural similarity of this thioxanthene derivative to other tricyclic psychotherapeutic agents. Like other members of this large group of compounds, it appears to be well absorbed orally, rapidly distributed, and metabolized to a variety of related compounds which are secreted mainly into the bile. The chemical similarity also suggests that it might bind to melanin. Although *in vivo* studies with hooded rats do indeed indicate a preference of thiothixene and/or its metabolites for pigmented over nonpigmented tissues, *in vitro* studies indicate that it is actually one of the least strongly bound of these drugs. In contrast to excreta and other tissues which contain a variety of metabolites, the brain contains only unchanged thiothixene.

THIOTHIXENE (I),[1] the *cis* isomer of *N,N*-dimethyl-9- [3 - (4 - methyl - 1 - piperazinyl)propylidene]-thioxanthene-2-sulfonamide, is a new potent tricyclic psychotherapeutic agent with antipsychotic activity comparable to that of several widely used phenothiazine drugs (1–5).



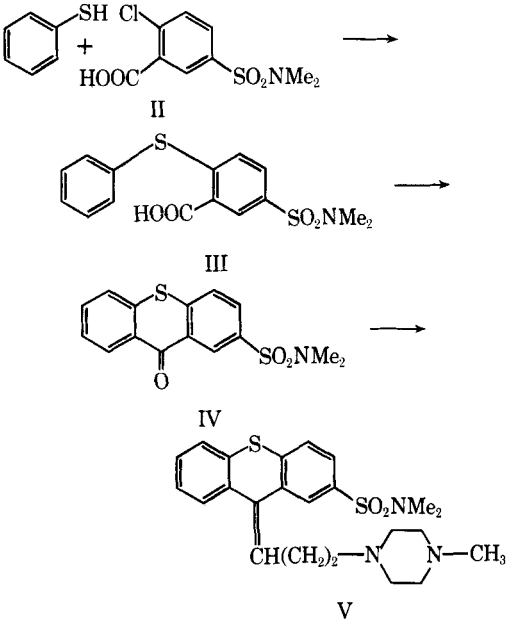
I

The studies to be reported here were undertaken to place the metabolism of thiothixene in perspective with that of existing tricyclic psychotherapeutic agents. In these initial studies using thiothixene labeled with ^{35}S in the nucleus, most of the doses employed (about 8 mg./Kg.) were those which elicit pharmacological effects in acute experiments. It should be noted, however, that these doses are at least ten to twenty-fold higher (on a mg./Kg. basis) than the usual daily human dose.

Since previous reports have indicated that certain tricyclic psychotherapeutic drugs chemically related to thiothixene interact with melanin *in vitro* and *in vivo* (6) and may be responsible for some clinical side effects in melanin-containing tissues (7), hooded rats, which have pigmented eyes and areas of black skin and hair, were included in some of the studies.

METHODS

Labeled Thiothixene—Thiophenol-^{35}S was condensed with 2-chloro-5-dimethylsulfamoylbenzoic acid (II) in alkaline dimethylformamide at 130–140°. The resulting acid (III) underwent ring closure with polyphosphoric acid at 70°. The ketone (IV), in a Wittig reaction with triphenyl-3-(4-methylpiperazinyl)propylphosphonium bromide hydrobromide, yielded V, a mixture of thiothixene and the undesired *trans* isomer. After removal of the latter as the crystalline phosphate, thiothixene-^{35}S was obtained by crystallization of the base from the mother liquor. The initial specific activity of the product was 13.4 mc./mmole. A second lot of material (1.7 mc./mmole) was obtained by dilution of the mother liquors with unlabeled thiothixene, followed by recrystallization. (Scheme I.)



Scheme I

Chromatographic examination of both lots of labeled thiothixene in paper and thin-layer systems established the identity and radiopurity (>98%) of the material.

Drug Administration—Thiothixene base, dissolved in pH 4, 0.25 *M* acetate buffer, was administered to rats and dogs by stomach tube or by intraperitoneal injection. Most of the studies were carried out at a dose level of 8 mg./Kg. However,

[a] Expressed as average (range) percent of dose administered. [b] These rats had previously received 1 mg. unlabeled thiothixene/day for several weeks. [c] Two of the animals in this group were greatly depressed and excreted very little feces, thus decreasing the apparent excretion of radioactivity.

the effects of chronic administration on levels of radioactivity in the liver, eyes, and dark skin of hooded rats were investigated in a group of animals given daily oral doses of 1 mg./Kg. Two animals were sacrificed each second day and the tissues assayed for radioactivity. After 13 days, drug administration was terminated in these animals and in another group of hooded rats which had been dosed simultaneously with 10 mg./Kg. thiothixene. Animals from both groups were then sacrificed at intervals to assess the rate of removal of drug from these tissues.

Sample Collection and Treatment—Animals were maintained in metabolism cages and excreta collected separately. Feces were homogenized with water, lyophilized, and assayed for radioactivity by scintillation spectrometry after digestion with a quaternary ammonium bactericide.[2] Tissue samples were homogenized with the bactericide and aliquots assayed; skin samples did not include the hair, and stomach contents were washed out prior to homogenization. Urine samples were assayed directly for radioactivity.

Chromatographic Procedures—Urine samples were accumulated from rats receiving daily intraperitoneal doses of unlabeled thiothixene. After treatment with a glucuronidase–sulfatase mixture,[3] an alkaline chloroform extract was prepared and concentrated for thin-layer chromatography. A similar extract was prepared from urine not treated with enzyme. Samples of feces from rats receiving labeled thiothixene by the oral and intraperitoneal routes were extracted before and after glucuronidase treatment at neutral, acid, and alkaline pH and concentrated extracts similarly chromatographed. Bile samples obtained 1–1.5 hr. after administration by these two routes were also included for comparison, as well as a neutral extract of liver. Thin-layer system EDW consisted of ethyl acetate-diethylamine–water (90:15:5) on Silica Gel GF. Areas on the thin-layer strips containing radioactive materials were delineated with a Vanguard model 880 Autoscanner and by autoradiography with Kodak type F X-ray film.

In Vitro Studies—Melanin was isolated from beef eyeballs by differential centrifugation, according to Potts (6). It was found that a concentration of 5 mg. melanin granules/ml. bound chlorpromazine to the same extent as that reported by Potts for 10 mg./ml. The former concentration was therefore used in the comparative study with 2.5 μmoles compound/ml.

Isolation of Sulfur-Containing Nondrug Related Materials—Twelve rats each received subcutaneous injections of 50 mg. of β-naphthylamine in oil (an amount found sufficient, in preliminary experiments, for the facile recovery of its metabolite) and 1 mg. labeled thiothixene (intraperitoneal) on each of 2 successive days. Urine was collected for a total of 5 days and 2-amino-1-naphthylsulfuric acid isolated by the method of Laidlaw and Young (8).

The method of Dziewiatkowski (9) was used to sample body cysteine in the form of an excreted mercapturic acid. Accordingly, 2 rats each received oral doses of 140 mg. of bromobenzene and intraperitoneal doses of 2 mg. of labeled thiothixene. Crystalline *p*-bromo-phenylmercapturic acid was isolated from the 24-hr. urines as described (9).

Cysteine was isolated (10) from the total carcass protein (except gastrointestinal tract contents) of rats 1 day (bromobenzene animals) and 5 days (β-naphthylamine animals) after administration of labeled thiothixene.

RESULTS

Excretion—Following single intraperitoneal or oral doses of labeled thiothixene, urine and feces were collected and assayed after various intervals (Table I). The route of drug administration did not appear to have an appreciable effect on the route or rate of excretion; the differences in fecal radioactivity were probably artifactual, resulting from the small amount of feces excreted by the depressed animals receiving intraperitoneal thiothixene. Some animals in each group were pretreated with several daily doses of unlabeled drug; these animals excreted the radioactive material earlier than those not pretreated. Whether this was due to saturation of tissue binding sites by the unlabeled material or to induction of drug metabolism cannot be answered by these data.

Most of the radioactivity was excreted in the feces, indicating extensive biliary secretion of thiothixene and/or its metabolites by the rat. That this actually occurred was established by direct measurement of radioactivity in the bile from two rats (Table II) and a dog (Table III) receiving labeled thiothixene. The high levels of radioactivity observed indicate the importance of this route of excretion and the high efficiency of drug absorption following administration by the oral and intraperitoneal routes. The dog excreted a greater fraction of the administered radioactivity *via* the urine than did the rat.

Distribution—Following single doses of labeled thiothixene in the rat, various tissues were removed after 4 or 24 hr. for estimation of tissue radioactivity (Table IV). Four hours after dosing, all tissues examined contained higher levels of radioactivity after the intraperitoneal dose than after the oral dose. However, this may not be a valid index of the relative efficiencies of absorption by these two routes; material absorbed from the intestinal tract goes first to the liver where it appears to be rapidly metabolized and excreted into the bile, whereas drug absorbed from the peritoneal cavity goes first to the general circulation.

At the earlier interval, the highest concentration was seen in the stomach, even after intraperitoneal administration. After 24 hr., however, the liver was the only tissue with appreciable amounts of label. To further investigate levels in the liver, a group of rats receiving single intraperitoneal doses of labeled thiothixene were sacrificed at intervals of up to 28 days; the decline in radioactivity occurred with an early half-life of 3 days and a later half-life of approximately 4.5 days (Table V). Plasma levels of radioactivity in these animals declined more rapidly.

The distribution of radioactivity within the brain of the rat 1 hr. after thiothixene administration was determined, as indicated in Table VI. Small differences were observed, but the ratio of the extreme values was only 1.7. Autoradiography of

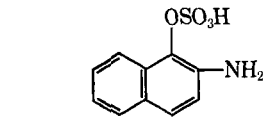
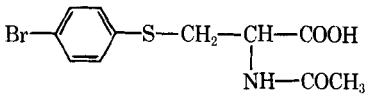
thin slices of brain indicated that more activity was associated with the gray matter than with the white matter.

Since thiothixene is to be administered chronically, tissue levels after multiple doses were investigated (Table VII). Under these conditions, higher and longer-lasting levels were noted in all of the tissues examined, the liver again showing the highest concentrations. Upon chronic administration, as after a single dose, the brain contained the lowest level of radioactivity of these tissues. An additional study was made of levels of radioactivity in liver, eyes, and skin of hooded rats receiving thiothixene in daily oral doses of 1 mg./Kg. [close to that found satisfactory for human clinical use (4)] and 10 mg./Kg. (Fig. 1). Amounts of label in these tissues of the low-dose animals had reached equilibrium by approximately the fifth dose. Following the cessation of drug administration, levels in liver and skin of both high-dose and low-dose animals declined logarithmically with a half-life of approximately 5 days. Levels in the eye remained stationary for several days, then declined at a rate considerably lower than that observed in the liver.

With the exception of the *N*-methyl group(s), fragments from the tricyclic psychotherapeutic drugs do not appear to be incorporated into normal tissue constituents. Some direct evidence on this point for thiothixene was obtained by the isolation of constituents which might contain labeled sulfur derived from thiothixene. Accordingly, 2-amino-1-naphthylsulfuric acid (VI), excreted as a result of the hydroxylation and etherification with sulfate of administered β-naphthylamine, and *p*-bromophenylmercapturic acid (VII), excreted upon condensation



VI



VII

of administered bromobenzene with *N*-acetylcysteine, were isolated. Cysteine, derived from total body protein, was also obtained. The absence of radioactivity in these substances indicates that the sulfur of tissue sulfate and cysteine cannot arise from the ring sulfur of thiothixene.

Interaction of Thiothixene with Melanin—To further assess the relative affinity of thiothixene for melanin-containing tissues as compared to the same tissues without melanin, the tissue levels in the eyes and skin of hooded (pigmented) rats were compared with those in albino animals (Table VIII). The dark skin of the hooded rats contained more label than the white skin of the same animals or the skin of albino rats. Statistical analysis indicated that the difference was significant at the 5% level. Drug concentrations in the pigmented eyes, although comparable to those of the liver at the same interval (Table IV), were nevertheless much higher than those observed in the eyes of the albino rats.

In vitro, the affinity of thiothixene for melanin isolated from beef eyeballs was compared with that of several other tricyclic psychotherapeutic drugs and the *trans* isomer of thiothixene (Table IX). Values for triflupromazine and amitriptylene were quantitatively different from those obtained by Potts (6) in a similar study, although the relative ranking of these two compounds and chlorpromazine was the same. This may have been due to a difference in the potency of the melanin preparations. The extent of binding noted with thiothixene (as well as its *trans* isomer) was similar to that observed with amitriptyline, the least bound of a much larger group of psychotherapeutic drugs investigated by Potts (6).

Metabolites of Thiothixene—Alkaline chloroform extracts of rat urine, before and after treatment with glucuronidase, upon thin-layer chromatography in system EDW, revealed the presence of several UV absorbing spots. There were only traces of material moving in the thiothixene region, but one

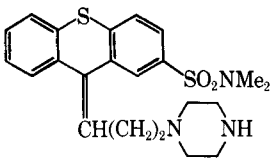
of the major metabolites was chromatographically similar to the demethyl derivative (VIII).



VIII

Extracts of feces, bile, and a neutral extract of liver from animals receiving labeled thiothixene were also examined in system EDW (Fig. 2). A large number of metabolites was again observed, including the demethyl derivative, with little or no unchanged thiothixene. All of the bile samples of Table II were chromatographed in the same system with no discernible changes in the pattern of metabolites during the course of the excretion.

Extracts of various portions of the rat brain 1 hr. after thiothixene administration, upon thin-layer chromatography, revealed a single radioactive substance, chromatographically identical to thiothixene. An extract of liver from the same animal showed the usual multiplicity of metabolites.

Extracts of feces (before and after glucuronidase treatment), prepared at neutral, acid, and alkaline pH levels and after heating with strong alkali gave qualitatively similar patterns of metabolites, the data of Fig. 2 being representative.

DISCUSSION

The experimental results reported here indicate that the absorption, distribution, and excretion patterns observed with thiothixene in the rat are generally similar to those of other tricyclic psychotherapeutic agents, as would be expected from the structural relationships involved.

As with other tricyclic psychotherapeutic agents (11–13), thiothixene was rapidly and extensively absorbed following oral administration, very little unchanged drug being recovered in the feces. Further evidence for its prompt assimilation is afforded by the high recovery of radioactivity in the bile of the rat. The low and rapidly diminishing blood levels observed with thiothixene, as with other related drugs (11, 13–16), in the presence of facile absorption indicate rapid excretion and/or distribution into various tissue compartments. The ratio of liver to plasma radioactivity increased with time indicating that the liver is a major depot for storage of thiothixene metabolites. Once absorbed, thiothixene was rapidly metabolized, since bile obtained 0.5 hr. after drug administration apparently contained all of the metabolites noted in later samples.

The relatively large amount of radioactivity excreted *via* the bile is in accord with the structure of thiothixene: comparative studies in rats (17) and dogs (13) with various phenothiazines indicate that biliary secretion is highest for those compounds which contain the 4-methyl-1-piperazinyl side chain. Reabsorption from the intestine (enterohepatic circulation) occurs with many phenothiazines (13, 18–20) and may also be a factor in the disposition of thiothixene. The 5:2 ratio of biliary to urinary excretion after thiothixene administration in the dog is considerably lower than that previously observed with prochlorperazine and trifluoperazine in the dog (13). Nevertheless, the feces still account for more than half of the material excreted. In both dogs and rats, therefore, the liver must play a dominant role in the excretion of thiothixene.

There appear to be no appreciable differences be-

tween the amounts of label excreted in the urine and feces from conditioned animals as compared to those not previously receiving unlabeled thiothixene. The amounts excreted in the feces of the orally dosed animals were greater than those derived from the intraperitoneally dosed animals, but this was probably due to the depressed state of some members of the latter group from which a smaller amount of feces was obtained and therefore does not represent depressed absorption of thiothixene. As discussed above, the biliary secretion was similar by both routes.

Data on tissue levels indicate that thiothixene and its metabolites are spread widely throughout the body, as is the case for the tricyclic psychotherapeutic drugs in general (12, 14, 18). Tissue concentrations in the rat 4 hr. after thiothixene administration were generally higher following intraperitoneal as compared to oral administration; however, at the 24-hr. interval, there were no appreciable differences between levels of radioactivity in the two groups of animals. Concentrations in the lung were lower than those previously noted with chlorpromazine and trifluoperazine (11), prochlorperazine (21), thioridazine (22), and perphenazine (16). The high initial drug levels in the stomach of rats after thiothixene parallel results obtained with chlorpromazine in mice (23) and were presumably a function of the basicity of the two compounds (and their metabolites) coupled with acidity of the gastric mucosa. This phenomenon is not associated with retention of drug within the stomach after oral dosing, since it also occurs upon intraperitoneal administration of thiothixene. Amounts of label in the liver were relatively high and declined at a slower rate than that of the other tissues examined (except the eye of pigmented rats). This long half-life, however, is similar to that observed with several other related drugs (11). Although multiple daily doses of thiothixene resulted in higher and longer-lasting levels in the liver (as well as other tissues), the ^{35}S-concentrations seen in this study were much lower than those achieved with comparable doses of chlorpromazine in cats (24) and prochlorperazine in rats (14, 21).

The low thiothixene levels found in the brain are typical for this type of drug, being noted also with promazine (25), thioridazine (11), trifluoperazine (11), and chlorpromazine (11, 20). The high brain levels of chlorpromazine relative to other tissues, noted by some investigators (24, 26–27) may have been due to methods of extraction and assay which are primarily responsive to unchanged drug. With thiothixene, as with perphenazine (28), chlorpromazine (29), and prochlorperazine (29), only the unchanged drug could be detected upon chromatographic examination of extracts of brain tissue 1 hr. after drug administration. Whether metabolites of thiothixene begin to appear at later intervals was not assessed. The uniform distribution of thiothixene throughout the rat brain at this morphological level has counterparts in studies with thioridazine (11), but differential accumulation has been observed with chlorpromazine (24, 29) and prochlorperazine (29). The higher levels of thiothixene in the gray matter as compared to white matter have also been seen with chlorpromazine (23).

The melanin-containing areas of the rat skin are definite sites of drug retention, having significantly more ^{35}S than unpigmented skin from the same animals or skin from albino rats. However, the pigmented structures of the eye appear to be the areas of highest retention. In the eye, levels approximating those of the liver were rapidly achieved; since the choroid, where the drug presumably accumulates (30), is only 8% of the total wet weight of the eyeball, levels in this structure corrected for more direct comparison with the data of Potts (6) are therefore much higher than those of the liver. Similarly, chlorpromazine and prochlorperazine result in concentrations in pigmented structures up to 100-fold higher than the corresponding liver concentrations (6). *In vitro* studies with thiothixene indicate that its increased psychotherapeutic potency is not reflected in an increased affinity for melanin. In fact, the extent of melanin binding was similar to that of amitriptyline, another nonphenothiazine and the least bound of a larger series of tricyclic psychotherapeutic drugs studied by Potts (6). Since chlorprothixene, another thioxanthene derivative, is highly bound *in vitro* to melanin, the relatively low binding observed with thiothixene may be associated with the dimethylsulfamoyl substituent rather than with a change in the nucleus from phenothiazine to thioxanthene. Nevertheless, the results here indicate that drugs bearing the thioxanthene nucleus behave qualitatively as do their phenothiazine counterparts.

Rapid equilibration of drug levels within the eye and liver was indicated in experiments involving daily oral administration of thiothixene. Concentrations of radioactivity stopped rising after only 5 days. The eye and liver tissue levels attained with doses of 10 mg./Kg. were approximately 10 times those achieved after 1 mg./Kg., indicating no impairment of absorption, distribution, or metabolism within this range. Following withdrawal, levels began to decline immediately in the liver and skin, but there was a lag phase in the eye following which label was removed at a rate slower than that in the liver. The absence of a similar lag in the removal of label from skin (where it is presumably also bound to melanin) may indicate a difference in the nature of the complex. This may be due to differences in the chemical nature of the thiothixene metabolite interacting with the melanin, or in further transformations in the complex once formed. It has been suggested (31) that 7-hydroxychlorpromazine or a further metabolite thereof is the active species involved in chlorpromazine pigmentation; a similar thiothixene derivative may conceivably be involved.

As with the related tricyclic drugs, thiothixene was rapidly metabolized to a wide variety of derivatives with little of the unchanged drug being recovered. The liver appears to be the major site of metabolism, since bile samples obtained within 0.5 hr. of drug administration contained as great a diversity of metabolites as urine and bile samples taken at later intervals. The only metabolite of thiothixene yet tentatively identified is the *N*-demethyl derivative; such demethylation on the side chain is a common feature in the metabolism of drugs of this type.

Although inorganic sulfate has been implicated as a metabolite of ^{35}S-labeled chlorpromazine (26), indicating fission of the ring system, later studies (32) with chlorpromazine and promazine revealed no

evidence for such a reaction. Ten percent of the sulfur of phenothiazine, but an insignificant amount from promazine, was excreted as inorganic sulfate by dogs (25). There have been no subsequent reports concerning the derivation of sulfate from the tricyclic psychotherapeutic agents. Since the thioxanthene nucleus may behave in a manner unlike that of the related phenothiazine drugs, direct evidence on the ultimate fate of the nuclear sulfur was sought. Cysteine has been shown to be derived, in part, from inorganic sulfate (33) and was therefore felt to be a reliable indicator of sulfur metabolism. Since a mercapturic acid derived from administered bromobenzene and cysteine, an ethereal sulfate resulting from detoxication of administered β-naphthylamine, and tissue protein cysteine were all devoid of measurable radioactivity following the administration of a single high dose of thiothixene-^{35}S, it can therefore be reasonably concluded that the nuclear sulfur of thiothixene cannot enter the body sulfur pool. This would also tend to indicate that the nucleus remains intact, as has been concluded for the phenothiazine drugs.

Acid Dye Method for the Analysis of Thiamine

By V. DAS GUPTA* and DONALD E. CADWALLADER

An accurate, precise, and simple method for the analysis of thiamine has been developed. The method is based on the salt formation of thiamine with an acid dye, bromothymol blue. There is no interference from other vitamins, hormones (ethinyl estradiol and progesterone), and excipients. The nature of reaction between thiamine and bromothymol blue appears to be a simple acid–base reaction. The stoichiometric balance has been established to be one part of dye to one part of thiamine.

THIAMINE is an essential nutritional or therapeutic component of a great many oral and injectable pharmaceutical preparations. Many biological and chemical methods for the quantitative determination of thiamine have been proposed. Chemical assay methods are usually preferred to biological methods, since analysis can be performed rapidly and economically, and they are usually more reliable for routine determinations.

Although a number of chemical assay methods of thiamine are known, only the coupling reaction with diazotized 6-aminothymol (1) and thiochrome reaction (2) have been developed as precise methods of assay. In recent years the thiochrome method has been used almost exclusively, but close attention to details makes this method unsuitable for rapid control work. The development of an accurate colorimetric method of analysis for thiamine is the object of this investigation. Schill and Marsh (3) and Schill (4–6) have studied the photometric determination of amines and quaternary ammonium compounds with bromothymol blue. They reported that thiamine reacts with bromothymol blue to form a salt which can be determined photometrically. The present investigation includes studies pertinent to the nature of the salt, factors influencing its formation, and the stoichiometric balance.

EXPERIMENTAL

Reagents—All the chemicals and reagents used were either USP, NF, or A.C.S. grade. Bromothymol blue was purchased from Fisher Scientific Co. and was used without further purification.

Preparation of Solutions—A chloroform solution of the dye (4×10^{-4} *M*) was prepared by dissolving 62.44 mg. of bromothymol blue in enough chloroform to make 250 ml. of solution. This solution was diluted with chloroform to obtain various other strengths as needed. These solutions were stable for at least 1 month.

Received June 21, 1967, from the School of Pharmacy, University of Georgia, Athens, GA 30601

Accepted for publication August 30, 1967.

Abstracted in part from a thesis submitted by V. Das Gupta to the Graduate School, University of Georgia, in partial fulfillment of Doctor of Philosophy degree requirements.

Adapted from the manuscript submitted by V. Das Gupta, which received first prize in the Southern Section in the 1967 Lunsford Richardson Pharmacy Awards Competition.

* Present address: College of Pharmacy, University of Houston, Houston, TX 77004

An aqueous buffer solution of bromothymol blue (2×10^{-4} *M*) was prepared by dissolving 62.44 mg. of the dye in approximately 0.5 ml. of 0.2 *M* sodium hydroxide solution and then adding enough pH 6.0 buffer solution to make 500 ml. The pH of the solution was determined with a Beckman Zeromatic pH meter. This solution was stable for at least 2 weeks.

Aqueous solutions of thiamine were prepared by dissolving 40.0 mg. of either thiamine hydrochloride or thiamine mononitrate in enough buffer solution to make 100 ml. These stock solutions could be used to prepare solutions of lower thiamine concentrations by diluting with appropriate buffer solutions. Solutions with pH 6.6 or lower were prepared fresh daily while those with values higher than pH 6.6 were prepared immediately before use, since thiamine is unstable at higher pH values.

Buffer solutions were prepared according to directions in the USP (7). Buffer solutions between pH 4.0 and 8.0 were prepared by taking 50 ml. of 0.2 *M* potassium dihydrogen phosphate solution, adding an appropriate amount of 0.2 *M* sodium hydroxide solution or 0.2 *M* hydrochloric acid solution, and then adding enough distilled water to make 200 ml. Solutions between pH 1.0 and 4.0 were prepared by adding an appropriate amount of 0.2 *M* hydrochloric acid to distilled water, and solutions between pH 9.0 and 11.5 were prepared by adding 0.2 *M* sodium hydroxide to distilled water. The pH of each solution was determined with a Beckman Zeromatic pH meter.

Determination of Thiamine Dye Salt in Organic Phase—*Procedure A*—A 10.0-ml. quantity of buffer solution containing an appropriate amount of thiamine alone or with other substances was placed in a 125-ml. separator. A 10.0-ml. quantity of dye solution in chloroform (1×10^{-4} *M* unless otherwise indicated) was added to 10.0 ml. of the aqueous solution, and the separator was shaken vigorously by hand for 1 min. The nonpolar and polar phases were allowed to separate and the chloroform layer was collected. The aqueous phase was extracted with 2 additional 10.0-ml. quantities of chloroform and the 3 chloroform extracts were combined. The chloroform solution was evaporated in a 50-ml. beaker using low heat (60°) to a volume less than 10 ml. After the solution had cooled to room temperature, chloroform was added to make 10.0 ml. of solution. A portion of this solution was centrifuged for 5 min. at 2500 r.p.m., and the absorbance of the clear solution was read at 420 mμ (slit width 0.03 mm.) using a Beckman DU spectrophotometer. A blank was prepared by substituting 10.0 ml. of plain buffer solution for thiamine solution in the above procedure.

Procedure B—This procedure is the same as above

except that only one 10.0-ml. quantity of chloroform was used for extraction instead of three.

Procedure C—A 5.0-ml. quantity of pH 6.0 buffer solution containing 10.0 mcg./ml. of thiamine hydrochloride was combined with 5.0 ml. of buffered dye solution in a 125-ml. separator. A 10.0-ml. quantity of organic solvent was added and the separator was shaken vigorously by hand for 1 min. The polar and the nonpolar phases were allowed to separate, and the organic phase was collected and centrifuged at 2500 r.p.m. for 5 min. The absorbance of the clear solution was read at 420 mμ. A blank was prepared by substituting plain buffer solution (5.0 ml.) for thiamine solution in the above procedure.

Determination of Dye in Aqueous and Organic Phases—To determine the amount of dye in the aqueous phase of an experimental run, the aqueous layer was collected and centrifuged for 5 min. at 2500 r.p.m., and the absorbance was measured at 503 mμ (slit width 0.015 mm.), the isosbestic point of bromothymol blue, with a Beckman DU spectrophotometer, and compared with a standard.

To determine the amount of dye in the organic phase of an experimental run, the organic layer was collected and a portion added to an equal volume of alkaline aqueous solution (pH 11.5) in a 125-ml. separator. The funnel was vigorously shaken by hand for 1 min., the aqueous phase was collected, and the absorbance of the solution measured at 503 mμ as described above.

The isosbestic point is that wavelength where the absorption of a dye in solution is dependent only on the concentration of dye and not the pH. The isosbestic point of bromothymol blue was determined according to the procedure of Reilley and Swayer (8). A stock solution of bromothymol blue was prepared by dissolving 100 mg. of the dye in enough 20% v/v ethyl alcohol to make 100 ml. Two milliliters of the stock solution was placed in a 50-ml. volumetric flask, 20 ml. of distilled water and 8 drops of concentrated hydrochloric acid were added, and the volume was brought to 50 ml. with distilled water. The pH of this solution was approximately 1. A pH 6.9 solution was prepared by placing 2.0 ml. of the stock solution in a volumetric flask and adding sufficient quantity of pH 6.9 phosphate buffer to make 50 ml. A solution having pH 13 (approximately) was prepared by placing 2.0 ml. of the stock solution in a 50-ml. volumetric flask, adding 28 drops of 3.5 *M* sodium hydroxide solution, and diluting to 50 ml. with distilled water. An absorption spectrum of each of the 3 solutions between 365 to 600 mμ was recorded on the same graph paper using a Perkin-Elmer 202 spectrophotometer. The point of intersection where the 3 curves have the same absorbance is the isosbestic point for bromothymol blue (Fig. 1).

Determination of Thiamine in Aqueous and Organic Phases—The determination of thiamine in aqueous phase was carried out according to the USP assay method (2). The fluorescence of each solution was measured using a Coleman model 12 C fluorophotometer and thiamine content was determined by comparison with standard readings.

The determination of thiamine in an organic solvent was carried out by first mixing the organic phase with an equal volume of 0.2 *M* hydrochloric acid in a 100-ml. beaker and evaporating the organic

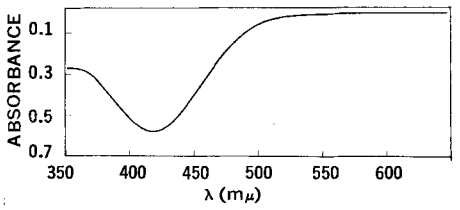

Fig. 1—Absorption spectrum of bromothymol blue.

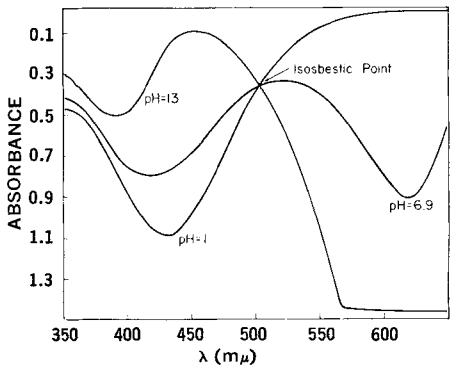

Fig. 2—Absorption spectra of thiamine dye salt.

phase by heating at 80°. After the solution was cooled to room temperature, 0.2 *M* hydrochloric acid was added to give a thiamine salt concentration of approximately 0.2 mcg./ml. The thiamine assay was then carried out as described above.

Determination of the Wavelength of Maximum Absorption—A 10.0-ml. quantity of pH 6.6 buffer solution containing approximately 8.5 mcg./ml. of thiamine hydrochloride was placed in a 125-ml. separator. A 10.0-ml. quantity of bromothymol blue solution (1×10^{-4} *M*) in chloroform was added to the aqueous solution, and the separator was shaken vigorously for 1 min. The two phases were allowed to separate, the chloroform phase was collected, and the absorption spectrum of the thiamine dye salt in solution was obtained by scanning on a Perkin-Elmer 202 spectrophotometer. The absorption spectrum is shown in Fig. 2.

Determination of Maximum Dye Concentration—Ten-milliliter quantities of pH 6.0 buffer solution containing 4.0 mcg./ml. of thiamine hydrochloride were placed in 125-ml. separators. Ten-milliliter quantities of dye in chloroform solutions (various concentrations of dye) were added to the separators, and each mixture was treated in the manner described under procedure *B* for the determination of thiamine dye salt. The results are presented in Table I.

Preparation of Calibration Curves—Using procedure *A*, pH 6.6 buffer solutions containing various concentrations of thiamine hydrochloride or thiamine mononitrate were assayed for thiamine dye salt concentrations. The absorbance readings were used to prepare calibration curves and to test for conformity to Beer's law. The results are shown in Fig. 3.

Determination of Best Organic Solvent—Using procedure *C*, various organic solvents were tested to determine the best solvent for extracting the

TABLE I—ABSORBANCE READINGS WITH INCREASING DYE CONCENTRATION[a]

Dye Concn., moles/L.	Absorbance at 420 mμ
2.5×10^{-5}	0.244
5.0×10^{-5}	0.272
1.0×10^{-4}	0.292
2.0×10^{-4}	0.325[b]

[a] Each absorbance value is an average of 3 experiments. Concentration of thiamine HCl was always 4.0 mcg./ml. All individual readings were within ±3% of the mean reading. [b] Reading is high probably due to emulsion formation. This limits the maximum concentration to 1×10^{-4} moles/L.

TABLE II—PERCENTAGE OF THIAMINE DYE SALT EXTRACTED BY VARIOUS SOLVENTS[a]

Solvent	% Extracted
Benzene	6.5
Carbon tetrachloride	1.3
Chloroform	95.3
Methylene chloride	80.4
Petroleum ether	2.6
Toluene	5.2
Xylene	5.2

[a] Each value is an average of 2 experiments. All individual readings were within ±3% of the mean reading.

TABLE III—EFFECT OF pH ON THE EXTRACTION OF THIAMINE DYE SALT[a]

pH	Absorbance at 420 mμ, Procedure B[b]	Absorbance at 420 mμ, Procedure A[c]
2.0	0.000	0.000
3.0	0.000	0.000
3.9	0.020	0.020
4.3	0.205	0.285
5.2	0.274	0.304
5.4	0.285	0.305
5.6	0.290	0.305
5.8	0.290	0.305
6.0	0.290	0.305
6.2	0.290	0.305
6.4	0.280	0.304
6.6	0.270	0.304
6.8	0.250	0.305
7.0	0.224	0.281
7.2	0.188	0.282
7.4	0.130	0.235
7.6	0.130	0.235
8.0	0.052	0 092
10.0	0.000	0.000

[a] Each absorbance value is an average of three experiments. All individual readings were within ±3% of the mean reading. [b] One 10.0-ml. portion of chloroform was used to extract the thiamine salt. [c] Three 10.0-ml. portions of chloroform were used to extract the thiamine dye salt.

thiamine salt. The results are presented in Table II.

Determination of the Effect of pH—Various solutions (pH range 2 to 10) containing 4.0 mcg./ml. of thiamine hydrochloride were prepared and assayed for thiamine dye salt according to procedures *A* and *B*. The results are shown in Table III.

Determination of Effect of Time and Temperature on Stability of Thiamine Dye Salt—A pH 6.6 buffer solution containing 4.0 mcg./ml. of thiamine hydrochloride was used in these studies.

Procedure *A* was used to determine the thiamine dye salt; however, after the absorbance of the chloroform layer was determined initially, it was allowed to stand for 1, 2, and 3 hr. at ambient temperature (25° ± 2°). The absorbance of the chloroform solution was measured at hourly intervals and the results are given in Table IV.

In other experiments the absorbance of the chloroform solution was determined initially, and then the solution was diluted to 3 times its initial volume with chloroform. This solution was heated in a beaker at 60° for approximately 10 to 15 min. until the volume was less than 10 ml. After cooling to room temperature, the solution was adjusted to its original volume and the absorbance of this solution measured. The result is shown in Table IV.

Tolerance of Assay Method to Diverse Substances—Buffer solutions (pH 6.0 and 6.6) containing various amounts of diverse substances were prepared. The concentration of each test substance in solution was approximately 4 times that usually present in commercial products. The interference of each substance was individually determined by substituting 10.0 ml. of the test solution for 10.0 ml. of thiamine solution and carrying out the assay according to procedure *A*. Any absorbance in the final chloroform solution was indicative of interference. The results are shown in Table V.

TABLE IV—EFFECT OF TIME AND TEMPERATURE ON THE STABILITY OF THE THIAMINE DYE SALT[a]

Time, hr.	Temp., °C.	Absorbance at 420 mμ
0	25	0.307
1	25	0.306
2	25	0.306
3	25	0.306
0.25	60	0.306

[a] Each absorbance value is an average of two experiments. All individual readings were within ±3% of the mean reading.

TABLE V—EFFECT OF DIVERSE SUBSTANCES[a]

[a] Each absorbance value is an average of two experiments. [b] Concentration expressed in ml./ml. for these liquids. [c] There is no interference if the alcohol present is evaporated using gentle heat before assaying.

Experiments were carried out in which pH 6.6 solutions were prepared to contain 0.0, 4.0, 6.0, and 8.0 mcg./ml. of thiamine hydrochloride or mononitrate and all of the substances listed in Table V. (Each substance was present in the concentration listed in Table V.) These solutions were tested for interference in the same manner as described above. The results are presented in Table VI.

Effect of decomposition products on the acid dye method was studied by preparing an aqueous solution containing 20 mcg./ml. of thiamine mononitrate and all the substances listed in Table V (the concentration of each substance in solution was 5 times the concentration listed in Table V). The pH of this solution was adjusted to 6.4 with sodium hydroxide (0.2 *M*). Initial assays for thiamine were run both by the USP method (2) and by the acid dye method (procedure *A* using pH 6.6 buffer). After storing this solution at 60° for 85 days, the thiamine content was again determined using the methods described above. Results are presented in Table VII.

Reproducibility of Results—To test the reproducibility of results, 12 assays were run by the USP method (2) and 12 by the acid dye method using procedure *A* and thiamine mononitrate (4 mcg./ml.) in a pH 6.6 buffer solution. Results are presented in Table VIII.

Determination of Stoichiometric Balance—Buffer solutions (pH 7.7) containing 10.0, 20.0, or 30.0 mcg./ml. of thiamine hydrochloride or thiamine mononitrate were prepared for these studies. The high pH was used to prevent the passage of any free dye into the chloroform layer. Each of the thiamine solutions was mixed with 2×10^{-4} *M* bromothymol blue in chloroform solution according to the directions in procedure *B*. After the nonpolar and polar layers were separated and collected, the chloroform and aqueous solutions were assayed for thiamine and dye according to the methods described under *Determination of Thiamine and Dye in Aqueous and Organic Phases*. The results are presented in Table IX. The stoichiometric balance was calculated by using the following equation:

$$\frac{\text{concn. of thiamine in } CHCl_3}{\text{mol. wt. of thiamine}} : \frac{\text{concn. of dye in } CHCl_3}{\text{mol. wt. of dye}}$$

Several experiments were carried out to confirm the stoichiometric balance of 1:1. Twenty milligrams of thiamine mononitrate was added to 100 ml. of bromothymol blue in chloroform solution (12.48 mcg./ml.) in a 250-ml. separator, and the mixture was shaken intermittently over a period of 3 hr. After 3 hr. the chloroform layer exhibited a lower absorbance value (at 420 mμ) than was expected for complete salt formation. A 5-ml. quantity of distilled water was then added and the mixture was shaken vigorously for several minutes, after which time the equilibrium was established. After the two phases had separated, the aqueous solution was colorless and the chloroform solution gave an expected absorbance reading. Subsequent experiments were carried out in which 5 ml. of water was added immediately and the 3-hr. shaking period was eliminated. Similar experiments were carried out using a higher dye concentration (24.96 mcg./ml.). The results are presented in Table X.

TABLE VI—COMBINED EFFECT OF DIVERSE SUBSTANCES[a]

Concn., Thiamine, mcg./ml.		Absorbance at 420 mμ	
HCl	Mononitrate	Thiamine Alone	Thiamine + Added Substances
0.00	0.00	0.000	0.000
4.00	0.00	0.305	0.306
6.00	0.00	0.456	0.457
8.00	0.00	0.608	0.609
0.00	4.00	0.312	0.313
0.00	8.00	0.622	0.624

[a] Each absorbance value is an average of 3 experiments. All individual readings were within ±3% of the mean reading. Each substance was present in the concentration listed in Table V. Procedure *A* and buffer solution of pH 6.6 were used in all the assays.

TABLE VII—EFFECT OF DECOMPOSITION PRODUCTS ON THE ACID DYE METHOD AS COMPARED WITH THE USP METHOD[a]

	Percentage Thiamine Mononitrate Remaining After	
	Initial	85 Days
USP method	100.3	10.1
Dye method	100.4	9.8

[a] Each percentage is an average of 3 assays. All individual readings were within ±3% of the mean reading.

TABLE VIII—REPRODUCIBILITY OF RESULTS (DYE METHOD *Versus* USP METHOD) ON A SAMPLE (4.0 mcg./ml.) OF THIAMINE MONONITRATE

Sample	Found, mcg./ml. Dye Method	Found, mcg./ml. USP Method	Deviation, mcg. Dye Method	Deviation, mcg. USP Method
1	4.08	4.04	0.08	0.04

Physical Properties of the Salts—A 300-ml. quantity of pH 6.6 buffer solution containing 100 mcg./ml. of thiamine hydrochloride or mononitrate was vigorously skaken with 300 ml. of dye in chloroform solution (1×10^{-4} *M*) in a 1,000-ml. separator for 1 min. The phases were allowed to separate and the chloroform solution containing the thiamine dye salt was collected in a 600-ml. beaker, and evaporated to a small volume (3 to 5 ml.) on a hot plate (60°). The remaining chloroform was allowed to evaporate at ambient temperature and the salt was dried in a desiccator. The melting points of the salts were determined using a Thomas-Hoover capillary melting point apparatus.

DISCUSSION AND CONCLUSIONS

Optimum Conditions for Assay—The results show that a method based on the reaction between bromothymol blue and thiamine (procedure *A*) in a pH 6.6 buffer solution can be used for the analysis

TABLE IX—DISTRIBUTION OF THIAMINE AND DYE BETWEEN CHLOROFORM AND WATER (pH 7.7) FOR THE DETERMINATION OF STOICHIOMETRIC BALANCE[a]

Total Thiamine Salt Concn., mcg./ml.	Concn., mcg./ml. of Thiamine Salt: In Water	Thiamine Salt: In Chloroform	Bromothymol Blue: In Water	Bromothymol Blue: In Chloroform	*M* Ratio of Thiamine to Dye
			Hydrochloride		
10.0	4.71	5.29	114.70	10.10	1.00:1.03
20.0	9.43	10.57	104.58	20.22	1.00:1.03
30.0	14.15	15.85	94.48	30.32	1.00:1.03
			Mononitrate		
10.0	4.50	5.50	114.35	10.45[b]	1.00:1.00
20.0	9.25	10.75	104.25	20.55	1.00:1.00
30.0	13.95	16.05	94.28	30.52	1.00:1.00

[a] Each value is an average of 3 experiments. All individual readings were within ±3% of the mean reading. [b] Absorbance value for this concentration of thiamine dye salt in chloroform was 0.398.

TABLE X—CONFIRMATION OF STOICHIOMETRIC BALANCE[a]

Dye Concn., mcg./ml.	Absorbance at 420 mμ: Expected[b]	Found
12.48	0.475	0.472
24.96	0.950	0.944

[a] Each absorbance value is an average of 3 experiments All individual readings were within ±3% of the mean reading. [b] From Table IX (*Footnote b*) we find that 10.45 mcg./ml. of dye in chloroform gives an absorbance value of 0.398. Assuming a stoichiometric balance of 1:1, a dye concentration of 12.48 mcg./ml. in chloroform will be expected to give an absorbance value of 0.475.

of thiamine in pharmaceutical preparations (Tables III and V) and the best dye concentration is 1×10^{-4} moles/L. (Table I). The optimum pH value of 6.6 is not in agreement with a 7.4 value reported by Schill (6).

Beer's law is followed within the range of 4 to 10 mcg./ml. of thiamine (Fig. 3) at 420 mμ (Fig. 2). The best solvent for extraction is chloroform (Table II) and the thiamine dye salt is very stable in this solvent (Table IV). The acid dye method is at least as accurate and precise as the USP method. The reproducibility of results based on 12 samples (4 mcg./ml.) was 4.00 ± 0.04 *versus* 4.00 ± 0.05 by the method (Table VIII).

Nature of Thiamine Dye Salt—The nature of the reaction between bromothymol blue and thiamine seems to be a simple acid–base reaction. The stoichiometric balance of the reaction is 1:1 (Tables IX and X). The thiamine salts formed with bromothymol blue have high molecular weights (925.2 for thiamine monochloride dye salt and 915.28 for thiamine mononitrate dye salt) as compared with thiamine hydrochloride (337.28) and thiamine mononitrate (327.36); hence they are more soluble in organic solvents. The melting points of thiamine dye salts were 255–258° (with decomposition). These high melting points indicate that ion–ion pairs are salts and not loose complexes. Additional work is being carried out to establish the composition of these salts.

Effect of Diverse Substances—No interference in the analytical procedure was observed from other vitamins, minerals, hormones (ethinyl estradiol and progesterone), and excipients except for a slight interference from ethyl alcohol and nicotinamide (Tables V and VI). Lack of interference was sxpected, since none of these substances is as etrong a base as is thiamine.

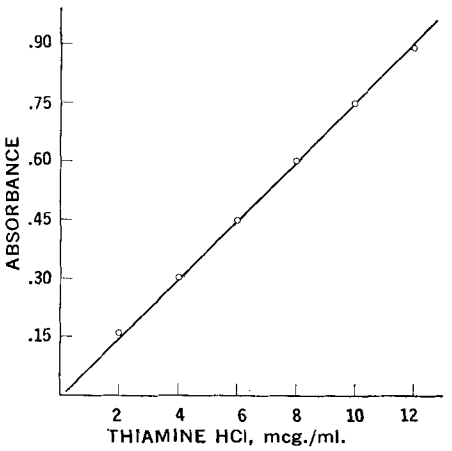

Fig. 3—Standard curve for thiamine hydrochloride. A similar curve was obtained with thiamine mononitrate.

The interference from ethyl alcohol may be due to increase in the polarity of the nonaqueous phase which results in the occurrence of more dissociated dye in this phase. A slight interference from nicotinamide at pH 6.0 and no interference at pH 6.6 was not studied further.

Interference from the decomposition products of thiamine and other vitamins is also negligible (Table VII). Apparently none of the products of decompositon behaves as a strong base. This being the case, it may be possible to ascertain the degradation products. If, for example, it is assumed that thiamine was oxidized on storage at 60°, then thiochrome, the decomposition product, is formed, which means the amino group of the pyrimidine ring, which is probably responsible for the formation of thiamine dye salt, is lost.

Shortcomings in Pharmacokinetic Analysis by Conceiving the Body to Exhibit Properties of a Single Compartment

By S. RIEGELMAN, J. C. K. LOO, and M. ROWLAND

In the past, pharmacokinetic assessment of drug absorption, metabolism, and excretion usually have been based on the concept of the body behaving as a single compartment. After rapid i.v. injection, provided that blood samples are taken sufficiently soon after injection, at least a bi-exponential curve is obtained. The initial portion of this curve, the so-called rapid distribution phase, has been ignored without proof, and it has been assumed that the single-compartment concept does not introduce large errors into the subsequent calculations. On the basis of first principles, at least one additional peripheral compartment must exist for virtually any compound introduced into the body. Such a model is physiologically compatible with distribution of the drug throughout the body under perfusion and diffusion forces. The two-compartmental open-system model is discussed in respect to the error introduced into the usual absorption rate and elimination rate calculations and on the estimation of the volume of distribution of various drugs.

PHARMACOKINETIC STUDIES are usually undertaken to attempt to define, as accurately as possible, the rates of absorption, metabolism, and excretion of a drug and its metabolites. The analyses of data, obtained after administration of a drug to man or animals, have most commonly been based on the presumption that it is adequate to consider the body as exhibiting the properties of a single compartment. Since a model is only conceived to serve the purposes of the scientist, it need not be any more complex (nor should it be any less simplified) than required to serve this function. However, it is scientifically unsound to continue to accept a model because it is often used; instead it should be questioned until there is sufficient evidence to support its adequacy for the purposes for which it was designed. Surprisingly, within the knowledge of the authors, there appears to have been no critical tests of the validity of the single-compartmental model. This paper is the first of a series which will attempt to examine this model and point to some of the limitations and incorrect reasoning that it imposes on these analyses.

It is the purpose of this paper to emphasize that a central and at least one peripheral compartment appear essential to describe adequately the distribution of the drug in the body. Not only is such a model sufficiently realistic when viewed on a physiological basis, but it is mathematically more acceptable than the one-compartmental model.

DISCUSSION

Physiological Aspects of the Mammillary Model—Compounds are distributed throughout the body by the blood and vascular network acting as a carrier system. One conceives of a model which represents drug distribution and elimination to be made up of a central compartment with interchanging connections with one or more peripheral compartments. Such a model has been called a mammillary model (1). While blood is a major

essential component of the central compartment, it will be made clear later that the compartment is larger than the plasma volume. When a drug is injected rapidly into a vein, it initially mixes with a small volume of plasma forming a bolus. However, as it passes through various capillary beds, filtration and diffusion forces cause some of the molecules to transfer into the surrounding tissues. These events take place extremely rapidly (2), so that even during the first few moments while the drug solution becomes physically mixed with the plasma, the solute has already penetrated into a much larger volume.

The rate of uptake of a compound into the tissues is controlled by several forces, including the rate of flow of blood through the tissue, the mass (volume) of the tissue, and the partition characteristics of the compound between the plasma and the tissue. The interrelationship of these factors is defined by Fick's law of perfusion and has been discussed in detail by Kety (3) and others (4, 5). The rate of flow of blood through the tissues varies in each tissue from highs of 500 ml. to less than 2 ml. of blood/100 ml. of tissue/min. The partition coefficient of the compound into the various tissues also is affected by many factors, such as its relative lipoid solubility, pH, and complexation with proteins, nucleic acids, *etc.* It is clear from the above that drugs will distribute into tissues in a highly complex manner and in a real sense will exhibit different concentrations down to the subcellular level. This almost infinite degree of complexity brings confusion into the issue of multiple-compartmental analysis merely because we are so anxious to place physiological meanings to the compartments defined by a particular experiment.

The distribution of a drug into various tissues as described above is spoken of in anesthesia and physiological literature (5, 6) as the perfusion-limited, multiple-compartmental model. If the body must be divided into N-compartments, there should be $N - 1$ exponential terms in the resultant equation.[1] The fact that it is rarely possible to determine more than two or three exponential terms in these studies indicates that many of the tissue compartments exhibit sufficient similar properties to pool into large groups or are too small to be detected. The anesthesiologist–physiologist conceives of the body as dividing into four groups according to their perfusion and partition characteristics.

A highly perfused lean tissue group, consisting of the heart, lung, hepatoportal system, kidneys, endocrine glands, and under certain instances the brain and spinal system.

A poorly perfused lean tissue group, consisting of the large mass of muscle and skin tissue.

A fat group, consisting of the adipose tissue, including marrow.

A negligible perfusion tissue group, consisting of bone (not marrow), teeth, ligaments, tendons, cartilage, contents of the alimentary canal, and hair. This final group can usually be ignored in pharmacokinetic analysis except in those cases when considering drugs (tetracyclines) or elements (calcium, phosphate) which concentrate in this compartment.

Recently, Perl and co-workers have shown (7) that the multiple-compartmental model based on distribution of the compound solely by a perfusion-limited process is unrealistic, at least as it applies to fat-soluble compounds (8). Even though fat is estimated to have approximately the same perfusion rate as muscle tissue, many compounds are much more soluble in the fat than in other tissue masses. Therefore, direct diffusion between the fat pads and the adjacent tissues becomes a significant pathway due to the gradient in concentration which develops as the neighboring tissues "fill up" at unequal rates from the common source, the arterial blood. Perl and co-workers propose that the adipose tissue should be considered to be stored into two types of depots. In one (subcutaneous, interstitial, *etc.*), the adipose tissue has a boundary surface in contact with the more slowly perfused lean tissues, such as the resting muscle and skin. In the other, the adipose tissue (omental, perirenal, *etc.*) has a boundary surface in contact with the highly perfused lean tissue. Strong evidence to support this contention was presented from studies on the simultaneous uptake of nitrous oxide and cyclopropane in man at subanesthetic levels. These compounds have identical partition characteristics into body fluids and tissues, except that cyclopropane is eight times more soluble in fat than is nitrous oxide. An approximately constant 5% difference in the alveolar concentration of the two gases was obtained when they were simultaneously administered. This was larger and more rapidly evolved than could be explained on any physiologically acceptable modification of the simple perfusion-limited, multicompartmental model. The magnitude and rate of onset of the concentration difference could only be adequately explained on the basis of diffusional forces modifying the perfusion-limited distribution and causing the cyclopropane to enter more rapidly the two separate fat compartments *via* the neighboring tissues.

From the above discussions it seems likely that one would not have to consider the body to be so highly compartmentalized as was originally thought. In effect, the two fat compartments surrounded by tissues of different perfusion characteristics simply modify the effective volume of these two tissue groups and their rate of equilibration at least insofar as the pharmacokinetic calculations are concerned. Therefore, since the uptake of the drug by the highly perfused tissue group is usually so rapid, it can be conceived mathematically to be part of the central compartment. Also, expanding the volume of the central compartment to include some extracellular fluids and the highly perfused tissue mass as well appears to be physiologically acceptable and mathematically logical.

Simultaneous to distributing throughout the body, virtually all drugs undergo metabolism. The effect of metabolism is superimposed on the distribution from the very instant the drug enters the tissues and the magnitude of its influence on the observed rate constants for the loss of the compound from the body varies from compound to compound. This effect will be discussed in detail below. The major site for metabolism, liver, as well as the minor sites, the kidneys and gastrointestinal tissues, are all included in the central compartment in the presently conceived model. This will simplify many mathematical considerations (9). From the viewpoint of what can be detected from the blood,

[1] The so-called two-compartmental open-system model in an exact sense has at least one additional compartment, the urine, feces, or metabolite.

it is, therefore, physiologically acceptable to conceive of a bi- or tri-exponential function representing body distribution of the drug from a central into one or two peripheral compartments, with metabolism and excretion taking place from the central compartment. This viewpoint in itself does not prove that a two- or three-compartmental model is better than the one-compartmental model, or that a more complex model may not be needed to meet the known physiological or pharmacological facts. The intent of the above discussion is to emphasize that a two-compartmental model may be all that is necessary to achieve the declared goals of accurate assessment of the rates of absorption, metabolism, and excretion. A possible method of establishing valid experimental support for a given model can be made through studies of absorption which will be presented later.

Mathematical Basis for Reducing N-Compartmental System into a Two-Compartmental Model—From a purely pragmatic point of view, the above simplification of complex physiological phenomena needs no further justification. Yet Sharney, Wasserman, and co-workers (10) have shown that under certain precise conditions a system consisting of an arbitrarily large number of interchanging pools can be represented exactly by a two-pool or three-pool model. These authors made no *a priori* assumptions about the relative sizes of the peripheral pools and, therefore, such mammillary systems may include very small as well as very large peripheral compartments. They emphasized that such a representation of complex mammillary systems by a simple two- or three-pool model is a perfectly valid and rigorous procedure. Because no individual compartment is detected, the corresponding rate constants out of the peripheral compartments are defined by Sharney to be equal since they are not specific in any sense nor do they apply to any real tissue compartment (10). They are, however, essential to the authors' model in that they define the disposition of the drug into the rest of the body. Without their definition, the absorption and probably the metabolism and excretion characteristics of the drug are not accurately definable.

Estimation of Tissue Compartment on Basis of Material Balance—One might suggest that a peripheral compartment is detectable only in the early phases of the time course of the drug in the body and that the body takes on the characteristics of a single-compartmental model when the blood data appear to indicate monoexponential decay. The loss of the drug from the body is then specified to be the elimination rate constant. However, without presuming any specific model for distribution of a drug after an intravenous injection, it can be shown that at least one peripheral (tissue) compartment exists *throughout* the time course of the drug in the body. Material balance requires that the following equation holds true at any time:

$$\text{dose} = V_pC_p + M + E + T \quad \text{(Eq. 1)}$$

where

V_pC_p = mass of the original dose, D, in the central compartment at any time, t, as indicated by the concentration of the drug in the plasma, C_p.

V_p = volume of the undefined central compartment.

$C_p^\circ = D/V_p$ = concentration of the drug at zero time as defined by extrapolation of the curve back to $t = 0$.

M = mass of the original drug metabolized (from central compartment) by *all* processes.

E = mass of original drug excreted (from central compartment) by all routes.

T = mass of the original dose distributed to the peripheral or so-called tissue compartment at any time.

It is further presumed that metabolism and excretion take place by first-order processes with the rate constants, k_m and k_e, respectively, *i.e.*,

$$dM/dt = k_mV_pC_p \quad \text{(Eq. 2)}$$

$$dE/dt = k_eV_pC_p \quad \text{(Eq. 3)}$$

Also, defining the sum of these two processes as the elimination rate constant, $k_{el} = k_m + k_e$, then the amount of the original dose lost by all processes of metabolism and excretion up to time, t, is obtained by integrating Eqs. 2 and 3:

$$M + E \Big|_0^t = k_{el}\, V_p \int_0^t C_p dt \quad \text{(Eq. 4)}$$

where the integral term $\int_0^t C_p dt$ is the area under the plasma concentration time curve from the time of the injection to time t. Substitution into Eq. 1 and rearranging gives:

$$T = D - k_{el}\, V_p \int_0^t C_p dt - V_pC_p \quad \text{(Eq. 5)}$$

At a sufficient time, arbitrarily defined as infinite time, for all the drug to be eliminated from the body, Eq. 4 becomes:

$$\text{dose} = M + E \Big|_0^\infty = k_{el}V_p \int_0^\infty C_p dt \quad \text{(Eq. 6)}$$

from which we can substitute for $k_{el}V_p$ in Eq. 5.

$$T = D - D\frac{\int_0^t C_p dt}{\int_0^\infty C_p dt} - V_pC_p \quad \text{(Eq. 7)}$$

Equation 7 is, therefore, a method of estimating the mass of the drug which is in the tissue compartment at any time. Dividing through by dose, results:

$$T/D = 1 - \frac{\int_0^t C_p dt}{\int_0^\infty C_p dt} - C_p/C_p^\circ \quad \text{(Eq. 8)}$$

Equation 8 is useful to describe the fate of the compound from data obtained from intravenous administration of that compound. The term C_p/C_p° is the fraction of the original dose remaining in the central compartment at any time. The term T/D is the fraction of the dose which has entered and remains in the peripheral compartment at any time. Finally, the term

$$\int_0^t C_p dt \Big/ \int_0^\infty C_p dt$$

is the fractional area term and represents the fraction of the original dose which has been lost from the

central compartment by metabolism and excretion. While both metabolism and excretion can take place from the peripheral compartments, on the basis of the present knowledge, both of these processes predominantly take place in tissues included within the central compartment. Figures 1–5 are based on calculations using Eq. 8 on selected data from compounds of interest. It is clear from these data that the size of the tissue compartment varies markedly from compound to compound, as does the instant at which the central and tissue compartments reach equilibrium ($dT/dt = 0$). However, in each of the examples illustrated the data indicate the continued existence of the tissue compartment throughout the test period.

The parallelism of the slope of the two lines is a point that creates a great deal of confusion. The fraction of the drug lost from each compartment is identical when the two compartments are in apparent distribution equilibrium. However, the two compartments are not in steady state of equilibrium throughout this period, since drug mass is exchanging between the compartments per unit time. Neither can they be lumped into a single compartment without loss of certain mathematical accuracy in the calculation of the absorption and the elimination rate constants.

Many drugs cannot be easily studied from blood specimens due to the small dose administered or at times when only a small fraction of the dose remains in the central compartment. This is particularly true of amine drugs. The value of the study of urinary excretion data was shown by the farsighted and basic studies of Nelson (16–18) and others (19, 20). It should be noted that Eq. 3 listed above intrinsically presumes constant urinary clearance. Therefore, if urinary excretion samples were taken at sufficient frequency, a similar analysis of the data could be made. This is seen in Fig. 6 where blood and urinary data on mannitol (21) are represented. Unfortunately, it is not easy to obtain sufficient urine samples for such an analysis in each case. However, analysis of urinary data for the absorption and elimination rate constants are no more valid than their counterparts calculated from the blood data; indeed, it is likely that they may be less accurate due to variations in urinary pH, flow rate, and when a small fraction of the drug is excreted intact.

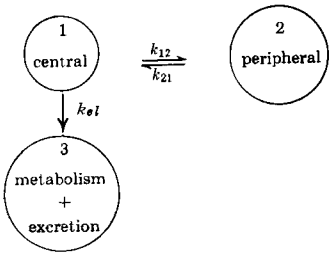
Two-Compartmental Open-System Model—The above discussions all lead to the inevitable conclusion that the body behaves more like a two-compartmental open system, such as is indicated in the diagram shown in Scheme I.



Scheme I

It is believed that this model was first related to drug kinetics by Teorell in 1937 (22). Since then it has been discussed in various degrees of sophistication by Dominguez (23), Sheppard (24), Solomon (25), Shore (26), Riggs (27), Mathews *et al.* (28), Nelson (29), Resigno and Segre (30), Sharney *et al.* (31), and others. Solution of the differential equations resulting from such a model yields the following integrated solution:

$$C_p = Ae^{-\alpha t} + Be^{-\beta t} \qquad \text{(Eq. 9)}$$

$$C_p^\circ = A + B \qquad \text{(Eq. 10)}$$

or

$$1 = A/C_p^\circ + B/C_p^\circ = A' + B'$$

$$A' = (k_{21} - \alpha)/\beta - \alpha;\ B' = (k_{21} - \beta)/\alpha - \beta \qquad \text{(Eq. 11)}$$

$$\alpha \cdot \beta = k_{21} \cdot k_{el} \quad \text{(Eq. 12)}$$

$$\alpha + \beta = k_{12} + k_{21} + k_{el} \quad \text{(Eq. 13)}$$

$$\int_0^\infty C_p dt = A/\alpha + B/\beta = C_p^\circ/k_{el} = D/V_p k_{el} \quad \text{(Eq. 14)}$$

Therefore

$$k_{el} = 1/(A'/\alpha + B'/\beta) \quad \text{(Eq. 15)}$$

$$k_{21} = A'\beta + B'\alpha \quad \text{(Eq. 16)}$$

$$k_{12} = A'B' (\beta - \alpha)^2/k_{21} \quad \text{(Eq. 17)}$$

The best method of estimating the coefficients, A and B, and the hybrid rate constants, α and β, of Eq. 9 are not the subject of this paper except to point out that no mathematical method will substitute for sufficient blood samples taken at the critical times and accurately assayed. Several authors have discussed the analysis of these curves (32–34) and present numerical and computer solutions of the equation. Wagner and Northam recently discussed the relationship between the volume of distribution and the half-life of a compound after an i.v. injection (35) wherein they present several equations equivalent to those listed above.

Influence of Two-Compartmental Open-System Model on Estimation of Absorption Rate Constant—It should be clear from examination of Figs. 1–6 that a variable fraction of the drug molecules leave the central compartment during the distributive phase. Therefore, when the drug is not injected but is absorbed from a site, such as the gastrointestinal tract, a fraction of the absorbed molecules is distributing into the tissue compartment. This phenomenon cannot be ignored while calculating the true absorption rate.

It will be shown in a later paper (36) that calculation of the absorption rate ignoring the existence of the peripheral compartment is subject to significant errors and that an absorption rate equation including a peripheral tissue compartment term allows recovery of known rates of drug infusion into the body, while the former methods lead to incorrect estimates. These facts lend significant support to the presently conceived model. Since such calculations are essential to the basic understanding of drug absorption, their correct interpretation is not unimportant, particularly since *in vivo–in vitro* relationships have been drawn up on the basis of these types of analyses (37, 38).

Influence of the Two-Compartmental Open-System Model on Calculations of Volume of Distribution—A detailed discussion of the calculations of the volume of distribution (V_d) as it is affected by the concept of a two-compartmental open-system model has been presented by Riggs (39). The volume of distribution of a compound can only be defined when the tissue compartment is in equilibrium with the central compartment (*i.e.*, when $dT/dt = 0$) at least insofar as this model is concerned.[2] The volume of distribution is merely one of the kinetic constants of the model being tested. Within the experimental error, the same value should be obtained from the various methods of estimation. The V_d's calculated by the several biased methods

[2] This is not mathematically the unambiguous definition for the steady state of equilibrium (27), but applies in the model since it is assumed that no drug loss takes place from the tissue compartment.

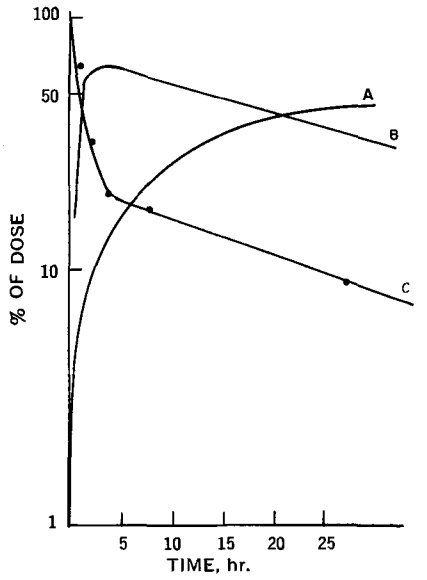


Fig. 3—Percent of dose estimated to be in the central compartment, tissue compartment, and eliminated after a 750-mg. i.v. injection of thiopentobarbital into a male (13). Key: A, amount eliminated; B, tissue compartment; C, central compartment.

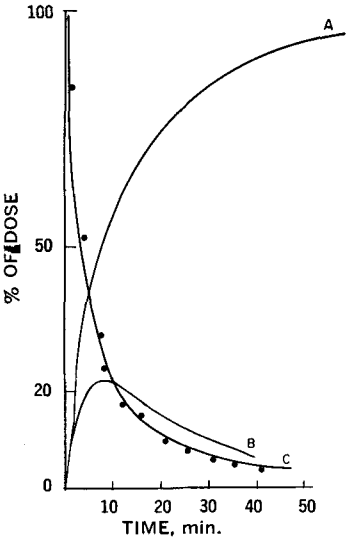

Fig. 4—Percent of dose estimated to be in the central compartment, tissue compartment, and eliminated after a 650-mg. i.v. injection of acetylsalicylic acid into a male (14). Key: A, amount eliminated; B, tissue compartment; C, central compartment.

vary considerably, when sufficient data points are taken, which they should not do if the single-compartmental model held. However, calculation of the volume constant defined by the two-compartmental open-system model presented above appears to yield a constant value independent of the method of calculation (40).

Influence of Two-Compartmental Open-System Model on Estimation of Metabolism and Excretion Rate Constants—It is clear from Eqs. 12 and 13

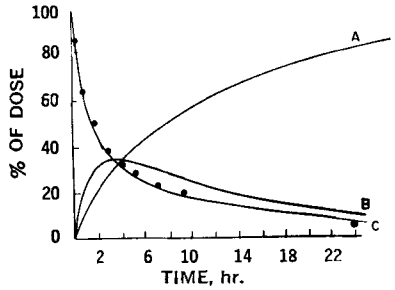

Fig. 5—Percent of dose estimated to be in the central compartment, tissue compartment, and eliminated after a 142-mg. i.v. injection of griseofulvin into a male (15). Key: A, *amount eliminated;* B, *tissue compartment;* C, *central compartment.*

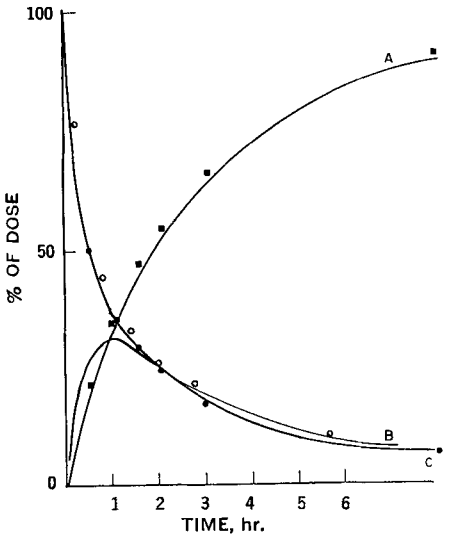

Fig. 6—Percent of dose estimated to be in the central compartment, tissue compartment, and eliminated after a 25.8-Gm. i.v. injection of mannitol into a male. Also included is a curve representing the normalized urinary excretion data (21). Data from subject: R = 3. *Curves drawn with two-compartment analog computer program. Points represent appropriate blood and urine data. Key:* A, *amount eliminated;* B, *tissue compartment;* C, *central compartment.*

that α and β are hybrid rate constants, each influenced by all of the rate constants of the system. One must be warned, therefore, that with such a multiple exponential equation, one has no right to identify a particular term with a particular process. The elimination rate constant for the process is denoted as k_{el} in the two-compartmental open-system model given above. It is incorrect to designate β, the slower rate constant of the bi-exponential, as the elimination rate constant as is the usual practice in pharmacokinetics. However, some descriptive term should be available to refer to this hybrid constant. Therefore, the term "*disposition* rate constant[3]" is proposed, attempting thereby to imply that it includes both distribution and elimination.

In order to illustrate the relation between the true elimination rate constant, k_{el} and β, Eq. 14 may be rearranged as follows:

$$k_{el} = C_p^\circ/(A/\alpha + B/\beta) \qquad \text{(Eq. 18)}$$

However, A/α is often negligible relative to the magnitude of B/β. Equation 18 may be reduced to the following approximation:

$$k_{el} \approx \left(\frac{C_p^\circ}{B}\right)\beta \qquad \text{(Eq. 19)}$$

The ratio C_p°/B varies from one drug to another, but often ranges from 1.5–2.5. However, compounds which distribute out of the central compartment into the peripheral compartment(s) to a large degree will show a much higher proportionality constant. For example, from the published data on intravenous injection of radioactive digitoxin (41), it can be estimated that k_{el} is at least 15 to 40 times larger than the slowest disposition rate constant.[4] Most amine drugs are known to distribute to a large extent into the tissues. This will result in a high ratio of C_p°/B, and therefore, the true elimination constant may be many times larger than the value of the slowest disposition rate constant. In some pharmacokinetic evaluations, this error may play a minor role, such as when one is attempting to evaluate dosage form effects. However, when urinary data are being analyzed, it is common to presume that the slowest disposition rate constant is identical with the true elimination rate constant and that the metabolic rate constant is equal to the disposition rate constant times the fraction of the drug metabolized. Such assumptions result in a large error.

When a pharmacologically related and structurally similar series of compounds are being studied, it is exceedingly important to attempt to evaluate the true elimination rate constant. Introduction of one organic substituent into a molecule may cause a significant change in the tissue distribution, as well as in the metabolism and excretion processes. It is important to discriminate among these factors to a greater extent than we have done to date if we are to better understand how substituents are influencing distribution, metabolism, and excretion characteristics.

Not only does the two-compartmental open-system model become important in the analysis of absorption, metabolism, and excretion of drug, it also markedly influences the analysis of turnover rate of normal body constituents, such as ascorbic acid (42), glucose (43), iron (44), and other compounds. The turnover rate cannot be defined by injecting a known dose and estimating the decline to the homeostatic level, presuming the drug is distributing into a single compartment. It is clear that such an analysis is based on a questionable postulate, since most of these drugs have been shown (45, 46) to require multicompartmental models to define their disposition and elimination from the body.

Relationships of Two-Compartmental Model to Consideration of Drug Interaction in Man—In recent years, it has become apparent that drug

[3] The term *dispose* is taken from the French, meaning to place apart.

[4] In this instance, a tri-exponential was observed by the author (41).

administered during or immediately before asecond compound is taken may influence the pharmacological activity of the second drug. Several different mechanisms have been proposed for these drug interactions. In one instance, the first drug is said to induce changes in the level of metabolizing enzymes. When the second drug is administered, it undergoes a more rapid rate of metabolism. A second form of drug interaction has been postulated for some drugs when given concurrently where the first drug partially displaces the second drug from protein binding sites, thereby allowing for a change in drug distribution. In other instances, the second drug may cause an increase in the excretion rate or may reduce the rate of absorption. It should be apparent that the two (or multiple) compartmental open-system model is a much more meaningful model to examine the relative effect of drug *A* on drug *B*.

In Vivo Determination of Certain Aralkylamines

By WINTHROP E. LANGE, JOSEPH M. THEODORE*, and FREDERICK J. PRUYN†

A micro-method has been developed by which blood concentrations of certain aralkylamines can be quantitatively determined. The method makes use of thin-layer chromatography and fluorometry. Quantitative determinations are made by measuring the fluorescence exhibited by the rose bengal complex of the drug. The method utilizes 0.1-ml. samples of capillary blood from which 0.05 mcg. of drug has been detected.

IN RECENT YEARS a pharmaceutical need has arisen for newer and more sophisticated analytical methods. This need has been brought about by the continuous development of potent therapeutic agents, the *in vivo* distribution and the metabolic fate of which have not been completely determined. Chlorpheniramine maleate, dextromethorphan hydrobromide, phenylephrine hydrochloride, and phenylpropanolamine hydrochloride are representative of the aralkylamines that fall into the above category.

Many *in vitro* analysis methods have been reported for the quantitation of aralkylamines contained in pharmaceutical preparations. Gas chromatography has been successfully employed whereby various polyethylene glycols and silicone gum rubber have served as column coating material (1–4). The sensitivities attained, however, were not sufficient to permit the *in vivo* quantitation of the drugs.

Several paper and thin-layer chromatographic separation procedures have been recently reported to effect resolution of some aralkylamines. Cox *et al.* (5) studied 12 antihistamines. Schriftman and Shultz (6) reported a two-dimensional paper chromatographic separation procedure for a mixture of chlorpheniramine maleate, dextromethorphan hydrobromide, and phenylephrine hydrochloride. The developing media were butanol–acetic acid–water (5:1:3), and chloroform–ether (1:1).

With the advent of fluorometric techniques it was possible to quantitate lower concentrations of many compounds. It was shown by Duggan *et al.* (7) that phenylephrine fluoresces maximally at pH 1.

Brodie, Udenfriend *et al.* (8, 9) reported general methods for the estimation of basic compounds. The methods generally included extraction procedures for the isolation of the compounds from their metabolic products and from naturally occurring substances. They concluded that fluorometry was the method of choice whenever possible.

Cohen (10) found that nonfluorescent compounds, or those that were weakly fluorescent, could be converted to a highly fluorescent complex by treatment with rose bengal.

Little has been reported about the *in vivo* distribution and the excretion rate of many of the common aralkylamines. Brossi *et al.* (11) could not determine dextromethorphan blood levels. They did report, however, that from 2 to 16% of the drug was excreted in the urine.

Woods *et al.* reported that blood levels had been determined for the *levo* isomer of the drug, which had been administered to dogs and to monkeys. The isotopic technique showed the maximum concentration of the drug to be present in the plasma after 1 hr. (12).

Willner reported on the excretion of the metabolic products of dextromethorphan (13). He found the drug to be excreted both *per se* and as demethylated derivatives. These findings were made when a paper chromatographic separation procedure was used.

The excretion rate for phenylpropanolamine hydrochloride was studied by Heimlich *et al.* (14). They reported that about 90% of an orally administered 50-mg. dose of the drug was excreted, according to first-order kinetics, within 24 hr.

Excretion rates for chlorpheniramine and phenylephrine were studied by Cavallito *et al.* (15). An isotopic procedure, which required 15-ml. samples of blood or of urine, showed the excretion rates to vary widely among individuals. No apparent relationship was found to exist between the blood level and the excretion rate of tritiated phenylephrine.

Although the information cited above is extremely valuable, it is clear that there has been no general method for the quantitative, *in vivo* determination of the aralkylamines. This paper

provides a practical means for performing such analyses both rapidly and accurately.

EXPERIMENTAL

Reagents and Chemicals

The reagents and chemicals used were: acetone, spectroanalyzed, Fisher certified reagent; chloroform, Fisher certified reagent; ethyl alcohol USP; ethyl ether USP; methanol, Fisher certified reagent; ammonium hydroxide solution USP; and ethyl acetate, Mallinckrodt. Dragendorff's reagent and 0.2% aqueous ninhydrin solution were used as indicators. Rose bengal, Fisher certified reagent, was used and was purified by extraction with ethyl acetate and chloroform by the method described by Cohen (10). Chlorpheniramine maleate, chlorpheniramine free base, dextromethorphan hydrobromide, dextromethorphan free base, phenylephrine hydrochloride, and phenylpropanolamine hydrochloride were supplied by Chesebrough-Pond's, Inc.

Apparatus

The thin-layer chromatographic plates used were prepared by coating 20 cm. square glass plates with 0.5 mm. of a Silica Gel G slurry, which was prepared by mixing 1 part by weight of Silica Gel G, Brinkmann Instruments, Inc., with 2 parts by volume of distilled water. The developing chambers and the appropriate micropipets were purchased from the Fisher Scientific Co. The instrument used was a Turner fluorometer, model 110. The instrument was equipped with a 520–560 mμ green lamp, Turner No. 110-854; primary excitation filters No. 1-60 (546 mμ) and No. 58 (525 mμ); and a No. 23-A (570 mμ) secondary emission filter. The 12 × 75 mm. cells used were carefully matched and were selected for low fluorescence.

Methods

Thin-Layer Chromatographic Separation of the Aralkylamines—A thin-layer chromatographic plate, which had been stored in a desiccator, was activated for 20 min. at 110°. A 25-μl. volume of a standard ethanolic solution, containing 25 mcg., 25 mcg., and 75 mcg. of chlorpheniramine maleate, dextromethorphan hydrobromide, and phenylephrine hydrochloride, respectively, was applied to the plate 3 cm. from the lower right corner. The solvent was allowed to evaporate spontaneously at room temperature.

The chromatogram was then developed in an ammoniacal methanol system, which was attained by placing a 50-ml. beaker, containing ammonium hydroxide solution, in a corner of the developing chamber 0.5 hr. before the insertion of the plate. The chromatogram was developed for 1.5 hr., during which time the front moved a distance of 15 cm. The chromatogram was air-dried for 1 hr. at room temperature, rotated clockwise through 90°, and developed in an ammoniacal chloroform–ether (1:1) system for 1.25 hr. The front moved a distance of 15 cm.

The two-dimensional chromatogram was air-dried at room temperature, sprayed with 0.2% aqueous ninhydrin solution, and heated for 15 min. at 110°. The appearance of a purple spot indicated the presence and the location of phenylephrine hydrochloride. After cooling to room temperature, the chromatogram was sprayed with Dragendorff's reagent. The immediate appearance of 2 reddish orange spots indicated the presence and the location of chlorpheniramine maleate and of dextromethorphan hydrobromide.

The resolution of a mixture of chlorpheniramine maleate, phenylephrine hydrochloride, and phenylpropanolamine hydrochloride was effected by the above procedure also. The phenylpropanolamine hydrochloride was detected by the ninhydrin reagent.

Quantitative In Vivo Determination of Chlorpheniramine Maleate—Two 0.1-ml. samples of whole capillary blood were collected from the fingertips of the subjects. The samples were collected with a sterile microlance and a serological pipet after the fingertips had been cleansed with alcohol. One sample was used as a blank and the other as a control, which was prepared by adding 0.05 mcg. of chlorpheniramine maleate to the 0.1-ml. blood sample. One 4-mg. chlorpheniramine maleate tablet[1] was then administered orally to each subject. Capillary blood samples were collected 1, 2, 3, 4, and 5 hr. after the administration of the drug.

All samples, including those to be used as blanks and as controls, were precipitated with 50 μl. of 10% aqueous trichloroacetic acid solution, mixed well with a small glass rod, and centrifuged until the supernatant liquid was clear. The supernatant liquids were applied to 0.5-mm. Silica Gel G chromatographic plates with a 100-μl. micropipet. The plates had previously been activated as has been described above. The chromatograms were developed in ammoniacal chloroform–ether (1:1) for 1 hr. and air dried at room temperature. The outermost columns of the chromatograms, to which had previously been applied 25 mcg. of chlorpheniramine maleate, were sprayed with Dragendorff's reagent to determine the exact R_f value of the drug. The areas of the chromatogram containing the drug were scraped from the plate, care being taken to insure the removal of equal areas. The samples thus removed were transferred to 18 × 150 mm. Pyrex test tubes. To each tube was added 2 ml. of ethanol. The tubes were shaken for 15 min. on a Burrell wrist action shaker. The contents of each tube were filtered through Whatman No. 1 filter paper, the filtrates being collected in 2-in. evaporating dishes. The tubes were rinsed with 2 ml. of ethanol and the rinsings passed through the appropriate filters, which were rinsed with 1 ml. of ethanol. To each filtrate was added 50 μl. of ammonium hydroxide solution.

The filtrates were evaporated to dryness on a steam bath. To each dish was added 1 ml. of an acetone–chloroform (1:1) solution containing 0.05 mcg. of rose bengal. Each sample was diluted with 3 ml. of acetone–chloroform (1:1). The contents of each dish were mixed by gentle swirling and transferred to fluorometric cells. Fluorometric analyses of the samples were carried out using the previously described filter system.

Tenth milliliter urine samples were also analyzed by the same procedure except that the urine samples were chromatographed directly.

Quantitative In Vivo Determination of Dextro-

[1] Chlortrimeton, Schering Corp.

TABLE I—R_f VALUES DETERMINED FOR CERTAIN ARALKYLAMINES[a]

Drug	Solvent A[b]	Solvent B[c]
Chlorpheniramine maleate	0.68	0.43
Dextromethorphan hydrobromide	0.51	0.53
Phenylephrine hydrochloride	0.43	0.00
Phenylpropanolamine hydrochloride	0.64	0.10

[a] All plates were coated with 0.5 mm. of Silica Gel G. [b] Ammoniacal methanol. [c] Ammoniacal chloroform–ether (1:1).

methorphan Hydrobromide—The preceding procedure for the determination of blood and of urine concentrations of chlorpheniramine maleate was used with the following exceptions. A 10-ml. dose of a dextromethorphan hydrobromide syrup,[2] containing 15 mg. of the drug in each 5 ml., was administered orally. Acetone was used to extract the drug from the Silica Gel G. Each sample was treated with 0.75 mcg. of rose bengal, and a 1% transmission filter was incorporated into the system.

In Vivo Determination of Phenylephrine Hydrochloride—The preceding procedure for the determination of blood and of urine concentrations of chlorpheniramine maleate was used with the following exceptions. A 5-ml. dose of a phenylephrine hydrochloride elixir,[3] containing 5 mg. of the drug in each 5 ml., was administered orally. Each sample was treated with 0.15 mcg. of rose bengal and 25 µl. of ethanol was added to each sample cell. The chromatogram was developed in ammoniacal methanol and 0.2% aqueous ninhydrin solution was used to indicate the R_f value of the drug.

RESULTS AND DISCUSSION

The two-dimensional thin-layer chromatographic separation procedure effected excellent resolution of the drugs. Table I shows the R_f values that were determined for each drug. It was noted that the ammoniacal chloroform–ether (1:1) solvent medium should be prepared freshly and that no more than two chromatograms be developed in such a system. The ammoniacal methanol solvent medium gave satisfactory results for up to five chromatograms.

The samples for fluorometric analysis were prepared in an acetone–chloroform (1:1) solvent medium. It was found that the acetone gave rise to an approximate tenfold fluorescence potentiation, which attained a maximum after about 20 min. Figure 1 shows the fluorescence exhibited by various concentrations of chlorpheniramine free base when complexed with rose bengal. The graph shows that accurate measurements could be made in the submicrogram concentration range.

The *in vivo* determinations were carried out using six normal males, from 23 to 34 years of age. All subjects were in a semifasting condition as only liquid nourishment was allowed during the 8 hr. preceding, and throughout the duration of, the test. All subjects had been deprived of drugs of any kind for the 72 hr. preceding the test.

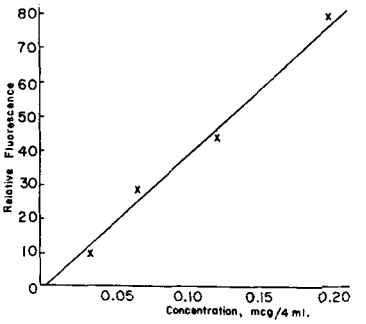

Fig. 1—Fluorescence-concentration relationship of chlorpheniramine free base when complexed with rose bengal.

TABLE II—CHLORPHENIRAMINE MALEATE BLOOD LEVELS OBTAINED FROM ORAL ADMINISTRATION OF THE DRUG[a]

Subject	(mg. % × 10²) 1 hr.	2 hr.	3 hr.	4 hr.	5 hr.
A	0.97	1.47	3.30	2.30	1.10
B	1.87	1.77	2.80	2.20	1.40
C	1.30	1.60	1.10	0.94	...
D	2.30	2.30	2.60	2.30	1.80
E	2.50	2.90	2.50	1.70	1.40
F	1.50	1.50	2.10	...	1.30

[a] Chlortrimeton, 4 mg., Schering Corp.

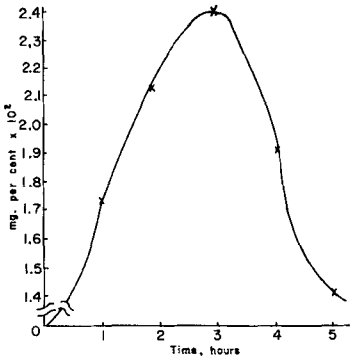

Fig. 2—Mean blood level distribution of chlorpheniramine maleate after oral ingestion of a 4-mg. dose.

The results of the analyses showed chlorpheniramine maleate to exhibit a definite absorption pattern. The maximum blood level appeared within 3 hr. after the oral administration of the drug and was followed by a rapid decline thereafter. Table II shows the chlorpheniramine maleate blood concentrations, in milligrams percent, that were determined from the subjects that were studied. Figure 2 shows the mean blood level distribution of chlorpheniramine maleate. The analysis of the urine showed that approximately 17% of the orally administered drug had been excreted unchanged within 6 hr.

A comparison of the blood concentrations that were produced from a 15-mg. and from a 30-mg. oral dose of dextromethorphan hydrobromide was made. Analyses were carried out 1, 2.5, 4.5, and 6 hr. after the ingestion of the drug. It was found that approximately 10, 25, and 16% of the orally admin-

istered 30-mg. dose was in the blood stream after 1, 2.5, and 6 hr., respectively. The 1 and the 2.5 hr. blood concentrations produced by the 15-mg. oral dose were insignificantly different from the respective concentrations produced by the 30-mg. dose, but the 4.5 and the 6 hr. concentrations were substantially lower. Approximately 8% of the orally administered drug was excreted unchanged within 6 hr.

The presence of phenylephrine hydrochloride was detected in human blood but statistical quantitative determinations have not as yet been carried out.

The *in vitro* applications of the fluorometric analysis procedure to other aralkylamines has been studied. Phenindamine required 3 times its weight of rose bengal to give the optimum degree of fluorescence. The dye–drug weight ratios were 25:1, 10:1, 1:1, and 0.5:1, respectively, for dextroamphetamine, phenylpropanolamine, phenyltoloxamine, and thonzylamine.

It should be noted that only the amine free bases respond to the fluorometric analysis procedure, thus it is necessary that the salts be converted to the free bases before analyses are carried out.

It was determined that a 99% recovery of the drugs from Silica Gel G had been effected. The recovery from blood and from urine was also nearly quantitative. The use of blanks and of controls, which were prepared from the subject's blood or urine, increased the accuracy of the procedure in that any inherent fluorescence would become nulled.

It is felt that this method can be applied to other aralkylamines and, since it has been shown that resolution of drug mixtures can be effected, that simultaneous determinations can possibly be carried out.

Concept of a Volume of Distribution and Possible Errors in Evaluation of This Parameter

By S. RIEGELMAN, J. LOO, and M. ROWLAND

To be pharmacokinetically correct, an estimate of the volume of distribution must establish a volume of a fictitious single compartment at a steady state of equilibrium and therefore independent of the role of metabolism and excretion. It has been shown previously that it is mathematically and physiologically more correct to conceive the body as exhibiting the properties of at least a two-compartmental rather than a single-compartmental model, which necessitates careful definition of the instant in time when the steady state (ss) of equilibrium exists. A mathematical relationship between the volume of distribution at steady state and those estimated by often used but incorrect methods is presented. Experimental data on acetylsalicylate, salicylate, griseofulvin, and several barbiturates are presented. The pharmacokinetic significance of these data is discussed.

THE VOLUME of distribution is not only an essential parameter in pharmacokinetic calculations, but is also a useful concept in physiology. However, examination of the literature in both fields clearly indicates a misunderstanding of the essential criteria which must be met when calculating this constant. Since the volume of distribution is a parameter of a particular model used to describe the distribution of a drug in the body, its physiological meaning is limited by the model. Nonetheless, it is a constant so that if the model is to be consistent its value must be independent of the method of measurement. In an earlier paper of this series (1), a detailed discussion was presented of the mathematical, physiological, and pharmacokinetic basis for representing the body as a mammillary model consisting of a central compartment with at least one peripheral compartment. Most of the presently published pharmacokinetic evaluations of drug absorption and elimination rates have been based on the supposition that the body need only be considered as a single compartment in assessing these constants. Little or no effort has been expended to evaluate the error involved in these measurements based on this presumption of a single-compartment model.

The purpose of this paper is to present some mathematical interrelationships of the various methods of calculation of the volume of distribution. A two-compartmental open-system model will be used to calculate the volume of distribution, Vd_{ss}, which exists at a steady state of equilibrium between these two compartments. The relationships between this Vd_{ss} and that obtained by various biased[1] methods of measurement will be derived. Data will be presented which allow one to predict the apparent Vd[2] obtained by one of the biased methods of calculating this constant and to assess its relative error.

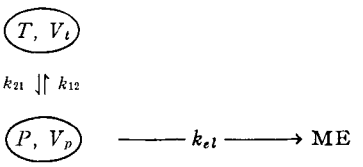
Presented to the Basic Pharmaceutics Section, APhA Academy of Pharmaceutical Sciences, Las Vegas meeting, April 1967.

DISCUSSION

Definition of the Two-Compartmental Open-System Model—The two-compartmental open system model may be represented as follows:



where T = the amount of drug in the peripheral (tissue) compartment at any time, t,

P = the amount of the drug in the central compartment at time, t,

ME = the amount of the drug eliminated by all processes of metabolism and excretion, assumed to take place exclusively in the central compartment, up to time, t.

V_p, V_t = the volumes of central and tissue compartments, respectively.

Where

$$Vd_{ss} = V_t + V_p$$

and

k_{12}, k_{21} = first-order rate constants of distribution,

k_{ei} = the sum of the simultaneous processes of metabolism and excretion all assumed to be first order.

Widmark and Tandberg (2), Teorell (3), and Dominguez (4) recognized that from the kinetic point of view the so-called central compart-

[1] It will be shown subsequently that these estimates are biased in that they are dependent upon the elimination rate constant and distribution constants.

[2] We shall arbitrarily define Vd as the so-called constant value arrived at when estimated assuming the single-compartmental model applies. All other volumes of distribution, analyzed on the basis of the two-compartmental model, will be specified with a subscript referring to the method of their calculation.

ment includes, in addition to the plasma volume, that portion of the intercellular fluids and tissues which appear to spontaneously come into equilibrium with the blood. Riegelman *et al.* (1) pointed out that the peripheral compartment may well represent the muscle, skin, and a portion of the fat depot. However, both of these volumes are kinetic parameters of the model, varying with the partition and binding characteristics of the compounds, so that it serves no useful purpose in attempting to attach any physiological meaning to the values obtained. Such a two-compartmental open-system model, as defined in the distribution and elimination scheme illustrated above, results in the following bi-exponential equation:

$$C_p = Ae^{-\alpha t} + Be^{-\beta t} \qquad \text{(Eq. 1)}$$

where C_p = concentration of drug in plasma
α and β = hybrid rate constants dependent on all three specific rate constants of the model (see under *Appendix*).
$C_p^0 = A + B$
V_p = volume of central compartment

and

$$V_p = \text{dose}/C_p^0 \qquad \text{(Eq. 2)}$$

When sufficient time has passed such that the first term in the bi-exponential $Ae^{-\alpha}$ becomes vanishingly small, Eq. 1 reduces to a mono-exponential, which according to the single-compartmental model[3] becomes:

$$C_p = Be^{-\beta t} \qquad \text{(Eq. 3)}$$

Upon integration between zero and infinity, we arrive at the area under the curve, whereupon Eq. 1 becomes:

$$\text{area} = \int_0^\infty C_p dt = A/\alpha + B/\beta \qquad \text{(Eq. 4)}$$

and Eq. 3 becomes:

$$\text{area} = B/\beta \qquad \text{(Eq. 5)}$$

Essential Criteria in the Definition of a Volume of Distribution—Riggs (5) has presented an excellent analysis of the volume of distribution concept and some of the biased methods of calculating this parameter. He emphasizes that essential to its basic definition is the concept of an equilibrium state. The volume of distribution of a given compound in the whole body, with reference to its equilibrium concentration, $(C_p)_{eq.}$, in the plasma, is given by

$$Vd_{ss} = (Q_{tot.})_{eq.}/(C_p)_{eq.} \qquad \text{(Eq. 6)}$$

where $(Q_{tot.})_{eq.}$ = the quantity distributed throughout the entire system at equilibrium.

In the two-compartmental open-system model several difficulties in the evaluation of Vd_{ss} are immediately apparent. Simultaneous to the distribution of the drug into the second compartment is the consecutive loss by metabolism and excretion. This results in a steady state of equilibrium of the drug between the two compartments, central and peripheral, occurring at only one instant following an i.v. injection, *i.e.*, when the rate of change of drug in the peripheral compartment is zero ($dT/dt = 0$).

Riggs (5) has shown that the volume of distribution, Vd_{ss} can be estimated from the rate constants into and out of the central and peripheral compartments,

$$Vd_{ss} = \frac{k_{12} + k_{21}}{k_{21}} V_p \qquad \text{(Eq. 7)}$$

The necessity for this definition lies in the fact that it is impossible to sample the (fictitious) peripheral compartment and, therefore, the drug is conceived to be distributed in a volume referred to the concentration in the plasma at equilibrium (see Eq. 6).

Extrapolation Method—When the single-compartment concept is applied to the calculation of Vd, the mono-exponential portion of Eq. 1 is extrapolated to the y-intercept, and the result is:

$$B = \text{dose}/Vd \qquad \text{(Eq. 8)}$$

or

$$Vd = \text{dose}/B \qquad \text{(Eq. 9)}$$

However, by the two-compartmental model, the extrapolated value B is given by:

$$B = \frac{\text{dose}\ (k_{21} - \beta)}{V_p(\alpha - \beta)} \qquad \text{(Eq. 10)}$$

so that

$$Vd_{\text{extrap.}} = \text{dose}/B = V_p(\alpha - \beta)/(k_{21} - \beta) \qquad \text{(Eq. 11)}$$

It will be shown under the *Appendix* that Eq. 11 can be expressed in terms of the specific rate constants as follows:

$$Vd_{\text{extrap.}} = \frac{2\ V_p \cdot Z}{k_{21} - k_{12} - k_{el} + Z} \qquad \text{(Eq. 12)}$$

where $Z = [(k_{12} + k_{el} - k_{21})^2 + 4k_{12} \cdot k_{21}]^{1/2}$.

Area or Clearance Method—According to the single-compartment model, a second method of calculating Vd is by application of the area equation (Eq. 5) which upon substitution into Eq. 8 results in:

$$Vd = \text{dose}/\beta \cdot \text{area} \qquad \text{(Eq. 13)}$$

The same volume is obtained from urinary clearance studies as the following will show. If the processes of excretion and metabolism are presumed to obey first-order kinetics with constants k_e and k_m, respectively, and:

$$k_m + k_e = \beta \qquad \text{(Eq. 14)}$$

or

$$f \cdot \beta = k_e \qquad \text{(Eq. 15)}$$

where $f = k_e/(k_e + k_m)$.

The amount of the dose excreted intact from zero time until the drug is entirely eliminated is:

$$f \cdot \text{dose} = k_e \cdot Vd\ C_p dt \qquad \text{(Eq. 16)}$$

Substituting for k_e from Eq. 15, rearranging, and cancelling we arrive at Eq. 13.

With the two-compartmental model, the Vd_{area} can be estimated by the following equation, which is derived under *Appendix:*

$$Vd_{\text{area}} = Vd_{ss} + \frac{k_{el} - \beta}{k_{21}} V_p \qquad \text{(Eq. 17)}$$

[3] Many authors use the symbol K instead of β for the first-order rate constant of Eq. 3.

Zero-Order Infusion Method—Occasionally a drug is administered by constant infusion. If this is continued for a sufficient length of time, the drug becomes equilibrated in the body fluids.

Correcting for the drug eliminated during the infusion process, an estimate of the volume of distribution can be obtained. Since drug is lost by metabolism and excretion during the infusion process, the amount of drug remaining in the body ($D_{corr.}$) can be estimated by the ratio of the area under the blood curve from zero to the end of the infusion, divided by the total area, or:

$$Vd = \text{dose}/(C_p)_{eq.}\left[1 - \frac{\int_0^t C_p dt}{\int_0^\infty C_p dt}\right] = \text{dose}_{(corr.)}/C_{p_{eq.}} \quad \text{(Eq. 18)}$$

where $C_{p_{eq.}}$ = the plasma concentration at equilibrium.

This volume of distribution can be estimated from the two-compartmental model, resulting in

$$Vd_{inf.}^0 = Vd_{ss} + k_{el}/k_{21}\ (V_p) \quad \text{(Eq. 19)}$$

A comparison can now be made of the methods of estimation using the different proposed compartmental models. One cannot be satisfied simply by obtaining a constant value for the volume of distribution, since it is obvious that by insufficient sampling in the early period, the experimenter would miss the distributive phase and only obtain a monoexponential. Under this situation all the methods of estimation would arrive at the same incorrect value. What is important, however, is to attempt to describe the error which would be involved in these estimates, using data which result in well-defined bi-exponential equations.

EXPERIMENTAL PROCEDURE

The *N*-methylglucamine salt of acetylsalicylic acid (ASA) and of salicylic acid (SA) was prepared by mixing equimolar amounts of the base and acid. The solution was bacteriologically filtered and injected into the antecubital vein by rapid i.v. injection (over 5–10 sec.) or by constant infusion over a 1-hr. period with a Harvard infusion pump. Griseofulvin was formulated into a parenteral solution by dissolving the drug in sterilized polyethylene glycol 300. The solution was not injected directly into the test subject, but by diluting it into a rapidly flowing normal saline solution, which was being administered intravenously over a 3–6-min. period. The griseofulvin was also infused at a constant rate over a 2-hr. period of time. The exact details of preparation will be given in a subsequent paper where each system will be discussed at length.

RESULTS AND DISCUSSION

Table I lists the calculated and predicted values of the various volumes of distribution after an i.v. injection of ASA to three males. All three subjects showed large differences between the various estimates. However, the resultant predicted values of $Vd_{extrap.}$, Vd_{area}, and $Vd_{inf.}^0$ are in excellent agreement with the observed biased estimates. Stated another way, these biased estimates would result in a constant value for Vd_{ss}. It is immediately seen that the $Vd_{extrap.}$ always produces the largest error and in this instance has a value which is approximately twice that of Vd_{ss}. If the single-compartmental model is assumed, these estimates of Vd would be identical and equal to $Vd_{extrap.}$, *i.e.*,

$$Vd = D/B = D/\beta \text{ area} = D_{corr.}/C_{p_{eq.}} = Vd_{extrap.} \quad \text{(Eq. 20)}$$

and had insufficient data points been taken so as to miss the distribution phase, it therefore follows that the error will be as great as that of the $Vd_{extrap.}$ estimate.

Table II includes the data obtained after injection of various doses of SA into the same three test subjects. In this instance, the values obtained from the biased methods are almost identical with the Vd_{ss}. One might presume, therefore, that the single-compartmental model is adequate to represent the fate of this drug in the body. However, when ASA is administered intravenously as indicated in Table I, the rapid metabolic transformation of ASA to SA results in the accumulation of SA in the body. Analog computer simulation of these data was studied using the two-compartmental system for the

TABLE I—VOLUME OF DISTRIBUTION ESTIMATES AFTER i.v. INJECTION OF ASA IN MAN

Subject[a]	Biased Vd's: D/B	$D/\beta \cdot$ Area	$D_{(corr.)}/C_{p_{eq.}}$	V_p
1	19,700	13,800	...	6500
2	17,600	14,100	...	6900
3	21,000	13,900	15,700	5650
	Predicted Values: $Vd_{extrap.}$	Vd_{area}	$Vd_{inf.}^0$	Vd_{ss}
1	19,800	13,800	...	10,400
2	17,300	14,000	...	11,700
3	21,000	13,800	16,400	10,100

[a] The appropriate constants from which the calculations were made are listed below in running sequence for subjects *1–3*, respectively. Dose = 650, 650, 325, 1240 mg. (inf.); A = 67, 56, 42 mcg./ml.; α = 0.23, 0.314, 0.257 min.$^{-1}$; B = 33, 37, 15.5 mcg./ml.; β = 0.0495, 0.0506, 0.0478 min.$^{-1}$; area = 956, 920, 487 mcg./ml. × min.; k_{el} = 0.105, 0.110, 0.117 min.$^{-1}$; k_{12} = 0.067, 0.105, 0.0825 min.$^{-1}$; k_{21} = 0.109, 0.157, 0.104 min.$^{-1}$.

TABLE II—VOLUME OF DISTRIBUTION ESTIMATES[a] AFTER i.v. INJECTION OF SA IN MAN

Subject[b]	Biased Vd's: D/B	$D/\beta \cdot$ Area	V_p
1	10,400	10,200	5700
2	9,680	9,650	5900
3	8,800	8,700	5300
	Predicted Values: $Vd_{extrap.}$	Vd_{area}	Vd_{ss}
1	10,400	10,350	10,200
2	9,680	9,650	9,620
3	8,750	8,590	8,500

[a] These volume estimates are valid for the doses used since it is known that the metabolism and excretion characteristic of SA varies with dose. [b] The appropriate constants from which calculations were made are listed in a running sequence for subjects *1–3*, respectively. Dose = 508, 484, 508 mg.; A = 40, 32, 38 mcg./ml.; α = 0.140, 0.216, 0.173 min.$^{-1}$; B = 49, 50, 58 mcg./ml.; β = 0.0032, 0.0026, 0.0027 min.$^{-1}$; area = 15,500, 19,400, 21,600 mcg./ml. × min.; k_{el} = 0.0058, 0.0040, 0.0044 min.$^{-1}$; k_{12} = 0.061, 0.085, 0.064 min.$^{-1}$; k_{21} = 0.078, 0.133, 0.1055 min.$^{-1}$.

TABLE III—VOLUME OF DISTRIBUTION ESTIMATES AFTER i.v. INJECTION OF GRISEOFULVIN IN MAN

Subject[a]	Biased Vd's		
	D/B	$D/\beta \cdot$Area	V_p
1	129,000	120,000	62,000
2	138,000	117,800	56,000
3	145,000	118,000	60,000
	Predicted Values		
	$Vd_{extrap.}$	Vd_{area}	Vd_{ss}
1	129,000	120,100	112,000
2	142,000	118,600	104,000
3	146,000	121,700	103,000

[a] The appropriate constants from which the calculations were made are listed below in a running sequence for subjects *1–3*, respectively. Dose = 142.128, 90 mg.; A = 1.2, 1.35, 0.90 mcg./ml.; α = 0.60, 0.63, 0.41 hr.$^{-1}$; B = 1.1, 0.93, 0.62 mcg./ml.; β = 0.0445, 0.075, 0.063 hr.$^{-1}$; area = 26.0, 14.5, 12.1 mcg./ml. × hr.; k_{el} = 0.0850, 0.157, 0.126 hr.$^{-1}$; k_{12} = 0.25, 0.284, 0.145 hr.$^{-1}$; k_{21} = 0.31, 0.243, 0.200 hr.$^{-1}$.

ASA disposition and both the one-compartmental and the two-compartmental constants for the SA disposition. It was immediately apparent that for each subject, the single-compartmental disposition of SA did not fit the data and underestimated the values of the SA in the earlier time periods (6). In contrast, when both the ASA and SA were conceived to be distributing into two compartments, an excellent fit was obtained. This is once again a strong indication that the two-compartmental model is essential to the treatment of the disposition of SA as well as ASA, particularly if one wishes to estimate the absorption rate constants.

It might appear from the data on salicylates that the results obtained with ASA were unique to this compound due to its very fast metabolism and that drugs with slower elimination rates may be adequately analyzed for their volume of distribution by one of the biased methods. However, the data given in Table III for the i.v. studies on griseofulvin, in which the values of $0.693/\beta$ were from 9.5 to 17 hr., do not support this postulate. The biased estimates result in significant variation with the various methods of calculation on all three subjects. Further, the relatively large error in the biased estimates when compared with Vd_{ss} indicate that all three rate constants defining the distribution and elimination processes interact in affecting the biased estimates. A 2-hr. zero-order infusion was performed on one subject; however, this was not long enough to result in equilibration between the compartments (which would have required continuous infusion for at least 4 hr.).

In reviewing the four equations by which the volume of distribution can be estimated, it can be seen that the Vd_{ss} defined by Eq. 7 is the only one which is not influenced by the elimination processes. The $Vd_{inf.}{}^0$ is defined by Eq. 19 and includes k_{el}. This is equally true of $Vd_{extrap.}$ defined by Eq. 12, and Vd_{area} as defined by Eq. 17. Since the drug itself or a second drug may induce changes in the metabolic rate, it seems illogical to accept a definition of a volume of distribution which is dependent on metabolic changes. Indeed, the same can be said for the excretion rate, which can be affected by concomitant administration of other drugs.

The foregoing discussion leads to a number of important points. All the biased estimates $Vd_{extrap.}$, Vd_{area}, and $Vd_{inf.}{}^0$ will result in overestimation of the value of Vd_{ss} and will only approach this latter value when the elimination rate constant, k_{el}, becomes small in respect to k_{12} and k_{21}. This is readily seen by making k_{el} zero in each relevant equation. However, the $Vd_{extrap.}$ will always result in the biggest error. This can produce erroneous results and therefore misleading conclusions. An example is seen in the case of ASA and SA. From the $Vd_{extrap.}$ values, one might deduce that the volume of distribution of ASA was approximately twice that of SA. Comparison of their Vd_{ss} values, however, show them to be quite similar, which would seem more plausible as they have similar physical chemical properties.

In 1953 Brodie and co-workers administered pentobarbital and thiopentobarbital by rapid intravenous injection into test subjects (7). The data were taken from the excellent figures found in the reference and the constants of the bi-exponential equations were estimated by the usual procedures. The following were the results: thiopentobarbital (dose = 750 mg.)—$C_p = 10e^{-1.15t} + 2.6e^{-0.03t}$; V_p = 60,500 ml.; Vd_{ss} = 270,000 ml. Pentobarbital (dose = 1000 mg.)—$C_p = 8.5e^{-1.4t} + 7.6e^{-0.017t}$; V_p = 62,000 ml.; Vd_{ss} = 130,000 ml.

Many studies of thiopentobarbital have indicated that a more complex distribution model is required for an understanding of period of sleep induced by the drug relative to its distribution and metabolism (8, 9). It appears from the data of Brodie *et al.*, however, that not more than a two-compartmental model is necessary to fit the available data, and if one were attempting to estimate the true absorption rate of the drug or assess its true elimination rate constant, that this model may be adequate. It is interesting to note the similarity of the estimated volume of the central compartment for the two drugs, approximately 61,000 ml., and the large difference in the estimated volume of the tissue compartment(s)—68,000 ml. with pentobarbital and over 210,000 ml. with thiopentobarbital. These estimates are compatible with the suggestion that the latter drug enters the muscle, skin, and fat depots of the body to a higher degree than does pentobarbital. While these data have been obtained for only two compounds within a test series, these results appear to indicate that much more definitive information could be obtained from careful application of the two-compartmental model.

Most of the earlier pharmacokinetic studies have utilized one of the biased methods of analyzing for the volume of distribution. Dost and co-workers (10), Krueger-Thiemer (11), Gladtke (12), and other European workers (13) have utilized the extrapolation procedure to estimate the volume of distribution and in effect have assumed a single-compartmental model. The area or clearance method has been used by Wagner and co-workers (14), by Levy (15), and by many other American workers in our field. In many of these studies, the authors also estimated the metabolism and excretion rate constants, by assuming that the apparent elimination rate constant was equal to k_{el}, the true elimination rate constant. However, one can assess the error involved in making this assumption. If one presumes that sufficient blood samples are taken after an i.v. dose to define the so-called distribution phase, the area under the concentration-time curve, can be expressed in two alternative fashions, namely:

$$\text{area} = \int_0^\infty C_p dt = \text{dose}/Vd_{ss}\cdot\beta = \text{dose}/V_p\cdot k_{el} \qquad \text{(Eq. 21)}$$

Cancelling common terms, we arrive at the following:

$$\beta = V_p/Vd_{\text{area}}\cdot k_{el} \qquad \text{(Eq. 22)}$$

Therefore estimates of the metabolism and excretion rates, based on the fraction excreted intact, and presuming Eq. 14 applies, will be seriously in error. From examination of the volume ratios for the drug discussed above, it can be seen that the true elimination rate constants will be from twofold to fivefold larger than the apparent elimination rate constant, β. These discrepancies are due to the fact that β is a hybrid rate constant, for which we propose the alternative designation, *disposition* rate constant to indicate that it is dependent on the distribution rate constants k_{12} and k_{21}, as well as the elimination rate constant, k_{el}. It seems essential, therefore, that due caution be taken in making these estimates of metabolism and excretion rate constants, for mathematically according to the multicompartmental models, β can never exactly equal k_{el}.

There are some pharmacokinetic situations in which it is not important to define the volume of distribution in accordance with the two-compartmental model in order to correctly make the desired mathematical analysis of the data. It is to be noted that the denominators in Eq. 21—$Vd_{\text{area}}\cdot\beta$ or $V_p\cdot k_{el}$—must be equal and both represent the total clearance value for the drug from the body[4] by all processes of metabolism and excretion. The units of clearance are volume per unit time (ml./min.). Wagner proposed a method of estimating the mean equilibrium concentration, $\bar{C}_{p_{\text{eq.}}}$, of a drug in the blood given without interruption over a sufficient time period with a constant dosing interval of $\Delta t = t_2 - t_1$. This method in effect utilizes the relationship defined in Eq. 21, which includes these equivalent clearance terms. He assumed that a constant fraction of the administered dose (F) would be absorbed during each administration, and that at equilibrium the area under the concentration–time curve for the dosing interval would become equal to the total area under the curve from a single dose:

$$\text{area}\Big|_0^\infty = \text{area}\Big|_{t_1}^{t_2} = \frac{F\cdot D}{\text{clearance}} = C_{p_{\text{eq.}}}\cdot\Delta t \qquad \text{(Eq. 23)}$$

Since clearance is merely the ratio of the dose divided by the area (expressed in proper units), the calculation of $C_{p_{\text{eq.}}}$ becomes independent of the model. A valid estimate of the mean equilibrium concentration can be made from an analysis of a single dose as long as the other assumptions apply.

SUMMARY

A calculated volume of distribution is only one parameter of a model describing the fate of a drug in the body. However, calculations of that volume can lead to some evidence of the deficiencies of the single-compartmental model for the drug at hand. Nevertheless, even if the calculations of the V_d for the single-compartmental model result in a constant value, this in itself is not adequate information as to the validity of the model and additional tests must be met.

[4] The term body clearance is used in the analogous context to urinary clearance and represents the ml. of plasma cleared from the drug by all metabolic and excretion processes per unit time.

APPENDIX

Definition of $Vd_{\text{extrap.}}$ from the Two-Compartmental Model—On the basis of the two-compartmental open-system model as defined in this paper, the constants of the resultant bi-exponential equation can be defined as follows:

$$C_p = \frac{D(k_{21}-\alpha)}{V_p(\beta-\alpha)}e^{-\alpha t} + \frac{D}{V_p}\frac{(k_{21}-\beta)}{(\alpha-\beta)}e^{-\beta t} \qquad \text{(Eq. 1}a\text{)}$$

where

$$\alpha = (b + \sqrt{b^2 - 4c})/2$$

$$\beta = (b + \sqrt{b^2 - 4c})/2$$

and

$$b = k_{12} + k_{21} + k_{el}$$

$$c = k_{21}\cdot k_{el}$$

After sufficient time the first exponential term vanishes and back extrapolation of the linear portion of the semilog plot to the y-intercept yields:

$$B = \frac{D}{V_p}\frac{(k_{21}-\beta)}{(\alpha-\beta)} \qquad \text{(Eq. 2}a\text{)}$$

On rearrangement one has:

$$Vd_{\text{extrap.}} = \frac{D}{B} = \frac{V_p(\alpha-\beta)}{k_{21}-\beta} \qquad \text{(Eq. 3}a\text{)}$$

which is identical to Eq. 11 in the text. However, it can be shown that:

$$\alpha - \beta = (b^2 - 4c)^{1/2} \qquad \text{(Eq. 4}a\text{)}$$

$$= [(k_{12} + k_{el} - k_{21})^2 + 4k_{21}\cdot k_{12}]^{1/2} = Z$$

and

$$k_{21} - \beta = {}^1/_2[k_{21} - k_{12} - k_{el} + (Z)] \qquad \text{(Eq. 5}a\text{)}$$

substitution from Eqs. 4a and 5a into Eq. 3a results in:

$$Vd_{\text{extrap.}} = \frac{2V_p(Z)}{k_{21} - k_{12} - k_{el} + (Z)} \qquad \text{(Eq. 6}a\text{)}$$

which is represented as Eq. 12 in the text.

Definition of Vd_{area} from the Two-Compartmental Model—After sufficient time after the i.v. dose, the bi-exponential curve reduces to a mono-exponential. Expressed in terms of mass of the drug in accordance with the single-compartmental model we have:

$$dP/dt = -\beta P \qquad \text{(Eq. 7}a\text{)}$$

However, according to the two-compartmental model throughout the total curve the following equation applies:

$$dP/dt = k_{21}T - (k_{12} + k_{el})P \qquad \text{(Eq. 8}a\text{)}$$

Substituting for the differential, dP/dt for Eq. 7a and dividing by P we have:

$$\beta = k_{12} + k_{el} - k_{21}\frac{T}{P} \qquad \text{(Eq. 9}a\text{)}$$

or on rearrangement:

$$\frac{T}{P} = \frac{(k_{12} + k_{el} - \beta)}{k_{21}} \quad \text{(Eq. 10a)}$$

The volume of distribution, Vd_{area} can be expressed as:

$$Vd_{area} = \frac{T + P}{P/V_p} = (1 + T/P)\ V_p \quad \text{(Eq. 11a)}$$

Substituting for T/P from Eq. 10a, we have:

$$Vd_{area} = 1 + \left(\frac{k_{12} + k_{el} - \beta}{k_{21}}\right) V_p \quad \text{(Eq. 12a)}$$

$$= \left(\frac{k_{21} + k_{12}}{k_{21}}\right) V_p + \left(\frac{k_{el} - \beta}{k_{21}}\right) V_p$$

and finally

$$Vd_{area} = Vd_{ss} + \left(\frac{k_{el} - \beta}{k_{21}}\right) V_p \quad \text{(Eq. 13a)}$$

which is Eq. 17 in the text.

Definition of $Vd_{inf.}^0$ from the Two-Compartmental Model—After a constant zero-order infusion is maintained for a sufficient length of time, an equilibrium is established. Then the rate in and the rate out are such that a constant concentration of drug is achieved in the central compartment and a $Vd_{inf.}^0$ can be calculated as follows:

$$dP/dt = k_{21}T - k_{el})P = 0 \quad \text{(Eq. 14a)}$$

$$k_{21}T = (k_{12} + k_{el})\ P \quad \text{(Eq. 15a)}$$

$$T/P = \frac{k_{12} + k_{el}}{k_{21}} \quad \text{(Eq. 16a)}$$

From Eq. 7 in the text, we have:

$$Vd_{inf.}^0 = \frac{(Q_{tot.})}{(C_p)_{eq.}} = \frac{P + T}{P/V_p} \quad \text{(Eq. 17a)}$$

$$Vd_{inf.}^0 = (1 + T/P)\ V_p \quad \text{(Eq. 18a)}$$

Substituting for T/P from Eq. 16a, we have:

$$Vd_{inf.}^0 = 1 + \left(\frac{k_{12} + k_{el}}{k_{21}}\right) V_p \quad \text{(Eq. 19a)}$$

which can be simplified according to the definition of Vd_{ss}:

$$Vd_{inf.}^0 = Vd_{ss} + \left(\frac{k_{el}}{k_{21}}\right) V_p \quad \text{(Eq. 20a)}$$

The latter is represented as Eq. 19 in the text.

Gas Chromatographic Determination of Ethanol in Pharmaceuticals

Comparison of Polyethylene Glycol 400 and Divinylbenzene Polymer Columns

By JOSEPH T. PIECHOCKI

Gas chromatography with a flame ionization detector was used with an official NF XII and a divinylbenzene polymer (DVBP) column to determine ethanol in pharmaceuticals. The DVBP column separated ethanol from methanol and gave results comparable to the polyethylene glycol 400 (PEG 400) column for various types of pharmaceuticals.

GAS CHROMATOGRAPHY has been used for the quantitative determination of alcohol in pharmaceuticals and other products for several years (1–5). Because of its numerous advantages, this method was investigated by the Pharmaceutical Manufacturers Association (6) and was adopted by the National Formulary (7). Elefant *et al.* (8) showed the advantages of the flame ionization detector over the thermal conductivity cell for the determination of ethanol.

Most earlier GLC methods for separating alcohols have utilized a polyethylene glycol column. Although this column was the most satisfactory of those available, ethanol could not be separated from methanol under the conditions suggested in NF XII (9). Another disadvantage is that the solvent peak elutes after the sample and internal standard peaks, unnecessarily prolonging the analysis time (8). The presence of water will affect the over-all sensitivity of the flame detector, although it does not give a response itself (10).

Recently a divinylbenzene polymer (DVBP) column[1] has been used for the separation of ethanol and chloroform in pharmaceuticals (11).

Hollis (12) introduced the use of porous polymer beads in gas chromatography. DVBP beads[2] more easily solved the problem of separating low molecular weight alcohols, acids, and glycols. Porous polymer beads have many advantages; they need no liquid phase, are hard and do not break during packing, require no pretreatment, have a large number of theoretical plates per unit volume, and condition in a relatively short time (approximately 1 hr.).

DVBP, unlike polyethylene glycol 400 (PEG 400),[3] does not retain water. When an aqueous solution is used, water will be eluted in the solvent peak or will be the first compound eluted from the DVBP column.

EXPERIMENTAL

Instrument—A Barber-Colman 5000 gas chromatograph equipped with a model 5062 oven, a flame ionization detector, and a 1-mv. recorder was used throughout this study.

PEG 400 Column—A 183 cm., 3-mm., U-shaped glass column was packed with 20% PEG 400 on 80/-100 mesh Anakrom ABS prepared by the slurry procedure (13), and conditioned at 125° for approximately 48 hr.

DVBP Column—A 120 cm., 3-mm., U-shaped glass column was packed with 80/100 mesh DVBP and conditioned at 235° for approximately 1 hr.

Operating Conditions—The column temperatures were 100° for PEG and 150° for DVBP. The temperatures of the detector and injector were 210° and 225°, respectively. The flow rates were nitrogen, 50 ml./min.; oxygen, 400 ml./min.; hydrogen, 50 ml./min. The voltage was 300 v., the sensitivity 100, the attenuation 5, and the AFS 1.0×10^{-9}.

Solutions—A standard alcohol solution was prepared according to the NF XII procedure (9), then diluted to approximately 2% (v/v). When necessary, samples were diluted with distilled water to approximately 2% alcohol (v/v). A 2% (v/v) solution of acetone in distilled water was used as an internal standard.

The final solution for injection was prepared by transferring 10.0 ml. of the diluted sample or stand-

DVBP column, 122 cm., 3 mm. i.d.; column temperature, 150°; injector temperature, 225°; flow rate, 50 ml. nitrogen 1 min.; flame ionization detector; detector temperature, 210°; sensitivity 1 × 10^{-9} AFS.

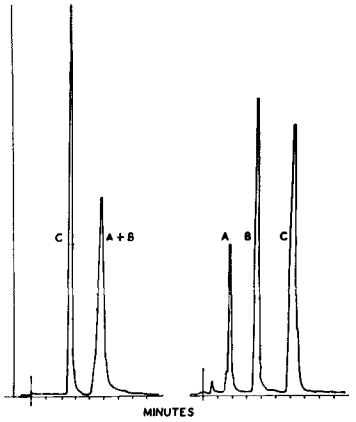

Fig. 2—Comparison of columns for gas chromatographic separation of alcohols. Key: A, methanol; B, ethanol; C, acetone. Left: PEG 400 column, 183 cm. ,3 mm. i.d.; column temperature, 100°. Right: DVBP column, 4 ft., 3 mm. i.d.; column temperature 150°. All other conditions identical: injector temperature, 225°; flow rate, 50 ml. nitrogen/min.; flame ionization detector; detector temperature, 210°; sensitivity 1 × 10^{-9} AFS.

ard alcohol solution and 10.0 ml. of the diluted acetone standard to a 100-ml. volumetric flask, diluting to volume with distilled water, and mixing.

If the sample contains acetone, two identical dilutions can be made, eliminating the internal standard from one solution and making the appropriate corrections, or another internal standard can be used.

Calculations—All calculations were made by using net integrator counts and the following formula:

$$\% \text{ alcohol} = \frac{\text{net sample counts}}{\text{net std. counts}} \times \frac{\text{net std. acetone counts}}{\text{net sample acetone counts}} \times \text{dilution factor} \times \text{concn. of std. (\%)}$$

RESULTS AND DISCUSSION

DVBP was used for about 6 months in this laboratory; no major difficulties were incurred and results are reproducible. However, solutions containing borates should not be injected into either column (14). Figure 1 shows that the three commonly used alcohols are completely separated on DVBP columns.

Retention times for ethanol and acetone were 4.0 and 6.0 min., respectively, on DVBP under the conditions stated in the experimental section (see Fig. 1).

If peak height is used as the method of quantitation, raising the column temperature to 200° will further reduce the retention time, with little loss in resolution. A complete chromatogram can then be obtained in approximately 4 min.

A comparison of the PEG 400 and DVBP is shown in Fig. 2. Methanol and ethanol are not separated on the PEG column with the conditions described in NF XII (9).

Varying amounts of the standard alcohol solution were injected onto the columns to determine the effect of injection size on response. Figure 3 shows a plot of the ratio of net alcohol counts to net acetone counts *versus* sample size. The DVBP column gave a higher net number of integrator counts/μl. of injected acetone than the PEG column.

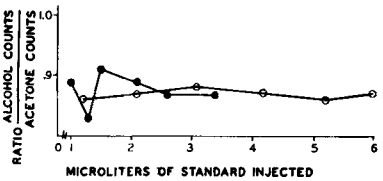

Fig. 3—Response ratio as a function of μl. injected: comparison of the two columns. Key: ○, DVBP; ●, PEG.

GLC direct on DVBP	13.8	13.7	13.7
Distillate on GLC	13.1	13.4	13.3

different types of pharmaceuticals on the DVBP column.

A synthetic mixture of elixir of phenobarbital USP was prepared and analyzed in duplicate on the DVBP column, by the distillation procedure (7), and by the immersion refractometer method (15). The results are shown in Table III. The amount of alcohol determined by refractometry on the distillate was in good agreement with the amount determined when the distillate was injected into the gas chromatograph.

CONCLUSIONS

Columns of DVBP (porous polymer beads) offer advantages for alcohol determinations, and give results as good as or better than the commonly used PEG 400 columns.

With a 150° column temperature, a sample can be injected every 7 min., resulting in 8 analyses/hr. By raising the column temperature to 200°, the time can be reduced to approximately 4 min. with little loss in resolution.

Quantitative Determination of Some Synthetic Antiparkinsonism Agents

By L. G. CHATTEN and W. J. RACZ

Nonaqueous titrimetry was employed to estimate quantitatively some of the compounds which are useful in treating Parkinsonism. The method was applied to both the crystalline material and their dosage forms. This technique was found to yield results which agreed well with those obtained by either the official procedures or by methods submitted by the manufacturer. Several solvent systems were employed for the analysis of the various compounds, but either chloroform alone or a phenol–chloroform mixture was found to be almost universally applicable. Indicators were found for all the medicinal agents investigated in both of the aforementioned major solvent systems. As an additional means of quantitative assay, the amine salts were precipitated as their tetraphenylborates and the resulting derivative was then determined quantitatively by nonaqueous titrimetry.

IN THE past decade, several synthetic anticholinergic compounds have been found to be useful in controlling the symptoms of Parkinsonism. These compounds are potent systemic pharmacological agents and, therefore, accurate methods of estimating both the crystalline materials and their dosage forms must be available.

A survey of the literature revealed a complete lack of methods for quantitatively determining some of these compounds. Furthermore, although procedures have been published for some of these organic medicinals, in general, they are long and tedious.

For biperiden hydrochloride, no method of quantitative estimation could be found in the literature. On the other hand, the "National Formulary" (1) describes a procedure for cycrimine hydrochloride tablets which is based upon the infrared absorbance of a chloroform solution. The major limitation of this procedure is the large number of extractions which must be performed to ensure complete removal of the drug. The pure drug is assayed by visual nonaqueous titrimetry in glacial acetic acid.

Chafetz (2) devised a method of quantitative estimation for phenyramidol hydrochloride which was based on periodate oxidation followed by ultraviolet spectrophotometric measurement of the resulting araldehyde.

The "British Pharmacopoeia" (3) presents a method for both pure procyclidine hydrochloride and the pharmaceutical dosage forms. It is based on extraction of the liberated base and its estimation by residual titrimetry, but the technique suffers from the same limitations as the NF method for cycrimine HCl tablets. Rogers (4) described an ultraviolet absorption method for procyclidine HCl which required special slit width adjustments, whereas Pellerin and coworkers (5) employed a technique which involved sodium lauryl sulfate as titrant. *Drug Standards* (6) contains a monograph which outlines a nonaqueous titrimetric procedure for the closely related compound, tricyclamol chloride. A mixed solvent system of chloroform and glacial acetic acid is utilized and the end point determined either potentiometrically or visually. The analysis of the capsules was carried out directly on the powdered substance. However, for tricyclamol chloride tablets, the active ingredient was extracted with methanol prior to estimation.

The "United States Pharmacopeia" (7) utilizes a nonaqueous titration in chloroform to assay pure trihexyphenidyl hydrochloride whereas the same compendium describes a colorimetric extraction procedure for the dosage forms. The BP (3) employs methods similar to those described in the USP (7). Kráčmar, Blazek, and Stejskal (8) devised a polarographic procedure for the quantitative estimation of trihexiphenidyl, and Bozsai and Vastogh utilized a similar technique (9). However, since this substance does not contain a functional group which can be readily oxidized or reduced under an applied potential, a suitable group must be introduced. This process may be lengthy and the reactions involved must be quantitative.

It is the purpose of this investigation to develop rapid and accurate analytical procedures which can be employed in routine quality control of these medicinal agents both as raw materials and in pharmaceutical dosage forms.

Received March 13, 1967, from the Faculty of Pharmacy, University of Alberta, Edmonton, Alberta, Canada.

Accepted for publication August 29, 1967.

W. J. Racz is indebted to the Canadian Foundation for the Advancement of Pharmacy and the National Research Council of Canada for financial assistance during the course of this investigation.

The organic medicinals and their dosage forms were generously supplied by the following pharmaceutical companies: Burroughs Wellcome & Co. (Canada) Ltd., procyclidine HCl and Kemadrin 5 mg. tablets); Eli Lilly and Co. (Canada) Ltd., cycrimine HCl, Pagitane 1.25 and 2.50 mg. tablets, tricyclamol chloride and Elorine 50 mg. capsules; Knoll Pharmaceutical Co., diperiden HCl and Akineton 2 mg. tablets; Mead Johnson Laboratories, Analexin 400 mg. capsules; Neisler Laboratories Ltd., phenyramidol HCl; Cyanamid of Canada Ltd., trihexyphenidyl HCl, Artane 2 and 5 mg. tablets.

EXPERIMENTAL

Apparatus

Metrohm Potentiograph model E.336 equipped with a glass-calomel electrode pair, Beckman Zeromatic II pH meter fitted with a glass-calomel electrode system, magnetic stirring apparatus, conventional laboratory glassware, sintered-glass funnels of medium porosity, sintered-glass crucibles of fine porosity, microburet graduated to 0.01 ml.

Reagents and Solutions

Acetone; chloroform; *N,N*-dimethylformamide; glacial acetic acid; phenol; sodium acetate; sodium tetraphenylboron; acetate buffer solution, pH 4.6; crystal violet T.S. USP; 0.1 *N* HCl; 0.05 *N* HCl; 2 *N* HCl; mercuric acetate T.S. USP; 0.5% methyl red in methanol; methyl red solution BP; 0.05 *N* perchloric acid in dioxane (standardized against primary standard potassium acid phthalate); 5% sodium tetraphenylboron solution in water (filtered through a sintered-glass funnel of medium porosity); thymol blue in *N,N*-dimethylformamide USP; 0.25% tropaeolin 00 in methanol.

All chemicals employed in this investigation were either A.C.S. or reagent grade quality.

The antiparkinsonism compounds and their commercial products studied in this investigation are as follows: biperiden HCl (2 mg.),[1] cycrimine HCl (2.5 and 1.25 mg.),[2] phenyramidol HCl (400 mg.),[3] procyclidine HCl (5 mg.),[4] tricyclamol chloride (50 mg.),[5] trihexyphenidyl HCl (5 and 2 mg.).[6]

Procedures for Crystalline Materials

The purity of trihexyphenidyl HCl was determined by the procedure of the USP (7). Procyclidine HCl was estimated by the BP (3) method and cycrimine HCl by the NF (1) procedure.

General Nonaqueous Procedure

Approximately 50 mg. of the material under investigation was accurately weighed into a 150-ml. beaker and dissolved in 50 ml. of the solvent of choice with the aid of magnetic stirring. Mercuric acetate T.S. (1.5 ml.) was then added and the titration followed potentiometrically using 0.05 *N* perchloric acid in dioxane as titrant.

Since official methods were not available for biperiden HCl, tricyclamol chloride, and phenyramidol HCl, the purity of these compounds was determined by the foregoing nonaqueous technique when glacial acetic acid was utilized as solvent system.

Modification 1—Chloroform was employed as the solvent for cycrimine HCl, procyclidine HCl, trihexyphendyl HCl, and tricyclamol chloride. In addition to the potentiometric determinations, visual titrations were also carried out using 3 drops of a saturated solution of methyl red in methanol as indicator. The end point was found to be purplish red in color.

Modification 2—A solvent system comprising equal parts of chloroform and *N,N*-dimethylformamide was employed for the same 4 substances mentioned under *Modification 1*. The end point was detected potentiometrically.

Modification 3—In this instance, the solvent system was similar to that employed by Chatten (10) for the titration of various nitrate and sulfate salts of organic bases. Methyl red was found to be the indicator of choice for biperiden HCl, whereas tropaeolin 00 in anhydrous methanol was employed for phenyramidol HCl. The end point for the latter was orange-brown in color.

For the general procedure as well as all modifications, a blank was performed on the solvent system. Where applicable, the appropriate indicator was included. Corrections were made of all titrant volumes.

Sodium Tetraphenylborate Procedure

This technique was a combination and a modification of the methods of Smith, Worrell, and Sinsheimer (11) and Chatten, Pernarowski, and Levi (12).

A sample (25 to 50 mg.) of the drug was accurately weighed into a 150-ml. beaker and 50 ml. of acetate buffer (pH 4.6) was added. The mixture was stirred magnetically until the drug had dissolved. An excess of the 5% solution of sodium tetraphenylboron was added and the mixture stirred for an additional 20 min. The precipitate was removed with the aid of suction filtration through a sintered-glass crucible of fine porosity. The beaker and the tetraphenylborate were washed with 200 ml. of water. Then the crucible and tetraphenylborate were dried for a period of not less than 18 hr. in a vacuum desiccator over phosphorus pentoxide. The magnetic stirring bar was washed with a small quantity of acetone, the acetone retained in the beaker, and the beaker also dried in a vacuum desiccator over calcium chloride.

Ten milliliters of acetone was added to the crucible containing the tetraphenylborate and the mixture was stirred to dissolve the compound. The solution was then filtered into the dried beaker in which the compound had been prepared. The crucible was washed with an additional 10 ml. of acetone and the filtrate collected in the beaker. Positive pressure was used to facilitate the filtration process. To the filtrate, 30 ml. of glacial acetic acid, 1.5 ml. of mercuric acetate T.S., and 1 drop of crystal violet T.S. were added and the mixture titrated to a blue end point (13) with perchloric acid in dioxane as titrant. A titration light was used to facilitate detection of the end point. A blank titration was performed on the solvent system.

All six antiparkinsonism agents were assayed by this method.

The tetraphenylborate of tricyclamol was prepared, purified, and the equivalent weight determined by the method of Chatten and Doan (13). The adduct was submitted for elemental analysis and the results were as follows: tricyclamol tetraphenylborate, m.p. 197–199°; purity by nonaqueous titrimetry, 99.5%.

Anal.—Calcd. for $C_{44}H_{52}BNO$: C, 84.93; H, 8.43; N, 2.25. Found: C, 84.78; H, 8.26; N, 2.11.

Procedures for Pharmaceutical Dosage Forms

All dosage forms were analyzed by pharmacopeial

[1] Trademarked as Akineton.
[2] Trademarked as Pagitane.
[3] Trademarked as Analexin.
[4] Trademarked as Kemadrin.
[5] Trademarked as Elorine.
[6] Trademarked as Artane.

procedures or by methods supplied by manufacturers, wherever this was possible.

Trihexyphenidyl HCl tablets, cycrimine HCl tablets, and procyclidine HCl tablets were assayed by the procedures of the USP (7), NF (1), and the BP (3), respectively.

Capsules of tricyclamol chloride and phenyramidol HCl were analyzed by methods provided by the respective manufacturers.

A published procedure was not available for the analysis of biperiden HCl tablets.

General Nonaqueous Procedure

A sample of the powdered tablet or capsule material was accurately weighed into a 150-ml. beaker and 25 ml. of chloroform was added. The mixture was stirred magnetically for 40 min. and the solution then filtered through a sintered-glass funnel of medium porosity. The beaker and funnel were washed with an additional 25 ml. of chloroform. A slight excess of mercuric acetate solution was added and the titration followed potentiometrically using perchloric acid in dioxane as titrant. The end point was also detected visually by employing methyl red as indicator. A blank titration was performed on the solvent system and the appropriate correction made.

This method was employed to analyze the dosage forms of the following compounds: cycrimine HCl, procyclidine HCl, and trihexyphenidyl HCl. Tricyclamol chloride capsules were also determined by the above procedure but the samples were not filtered prior to titration.

Tricyclamol chloride capsules were also titrated by a modification in which a 1:1 mixture of dimethylformamide–chloroform was used as solvent. The end point was detected potentiometrically.

Biperiden HCl tablets were assayed by another modification in which the solvent system was 2.5% phenol in chloroform. The same solvent system with a stirring time of 30 min. was employed for phenyramidol capsules. The end point was determined either potentiometrically or visually using tropaeolin 00 as indicator. The end point was found to be orange-brown in color. A blank was determined on the solvent system and capsule excipients prior to the addition of mercuric acetate.

Sodium Tetraphenylborate Method

The pharmaceutical dosage forms were also assayed by the tetraphenylborate method, with the introduction of certain modifications. The finely ground tablet or capsule material was accurately weighed into a 150-ml. beaker and about 2 ml. of acetate buffer was added. The powder was triturated with buffer solution until a smooth paste resulted. The remainder of the 50 ml. of buffer was added and the mixture stirred magnetically for 40 min., and the general procedure was followed beginning with the words "An excess of a 5% solution of sodium tetraphenylboron ...."

The commercial products of biperiden HCl, phenyramidol HCl, procyclidine HCl, tricyclamol chloride, and trihexyphenidyl HCl were determined by this method.

RESULTS AND DISCUSSION

Glacial acetic acid was chosen as the solvent system for determining the purity of those compounds for which no published or accepted procedures existed. It has been extensively used for the analysis of crystalline pharmaceutical substances (3, 7) because of its excellent solvent properties for organic medicinal agents. The potentiometric break obtained in glacial acetic acid was well-defined and thus the end point could be determined accurately. However, this solvent is not suitable for the nonaqueous titration of pharmaceutical dosage forms, because a large number of interfering excipients are soluble in it (14). As noted from Table I, the results obtained in this solvent are in excellent agreement with the theoretical values.

In order to select a suitable titration medium, the solubility of each compound was determined in a variety of solvents which could also be applied to the dosage forms. Trihexyphenidyl HCl, procyclidine HCl, cycrimine HCl, and tricyclamol chloride were found to be soluble in chloroform and 2-propanol. While compounds with the exception of tricyclamol chloride were readily soluble in chloroform, dissolution was slow in 2-propanol.

The potentiometric titration of trihexyphenidyl HCl was attempted in 2-propanol but the inflection point was not well-defined and hence the end point was difficult to determine. On the other hand, in chloroform, the potentiometric break was well-defined and the end point easily detected. Clair and Chatten (14) reported that very few tablet excipients interfere with nonaqueous titrations which are performed in chloroform and hence it was the solvent of choice for the aforementioned materials as it possessed many desirable attributes.

The four antiparkinsonism agents were also titrated in chloroform and the end point was detected with methyl red in anhydrous methanol. Thymol blue can also be utilized as an indicator for the titration of these substances and, in fact, is recommended by the USP (7) for the assay of trihexyphenidyl HCl. However, the former indicator was selected because its color change appeared to be more distinct than that of thymol blue.

In Fig. 1, curve A depicts the potentiometric curve for the titration of procyclidine HCl in chloroform, whereas curve B illustrates the titration of tricyclamol chloride in chloroform. The color changes of methyl red are illustrated on the same figure. Curve C shows the titration of procyclidine HCl in chloroform with thymol blue as indicator.

Tricyclamol chloride was found to be only slowly soluble in chloroform. Therefore, a more suitable solvent, *N,N*-dimethylformamide, was selected. In addition, this solvent was observed to possess excellent solubilizing properties for the hydrochlorides of trihexyphenidyl, cycrimine, procyclidine, and phenyramidol. However, titration of tricyclamol chloride in *N,N*-dimethylformamide resulted in a depressed and poorly defined end point. Investigation of mixed solvent systems resulted in a mixture of chloroform and *N,N*-dimethylformamide (1:1) which gave sharp end points and yet retained excellent solvent powers for the compounds previously mentioned. Unfortunately, a suitable indicator could not be found for the chloroform–*N,N*-dimethylformamide solvent system.

Phenyramidol HCl could not be titrated in *N,N*-dimethylformamide–chloroform as the potentio-

metric break was very poorly defined. In addition, biperiden HCl was found to possess a low solubility in chloroform and hence a combination of the two factors created the need for another solvent system for these two compounds. The present investigation showed that biperiden HCl and phenyramidol HCl were soluble in a system containing 2.5% phenol in chloroform and these substances were readily titratable in this solvent system. The weak acidity of the solvent system may enhance the weak basicity of phenyramidol HCl whereas *N,N*-dimethylformamide would have the opposite effect upon the antiparkinsonism agent.

Tropaeolin 00 in methanol was the indicator of choice for phenyramidol HCl in the phenol–chloroform system and Fig. 2, curve A depicts the titration curve together with the indicator changes. Methyl red can also be used and was, in fact, selected for biperiden HCl. Curve B illustrates the titration curve and indicator changes for that substance.

Tetraphenylborate Method

Sodium tetraphenylboron has been used for the characterization and determination of organic medicinal agents containing basic nitrogen functional groups. Smith, Worrell, and Sinsheimer (11) have titrated some sympathomimetic amines with sodium tetraphenylboron and detected the end point amperometrically.

In a previous report, Chatten and Doan (13) prepared in excellent yields the tetraphenylborates of the compounds under study in this project. It was of interest, therefore, to attempt to modify their procedure in order to obtain quantitative results.

An acidic pH in the range of 4 to 6 has been reported to be suitable for the preparation of the tetraphenylborates of organic bases (11). It was found that buffered solutions in the pH range of 4 to 5.6 gave reasonable analytical results, while in a more acid system, the tetraphenylborates of the substances in this investigation exhibited increased solubility. Hence, the acetate–acetic acid buffer pair (pH 4.6) was selected for solvent power and convenience

One disadvantage of the tetraphenylborate method is the difficulty encountered in removing the precipitate from the vessel in which it was prepared. To overcome this problem, the beaker was allowed to dry and the acetone solution of the tetraphenylborate filtered into it.

The end point of the titration was found to appear very slowly and false end points occurred prior to the stoichiometric end point. The addition of mercuric acetate T.S. to the tetraphenylborate solution allowed the stoichiometric end point to be reached in a shorter space of time because the premature end points were few and very short-lived.

Examination of Table I reveals the various nonaqueous methods which were developed in this

investigation for the hydrochlorides of trihexyphenidyl, procyclidine, and cycrimine gave excellent agreement with the official procedures. No official methods were available for biperiden HCl, phenyramidol HCl, and tricyclamol HCl. Because of their widespread utility, however, potentiometric titrations in glacial acetic acid were accepted as standards and all other techniques were compared to them. For reasons of solubility, which have been already explained, the hydrochlorides of biperiden and phenyramidol were titrated in a phenol–chloroform solvent system. The results obtained are in excellent agreement with those in glacial acetic acid. For tricyclamol chloride, all nonaqueous techniques gave virtually identical results. Although the results by the tetraphenylborate method were slightly lower in almost every instance than those obtained with all other techniques, the values were believed to be within experimental error between two methods. In general, the recoveries were considered to be acceptable.

The results obtained from the analysis of the pharmaceutical dosage forms are listed in Table II. No official or manufacturers' procedure was available for biperiden HCl tablets. In addition, quantitative recoveries could not be obtained for this preparation by the tetraphenylborate method.

The analysis of phenyramidol HCl capsules was carried out by four methods: (*a*) and (*b*) potentiometric and visual nonaqueous titration in the phenol–chloroform solvent system, (*c*) preparation and titration of the tetraphenylborate, and (*d*) the manufacturers' procedure. Excellent agreement was obtained by the four methods of assay applied to this dosage form.

For trihexyphenidyl HCl, the four methods of analysis gave very good agreement, as shown by Table II, for the 5-mg. tablet. Small but not significant anomalies occurred with the 2-mg. product. For both nonaqueous procedures, it was necessary to remove interfering excipients by filtration, prior to titration.

The results of the nonaqueous assays for tricyclamol chloride in chloroform were below those obtained by the manufacturers' method. This may be caused by the slow solubility of the drug in chloroform. The higher recoveries in a mixed solvent system of *N,N*-dimethylformamide–chloroform are probably due to the enhanced solubility of tricyclamol chloride in that system. The low recoveries obtained by the tetraphenylborate procedure may be attributed to the suggestion that the quaternary ammonium compound does not form tetraphenylborates as readily as the other substances do.

As noted from Table II, the results obtained by the nonaqueous methods for procyclidine HCl are in good agreement with the official procedure of the BP (3). Filtration of the chloroform solutions prior to carrying out the titrations was found to be necessary as undissolved excipients interfered with the end points. It is noted that the tetraphenylborate method yielded values which appear to be higher than those obtained by the official procedure. This discrepancy is probably due to excipient interference.

For cycrimine HCl the results with the nonaqueous procedures agreed well with the NF (1) method for the 2.5-mg. tablet. However, for the 1.25-mg. product, the results by the nonaqueous techniques were much too low. No satisfactory explanation can be offered for this anomaly, since increasing the extraction time did not increase the percent recovery.

The tetraphenylborate method could not be applied to cycrimine HCl tablets as the recoveries obtained were much above the theoretical values. It would appear that these tablets contain an excipient which is capable of reacting with sodium tetraphenylboron and this results in overestimation.

It is worthy of mention that analysis of procyclidine HCl 5 mg., trihexyphenidyl HCl 5 mg., and cycrimine HCl 2.5-mg. tablets was attempted in the *N,N*-dimethylformamide–chloroform mixture but gross overestimation occurred in all three instances. This would seem to indicate that a titratable excipient which is soluble in dimethylformamide but not in chloroform must be present in the tablet formulations.

SUMMARY

A nonaqueous method of analysis utilizing chloroform as solvent has been developed for four compounds and their dosage forms. The results obtained are in excellent agreement with those obtained by the official or manufacturers' methods, but the nonaqueous procedure is much more rapid.

Phenol–chloroform mixture was employed with good results as solvent for the analysis of two of the organic medicinal agents investigated.

N,N-Dimethylformamide–chloroform mixture was successfully utilized as a solvent system for the nonaqueous titration of four of the crystalline salts. However, the solvent could be applied only to one dosage form.

A method based on precipitation of the amine as the tetraphenylborate and then estimating the tetraphenylborate by nonaqueous titrimetry was developed. This procedure does not have as wide an application as does direct nonaqueous titrimetry, but good analytical data were obtained for five of the dosage forms. This method would appear to be susceptible to excipient interference.

Gas Chromatographic Determination of Trisulfapyrimidines in Tablets

By JOHN W. TURCZAN

A procedure for the quantitative determination of individual sulfapyrimidines in mixtures has been developed. Analyses of known mixtures show an accuracy of 1–2 percent. The method is based on acid hydrolysis of the trisulfapyrimidines to sulfanilic acid and their respective heterocyclic amines, followed by the separation and determination of the amines by gas chromatography.

THE SEPARATION and quantitative determination of the three sulfapyrimidines, which are frequently dispensed together, is a difficult problem. In the usual methods of analysis the aromatic primary amino group or the acidic hydrogen (1) is determined. These procedures are therefore not specific and cannot determine individual sulfapyrimidines in a multi-sulfapyrimidine mixture. A paper chromatographic procedure (2) has been developed which identifies and quantitates mixtures of sulfapyrimidines and other sulfonamides.

An alternative method proposed here is based on gas chromatography after an acid hydrolysis (3, 4) of the sulfapyrimidines to sulfanilic acid and their respective heterocyclic amines. A study was made to determine optimum conditions for the hydrolysis. The following procedure was then used to analyze known mixtures and commercial tablets.

EXPERIMENTAL

Apparatus—A Barber-Colman 5000 gas chromatograph with a hydrogen flame detector was used. The column, 6 ft. by 4 mm., was packed with 5% SE-30 and 5% Carbowax 20M on Chromosorb W (60–80 mesh; hexamethyldisilazane-treated). The column was conditioned overnight at 180° with a nitrogen flow of 140 ml./min. The operating conditions were: column temperature, 150°; flash heater temperature, 260°; cell temperature, 260°; carrier gas, prepurified nitrogen; flow rate of carrier gas (outlet), 120 ml./min.; pressure of hydrogen, 16 p.s.i.; air, 40 p.s.i.

The instrument was equipped with a 1-mv. recorder and all determinations were made with an electrometer setting of 300 and an attenuation of 2×; at this setting 1.2 mcg. of 2-amino pyrimidines will give a recorder response of about 70% of full-scale deflection.

Standard Solutions—*Internal Standard*—Four milligrams per milliliter, 2-amino-4,6-dimethylpyridine or 2-amino-4-methylpyridine in water. If procedure given below is to be used, take 5-ml. aliquot (yielding concentration of 0.2 mg./ml. when diluted) for standard and sample solution.

Standard Solution—A mixture containing 0.2 mg./ml. of 2-aminopyrimidine, 0.2 mg./ml. of 2-amino-4-methylpyrimidine, 0.2 mg./ml. of 2-amino-4,6-dimethylpyrimidine, and 0.2 mg./ml. of internal standard in water.

Procedure—*Preparation of Sample*—Weigh and finely powder not less than 20 trisulfapyrimidine tablets. Weigh accurately a portion of the powder equivalent to about 150 mg. of total sulfapyrimidines into a glass-stoppered 50-ml. centrifuge tube, add 4 ml. of concentrated sulfuric acid, stopper, mix, and place in an oven at 130° for 1.5 hr. Shake every 15 min. to insure complete contact of powder with hot acid. Cool by holding under running water and transfer quantitatively, using approximately 50 ml. of water, into a 100-ml. volumetric flask. Make alkaline to litmus by slowly adding approximately 8 ml. of 50% sodium hydroxide, maintaining solution at room temperature. Add 5.0 ml. (equivalent to 20 mg.) of internal standard and dilute to volume.

Chromatography and Calculations—Inject enough standard solution to insure 30–80% deflection (about 4–6 μl. if above procedure is followed). Measure the retention time (R.T.) of the standards from the solvent front to the apex of the peaks and calculate recorder response for each by multiplying retention time by the peak height (5–7). Using the recorder response for each standard and for the internal standard in the standard mixture, and their respective concentrations, determine the R value by Eq. 1. To obtain consistent results, try 3–4 preliminary injections. The R value should be constant within 3%; if it is not constant, make additional injections. When consistent responses are obtained, inject a sample to give approximately the same peak heights as the standard solution. Calculate the concentration of each sulfapyrimidine (using recorder responses) in its final solution by Eq. 2.

$$R = \frac{A_0 C_1}{A_1 C_0} \qquad \text{(Eq. 1)}$$

$$C_3 = \frac{A_3 C_2 A_1 C_0}{A_0 C_1 A_2} \qquad \text{(Eq. 2)}$$

where

A_0 = (R.T. × h) = recorder response for standard,
A_1 = recorder response of internal standard in standard mixture,
A_2 = recorder response of internal standard in sample mixture,
A_3 = recorder response of sample,
C_0 = concentration of standard,
C_1 = concentration of internal standard in standard mixture,
C_2 = concentration of internal standard in sample mixture,
C_3 = concentration of sulfapyrimidine in sample mixture.

Note: if the concentration of the internal standard in standard and sample is the same ($C_1 = C_2$), then Eq. 2 becomes:

TABLE I—KNOWN USP MIXTURE OF TRISULFAPYRIMIDINES

4	55.3	54.69	98.9	50.2	49.55	98.7	49.7	50.35	101.9
5	52.7	51.86	98.4	49.1	48.51	98.8	48.6	48.21	99.2

TABLE II—COMMERCIAL TABLET PREPARATION

	Sulfadiazine			Sulfamerazine			Sulfamethazine		
Sample	Declared, mg.	Found, mg.	Declared, %	Declared, mg.	Found, mg.	Declared, %	Declared, mg.	Found, mg.	Declared, %
1	167	165.0	98.8	167	166.5	99.7	167	165.3	99.0
2	161	159.1	98.8	161	164.1	101.9	161	163.4	101.5
3	167	168.8	101.1	167	170.1	102.2	Not present or declared		
4	163	159.9	98.1	163	165.1	101.3	163	165.4	101.5
5	167	163.3	97.8	167	165.2	98.2	167	165.5	99.1
6	161	158.3	98.3	161	161.8	100.5	161	158.6	98.5
7	163	158.4	97.2	163	160.7	98.6	Not present or declared		
8	167	161.8	96.9	167	165.0	98.8	167	166.3	99.6

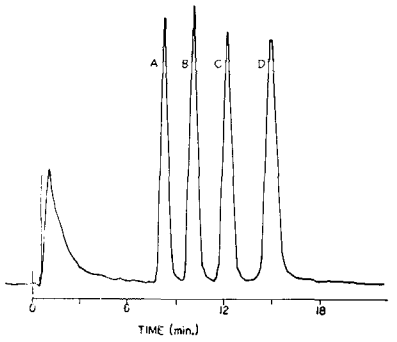

Fig. 1—Chromatogram of 3 sulfapyrimidines and internal standard mixtures. Key: A, 2-aminopyrimidine; B, 2-amino-4-methylpyrimidine; C, 2-amino-4,6-dimethylpyrimidine; and D, 2-amino-4,6-dimethylpyridine (internal standard); 1.2 mcg. of each injected.

$$C_3 = \frac{A_3 C_0 A_1}{A_0 A_2} \qquad \text{(Eq. 3)}$$

All calculations are made in terms of the final dilution. To calculate the concentration in the original sample, the sample size, the molecular weights, and the average weight per tablet must be taken into account; then Eq. 3 becomes:

$$C_3 = \frac{A_3 C_0 A_1}{A_0 A_2} \times \frac{\text{av. wt./tab.} \times \text{mol. wt. of sulfa drug}}{\text{wt. of spl.} \times \text{mol. wt. of hydrolysis product}}$$

$$= \text{mg. of sulfa drug/tablet} \qquad \text{(Eq. 4)}$$

DISCUSSION AND RESULTS

To determine the optimum conditions for hydrolysis, the experimental conditions were varied and completeness of hydrolysis was determined by UV spectrophotometry. The time of hydrolysis was kept at 1 hr. and the amount of sulfapyrimidine at 100 mg., while the concentration of hydrolyzing acid was varied from 20% to concentrated. Concentrated sulfuric acid (reagent grade) was found to be necessary for complete hydrolysis.

The time of hydrolysis was varied from 10 min.–180 min., while the amount of acid was kept constant at 2 ml. of concentrated sulfuric acid and the amount of sulfapyrimidine at 100 mg. The minimum time necessary for complete hydrolysis was found to be 1 hr.

An experiment in which the amount of sulfapyrimidine was varied from 50–220 mg., while the amount of concentrated acid was kept constant at 2 ml. and the time at 1 hr., demonstrated that no more than 190 mg. should be treated with 2 ml. of acid.

Individual 150-mg. portions of sulfadiazine, sulfamerazine, and sulfamethazine were hydrolyzed under the following conditions: 4 ml. of concentrated sulfuric acid, 90 min., at 130°. The resulting solutions were analyzed by both UV spectrophotometry and gas chromatography. Recoveries by gas chromatography correlate well with those by UV spectrophotometry. They ranged from 98.9–101.1% by UV and from 95.6–99.5% by GC for sulfadiazine; 98.1–101.5% by UV, and 97.8–99.1% by GC for sulfamerazine; 98.0–102.0% by UV, and 97.4–99.2% by GC for sulfamethazine.

Five synthetic mixtures containing equal parts of sulfadiazine, sulfamerazine, and sulfamethazine were analyzed by the proposed procedure (GLC) (Table I) with very good results. Analysis of eight commercial preparations (Table II) showed good agreement with declared values.

If the relative retention time (R.R.T.) of sulfadiazine, which yields 2 aminopyrimidine, is taken as 1.00, then the R.R.T. of sulfamerazine, which yields 2-amino-4-methylpyrimidine, is 1.24, that of sulfamethazine, which yields 2-amino-4,6-dimethylpyrimidine, is 1.52, and that of the internal standard, 2-amino-4,6-dimethylpyridine, is 1.89 (Fig. 1).

Determination of Terpin Hydrate in Elixirs Containing Codeine or Dextromethorphan Hydrobromide by Gas–Liquid Chromatography

By F. P. MAHN, V. VISWANATHAN, and B. Z. SENKOWSKI

A gas–liquid chromatographic procedure for the quantitative analysis of terpin hydrate was investigated. A Pyrex column packed with 10 percent Carbowax 20M terephthalic acid on Chromosorb W, hexamethyldisilane (HMDS) treated, was found to give satisfactory elution characteristics. Pharmaceutical preparations containing terpin hydrate, such as elixirs with dextromethorphan hydrobromide or codeine, were analyzed by the proposed procedure with recoveries of 100 ± 3 percent. The internal standard used was biphenyl. The effect of temperature on retention volume is reported.

THE CHEMICAL STRUCTURE of terpin hydrate indicated that the compound could lend itself to rapid and precise gas chromatography. A survey of the literature failed to disclose any previous studies utilizing this technique.[1] Procedures were reported by Platt and James (1) for the quantitative analysis of terpin hydrate using colorimetry. These authors treated phosphomolybdic acid with terpin hydrate under controlled conditions and measured the resulting color. Milos (2) reported on collaborative results which supported the adoption of the colorimetric determination. Vadodaria, Parikh, and Mukheyi (3) modified the colorimetric method of Platt and James and reported results with a precision of ±3%. These methods are time-consuming and involve the isolation of terpin hydrate in comparatively pure form by solvent extraction prior to actual analysis. Microscopic methods (4, 5) and refractometric methods (6) also were reported for the analysis or identification of terpin hydrate. However, the use of these techniques was limited primarily to qualitative identification.

Vapor-phase chromatography was investigated, and it was found that elution of terpin hydrate under isothermal conditions resulted in a symmetrical peak. The column selected for best results was 10% Carbowax 20M terephthalic acid on Chromosorb W, HMDS treated. Since analysis could be carried out directly on alcoholic dilutions of terpin hydrate preparations, errors due to excessive handling were minimized. The precision of the method therefore is dependent primarily upon the instrumental conditions and response. In order to compensate for column characteristics, instrumental variations, and sample introduction technique, an internal standard, biphenyl, was employed. Biphenyl is well suited for the experimental conditions in terms of detector linearity and retention time. Analyses were carried out on elixir terpin hydrate and elixir terpin hydrate with codeine or dextromethorphan hydrobromide NF.

Linearity of detector response with concentration, detection levels, interferences, and recovery data are presented.

EXPERIMENTAL

Operational Parameters—The instrument used for this work was a Varian Aerograph model 600 gas chromatograph equipped with a hydrogen flame ionization detector. The column used was a Pyrex coil, 5 ft. long and 3 mm. i.d., packed with 10% Carbowax 20M terephthalic acid on Chromosorb W, HMDS treated, 60/80 mesh. The temperatures were: column, 160°; injector port, 250° with a Pyrex insert; and detector, 160°. The flow rates were: carrier gas, nitrogen, 40 ml./min.; detector gas, hydrogen, 20 ml./min.; and air, 300 ml./min. All injections were made using a 10-μl. Hamilton syringe with the injection volume being approximately 2 μl. The instrument was operated at a range of 10 and attenuation of 64×, or equivalent, to result in at least a 50% response of the recorder scale. The recorder used was a 0–1 mv. Texas Instrument with a pen response of 0.4 sec. and a chart speed of 0.75 in./min. All peak areas were measured using a disk integrator. Under the conditions stated the relative retention time of terpin hydrate was 1.38 with respect to the internal standard, biphenyl, which has a specific retention time of approximately 4 min. (Fig. 1).

Standard Preparation—*Internal Standard*—Accurately weigh 50 mg. of biphenyl into a 25-ml. volumetric flask. Dissolve and dilute to volume with absolute ethanol. Mix well.

Reference Standard—Accurately weigh 85 mg. of terpin hydrate into a 25-ml. volumetric flask. Dissolve and dilute to volume with absolute ethanol. Mix well.

Working Standard (Prepare in Duplicate)—Into a small glass-stoppered flask, pipet 1 ml. of the bi-

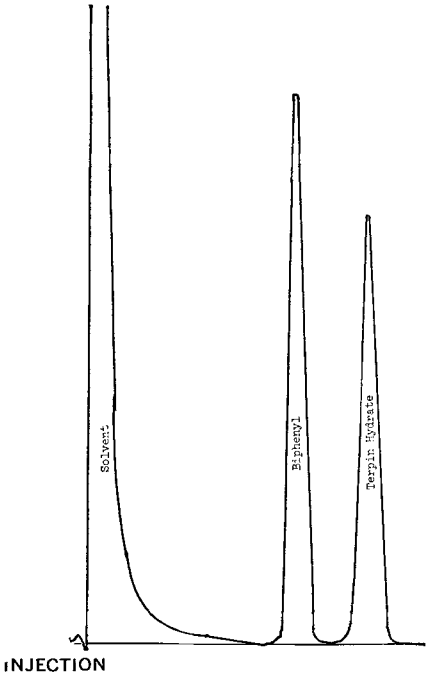

Fig. 1—Standard chromatogram.

phenyl standard solution and 1 ml. of the terpin hydrate standard solution. Stopper and mix thoroughly. Chromatograms were run and all peak areas were measured from the integrator pen trace.

Sample Preparation—Accurately pipet a 5-ml. aliquot of elixir terpin hydrate sample, equivalent to 85 mg. of terpin hydrate, into a 25-ml. volumetric flask. Dilute to volume with absolute ethanol and mix thoroughly.

Into a small glass-stoppered flask, pipet 1 ml. of the above prepared sample solution and 1 ml. of the biphenyl solution (internal standard solution). Stopper and mix the solutions thoroughly (working sample solution).

Chromatograph this mixture in duplicate as described in the above procedure. After the elution of the terpin hydrate, the chromatogram is allowed to run for an additional 10 min. to allow for the elution of glycerol, if present, which has an approximate retention time of 12 min. When the glycerol peak has been completely eluted, the column is ready for another run.

Calculations—Assay for terpin hydrate in the elixir.

mg. of terpin hydrate per 5 ml. of elixir =

$$\frac{Ths}{Bps} \times \frac{Bp}{Th} \times 85 \text{ mg.}$$

Ths = peak area of terpin hydrate in sample,
Bps = peak area of biphenyl in sample,
Bp = peak area of biphenyl in standard,
Th = peak area of terpin hydrate in standard,
85 = mg. of terpin hydrate.

RESULTS AND DISCUSSION

Although daily conditioning of the column was found to be unnecessary, it is not advisable to use the first run for quantitative information. This initial run should be used to determine instrument sensitivity and retention data.

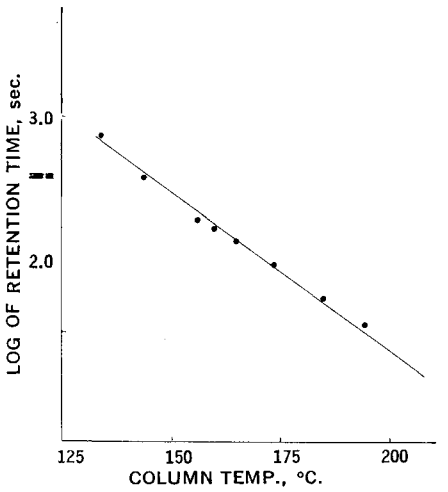

Fig. 2—Column temperature versus *retention time for terpin hydrate.*

As is well known, insufficiently loaded columns may cause tailing due to adsorptive effects which result from incomplete coverage of the support by the liquid phase. If adsorption occurs, quantitative work is considerably hampered. The column used in this study contained a high ratio of liquid phase to inert support in order to minimize any adsorptive effects.

An attempt was made to utilize standard copper tubing for the column, however, the erratic results obtained were indicative of possible decomposition due to catalytic effects. A Pyrex column therefore was used in all experiments.

The detector response for approximately 3.4 mcg. of terpin hydrate and 2.2 mcg. of biphenyl with the change in hydrogen flow rate, at constant air and carrier gas was obtained. The optimum flow ratio of hydrogen to carrier gas was 1:2.

The detector response with varying concentrations of terpin hydrate and biphenyl followed a linear relationship and the minimum measurable quantity was 5 nanograms.

The effect of column temperature on retention time was investigated and a linear relationship obtained (Fig. 2). The equation calculated by the method of least squares is $\log t_r = -0.014\ T_c + 4.7$, where t_r = retention time in seconds and T_c is the column temperature in °C. A plot of the log of the retention volume *versus* $1/T$, where T = absolute temperature, also yielded a linear relationship. The apparent ΔH_s was calculated from the equation $\log V_R = -\Delta H_s/2.3RT + C$ and found to be −12.4 Kcal./mole, where the slope of the resulting straight line was determined by the method of least squares.

A number of products containing terpin hydrate was assayed. The results and recovery data are presented in Table I. The precision is ±3%.

Under the conditions described, no interference in the analysis of the samples was encountered. Apparently dextromethorphan hydrobromide and codeine were not eluted, or were in too low a concentration to result in a measurable detector response. However, it should be pointed out that measurable interference due to glycerol will occur unless complete elution of this compound from the column is carried out prior to subsequent injections. The retention time of glycerol is approximately 12 min. Continued use of the column will result in the build-up of sugar which tends to skew the elution peaks and decrease the precision of the method. When this occurs, the column should be replaced.

SUMMARY

A gas–liquid chromatographic method for the determination of terpin hydrate in elixirs has been developed. The procedure involves diluting the sample with ethanol, adding an internal standard, biphenyl, and chromatography.

The precision of the developed method was ±3% and duplicate analyses can be completed within 1 hr.

Detection levels, interferences, and recovery data are presented.

Unit Tablet Assay of 17α-Ethynylestradiol-3-methyl Ether (Mestranol) by a Direct Colorimetric and an Automated Fluorometric Method

By J. P. COMER, P. HARTSAW, and C. E. STEVENSON

Unit tablet assays of 17α-ethynylestradiol-3-methyl ether (mestranol) were obtained with optimum precision and accuracy by direct dissolution of sample tablets and standardized reference tablets in sulfuric acid–methanol (70:30) reagent. An automated method which utilized basic automatic analyzer (AutoAnalyzer) components and a Turner fluorometer was more rapid but less precise than the direct method.

THE ASSAY of low dosage combination steroid tablets has been a challenge to several analysts. Gänshirt and Polderman (1) separated ethinyl estradiol from tablet excipients and decomposition products by thin-layer chromatography (TLC), and measured the color formed with sulfuric acid–water (80:20) with a relative standard deviation (RSD) of ±3.2%. Comer (2) mentioned the utility of the sulfuric acid–methanol (70:30) reagent for the determination

Received April 14, 1967, from the Analytical Development Department, Eli Lilly and Co., Indianapolis, IN 46206
Accepted for publication August 30, 1967.

of 17α-ethynylestradiol-3-methyl ether (mestranol) in combination with 6-chloro-6-dehydro-17-α-acetoxy progesterone (chlormadinone acetate). The reagent had been used for several years for routine control assays of mestranol.

Schultz (3) compared a gas chromatography (GC) method and a TLC method for mestranol in the presence of chlormadinone acetate. Recoveries of 96.4 and 98.2% with a 1.5-hr. assay time by GC and 95.5% with a 3–4 hr. assay time for TLC were reported on tablets containing 80 mcg. of mestranol. The mestranol, separated by TLC, was measured at 278 mμ. Boughton *et al.* (4) formed the trimethylsilyl ethers of ethinyl estradiol and 17-β-hydroxy-6-α-methyl-17-(1-propynyl]-androst-4-en-3-one and separated them by GC. An accuracy of 98% with RSD of ±8.6% was reported for 100-mcg. ethinyl estradiol tablets by the GC method.

Heusser (5) separated mestranol and chlormadinone acetate on Silica Gel G using ether–cyclohexane (8:2) as the solvent. After extraction of the silica gel the mestranol was determined colorimetrically with 1.5% titanium chloride in sulfuric acid solution. Using composite samples of 20 tablets containing 100 mcg. of mestranol, Heusser obtained an accuracy of 97.9% and a RSD of ±4.2% from 20 determinations. Tsilifonis and Chafetz (6) reported on a similar method for ethinyl estradiol. Cali and Khoury (7) then presented their studies on an automated method for ethinyl estradiol and mestranol. This paper presents a direct method and an automated method which offered advantages in economy, precision, and accuracy over previous methods for unit tablet assays.

EXPERIMENTAL

Direct Method—Many problems normally involved in the quantitative measurement of microgram amounts of tablet ingredients were simplified by the utilization of the properties of a simple tablet formulation of the two steroids with sodium bicarbonate. During the assay development, it was found that when unit tablets were ground prior to sampling, adsorption of mestranol to the grinding vessel became a significant error. Dissolution of the whole tablet in an aqueous solution and subsequent addition of the color reagent resulted in considerable retardation of color formation. The dissolution of the whole tablet directly in the color reagent was achieved. However, quantitation by the addition of mestranol standards dissolved in methanol to the color reagent proved unsuccessful due to a dilution of the color reagent and the change in the sulfuric acid–methanol concentrations. Color development of dry residue mestranol standards gave erratic results. Quantitation was obtained when a tablet of known concentration was dissolved under the same conditions as sample tablets.

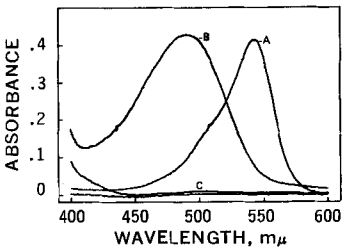

Fig. 1—Spectra in sulfuric acid–methanol (70:30) reagent. Key: A, *mestranol tablet at 5° for 2 hr.;* B, *chlormadinone acetate tablet at 25° for 2 hr.;* C, *chlormadinone acetate tablet at 5° for 2 hr.*

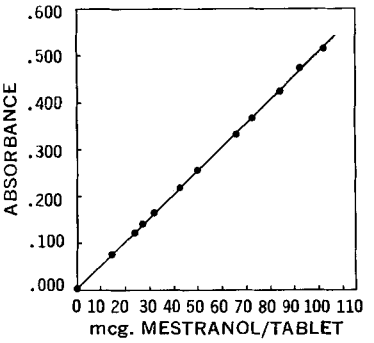

Fig. 2—Absorbance versus *concentration.*

The method thus evolved in which a weighed single tablet is placed into a 25-ml. conical flask containing 20 ml. of the sulfuric acid–methanol (70:30) color reagent which is situated in an ice bath equipped with a magnetic stirring assembly. The solution is stirred with a magnetic stirring bar, and the mestranol color developed simultaneously as the tablet dissolves. The absorbance of the clear solution containing the completely reacted tablet is then measured at 545 mμ *versus* a reagent blank in 5-mm. cells. The spectrum is shown in curve A of Fig. 1. When the color reaction is carried out in the presence of chlormadinone acetate, the mestranol color development process must be carried out at a reduced temperature or a positive interference occurs due to a reaction of chlormadinone acetate with the color reagent. Spectra B and C show the interference of chlormadinone acetate at 25° and 5°.

The linearity of the color reaction was determined by placing weighed portions of reference tablets into the color reagent. The tablets had previously been standardized in mcg. steroid/Gm. by a manual multiple chloroform extraction technique performed by several analysts on several days. The data in Fig. 2 illustrate the conformance to Beer's law. The RSD of the dozen replicates listed in Table I was 1.05% including tablet heterogeneity.

For routine control purposes, nine sample tablets and three reference tablets are run simultaneously in a special stirrer—ice bath apparatus illustrated in Fig. 3. The stirrers are a series of 12 small clock

motors with attached magnets. The motors are mounted on the bottom of an inverted aluminum cake pan. Nonmagnetic metal grids were placed in an upright pan to separate the flasks (8). The individual tablet weights and absorbance values are submitted to a computer and various parameters printed out. The data in Table II are a condensation of computer information from several of these nine tablet replicates on various lots of tablets fron export areas. These are expressed in terms of the RSD of mcg. of mestranol/Gm. tablet to remove variance of tablet weight. The comparison statistic is the assay value of a conventional extraction assay on a composite of 10 tablets. The direct method described yielded about six samples/hour/analyst counting reagent preparation and clean-up time and produced the optimum accuracy and precision over many other methods evaluated for unit tablet assay for control purposes.

Automated Method—An automated procedure was desired that would minimize variation and permit a greater number of unit tablet assays. Cali and Khoury (7) outlined an automated fluorometric assay using 90% sulfuric acid. Jakovljevic (9) had previously utilized the author's color reagent (70:30) for the fluorometric assay of mestranol in urine.

The excitation spectrum at an emission of 556 mμ and the emission spectrum at an excitation of 526 mμ for the automated sulfuric acid reagent for mestranol are shown in Fig. 4. This method utilizes basic automatic analyzer[1] components and a Turner model 111 fluorometer with a flow cell door conversion kit.[2]

The description below follows the flow diagram in Fig. 5. A weighed tablet is dropped into the blender of the Solid prep unit,[2] and 120 ml. diluent [H_2O–denatured alcohol (100 parts alcohol + 5 parts methanol) 85:15] are added. Dissolution of the tablet in the blender occurs, and an air segmented sample is withdrawn. The air is then debubbled at the A_2 glass fitting. An unsegmented portion of the sample stream is pumped to a 0.038 in. (0.965 mm.) i.d. Teflon mixing coil where it is segmented into a stream of ethylene dichloride. This coil was described by Kuzel (10). It consists of 36 loops of Teflon tubing wound around an empty chart paper roller. After leaving the first Teflon extraction coil, the aqueous portion is desegmented from the ethylene dichloride stream by pumping all of the aqueous phase along with a portion of the ethylene dichloride to waste from a C_2 glass fitting. The remainder of the ethylene dichloride is forced by difference into a 36 loop 0.053 in. (1.35 mm.) i.d. Teflon mixing coil where it is segmented into a stream of H_2SO_4. Upon leaving the second Teflon extraction coil, the ethylene dichloride is desegmented from the H_2SO_4 stream in a modified fluorometric flow cell and the fluorescence of the H_2SO_4 is measured in the Turner instrument. The shape of this flow cell is indicated in the flow diagram. The system operates at a rate of 20 determinations/hour.

Interferences—An interesting quality control problem was solved by a study of interference on the color reaction. A lot of tablets from a foreign production facility assayed low by the direct colorimetric method but assayed correctly by the manual extraction procedure. The actual raw material excipients used in the lot, or water up to 5%, in the tablets did not retard the color reaction. Sulfite, thiosulfate, phosphate, chloride, bicarbonate, and sodium ions alone in small amounts caused no problems. Exhaustive analyses of the tablets for many components showed no significant difference over normal tablets except for nitrate content. Normal tablet values were less than 1 p.p.m. nitrate, and the troublesome lot 6 p.p.m. Experiments were made to evaluate the effect of nitrate. Aliquots of $NaNO_3$ were evaporated along with solutions containing 80 mcg. of mestranol or ethinyl estradiol. Bicarbonate and color reagents were added and the color developed for 1 hr. The effect of nitrate on fluorescence on 1 mcg. of mestranol was studied in a similar manner excluding the bicarbonate. Fluorescence measurements were made on a model 110 Turner fluorophotometer using No. 58 Kodak Wratten and 1-60 Corning primary filter and a No. 22 Kodak Wratten secondary filter. Since the retardation of the reactions by nitrate was confirmed, the search for its source in the tablet was continued.

Nitrate was not observed in any of the tablet raw materials. The source of nitrate was found to be the glassine paper used in manufacturing at the foreign facility. Typical assays for nitrate for foreign glassine paper were 18–21 p.p.m. and for domestic glassine paper 0.1 p.p.m. The colorimetric nitrate assays (11) were confirmed by a

polarographic procedure (12). When the source of nitrate was removed, the assay results returned to normal values. Hydrogen peroxide and nitrites also inhibited color formation but these were not found in tablets. Related steroids such as estradiol methyl ether, estrone methyl ether, and estrone produced insignificant positive interference when added in amounts up to 500 mcg. per tablet.

RESULTS AND DISCUSSION

The direct colorimetric method for mestranol using a reference standard tablet has proved to be a very precise and accurate method for routine control (Table II) with a relative standard deviation often less than 1% including tablet heterogeneity but excluding tablet weight variance. The interference of chlormadinone acetate is insignificant if the temperature is held below 5°. The use of the special stirrer shown in Fig. 3 allowed a multiple assay at a rate of about six samples/hour/analyst.

The fluorescence of mestranol in sulfuric acid which is more sensitive than the color reaction was used as the means of measurement for automation. The interferences caused by nitrate by direct dissolution of the tablet led to the solvent extraction scheme as outlined in the flow diagram of the automated method. The relative fluorescence intensity was found to have a linear relationship to mestranol concentration as illustrated by the straight line connecting the peak heights in Fig. 6. The mestranol was added in solution in varying amounts to the sample cups. A run of 12 reference standard tablets, shown in Fig. 7, produced a RSD of 1.3% including tablet heterogeneity. These values are listed in Table I.

The retardation of the color and fluorescence reaction if nitrate is present is significant in con-

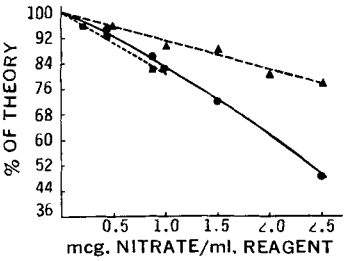

Fig. 8—Effect of nitrate on reactions. Key: ▲, mestranol fluorometric assay; ●, mestranol colorimetric assay; ■, ethinyl estradiol colorimetric.

centrations above 0.1 mcg./ml. of reagent as shown in Fig. 8.

SUMMARY

The utility of H_2SO_4 to produce color or fluorescence of α-ethinyl estradiol and derivatives has been established by several authors (1, 2, 5–7). When used in conjunction with a standardized reference tablet, the method yields optimum precision and accuracy for mestranol. The fluorescence measurement is more sensitive and more suitable for automation but less precise than the color measurement. Nitrate, nitrite, and hydrogen peroxide retard the reaction with sulfuric acid.

Preparation of Some Phenyl Pyridyl Ethers with Antifungal and Antibacterial Properties

By RICHARD O. MUHLHAUSER* and EUGENE C. JORGENSEN†

2-Methyl-4-chlorophenyl-4′-pyridyl ether (II) and 2-chlorophenyl-4′-pyridyl ether (III) were prepared by condensation of *N*-pyridyl-4-pyridinium chloride hydrochloride (I) with appropriate phenols. These compounds were found to be effective as antifungal agents but were less effective as antibacterial agents. Compound II had the greatest antifungal activity and the least toxicity.

As PART of a program dealing with the synthesis of thyroxine analogs, a series of phenyl pyridyl ethers (II–VI) has been prepared. Two of these compounds, 2-methyl-4-chlorophenyl-4′-pyridyl ether (II) and 2-chlorophenyl-4′-pyridyl ether (III), were found to have antifungal and antibacterial activity.

The synthetic sequence utilized is shown in Scheme I.

N-Pyridyl-4-pyridinium chloride hydrochloride (I) was prepared as described by Jerchel (1). Compounds II–V were then prepared by condensing (I) with the appropriate phenols as described by Jerchel (2). Compound VI was prepared from V by acid hydrolysis using a mixture of concentrated hydrochloric and glacial acetic acids. Pertinent data are listed in Table I.

Nuclear magnetic resonance and infrared spectral studies supported the structures assigned to com-

centrations above 0.1 mcg./ml. of reagent as shown in Fig. 8.

SUMMARY

The utility of H_2SO_4 to produce color or fluorescence of α-ethinyl estradiol and derivatives has been established by several authors (1, 2, 5–7). When used in conjunction with a standardized reference tablet, the method yields optimum precision and accuracy for mestranol. The fluorescence measurement is more sensitive and more suitable for automation but less precise than the color measurement. Nitrate, nitrite, and hydrogen peroxide retard the reaction with sulfuric acid.

VI, R = I, R′ = I, R″ = CH_2—CH(NH_2)—COOH

Scheme I

pounds II-VI. In the case of compound V, the NMR spectrum was correlated with spectra obtained for substituted thyronines by Lehman and Jorgensen (3). A broad peak at approximately 8.5 p.p.m. was assigned to the α protons adjacent to the pyridyl nitrogen of V (4–5).

Antimicrobial and antifungal evaluation of compounds II and III was performed by the small-tube screening procedures of Catalfomo and Schultz (8) and by the paper disk diffusion method (9).

The data in Tables II and III illustrate the activity of these compounds against representative fungi and bacteria.

These results agree with those obtained by Hata *et al.* (10) and Tomita *et al.* (11), and suggest that both the pyridyl ring and the phenolic ether are operative in producing the antifungal activity.

Results from the screening tests showed that compound II completely inhibited the growth of *T. mentagrophytes* at a concentration of 0.142 mmoles/L. (31.2 mcg./ml.). Partial inhibition was obtained at a concentration of 0.045 mmoles/L. (10 mcg./ml.). Undecylenic acid at a concentration of 0.054 mmoles/L. (10 mcg./ml.) proved less effective.

Evaluation of antifungal activity by the paper disk method (9) showed that a concentration of 2 mg./ml. of II completely inhibited the growth of several other fungal species. Results obtained by this method are shown in Table III.

Compound II had no apparent effect on the mean survival time of mice infected with *Plasmodium berghei*, whereas compound III significantly decreased the life span of these mice. This indicates that compound II, the more effective antifungal agent, is the less toxic of the pair of compounds tested.

Compounds V and VI were synthesized for testing as possible thyromimetic compounds and were not tested for antifungal activity. They were found to be inactive as thyromimetics by the rat antigoiter assay method (12).

EXPERIMENTAL

All melting points were taken on a Thomas-Hoover melting point apparatus and are uncorrected. The infrared spectra were determined with a Beckmann IR5 spectrophotometer by suspending the solid materials in potassium bromide disks. Nuclear magnetic resonance spectra were determined in deuterochloroform with tetramethylsilane as an internal standard. Microanalyses were performed by the Microanalytical Laboratory, University of California, Berkely, Calif.

Substituted Phenyl Pyridyl Ethers (Table I; II–IV) General Procedure—A mixture of *N*-pyridyl-4-pyridinium chloride hydrochloride (1) (I, 15.0 Gm., 0.0645 mole) and the appropriate phenol (0.071 mole) was heated at 160–165° in an oil bath, forming a clear melt within a few minutes. On cooling, the residue was treated with 10% sodium carbonate solution and the dark-colored upper layer was removed and taken up in chloroform. The chloroform solution was extracted twice with 2 *N* sodium hydroxide solution (400 ml. total) and with water (800 ml.) and dried over sodium sulfate. After filtration, the chloroform was removed *in vacuo*, and the oil was purified by washing it several times with water (to remove pyridine) followed by distillation *in vacuo*. The clear distillates obtained crystallized after standing at room temperature for a few days. Pertinent data are listed in Table I.

N-Acetyl-3,5-diiodo-4-(4′-pyridinoxy) Phenyl-L-alanine (V)—Prepared from I (5 Gm., 0.0215 mole) and *N*-acetyl-3,5-diiodo-L-tyrosine ethyl ester (13) (11.92 Gm., 0.0237 mole). The mixture was fused at 165–180° as described above. The cooled, brittle, black solid was stirred with a hot solution of sodium carbonate (250 ml.) and the suspension was allowed to stand overnight. The next day, the polymeric-like suspension was treated again with hot sodium carbonate solution and insoluble material was collected by filtration. The gummy solid was dissolved in acetone, treated three times with decolorizing carbon,[1] and filtered. The solvent was concentrated and water added. A buff-white solid, m.p. 169-170°, was obtained. The product was recrystallized from acetone–water to give a white solid, m.p. 169-171°. A mixed melting point determination with *N*-acetyl-3,5-diiodo-L-tyrosine ethyl ester gave a depression in melting point. The solid was chromatographically homogeneous on Silica Gel H with an R_f = 0.75 (ethyl acetate); $\bar{\nu}_{max.}$ in cm.$^{-1}$, 1257 (s), 1269 (s) (ether), 1669 (s) (amide), 1751 (vs) (ester), 3349 (m); NMR peaks at δ = 8.5 p.p.m. (broad) (α protons), δ = 7.65 p.p.m. (2,6 protons), δ = 6.7 p.p.m. (β protons).

3,5-Diiodo-4-(4′-pyridinoxy) Phenyl-L-alanine (VI)—Prepared from compound V by acid hydrolysis. A mixture of V (0.736 Gm., 0.00127 mole), glacial acetic acid (24.5 ml.), and concentrated hydrochloric acid (16.36 ml.) was heated at reflux temperature for 3.5 hr. according to the method of Jorgensen and Slade (12). [a] +, growth; 0, no growth; 0?, uncertain growth.

(100:30:10) showed a single spot (ninhydrin positive) for the white solid. The starting material (V) was negative to ninhydrin.

Biological Materials and Methods—The fungal species used were *Trichophyton mentagrophytes*, ATCC 9972, and *Botrytis cinerea*. The bacterial species employed were *Escherichia coli* and *Staphylococcus aureus* from the collections maintained at the department of Pharmacognosy, School of Pharmacy, University of California.[2]

The fungal organisms were maintained on Sabouraud dextrose medium[3] (liquid and agar), and the bacteria were maintained on nutrient medium[4] (broth and agar). The liquid cultures also served as a source of inocula.

For studies using *T. mentagrophytes*, the mycelial growth from 5–7-day old stationary cultures was homogenized in a sterile semimicro Waring blender for 30 sec. and added as 0.5 ml. inocula to the surface of an agar slant containing 9.5 ml. of Sabouraud's agar containing the test compounds. The tubes were incubated for 2 weeks at room temperature and growth was recorded at 7-day and 14-day intervals.

For antibacterial studies, actively growing 2–4-day old liquid cultures of *S. aureus* No. 209 P and *E. coli* No. 6522 were used as inocula. A bacterial suspension of 0.5 ml. was added to 9.5 ml. of nutrient broth No. 4A containing the dilutions of the compounds to be tested. The broth cultures were incubated for 48 hr. at 37°, and turbidity was then read to determine growth.

Results of the preliminary antifungal and antibacterial screening tests are shown in Table II.

In all cases, sterility controls were run for each sample of nutrient culture medium and for alcohol controls plus organism. Solutions of the agents to be tested were prepared in 95% ethanol and then diluted. In the case of griseofulvin, the compound was dissolved in dimethylformamide at various dilutions, and these dilutions were again diluted with phosphate buffer.

The second antifungal screening test on compound II was carried out in another laboratory.

Four sterile S and S absorbent disks (12.5 mm.) were placed in four Petri dishes containing Sabouraud's medium. The dishes were labeled as control, ethyl alcohol, $^1/_{100}$, and $^1/_{500}$. Compound II was dissolved in ethanol and dilutions of $^1/_{100}$ and $^1/_{500}$ were prepared. To the disks were added 2 drops of ethanol to one dish, 2 drops of $^1/_{100}$ dilution, 2 drops of $^1/_{500}$, and control was untouched. The disks were allowed to set 30 min. Then each set of disks was inoculated with a single culture of the respective organism and the plate was sealed with 3M Parafilm. The plates were then incubated at room temperature. Observations were taken at the end of 7 and 13 days. Results are shown in Table III.

Antimalarial Test[5]—Compounds II and III were administered subcutaneously in oil to mice at dose levels of 40, 160, and 640 mg./Kg. of body weight. The mice were infected with a lethal dose of *Plasmodium berghei* 3 days prior to administration of test compounds. With compound III, toxic deaths of all test animals were observed at all dose levels. No toxic deaths were observed with compound II, but the mean survival time of 6.2 days was not significantly prolonged.

Analog Computer Simulation of Rheological Systems I Pseudoplastic Flow

By GERALD J. YAKATAN and OSCAR E. ARAUJO

A method for the quantitative characterization of pseudoplastic systems using the analog computer was reported. Three parameters were obtained (one of which can be maintained constant for a given system) which completely describe the shape of rheograms for various CMC mucilages. The method developed can be carried out rapidly, the computer program is relatively simple, and the results should provide an easy means of communication among rheologists desiring to accurately compare experimental data on pseudoplastic systems.

THE IMPORTANCE of pseudoplastic flow in pharmaceutical systems is apparent when one considers that most hydrocolloids and dilute suspensions exhibit this rheological pattern. A large number of pharmaceutical emulsions and semisolid preparations also behave as pseudoplastic systems.

The quantitative characterization of pseudoplasticity has been a difficult problem for the rheologist. The application of an empirical exponential equation involving the use of a log-log plot has been commonly accepted (1–3). However, the use of this equation has been questioned by several workers (4).

Other investigators have proposed various equations with a theoretical basis, but the involved calculations necessary to obtain the constant described considerably reduced their practical value (5–7).

In 1961 Shangraw *et al.* (8) proposed another equation in an attempt to provide a much better representation of non-Newtonian systems. The equation is:

$$F = f + \eta_\alpha S - b_\gamma e^{-aS} \qquad \text{(Eq. 1)}$$

where F is the shearing stress, S is the rate of shear, and f, η_α, a, and b_γ are constants characteristic of a particular system.

The problems involved in adequately characterizing pseudoplastic flow systems seemed to offer a challenging area of research. The concept of developing an equation with a minimum number of parameters which would completely characterize all pseudoplastic systems was an interesting one. It was also felt that the analog computer would be of great assistance in solving these problems.

A typical rheogram of a pseudoplastic substance appeared to be composed of a "first-order" and a "zero-order" segment. Consequently, a general equation combining the integrated expressions for a zero-order and a first-order process would be (9):

$$y = ax + b(1 - e^{-cx}) \qquad \text{(Eq. 2)}$$

where y and x are variables for the particular system and a, b, and c are constants for the system.

For a specific rheological system, Eq. 2 becomes:

$$F = aS + b(1 - e^{-cS}) \qquad \text{(Eq. 3)}$$

where F is the shearing stress, S is the rate of shear, and a, b, and c are constants. For purposes of computer programming, F was made directly proportional to voltage and S directly proportional to time, and Eq. 3 becomes:

$$V = at + b(1 - e^{-ct}) \qquad \text{(Eq. 4)}$$

EXPERIMENTAL

The analog computer is rapidly becoming an extremely important tool in aiding the solution of complex scientific and engineering problems. In most modern computers, the continuous variables are d.c. voltages. The electronic analog computer makes possible the building of an electrical system in which d.c. voltages will vary with time in a manner similar to the variable of interest in the actual system under study.

By GERALD J. YAKATAN and OSCAR E. ARAUJO

A method for the quantitative characterization of pseudoplastic systems using the analog computer was reported. Three parameters were obtained (one of which can be maintained constant for a given system) which completely describe the shape of rheograms for various CMC mucilages. The method developed can be carried out rapidly, the computer program is relatively simple, and the results should provide an easy means of communication among rheologists desiring to accurately compare experimental data on pseudoplastic systems.

THE IMPORTANCE of pseudoplastic flow in pharmaceutical systems is apparent when one considers that most hydrocolloids and dilute suspensions exhibit this rheological pattern. A large number of pharmaceutical emulsions and semisolid preparations also behave as pseudoplastic systems.

The quantitative characterization of pseudoplasticity has been a difficult problem for the rheologist. The application of an empirical exponential equation involving the use of a log-log plot has been commonly accepted (1–3). However, the use of this equation has been questioned by several workers (4).

Other investigators have proposed various equations with a theoretical basis, but the involved calculations necessary to obtain the constant described considerably reduced their practical value (5–7).

In 1961 Shangraw *et al.* (8) proposed another equation in an attempt to provide a much better representation of non-Newtonian systems. The equation is:

$$F = f + \eta_\alpha S - b_\gamma e^{-aS} \qquad \text{(Eq. 1)}$$

where F is the shearing stress, S is the rate of shear, and f, η_α, a, and b_γ are constants characteristic of a particular system.

The problems involved in adequately characterizing pseudoplastic flow systems seemed to offer a challenging area of research. The concept of developing an equation with a minimum number of parameters which would completely characterize all pseudoplastic systems was an interesting one. It was also felt that the analog computer would be of great assistance in solving these problems.

A typical rheogram of a pseudoplastic substance appeared to be composed of a "first-order" and a "zero-order" segment. Consequently, a general equation combining the integrated expressions for a zero-order and a first-order process would be (9):

$$y = ax + b(1 - e^{-cx}) \qquad \text{(Eq. 2)}$$

where y and x are variables for the particular system and a, b, and c are constants for the system.

For a specific rheological system, Eq. 2 becomes:

$$F = aS + b(1 - e^{-cS}) \qquad \text{(Eq. 3)}$$

where F is the shearing stress, S is the rate of shear, and a, b, and c are constants. For purposes of computer programming, F was made directly proportional to voltage and S directly proportional to time, and Eq. 3 becomes:

$$V = at + b(1 - e^{-ct}) \qquad \text{(Eq. 4)}$$

EXPERIMENTAL

The analog computer is rapidly becoming an extremely important tool in aiding the solution of complex scientific and engineering problems. In most modern computers, the continuous variables are d.c. voltages. The electronic analog computer makes possible the building of an electrical system in which d.c. voltages will vary with time in a manner similar to the variable of interest in the actual system under study.

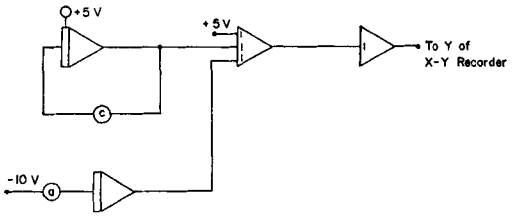

Fig. 1—Analog computer program for simulation of pseudoplastic flow systems.

The analog computer offers a number of distinct advantages for its utilization in the simulation of physical systems. The simple turn of a knob feeds in design parameters. The computer provides an instant-by-instant dynamic picture of each change in a parameter, and each change can be visually compared with any other. Above all, the computer offers simplicity, rapidity, and accuracy in operation.

The present study made use of the Pace TR-10 analog computer[1] and the output from the computer was fed into a Moseley Autograf model 2D-2 X-Y recorder[2] on which the curves were recorded.

The program used to simulate Eq. 4 is shown in Fig. 1. Variable potentiometer settings were used for the parameters a and c. The value of b was maintained constant at +5 v. throughout the study. Plots of shearing stress against rate of shear for pseudoplastic systems pass through the origin. The corresponding computer plot represented by Eq. 4 will also pass through the origin since at $t = 0, v = 0$. Equation 4 was now used to simulate pseudoplastic flow systems by varying two parameters, a and c.

Assuming that pseudoplastic rheograms, obtained by plotting shearing stress *versus* rate of shear, are composed of first-order and zero-order segments, it was deemed advisable to vary one of the two available parameters while holding the other constant. This would show the separate effect of each parameter on the shape of the pseudoplastic curves. The results of this study are shown in Figs. 2 and 3. As expected, the effect of each parameter cannot be separated entirely over the range of values chosen. Nevertheless, an extremely good indication of the effect of varying each parameters was obtained. From these data it seemed probable that by judiciously varying the parameters a and c, rheograms could be drawn which simulate pseudoplastic curves obtained from real systems. To test this theory it was decided to obtain actual experimental data on CMC mucilages known to exhibit pseudoplastic flow.

The rheological measurements were carried out on a Stormer viscosimeter. A weight hanger with various slotted weights provided the shearing stress in Gm. The rate of shear was reported in r.p.m. The CMC mucilages were allowed to equilibrate for 6 hr. after preparation, before any measurements were made. The rheological data, obtained at 20 ± 0.1°, are given in Table I.

Figure 4 shows the plots of the experimental points for the various mucilages and the computer curves which were drawn to fit these points. The values of a and c used to draw the simulated computer curves are listed in Table II, along with the values of a and c for the real systems corrected for scaling factors used by the computer. The values of these parameters were determined in the following manner.

A—The experimentally obtained curves, in Gm. *versus* r.p.m., were plotted on graph paper of the same size as that used to draw Figs. 2 and 3.

B—The plot of the experimentally determined points was superimposed on Fig. 2 to roughly estimate the value of c. This procedure was repeated using Fig. 3 to approximate the value of a.

C—These approximate values of a and c were then fed into the computer by adjusting the appropriate potentiometers, and the resulting curve was drawn by the computer on the graph paper containing the experimental points. The recorder was set so that 1 v. = 1 in. and 1 sec. = 1 in. of chart paper.

D—The first curve drawn by the computer never exactly fits the data. However, from this first approximation, changes were made in the values of a and c until a good fit was obtained. This adjustment was always accomplished within 10 min.

E—Now values of a, b, and c are simply read off the potentiometer settings. These values are the parameters of Eq. 4 and consequently must be corrected to the parameters of Eq. 3, which describes the experimental system.

To correct c, the following equation should be used:

$$c_{corr.} = P \times \frac{M}{R} \qquad \text{(Eq. 5)}$$

where P is the potentiometer setting c in Fig. 1, M is actual machine time at R r.p.m., *i.e.*, if it takes the computer 1 sec. to move 50 r.p.m. on the abscissa then $M/R = 1/50$. To correct a, the following equation should be used:

$$a_{corr.} = P' \times \frac{k}{k'} \qquad \text{(Eq. 6)}$$

where P' is the potentiometer setting a in Fig. 1, k is the proportionality constant relating F to V, and k' is the proportionality constant relating S to t. To correct b, the following equation should be used:

$$b_{corr.} = P'' \times k \qquad \text{(Eq. 7)}$$

where P'' is the potentiometer setting represented by +5 V in Fig. 1, and k is the proportionality constant relating F to V. Thus for the systems investigated $b_{corr.} = 5\ V \times 100 = 500$. The corrected values for a, b, and c may now be substituted into Eq. 3 to give an equation which completely describes the pseudoplastic rheogram.

Since the Stormer viscosimeter was used in the present study, it should be pointed out that the constants obtained by computer fit of these data will be different from those obtained from data accumulated from another viscosimeter. However, the general equation and the computer program are applicable regardless of the instrument employed.

DISCUSSION

The empirical log-log plot frequently used to describe pseudoplastic flow very often does not truly characterize the experimental curve. It is not unusual for this type of plot to produce a great deal of scatter in the points or even another curved line.

500	127	200	94.4	100	120
650	198	250	128	150	195
800	286	300	163	200	286
900	351	400	238	250	373
		500	328		

The slope of this "line" yields a so-called index of pseudoplasticity.

The method proposed in this study offers three parameters to describe the experimental data and characterize the entire flow curve quantitatively. While the approach is still admittedly empirical, no difficulty has been encountered in successfully characterizing any of the experimental data employed. Figure 4 clearly demonstrates that a wide variety of pseudoplastic curves can be accurately simulated.

It is realized that not all rheologists can count an analog computer as one of the research tools commonly at his disposal in the laboratory. Nevertheless, almost every research investigator in rheology, whether in industrial or academic circles, has an analog computer within reasonably easy reach. The computer program presented here is a model of simplicity, mastery of which would require no

more than 30 min. instruction even to those completely alien to computer programming.

In summary, this paper has presented a method for the quantitative determination of three parameters which completely characterize the shape of pseudoplastic flow curves. Evidence has been presented regarding the general applicability of the method by making use of actual experimental data. The method is rapid and avoids any extensive calculations. It is hoped that the use of this procedure will lead to a common means of communication among rheologists, working with pseudoplastic systems, who wish to compare experimental data. It is also possible that with the aid of the analog computer some new light may be thrown on the mechanism of pseudoplastic flow. There is a distinct possibility that the same type of treatment presented here may be applied to other rheological systems. Work in these areas is being pursued at the present time.

Apparent pH Dependence of Ethanol Absorption Rate in the Common Guppy

By WILLIAM L. HAYTON and NATHAN A. HALL

The uptake of ethanol from buffered solution by guppies has been studied. There was an apparent increase in the rate of absorption with increasing pH. In contrast, similar experiments made with goldfish failed to show an increase in absorption rate as the pH was increased. The guppy should be used with caution as a model for investigating the effects of varying pH upon drug absorption.

FISH ARE widely used for experimental purposes and for biological assays and have been used for a variety of biological studies including outstanding works in experimental embryology, endocrinology, and nerve physiology (1). The gross anatomy and physiology of fish are comparable to that of mammals, and fish contract many of the same diseases as do mammals. Fish have become popular as experimental tools because they are relatively inexpensive and easily kept in the laboratory.

The use of fish in drug absorption studies has led to the development of a theory by Levy and Gucinski (2) describing the uptake of drugs from a bathing solution by goldfish. The theory describes the uptake of drugs by fish under appropriate conditions as a simple diffusion process dependent upon the concentration of the drug in the external bathing solution.

This article is based in major part upon a manuscript for which William L. Hayton was the recipient of the Lunsford Richardson Pharmacy Award for Region I, 1967.

The uptake of a weak acid over a pH range encompassing the pKa of the drug has been studied in goldfish and was shown to be consistent with the pH- partition theory. In their studies Levy and Gucinski have shown that the uptake of a nonelectrolyte, ethanol, by goldfish does not depend upon the pH of the external medium.

Levy's theory for goldfish has been applied to the common guppy (*Lebistes reticulatus*) (3). The uptake of ethanol was found to conform to the theory within certain concentration limits. The guppy appeared to show promise as a suitable animal for drug absorption studies. Guppies previously have been used as experimental animals in many types of toxicity studies (4).

The effect of pH on the rate of absorption of nonelectrolytes has not been examined in detail. A variable pH should have no profound effect on the physical characteristics of a nonelectrolyte, but absorbing membranes might be sensitive to these changes. Membranes generally are believed to possess pores, allowing for the diffusion of small molecules through the membrane without entering the lipid phase. Kavanau (5) has proposed a mechanism whereby the diameter of the pores changes between open and closed configurations. In his theory the transformation is mediated by proton activity. It is possible then that varying pH could significantly alter the rate of absorption of a neutral molecule by causing a structural change in the absorbing membrane. The study reported here was undertaken to find what effect pH variability might have on the rate of absorption of a neutral molecule in guppies and goldfish.

EXPERIMENTAL

To investigate the effect of varying pH upon the absorption of ethanol through intact membranes both the guppy and the goldfish were used. The time for a pharmacological effect to occur has been shown previously to be a function of the rate of absorption (2, 3). A change in the time required for the effect to occur at constant ethanol concentration was considered to reflect a change in the absorption rate.

Two different pharmacological effects were used as end points—overturn (loss of equilibrium) and death (cessation of gill and mouth movement). The times required to attain the end point from the immersion were termed "overturn time" and "survival time," respectively. The overturn end point was used with the guppies because cessation of gill and mouth movements was difficult to detect due to their size. The death end point was used on goldfish because they did not give a "sharp" overturn end point but appeared to lose their equilibrium by degrees. Both end points used on the same lot of fish gave parallel log-log plots of time for effect *versus* concentration, indicating that both end points were the same function of concentration.

Materials—The ethanol solutions were prepared from absolute ethanol of reagent quality (U. S. Industrial Chemical Co.). The solutions were prepared by accurately measuring the ethanol into a volumetric flask. A quantity of buffer and sodium chloride necessary to give 0.05 *M* buffer concentration and an ionic strength of 0.05 was added with distilled water; the pH was adjusted to the desired value with dilute NaOH or HCl, and the solution was made to volume. The ionic strength adjustment was based upon calculation of the fraction of the buffer in its ionic form at each pH. All solutions contained 0.05 *M* buffer adjusted to 0.05 in ionic strength.

Three buffers were used in preparing the solution: 2-(*N*-morpholino)-ethane-sulfonic acid.H_2O(MES, Calbiochem), *N,N* - bis(2 - hydroxyethyl)glycine (bicine, Calbiochem), and tris-(hydroxymethyl)-aminomethane (tris or THAM, Fisher Scientific Co.). The buffers supplied by Calbiochem are relatively new in biological studies. The pKa of MES is 6.09, of bicine 8.26, and of tris 8.14 at 25° (6). The buffers were found by preliminary experiments to be innocuous to the fish.

Fish—Common guppies (*Lesbistes reticulatus*) were obtained from a local supplier of tropical fish. They were maintained at 25° and sized as described previously (3). Only male fish were used.

Goldfish (*Carassius auratus*), approximately 4 cm. in length, were purchased in a single lot from a local pet shop.

Method—A 4% ethanol solution was used with the guppies and a 6% ethanol solution with the goldfish. Nine solutions were used in the guppy study and 10 in the goldfish study. The solutions in each study were identical except for pH and buffer. The solutions were hypotonic to fish blood so the osmotic pressure vector across the absorbing membranes was in the same direction as in natural environmental conditions, although not quite so large (7). Prior to use, the solutions were placed in a water bath at 25° and allowed to attain temperature equilibrium.

The fish were exposed to the drug solutions by removing them from the tank with a plastic net and dropping them into the ethanol solution. Thirty milliliters of solution in a 100-ml. beaker was used for the guppies, and 100 ml. of solution in a 250-ml. beaker was used for the goldfish. A stopwatch was started when the fish made contact with the solution. The 100- or 250-ml. beaker was then placed inside a 600-ml. beaker that was suspended in a constant-temperature bath at 25°. The temperature of the bathing solution was thus maintained at 24–25°. Each fish was observed until the end point was reached. The stopwatch was stopped, the fish removed from the solution, and the time recorded. A fresh solution was used for each fish, and the fish were used only once. Twelve guppies and six goldfish were used for each solution.

To minimize bias in determining the end point, the solutions were coded by letter, the code being unknown to the person determining the end point. The solutions were administered in a random order established from a table of random numbers. These procedures were designed to eliminate the effects of the order in which the fish were removed from the tank and the bias of the observer in end point determination and fish selection.

RESULTS

Table I lists the results of the studies with guppies. At each pH the means from all buffers are averaged to give a collected mean. A *t* test of differences among the means in the guppy experiments showed that at the 95% confidence level there are significant differences between the collected

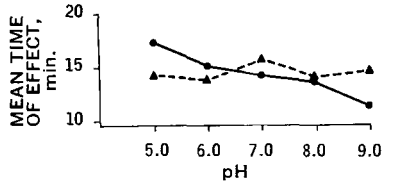

Fig. 1—Variation of mean time of the effect of ethanol in buffered solutions at different pH levels. Points represent collected means for all solutions buffered with MES, tris, and bicine. Key: ▲, survival times (min.) for goldfish in 6% ethanol; ●, overturn times (min.) for guppies in 4% ethanol.

means at pH 5 and 6, pH 6 and 8, pH 7 and 9, pH 8 and 9, as well as between pH values farther apart than these. With the individual buffers there is a trend toward shorter overturn times with increasing pH, except for the tris-buffered series. The differences among the means for the tris series are not statistically significant.

Table II lists the results of the studies with goldfish. There are no statistically significant differences at the 95% confidence level among any of the collected means, and there appears to be no trend paralleling the changes in pH with individual buffers.

Figure 1 depicts the comparison between goldfish and guppies of the effect of ethanol at various pH levels.

DISCUSSION

Several factors may have an appreciable effect on the absorption rate of a molecule. The more important factors are concentration, temperature, pH, osmotic pressure, ionic strength, degree of ionization of the molecule, size of the molecule, and its lipid solubility. If a buffer is present, as in this study, the degree of ionization of the buffer may be important.

In these experiments, the concentration of the ethanol (4% for guppies and 6% for goldfish) and the buffer (0.05 *M*) was held constant. The osmotic pressure of all the solutions was nearly equal although the exact osmotic pressure exerted by the buffers is not known. The ionic strength of the solutions was constant at 0.05. Because ethanol is nonionized in aqueous solutions, the ionization of the molecule was not a variable. The size of the molecule and its lipid solubility also remained constant in all of the solutions.

The degree of ionization of the buffer could possibly have an effect upon the absorbing membranes of the fish due to ion-membrane interactions. In their buffer ranges MES and bicine are anionic as their molecules have fully dissociated carboxyl groups and partially ionized amino groups depending on the pH of the solution. As the pH is increased in the buffering range of the molecule the amino group becomes less ionized, resulting in an increased net negative charge on the molecule from the fully ionized carboxyl group. Tris, however, is not zwitterionic but is a substituted amine, and as the pH is increased, the number of positively charged buffer ions decreases in the buffering range of the molecule. It is unlikely that charges upon the buffer molecules would influence the absorption rate of ethanol in this study as all solutions were of equal ionic strength, and there is no qualitative difference among the charges on the buffer ions and the sodium and chloride ions present. To maintain the pH of the solutions it is necessary that buffers be present.

The parameter which this study concerns is pH and its effect upon the absorbing membranes of guppies. From the data collected in this study it appears that the pH of the solution has a significant effect upon the rate of absorption of ethanol by guppies. The absorbing membranes of the fish are

apparently altered, causing an increase in the rate of absorption as the hydrogen-ion activity becomes less. The nature of this alteration could be a change in the membrane pore size or some other structural change in the membrane.

The extremes of the pH range used in this study are not harmful to either of the fish which may live for extended periods at either pH 5.0 or 9.0. Further, it is doubtful that the changes in pH have interfered with the integrity of the membrane. The possibility of a synergistic toxicity of the hydrogen ion–ethanol combination, independent of absorption rate, could not be ruled out. Preliminary experiments on guppies with strychnine, however, showed a similar increase in absorption rate at high pH levels. The observed absorption rate increase was considerably greater than that accounted for by calculation of the amount of strychnine present as the free base at elevated pH levels.

Results from this study indicate that the absorbing membranes of the guppies are pH sensitive. The use of this fish as an experimental model in studying drug absorption probably should be limited to those studies in which the pH of the solutions used is constant. Absorption studies that are run with pH as a variable factor probably will be influenced by the changing absorption rates due to varying pH, and any change in absorption rate in such a study may not be meaningful. Goldfish, on the other hand, appear to have absorbing membranes which are not appreciably altered by pH changes *per se*.

Mixed Glycol Acetal Dimethylcarbamates *via* Transacetalation of Certain Di- and Trihydric Alcohols

By CLAUDE PIANTADOSI, FRED T. SEMENIUK, and ROBERT K. RAUCH

Mixed acetals of a new type were synthesized by an acetal exchange reaction between the mono dimethylcarbamate of ethylene, propylene, and trimethylene glycols and the diethyl acetals of butyraldehyde, heptaldehyde, and benzaldehyde. The glycerol carbonate (followed by dimethylaminolysis) also underwent transacetalation and dimethylcarbamate esters of the dioxolane-type were synthesized.

A NUMBER of acyclic acetals (1), cyclic acetals (2), and their derivatives (3–9) have been reported in the literature. Their potentialities as hypnotics, anticonvulsants, and skeletal muscle relaxants (3–9) have been noted. In view of the fact that mixed acetals are similar in structure to the pharmacologically active glycerol ethers, it was of interest to synthesize some of the mixed acetal carbamates in order to determine the feasibility of the transacetalation reaction for preparing such compounds. Exchange reactions between alcohols in acetal linkage and alcohols have long been known. They have been reported to be applicable for primary alcohols (10, 11), for secondary and tertiary alcohols and phenols (11), for ethylene and trimethylene glycol (12), and for glycerol (13–15). The term "transacetalation" has been coined and may be applied generally to cover all such acetal exchange reactions (13). The experimental procedures presented in this paper describe the use of this reaction with the glycol monocarbamates of ethylene, propylene, trimethylene, and glycerol with the diethyl acetals of benzaldehyde, butyraldehyde, and heptaldehyde. Attempts to prepare the unsubstituted carbamate derivatives by this method were not successful.

The diethyl acetals of butyraldehyde, heptaldehyde, and benzaldehyde were prepared according to the method of Claisen (16). The method of Najer *et al.* (17) was used for the preparation of propylene glycol carbonate and the method of Carothers *et al.* (18) for trimethylene glycol carbonate. An adaptation of the method of Delaby *et al.* (19) for the synthesis of ethylene glycol monocarbamate was used in preparing the carbamates. The synthesis of heptaldehyde and benzaldehyde mixed glycerol carbonate acetals and dioxolane dimethylcarbamates were carried out as previously described by Piantadosi *et al.* (13). An examination of the infrared spectrum of the compounds synthesized revealed the presence of characteristic ester absorption due to C=O stretching in the region of 1620–1829

apparently altered, causing an increase in the rate of absorption as the hydrogen-ion activity becomes less. The nature of this alteration could be a change in the membrane pore size or some other structural change in the membrane.

The extremes of the pH range used in this study are not harmful to either of the fish which may live for extended periods at either pH 5.0 or 9.0. Further, it is doubtful that the changes in pH have interfered with the integrity of the membrane. The possibility of a synergistic toxicity of the hydrogen ion–ethanol combination, independent of absorption rate, could not be ruled out. Preliminary experiments on guppies with strychnine, however, showed a similar increase in absorption rate at high pH levels. The observed absorption rate increase was considerably greater than that accounted for by calculation of the amount of strychnine present as the free base at elevated pH levels.

Results from this study indicate that the absorbing membranes of the guppies are pH sensitive. The use of this fish as an experimental model in studying drug absorption probably should be limited to those studies in which the pH of the solutions used is constant. Absorption studies that are run with pH as a variable factor probably will be influenced by the changing absorption rates due to varying pH, and any change in absorption rate in such a study may not be meaningful. Goldfish, on the other hand, appear to have absorbing membranes which are not appreciably altered by pH changes *per se*.

cm.$^{-1}$ and the C—O—C bands at 1050–1275 cm.$^{-1}$. Scheme I for the synthesis of 3-(1-ethoxybutoxy) propyl dimethylcarbamate(I) illustrates the reaction sequence for the preparation of mixed acetal dimethylcarbamates. Data with respect to these derivatives are listed in Table I. Scheme II depicts the route used in the synthesis of dioxolane carbamates (*Va*) and mixed glycerol carbamate acetals (IV*b*).

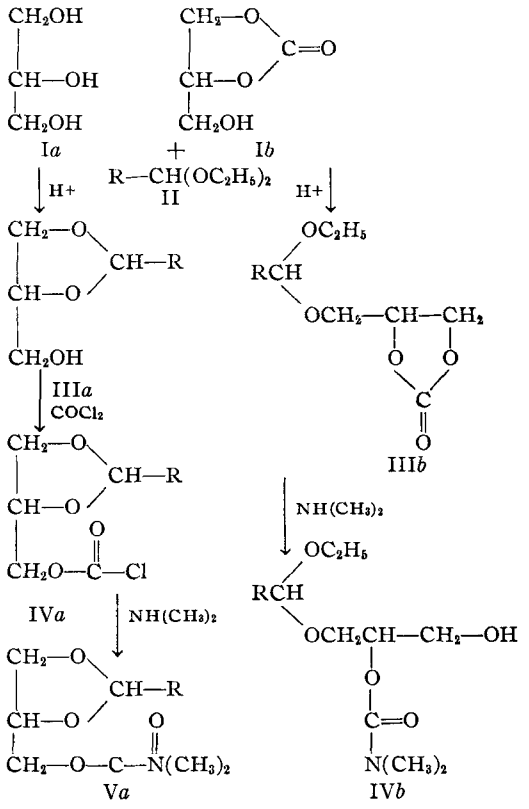
EXPERIMENTAL

All boiling points and melting points are uncorrected. Analyses were determined by Weiler and Strauss Microanalytical Laboratory, Oxford, England, Spang Microanalytical Laboratory, Ann Arbor, Mich., and M-H-W Laboratories, Garden City, Mich. Infrared spectra were recorded with a Perkin-Elmer Infracord.

3-(1-Ethoxybutoxy)propyl Dimethylcarbamate (I)—The following procedure is based on a modification of the method of Alquier (20) and subsequently of others (15). This method was used for all the products obtained from ethylene, propylene, and trimethylene glycols. Table I indicates pertinent data with respect to the mixed acetal dimethylcarbamates synthesized.

In a three-necked flask equipped with a stirrer, a thermometer, and a distilling head for the collection of the alcohol evolved, were placed 13.3 Gm. (0.1 mole) of ethylene glycol monodimethylcarbamate and 58.4 Gm. (0.4 mole) of butyraldehyde diethyl acetal. The reaction mixture was heated with vigorous stirring on an oil bath. When the temperature of the reaction mixture reached 115°, a drop of concentrated HCl was added, and ethanol began to evolve. After the theoretical amount of ethanol was obtained, the reaction mixture was cooled, and 50 ml. of ether was added. The ethereal solution was washed once with 30 ml. of saturated $NaHCO_3$, and three times with 30-ml. portions of cold water. The ether extract was dried over anhydrous sodium sulfate and the ether was removed under reduced pressure. The resulting product was purified by distillation under reduced pressure. Compounds listed in Table I were prepared in an analogous manner.

4 - Hydroxymethyl - 2 - n - hexyl - 1,3 - dioxolane Dimethylcarbamate (Va)—To 37.6 Gm. (0.2 mole) of 4-hydroxymethyl-2-*n*-hexyl-1,3-dioxolane dissolved in 80 ml. of benzene was added dropwise 0.2 mole of phosgene. The mixture was stirred for 3 hr. at which time 0.2 mole of dimethylaniline was added. Stirring was maintained for another 30 min. and the mixture was washed with ice water. A separation of benzene and water layers occurred, and the benzene layer was poured into 150 ml. of a 25% aqueous solu-



Scheme II

tion of dimethylamine. The reaction mixture was placed in an ice bath and stirred for 3 hr. The benzene layer was separated, dried over anhydrous potassium carbonate, and removed by evaporation. The residue was purified by distillation under reduced pressure, b.p. 106–107° (0.14 mm.); n_D^{25} 1.4517.

Anal.—Calcd. for $C_{13}H_{25}NO_4$: C, 60.20; H, 9.72; N, 5.40. Found: C, 60.76; H, 9.54; N, 5.46.

In a similar manner the benzaldehyde analog was prepared. After evaporation of the benzene, distillation of the residue under vacuum afforded 12.8 Gm. of a yellow colored liquid, b.p. 140° (0.14 mm.); n_D^{25} 1.5180. Upon standing in the cold (5°), approximately 1 Gm. of white crystals was collected from this liquid fraction, m.p. 115–116°. Both liquid and solid were submitted for analyses.

Anal.—Calcd. for $C_{13}H_{17}NO_4$: C, 63.13; H, 6.82; N, 5.58. Found: (solid) C, 63.23; H, 6.88; N, 5.26. (Liquid): C, 63.26; H, 6.66; N, 5.36.

Mixed Glycerol Carbamate Acetals (IVb)—To 11.8 Gm. (0.1 mole) of freshly distilled glycerol carbonate was added 75.2 Gm. (0.4 mole) of heptaldehyde diethyl acetal. The reaction mixture was heated to 150° and two drops of concentrated HCl was added. After cooling, ether was added, followed by neutralization with a weak base. The mixture was then washed with water, and the organic layer was dried over anhydrous potassium carbonate and subsequently removed by evaporation. Distillation of the residue gave a product (III*b*) with b.p. 147° (0.23 mm.); n_D^{27} 1.4444.

Anal.—Calcd. for $C_{13}H_{24}O_5$: C, 59.98; H, 9.29. Found: C, 59.78; H, 9.17.

Similarly, the corresponding benzaldehyde derivative was obtained, b.p. 155–157° (0.14mm.); n_D^{27} 1.5079.

Anal.—Calcd. for $C_{13}H_{15}O_5$: C, 61.89; H, 6.39. Found: C, 62.03; H, 6.35.

To obtain the carbamate (IV*b*) 0.1 mole of III*b* was placed in 100 ml. of a 25% aqueous solution of dimethylamine. The mixture was set aside for 4 days, and the layers separated and distilled, b.p. 143° (0.15 mm.); n_D^{25} 1.4488.

Anal.—Calcd. for $C_{15}H_{31}NO_5$: C, 58.99; H, 10.23; N, 4.59. Found: C, 59.07; H, 10.06; N, 4.50.

The corresponding benzaldehyde derivative was obtained as a viscous yellowish-brown liquid. This oil was purified in a molecular still, b.p. 160° (0.13 mm.); n_D^{25} 1.5020.

Anal.—Calcd. for $C_{15}H_{23}NO_5$: C, 60.59; H, 7.80; N, 4.71. Found: C, 61.00; H, 8.03; N, 4.59.

Utilization of Hydrophilic Gums for the Control of Drug Substance Release from Tablet Formulations II. Influence of Tablet Hardness and Density on Dissolution Behavior

By H. E. HUBER and G. L. CHRISTENSON

The influence of tablet hardness and density variation on *in vitro* dissolution of dye from controlled release tablets made with different types and viscosity grades of hydrophilic polymers was investigated. Tablet volumes were maintained constant and the weight varied to obtain varying degrees of hardness and density. Tablets made at varying hardness did not show markedly different release characteristics as evaluated by an *in vitro* method. Different release patterns were, however, observed with tablets prepared from different gums.

A PREVIOUS REPORT (1) from these laboratories presented data to illustrate the utilization of hydrophilic gums as a means of controlling rate of drug release from tablet formulations. It was shown that the type and concentration of gum in a formulation could markedly influence disintegration and dissolution behavior. Recently, Lapidus and Lordi (2) published the results of their related investigations on factors affecting the release of water-soluble drugs from a compressed hydrophilic matrix. Their studies were concerned with theoretical aspects of the problem and focused attention on the kinetics of drug release in the initial stages of the process and from a single face of a tablet. They were able to show that under such conditions the release pattern appeared to follow the same relationships as were proposed by Higuchi (3, 4) for solid drugs dispersed in solid matrices.

The present investigation was conducted to determine, in part, the influence of formulation and processing variables on the release rate characteristics of tablets formulated with hydrophilic gums as the delaying matrix. In this study, the relationships between tablet hardness and release rate characteristics have been investigated. It was felt that a comparison of hardness measurements would reflect, quantitatively, differences in density and porosity of tablets made at different compressional forces.

Differences in density and porosity could possibly influence the rate of tablet dissolution by, for example, affecting the initial rate of penetration of water at the tablet surface and thus the rate of formation of the gel barrier at the tablet periphery. Such considerations are of practical importance since complete uniformity of compressional force is difficult to maintain in production operations and variations of release rate as a function of processing variables must be known to maintain reasonable tablet-to-tablet uniformity with regard to release rate characteristics.

Tartrazine (FD&C Yellow No. 5) was used in this study as a tracer to evaluate release characteristics. It was chosen because of analytical considerations. The release of the dye from a tablet could be easily followed spectrophotometrically and the spectral characteristics of the dye are pH independent over the pH range investigated. In addition, the dye served to visually indicate uniformity of distribution throughout the tablet. The gums selected for this study were carboxypolymethylene (CPM), sodium carboxymethylcellulose (NaCMC), and hydroxypropyl methylcellulose (HPMC). Three different viscosity grades of the latter gum were investigated (HPMC 100 cps., 4,000 cps., and 15,000 cps.).

EXPERIMENTAL

Tablet Granulations—Five different gums were investigated, CPM, NaCMC, HPMC 100 cps., HPMC 4,000 cps., and HPMC 15,000 cps. In each formulation equal parts of lactose and gum were mixed with 0.4% micropulverized tartrazine. The mix was slugged and screened, and 2% magnesium stearate was added for lubricant.

Preparation of Tablets—Two approaches can be used to vary the hardness characteristics of tablets. A constant weight of granulation can be used and the compression pressure exerted by the machine varied through adjustment of the die fill volume. As a result, tablets of different hardness would be obtained but the tablets would also have different volumes. Alternatively, tablets with different hardness values and constant volume can be prepared by using different weights of granulation and maintaining a constant fill volume. The second approach was used, because if weight is held constant and volume varied, differences in dissolution rate could be expected as a result of differences in surface area, and therefore the data would have little value in answering the basic question regarding influence of hardness on release rate characteristics.

Granulation was weighed out on a class A prescription balance and compressed on a Stokes model F tablet machine adjusted to provide a $^3/_8$-in. flat-faced tablet 4.1 to 4.2 mm. thick and with Pfizer hardnesses of approximately 6, 10, or 15 Kg. Once the weight required to obtain a desired hardness was found, additional tablets were made and hardness checked.

Six tablets were then made by weighing out granulation and compressing it at that particular machine setting. These 6 tablets were then weighed on a Mettler balance to the nearest 0.1 mg. and their thickness measured with an Ames micrometer to the nearest 0.01 mm. Volume was calculated using $\pi r^2 h$. Apparent density was calculated from average tablet weight/volume. Three of the 6 tablets, with apparent density values on the high and low side, were used to determine an average hardness. The remaining tablets were subjected to *in vitro* dissolution.

Received April 14, 1967, from the Pharmaceutical Research and Development Department, Scientific Laboratories, The Wm. S. Merrell Co., Division of Richardson-Merrell, Inc., Cincinnati, OH 45215

Accepted for publication August 16, 1967.

Presented to the Basic Pharmaceutics Section, APhA Academy of Pharmaceutical Sciences, Las Vegas meeting, April 1967.

Dissolution Study—Each tablet was placed in the basket rack assembly of a USP Stoll-Gershberg apparatus, lowered into an 800-ml. beaker containing 600 ml. of simulated gastric fluid (no enzymes) maintained at 37 ± 0.5° and operated for 1 hr. At the end of 1 hr., the basket rack, with tablet, was transferred to another 800-ml. beaker containing 600 ml. of simulated intestinal fluid (no enzymes) and the operation continued. A sample of the simulated gastric fluid was filtered through Whatman No. 42 paper and its absorbance measured at 420 mμ on a Spectronic 20 colorimeter. At hourly intervals the apparatus was stopped, the volume of simulated intestinal fluid adjusted to 600 ml., operated again for a short interval to assure mixing, and a 10-ml. sample was withdrawn. After filtration and reading the absorbance, the sample was returned to the beaker. Hourly assays were made until the tablet was dissolved or 7 hr. of data were obtained. Those tablets that remained undissolved were stirred on a magnetic stirrer until dissolved and an end point assay run. Three determinations were made for each hardness value.

Percent dye released each hour was calculated on the basis of total dye released for each tablet. By treating the data in this manner, differences in tablet weight and therefore total tablet dye content were eliminated.

NaCMC	5.7	1.33
	11.7	1.41

RESULTS

No significant differences in release rate of dye could be seen for tablets made with CPM, HPMC

100 cps., and HPMC 4,000 cps. at approximately 6, 10, and 15 Kg. hardness (Figs. 1, 2, and 4). Average apparent tablet densities and corresponding hardness values are shown in Table I.

HPMC 15,000 cps. and NaCMC tablets demonstrated a slightly reduced rate of dye release during the first hour of *in vitro* dissolution as a result of increased hardness and density. The rates of dye release for the remaining dissolution period remained approximately the same, regardless of tablet hardness (Figs. 3 and 5 and Table I).

DISCUSSION

The data indicate that one can expect little or no change in dissolution rate pattern as a result of alteration in tablet density and porosity for some hydrophilic gum formulations. If changes occur, they probably will appear during the initial phase of the dissolution period and the shape of the dissolution profile will not be markedly altered. Apparently, the affinity of some gums for water will overcome any deterring influence which an increased density or decreased porosity may tend to exert on the initial rate of water penetration into the tablet surface. In those cases where the gum and/or formulation exhibit a decreased affinity for water, an increase in density will deter water penetration and reduce the rate of drug substance dissolution until a gel barrier is formed. After the gel barrier is formed, the rate of drug substance release is further reduced and becomes dependent on the rate at which drug substance diffuses through the gel and the rate at which the gel barrier is mechanically removed by agitation.

SUMMARY AND CONCLUSIONS

In an investigation of *in vitro* dissolution behavior for tablets compressed to different degrees of hardness, no changes in dissolution rate pattern were observed for three formulations. In two formulations, a slightly reduced rate of dissolution was noted during the first hour; however, no marked change in the total dissolution profile was observed. Different release rate profiles were observed with tablets prepared from different gums.

Tetracyclic Phenothiazines I. Reinvestigation of the Brominations of Some Pyrido[3,2,1-*kl*]phenothiazines

By ARNOLD R. MARTIN, GERALD G. BRIGGS, and TIMOTHY J. YALE

Brominations of both 1,2-dihydro-3-keto-3*H*-pyrido[3,2,1-*kl*]phenothiazine (I) and its sulfoxide (VII) gave 3-hydroxypyrido[3,2,1-*kl*]phenothiazinium bromide (VI). Treatment of 3-keto-3*H*-pyrido[3,2,1-*kl*]phenothiazine (II) with bromine gave 2-bromo-3-hydroxypyrido[3,2,1-*kl*]phenothiazinium bromide (XII). Structural assignments of VI and XII have been made on the basis of their spectral properties, correcting those previously reported.

As a result of an interest in tetracyclic phenothiazine derivatives as intermediates for the synthesis of pharmacologically interesting agents, the reactions of 1,2-dihydro-3-keto-3*H*-pyrido-[3,2,1-*kl*] phenothiazine (I) and 3-keto-3*H*-pyrido-[3,2,1-*kl*]phenothiazine (II) with bromine (Scheme I) were reinvestigated. Harfenist (1) reported the bromination of I to give a "bromo derivative," which he assumed to be the bromoketone (III), on the basis of its elemental analysis. Heating of the "bromo derivative" in aqueous methanol caused its conversion to the unsaturated ketone (II). The reaction of II with bromine gave an unstable "dibromide," assumed to be the addition product (IV). Attempts to recrystallize IV reportedly gave the unsaturated bromoketone (V). The interpretation of the infrared and ultraviolet spectra of the two bromination products originally prepared by Harfenist requires reassignment of their structures.

RESULTS AND DISCUSSION

The infrared spectrum of the "bromo derivative" obtained from I lacks a carbonyl band, but shows the characteristics of an ionized amine salt, *i.e.*, a nearly continuous series of bands in the region of about 2300–2700 cm.$^{-1}$(2). The high melting point of the "bromo derivative" and its solubility behavior (it is insoluble in nonpolar solvents) further militate against the bromoketone structure III. The aromatized salt structure VI, on the other hand, is consistent with the analytical, spectral, and

Tetracyclic Phenothiazines I. Reinvestigation of the Brominations of Some Pyrido[3,2,1-*kl*]phenothiazines

By ARNOLD R. MARTIN, GERALD G. BRIGGS, and TIMOTHY J. YALE

Brominations of both 1,2-dihydro-3-keto-3*H*-pyrido[3,2,1-*kl*]phenothiazine (I) and its sulfoxide (VII) gave 3-hydroxypyrido[3,2,1-*kl*]phenothiazinium bromide (VI). Treatment of 3-keto-3*H*-pyrido[3,2,1-*kl*]phenothiazine (II) with bromine gave 2-bromo-3-hydroxypyrido[3,2,1-*kl*]phenothiazinium bromide (XII). Structural assignments of VI and XII have been made on the basis of their spectral properties, correcting those previously reported.

As a result of an interest in tetracyclic phenothiazine derivatives as intermediates for the synthesis of pharmacologically interesting agents, the reactions of 1,2-dihydro-3-keto-3*H*-pyrido-[3,2,1-*kl*] phenothiazine (I) and 3-keto-3*H*-pyrido-[3,2,1-*kl*]phenothiazine (II) with bromine (Scheme I) were reinvestigated. Harfenist (1) reported the bromination of I to give a "bromo derivative," which he assumed to be the bromoketone (III), on the basis of its elemental analysis. Heating of the "bromo derivative" in aqueous methanol caused its conversion to the unsaturated ketone (II). The reaction of II with bromine gave an unstable "dibromide," assumed to be the addition product (IV). Attempts to recrystallize IV reportedly gave the unsaturated bromoketone (V). Scheme I

physical data. The salt would be expected to lose a proton in polar solvents readily to give the weak conjugate base II.

The ultraviolet spectra of I, II, and VI are shown in Fig. 1. The spectra of I and II in acetonitrile have been reported previously (3). Comparison of the spectra of I and VI reveal differences which appear unreconcilable on the basis of anticipated relationships between the spectra of an aromatic ketone and its corresponding α-bromo derivative. The relationship of VI as the conjugate acid of II was confirmed by investigating the spectral behavior of II in 50% ethanol containing varying concentrations of hydrochloric acid. The behavior of the long wavelength band is shown in Fig. 2. An isosbestic point is evident at 413 mμ. The absorption maxima of II in the presence of ethanolic hydrochloric acid are essentially the same as those of VI in acetonitrile, except for minor wavelength shifts due to differences in solvent and differences in absorptivity, probably resulting from differences in the amount of dissociation in the two solvents.

Hromatka *et al.* (4), in an effort to obtain a derivative of I chlorinated in one or both of the benzene rings, reacted the sulfoxide VII in hot aqueous ethanolic hydrochloric acid. A good yield of the unsaturated ketone II was obtained. This result prompted us to react VII with bromine, giving an excellent yield of VI. It would seem likely that the synthesis of VI (or II, depending on the workup) by bromination of I or VII, or from the action of hydrochloric acid on VII, might proceed through the common intermediate VIII. This intermediate was originally suggested by Harfenist (1) for Hromatka's preparation of II. A doubly charged intermediate like VIII has been proposed by Schmalz and Burger (5) to explain the reductive nuclear chlorination and nitration of *N*-alkylphenothiazine sulfoxides. Loss of a proton from VIII, followed by enolization, would give VI (Scheme II). The intermediate VIII could possibly rise from either of the perbromides, IX or X, or the protonated form of the sulfoxide XI, depending on the reactants.

It is noteworthy that, if the bromination of I is carried out at ice bath temperature, a brown solid containing roughly two equivalents of bromine and exhibiting a carbonyl band in the infrared can be isolated. Heating the solid causes evolution of hydrogen bromide, giving VI. Efforts to obtain a

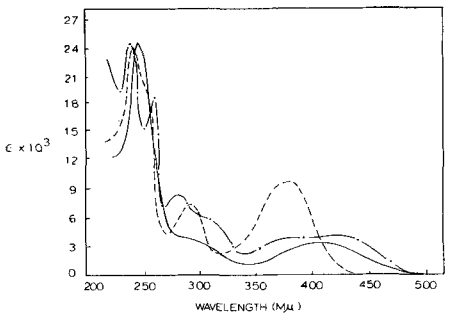

Fig. 1—1,2-Dihydro-3-keto-3H-pyrido[3,2,1-kl]-phenothiazine (I) (——) in 95% ethanol; 3-keto-3H-pyrido[3,2,1-kl]phenothiazine (II) (- - -) in 95% ethanol; 3-hydroxypyrido[3,2,1-kl]phenothiazinium bromide (VI) (— · —) in acetonitrile.

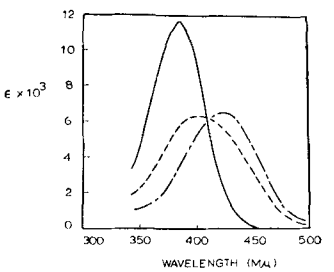

Fig. 2—3-Keto-3H-pyrido[3,2,1-kl]phenothiazine (II) (——); II in 1.6 N HCl (- - -); II in 3.8 N HCl (— - —) (all in 50% ethanol).

satisfactory analysis of the intermediate, thought to be the S-perbromide (IX), have not been successful. The possibility that the brown solid is the bromoketone (III), which eliminates hydrogen bromide when heated, cannot be entirely ruled out.

It occurred to the authors that Harfenist's "dibromide," obtained from the reaction of II with bromine, is probably the hydrobromide salt XII. The infrared spectrum of this substance, consistent with expectations, lacks a carbonyl band and shows a continuous series of absorptions in the 2300–2700 cm.$^{-1}$ region. Efforts to study the ultraviolet spectrum of XII were frustrated by its lack of solubility in nonpolar solvents and by its conversion to the unsaturated bromoketone (V) in polar solvents. A study of the spectral behavior of V in the presence of acid demonstrated that it is a much weaker base than II. Concentrations of hydrochloric acid causing significant wavelength shifts in the spectrum of II did not effect comparable changes in the spectrum of V. Evidently, the base weakening inductive effect of the bromine atom is more important than possible stabilization of the conjugate acid of II by intramolecular hydrogen bonding of the proton with the nonbonding electrons of the bromine atom. The aromatized salt XII can be visualized as being formed *via* enolization of an intermediate ion XIII as shown in Scheme III.

The fact that II undergoes electrophilic substitution rather than addition is a further indication of its aromatic character. Infrared data also suggest a high degree of aromaticity exists in this and related systems (3). Comparable substitution reactions of *N*-substituted-2- and 4-pyridones appear in the literature (6–8). For example, bromination of 1-methyl-2-pyridone is reported to give 3,5-dibromo-2-pyridone (6). The reaction of 3,5-dicarboxy-1,2,6-trimethyl-4-pyridone with iodine in acetic acid reportedly gave the corresponding 3,5-diiodo derivative in which loss of the carboxy groups occurred (8). The behavior of II toward other electrophilic reagents is under investigation in this laboratory.

Scheme III

EXPERIMENTAL

Melting points were taken in a Thomas-Hoover capillary apparatus and those below 240° are corrected. Infrared spectra were determined in KBr pellets with a Beckman IR-5 spectrophotometer. Ultraviolet spectra were determined with a Cary model 15 spectrophotometer.

3-Hydroxypyrido[3,2,1-kl]phenothiazinium Bromide (VI)—The procedure employed by Harfenist (1) for the bromination of 1,2-dihydro-3-keto-3*H*-pyrido[3,2,1-*kl*]phenothiazine (I) was employed. Concentration of the mother liquid improved the yield to 85–90%. $\nu_{max.}$ 3058, 3012 (aromatic C—H); about 2300–2700 continuous band series (ionized OH); 1616 (aromatic C=C); no ketone band in the region 1680–1690 or aliphatic C—H band near 2900. When the addition of bromine was carried out in an ice bath, a brown solid was formed almost immediately. It was collected on a filter, washed with carbon tetrachloride, and allowed to dry at 25°. When heated on a melting block the substance evolved hydrogen bromide. The infrared spectrum of the brown solid showed it to contain some VI. A ketone band at 1682 cm.$^{-1}$ was also evident in the spectrum.

Bromination of 1,2-Dihydro-3-keto-3H-pyrido-[3,2,1-kl]phenothiazine-7-oxide (VII)—A solution of 3.25 Gm. (12 mmoles) of VII in hot anhydrous dioxane was cooled to 50° and 2.1 Gm. (13.2 mmoles) of bromine in 25 ml. of dioxane was added with stirring over a 3-min. period. The mixture was then heated for 10 min. on a steam bath causing copious evolution of hydrogen bromide and the precipitation of an orange solid, m.p. 255–266°, following recrystallizations from nitromethane. Concentration of the reaction mixture gave additional material, totaling 3.4 Gm. (85%).

3-Keto-3H-pyrido[3,2,1-kl]phenothiazine (II)—A mixture of 3.32 Gm. (10 mmoles) of VI and 10 ml. of triethylamine was allowed to stand 15 min. The triethylamine was removed and the resulting solid was collected on a filter and washed with water. A nearly quantitative yield of II was obtained, m.p. 206°·[Lit. (1) 207°]. $\nu_{max.}$ 3064, 3014 (aromatic C—H); 1621 (C=O).

2 - Bromo - 3 - hydroxypyrido[3,2,1 - kl]phenothiazinium Bromide (XII)—Harfenist's procedure for the reaction of II with bromine was employed (1). Recrystallization of the material thus obtained from anhydrous ethyl acetate gave orange needles, m.p. 149–155°. [Lit. (1) 146–about 159°.] $\nu_{max.}$ 3060, 3015 (aromatic C—H); about 2300–2700 continuous band series (ionized O—H); 1628 (aromatic C=C); no keto band in the region of 1680–1690 or aliphatic C—H band near 2900. Attempts to determine the ultraviolet spectrum of XII in dioxane or acetonitrile gave a spectrum identical with that of V (see below).

2 - Bromo - 3 - keto - 3H - pyrido[3,2,1 - kl]phenothiazine (V)—A mixture of 4.11 Gm. (10 mmoles) of XII and 15 ml. of triethylamine was allowed to stand 15 min. The triethylamine was removed; the residue was collected on a filter and washed with water. A nearly quantitative yield of V was

obtained, m.p. 146–147° from 95% ethanol. [Lit. (1) 145–147.3°.] $\nu_{max.}$ 3048, 3022 (aromatic C—H); 1620 (C=O). $\lambda_{max.}$ 248 (ϵ 32,000); 301 (ϵ 6,800); 387 (ϵ 11,700). The ultraviolet absorption maxima did not undergo appreciable wavelength shifts in 4 *N* hydrochloric acid in 50% ethanol.

Quantitative Separation and Estimation of Steroid Mixtures by Thin-Layer Chromatography II. Determination of Progesterone and Estradiol Benzoate and of Progesterone, Testosterone Propionate, and Estradiol Benzoate in Mixtures

By TATJANA BIĆAN-FIŠTER

Rapid and simple procedures were developed for the TLC separation and subsequent quantitative determination of progesterone and estradiol benzoate as well as progesterone, testosterone propionate, and estradiol benzoate in vegetable oil solutions and microcrystalline water suspensions. The solvent system proposed permits not only a rapid quantitative separation of the steroids from one another but at the same time enables the separation of the steroids from the vegetable oil. No special extraction of steroids from the oil is thus necessary. The separated steroids after extraction from the adsorbent are each determined by the colorimetric and fluorimetric method, respectively.

In a recent communication (1) concerning the quantification on a microscale of steroid mixtures after thin-layer chromatographic (TLC) separation a procedure was proposed for the determination of progesterone and testosterone propionate in oil solution.

Because of the lack of rapid methods for the routine control of preparations containing steroid mixtures, the present communication describes rapid and simple procedures for the determination of mixtures of progesterone and estradiol benzoate as well as progesterone, testosterone propionate or butyrate, and estradiol benzoate.

The procedures described have been adapted to the quantification of steroid mixtures in vegetable oil solutions and crystalline water suspensions commercially available in Yugoslovia.

EXPERIMENTAL

Materials and Apparatus

Reagents—Dissolve 0.4 Gm. of isonicotinhydrazide in methanol, add 0.5 ml. hydrochloric acid (37%), and fill up to 100 ml. with methanol. Set aside the reagent for 24 hr. before use.

Received March 20, 1967, from the Institute for the Control of Drugs, Zagreb, Yugoslavia.
Accepted for publication August 15, 1967.
The author thanks Mrs. A. Harapin for technical assistance.

Adsorbent—Fluorescent Kieselgel HF_{254} (E. Merck, Darmstadt).

Reference Standards—Progesterone, testosterone propionate, estradiol benzoate [Organon, Oss (Holland)].

Apparatus—Thin-layer chromatography outfit with regulation thickness spreader (Desaga, Heidelberg), Agla micrometer syringe (Burroughs Wellcome & Co., London), ultraviolet lamp, 254 mμ (Hanau), fluorimeter [Kipp (Delft)].

Solvent System—Cyclohexane–ether–ammonia (8:2:0.5 v/v).

Preparation of Plates

Chromatoplates were prepared following the technique described by Stahl. Plates 20 × 20 cm. were coated (0.5 mm. layer thickness) with a slurry prepared by mixing with a pestle 35 Gm. Kieselgel HF_{254} with 85 ml. of water in a mortar. A batch suffices for six plates. The plates were air-dried for 10 min. at room temperature and thereafter activated by heating at 130° for 4 hr. and stored in a desiccator until used.

Procedures

A—TLC Separation of Progesterone and Estradiol Benzoate in Oil Injection Solutions—A 3.0-ml.

obtained, m.p. 146–147° from 95% ethanol. [Lit. (1) 145–147.3°.] $\nu_{max.}$ 3048, 3022 (aromatic C—H); 1620 (C=O). $\lambda_{max.}$ 248 (ϵ 32,000); 301 (ϵ 6,800); 387 (ϵ 11,700). Reference Standards—Progesterone, testosterone propionate, estradiol benzoate [Organon, Oss (Holland)].

Apparatus—Thin-layer chromatography outfit with regulation thickness spreader (Desaga, Heidelberg), Agla micrometer syringe (Burroughs Wellcome & Co., London), ultraviolet lamp, 254 mμ (Hanau), fluorimeter [Kipp (Delft)].

Solvent System—Cyclohexane–ether–ammonia (8:2:0.5 v/v).

Preparation of Plates

Chromatoplates were prepared following the technique described by Stahl. Plates 20 × 20 cm. were coated (0.5 mm. layer thickness) with a slurry prepared by mixing with a pestle 35 Gm. Kieselgel HF_{254} with 85 ml. of water in a mortar. A batch suffices for six plates. The plates were air-dried for 10 min. at room temperature and thereafter activated by heating at 130° for 4 hr. and stored in a desiccator until used.

Procedures

A—TLC Separation of Progesterone and Estradiol Benzoate in Oil Injection Solutions—A 3.0-ml.

quantity of the olive oil solution (about 60 mg. progesterone and about 9.0 mg. estradiol benzoate) was diluted in a 10-ml. volumetric flask with chloroform up to the mark. Twice, 20 µl. of this sample solution (samples *1* and *2*) and 20 µl. of each of the corresponding standard solutions were applied with a microsyringe on a Kieselgel HF $_{254}$ coated plate along the starting line (2 cm. from the lower edge) as 2 cm. horizontal lines. The chromatogram was developed in a chamber previously saturated for 24 hr. with the solvent. When the solvent reached about 1 cm. from the upper edge of the plate (about 60 min.), the plate was removed from the chamber, air-dried for a few minutes, and the separated steroids located under low wavelength light (Fig. 1). The UV absorbing zones of the sample and the standards were marked with an ample margin around each zone and quantitatively scraped off the plate, each into a separate 50-ml. glass-stoppered flask. Progesterone was thus extracted from the adsorbent with 5 ml. methanol while estradiol benzoate was extracted with 5 ml. chloroform. The flasks were stirred well for 30 min. and centrifuged.

Determination of Progesterone—Three-milliliter aliquots of each supernatant solution of sample and standard progesterone were pipeted into 50-ml. flasks, 4 ml. of the INH reagent was added, and the mixtures were set aside for 1 hr. The absorbances were measured at 380 mµ against a reagent blank.

$$\text{concn.}_x = \frac{\text{concn.}_{st.} \cdot A_x}{A_{st.} \cdot 3}$$

concn.$_x$ = concentration of progesterone per ml.,
concn.$_{st.}$ = concentration of progesterone in 10 ml. standard solution,
A_x = mean value of absorptivities of samples *1* and *2*,
A_s = absorptivity of standard solution,
3 = dilution factor.

Determination of Estradiol Benzoate—Three-milliliter portions of each supernatant solution of sample and standard estradiol benzoate were evaporated to dryness in 10-ml. volumetric flasks by heating on a water bath. The residues were dissolved in 88% sulfuric acid filled to the mark with the same acid. After 1 hr. the developed fluorescences were determined relative to the standard fluorescent solution of estradiol benzoate using filter B_2.

$$\text{concn.}_x = \frac{\text{concn.}_{st.} \cdot A_x}{A_{st.} \cdot 3}$$

concn.$_x$ = concentration of estradiol benzoate per ml.,
concn.$_{st.}$ = concentration of estradiol benzoate in 10 ml. standard solution,
A_x = mean value of absorptivities of samples *1* and *2*,
A_s = absorptivity of standard solution,
3 = dilution factor.

Standard Solution of Progesterone—Dissolve 60.0 mg. progesterone in a 10-ml. volumetric flask in chloroform and fill to the mark with the same solvent.

Standard Solution of Estradiol Benzoate—Dissolve 9.0 mg. estradiol benzoate in a 10-ml. volumetric flask in chloroform and fill to the mark with chloroform.

Standard Fluorescent Solution of Estradiol Benzoate—Dilute 10 µl. of the standard solution of estradiol benzoate in a 10-ml. volumetric flask with 88% sulfuric acid to the mark.

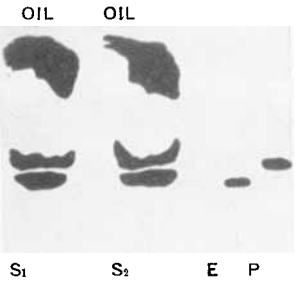

Fig. 1—Chromatogram for olive oil solution of progesterone and estradiol benzoate solution. Key: S_1, S_2 = duplicate test samples; E = estradiol benzoate; P = progesterone.

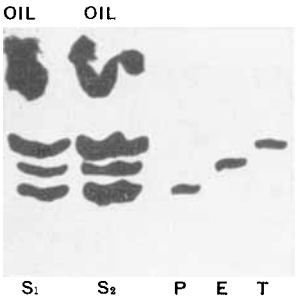

Fig. 2—Chromatogram for olive oil solution of progesterone, estradiol benzoate, and testosterone propionate. Key: S_1, S_2 = duplicate test samples; P = progesterone; E = estradiol benzoate; T = testosterone propionate.

B—TLC Separation of Progesterone, Testosterone Propionate, and Estradiol Benzoate in Oil Injection Solution—A 3.0-ml. quantity of the olive oil solution (about 60 mg. progesterone, 75 mg. testosterone propionate, and 9 mg. estradiol benzoate) was diluted in a 10-ml. volumetric flask filled to the mark with chloroform. Proceed as described under *TLC Separation of Progesterone and Estradiol Benzoate* in procedure *A* using the additional standard solution of testosterone propionate (Fig. 2).

Determination of Progesterone and Testosterone Propionate—Three-milliliter aliquots of each supernatant solution of sample and standard progesterone and testosterone propionate were pipeted into 50-ml. volumetric flasks and the determination of both steroids proceeded as described under *Determination of Progesterone* in procedure *A*.

Determination of Estradiol Benzoate—A 3.0-ml. quantity of each standard and sample supernatant chloroform solution of estradiol benzoate was treated in the same manner as described under *Determination of Estradiol Benzoate* in procedure *A*.

Standard Solution of Testosterone Propionate—Dissolve 75.0 mg. testosterone propionate in a 10-ml. volumetric flask in chloroform and fill to the mark with chloroform.

C—Testosterone Butyrate and Estradiol Benzoate in Microcrystalline Water Suspension—The contents of 1 ampul (about 7.5 mg. estradiol benzoate and 150 mg. testosterone propionate) is extracted in a separator with three times 10 ml. chloroform. The combined chloroform extracts are collected in a 50-ml. volumetric flask which is then filled to the mark with chloroform. Twenty microliters of this solution and of the corresponding standard solutions are applied to a Kieselgel HF_{254} plate along the start as 2-cm. horizontal lines, and the separation and determination of testosterone butyrate is carried out as

directed for progesterone, and that of estradiol benzoate as directed for the same steroid in procedure *A*.

Standard Solution for Testosterone Butyrate—Dissolve 150.0 mg. testosterone butyrate in a 10-ml. volumetric flask in chloroform and fill to the mark with chloroform.

Standard Solution of Estradiol Benzoate—Dissolve 10.0 mg. estradiol benzoate in a 10-ml. volumetric flask in chloroform and fill to the mark with the solvent.

D—Progesterone and Estradiol Benzoate in Microcrystalline Suspension—The contents of 1 ampul (about 200 mg. progesterone and 10 mg. estradiol benzoate) are extracted in the same manner as described under procedure *C*. Twice, 20 μl. of the chloroform extract and 20 μl. each of the corresponding standard solutions are applied to the plate, and the separation and determination of steroids are carried out as directed under procedure *A*.

Standard Solution of Progesterone—Dissolve 40.0 mg. progesterone in a 10-ml. volumetric flask in chloroform and fill up to the mark with chloroform.

Standard Solution of Estradiol Benzoate—Dissolve 10.0 mg. estradiol benzoate in a 10-ml. volumetric flask in chloroform and fill up to the mark with chloroform.

RESULTS AND DISCUSSION

The separation of progesterone from estradiol benzoate and progesterone, testosterone propionate, and estradiol benzoate achieved best resolution when 0.5 ml. of ammonia was added to the nonpolar cyclohexane–ether system to make it more polar. [The nonpolar cyclohexane–ether system was previously used (1) for the separation of progesterone and testosterone propionate.] It is known that the R_f values of steroids mainly depend on the number of C and O atoms, *i.e.*, the C/O index, which is largely determined by the polarity of the molecule. The migration of steroids on the plate can thus be explained by the fact that the less polar ester, testosterone propionate, with a longer side chain and a C/O index of 7.3, migrated faster than the more polar diketone, progesterone, with a C/O index of 10.3, and the phenolic ester, estradiol benzoate, with a C/O index of 8.3 (Fig. 2).

The methods used for the quantification of steroids extracted from the adsorbent permit the determination of about 50 mcg. of testosterone propionate and progesterone and about 6 mcg. of estradiol benzoate. This is important since steroids are generally compounded in pharmaceutical formulations in low concentrations. For the determination of the Δ^4-3 ketosteroids, progesterone and testosterone propionate, the colorimetric method by Umberger (2) was adapted. The visual fluorescence of estradiol benzoate, in sulfuric acid solution as an approach to determining steroid substances present in preparations in submicrogram amounts was found to be very useful. Data given by Szalikowsky (3) on the sulfuric acid fluorescence of various steroids proved valuable as a basis for the development of a quantitative procedure. It was found that steroid levels of 3 mg./ml. in 88% sulfuric acid could be measured satisfactorily. The Beer-Lambert law was obeyed over a suitable range of 20 to 140 mcg. of the steroid.

Table I—Analysis of Standard Steroid Mixtures

Progesterone	200.0	193.0	195.8	96.5	97.9
Estradiol benz.	10.0	9.9	10.5	99.6	105.2

The effect of time on the formation of fluorescence was determined by treatment of 20 mcg. of estradiol benzoate with 10 ml. of 88% sulfuric acid. The fluorescence was stabilized at room temperature after 1 hr. and was found to be practically stable for an additional hour.

To determine the precision of the procedures, analyses were carried out with standard steroid vegetable oil solutions prepared in this laboratory and containing exactly known quantities of steroids in approximately the same concentrations present in commercial preparations.

It is evident from the data in Table I that good reproducibility with a satisfactory standard deviation is obtained. The determination of steroids in commercial dosage forms showed that the results obtained are in good agreement with the labeled amount of the respective steroids. Results of these determinations are given in Table II.

Miotic Activity Produced by Inhibitors of Acetylcholinesterase

By A. Z. BOOTH, J. P. LONG, and K. R. LONG

Various biological activities of bis-phenacyl derivatives were investigated. The picoline derivatives demonstrated potent activity as inhibitors of human red blood cell cholinesterase. The compounds were effective miotic agents in mice and rabbits. Marked differences in toxicity of the positional isomers were noted. The 3-picoline derivative is a very toxic agent in mice, however it is equal to 2-picoline in activity as an inhibitor of acetylcholinesterase. Since the 2-picoline derivative is much less toxic, some mechanism other than inhibition of acetylcholinesterase must be involved to explain the high toxicity of the 3-picoline derivative.

SEVERAL SERIES of bis-quaternary compounds have been prepared that demonstrate potent inhibition of acetylcholinesterase. In general these compounds are much more selective for acetylcholinesterase than they are for pseudo cholinesterase (1). Since the innervation of the circular muscles of the iris is cholinergic and thus the degree of muscle tone is indirectly controlled by functional acetylcholinesterase, the biological activity was evaluated for the potent inhibitors of acetylcholinesterase described in this report. Quaternary compounds that are inhibitors of cholinesterase (*e.g.*, neostigmine) have not been particularly effective as miotic agents, probably because of difficulty of penetration across the cornea. In this series of agents this difficulty apparently was overcome by obtaining compounds that are more active biologically than neostigmine and incorporating into the structure components that would be expected to increase the lipid solubility.

METHODS

The ability to inhibit human red blood cell cholinesterase was measured using a Radiometer titrator type TTTlc titrograph type SBR 2C with Alga syringe buret. The reagents used were as follows: NaCl, 21.6%; NaCl, 22.5%; NaCl, 0.9%; acetylcholine iodide, 0.250 *M*; acetyl-β-methylcholine bromide, 0.5 *M*; Potassium hydrogen phthalate, 0.7351 Gm./200 ml. (2.0 ml. = 36 μmoles NaOH); 0.1 *N* NaOH (carbonate free). Two milliliters of potassium hydrogen phthalate is added to 10.0-ml. distilled water and this solution is titrated under N_2 with 0.1 *N* NaOH. From this titration curve the ordinate of the titrigraph chart is calibrated directly in μmoles NaOH used, which is equivalent to μmoles of liberated acid (cholinesterase activity). The abscissa of the chart gives time in minutes. Values are read as μmoles/ml./min. Red cells are prepared by centrifuging the blood sample at a fixed RFC and then washing twice with normal saline. The washed cells are suspended in an equal volume of normal saline (*i.e.*, 50% solution). To 22.0 ml. of distilled water is added 1.0-ml. whole blood, washed red cells, or plasma. The mixture is allowed to stand for 10 min. at 37–38° to allow for hemolysis and temperature equilibration. A 1.0-ml. amount of 21.6% NaCl is added and the mixture is again allowed to stand for a few minutes so that the temperature will equilibrate. The reaction mixture is then placed on the titrator and N_2 is blown over the top. After adjusting to pH 7.4 (preliminary titration), 1.0 ml. of acetylcholine iodide (0.250 *M*) is added and the reaction rate followed for about 8 min. If the true cholinesterase only is to be measured, 1.0 ml. of acetyl-β-methylcholine (0.5 *M*) is added in place of the acetylcholine iodide. Some samples were found to have too much

activity to measure even when 0.5 ml. of sample was used. In these instances 0.25 ml. of sample diluted with 0.25 ml. of normal saline was used. Inhibition studies were performed by allowing the enzyme reaction to proceed 3–5 min. to attain maximum activity and let the rate become linear. The inhibitors were added to 0.1-ml. amounts and the concentration in the reaction varied from 10^{-6} to 10^{-9} *M* depending upon the particular inhibitor employed.

The LD_{50} was calculated from data obtained with mice weighing 17–22 Gm. The compounds were administered intraperitoneally to three groups of 10 mice/group. Each compound was dissolved in distilled water and concentrations varied by 0.3 log intervals. The LD_{50}, 95% fiducial limits, and their relative activities were calculated by the methods of probits (2).

The miotic activities of the compounds were evaluated in mice and rabbits. The mice weighed 17–25 Gm. and 10 mice were used for each concentration of each drug. The compounds were prepared in distilled water and applied to the right cornea. The concentrations were varied by 0.48 log intervals. The solution was allowed to remain in contact with the cornea for 10 sec. and then the drug was washed off with distilled water (3). The amount of miotic activity was recorded at 10-min. intervals using a calibrated eyepiece and a dissecting scope (3). The relative activities of the compounds were calculated using a 2 × 2 parallel line assay (2).

Similar experiments were performed with Dutch rabbits weighing from 2–2.5 Kg. Seven rabbits were used for each dose of each compound. The pupil diameters were measured by a karatometer before and at 0.5-hr. intervals after the application of the compounds, which were dissolved in saline, with concentrations varied by 0.48 log intervals. The animals were observed for systemic effects such as diarrhea and salivation. The data were treated statistically as described above for mice.

A series of rabbits were anesthetized with sodium phenobarbital (200 mg./Kg.) administered intravenously and the influence of compounds *A* and *B* on pupil size and any alteration of arterial blood pressure responses to acetylcholine administered intravenously was evaluated.

RESULTS

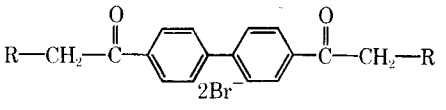
A summary of the structures and corresponding biological activity is shown in Table I.

Toxicity—A wide variation in the LD_{50} following intraperitoneal administration was demonstrated by the compounds. One of the compounds, *B*, exhibited very high toxicity and it appeared to produce death by a mechanism other than inhibition of cholinesterase. The onset of observable symptoms and time for death with this compound in mice was slow, usually requiring 10 to 20 min. In contrast, the time for death for the remaining compounds was usually less than 8 min. The toxicity of the other compounds was less than that observed for neostigmine.

Inhibition of Acetylcholinesterase—The α- and β-picolines (compounds *A* and *B*) were approximately 1000 times more active than neostigmine bromide. Compound *C*, α,β-picoline, was somewhat less active. The γ-picoline derivative as well as the piperidine derivative (compounds *D* and *E*) were less active. Also the picoline compounds indicated a more rapid inhibition of the acetylcholinesterase than did neostigmine.

Miotic Activity—These quaternary compounds demonstrated miotic activity in both mice and rabbits. The duration of action was more than 2

TABLE I—BIOLOGICAL ACTIVITIES OF VARIOUS BIS-QUATERNARY INHIBITORS OF ACETYLCHOLINESTERASE



Compd.	R	LD_{50}[a] mg./Kg. (95% CI)	Acetylcholinesterase MI_{60}	Relative Miotic Activity (95% Fiducial Limits) Mice	Rabbits

[a] The compounds were administered intraperitoneally. [b] The minimal concentration used for assay in mice was 0.011%. [c] The minimal concentration used for assay in rabbits was 0.033%.

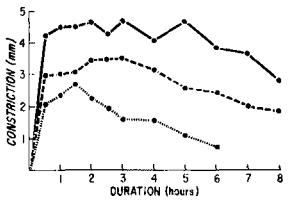

Fig. 1—Duration response curves in unanesthetized Dutch rabbits following topical application of compound A. Key: top, 0.44%; middle, 0.15%; bottom, 0.033%.

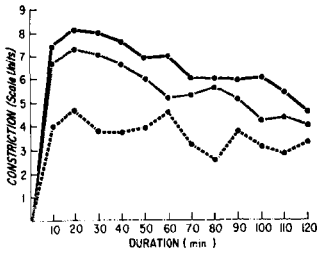

Fig. 2—Duration response curves for miosis in mice for compound A following topical application. Key: top, 0.1%; middle, 0.033%; bottom, 0.011%.

hr. in mice and 8 hr. in rabbits. The time to reach maximal inhibition in mice was 20 min. and approximately 0.5 hr. in rabbits. The dose-effect curves for compound *A* in rabbits and mice are shown in Figs. 1 and 2. Five rabbits were anesthetized and the right carotid artery was cannulated for blood pressure measurements. Control responses to acetylcholine, epinephrine, and norepinephrine were obtained. Compound *A* (0.6%) was applied to the cornea. During the following hour no alteration in blood pressure occurred and no potentiation or antagonism of the acetylcholine depressor response was observed. Also there was no alteration in the pressor responses to epinephrine or norepinephrine. With compound *B*, topical application of 0.5% solution to the anesthetized rabbits produced respiratory failure after a period of about 1 hr.

DISCUSSION

If heterocyclic substitution is placed on the bisphenacyl moiety, potent inhibitors of acetylcholinesterase are obtained. Compound *B* is of interest because of the high toxicity that apparently cannot be explained by its inhibition of cholinesterase. Since these are analogs of hemicholinium (4) it may be that this compound is exhibiting hemicholinium-type action.

Apparently these compounds cross the "corneal barrier" and reach acetylcholinesterase in concentrations sufficient to produce miosis of considerable duration. With the biphenyl nucleus as well as the substituted pyridine derivatives, the compounds may have components that contribute considerably to lipid solubility.

With the exception of compound *B* there was no evidence of systemic absorption of the compounds. Therefore it may be that the compounds can be localized effectively to the site of application, namely the cornea and anterior chamber of the eye.

SUMMARY

It has been demonstrated that a series of bis-quaternary phenacyl derivatives are potent inhibitors of acetylcholinesterase and are active miotic agents when applied topically to the cornea of both mice and rabbits. There is a wide variation in the LD_{50} of the compounds and the mechanism of toxicity is unknown for compound *B*. The high toxicity of this compound does not appear to be related to its ability to inhibit cholinesterase. The compounds, with the exception of compound *B*, do not appear to be absorbed systemically in quantities sufficient to potentiate the depressor response of acetylcholine.

Crystal Structure of Thiolphthalide

By ELI SHEFTER

The crystal and molecular structure of thiolphthalide has been determined by X-ray crystallographic analysis. The crystals of this compound are orthorhombic (space group P $2_12_12_1$) with cell dimensions of a = 4.104 Å., b = 11.835 Å., and c = 14.602 Å. The structure was determined by Patterson and Fourier methods and refined by least squares to a final R value of 0.070. The two C—S bond lengths are 1.83 Å. and 1.77 Å., with the latter bond adjacent to the carbonyl group. The angle subtended by the C—S bonds is 94°.

THOUGH THE importance of thiolesters in biological systems has been well established (1), there appears to be a lack of structural data on such compounds in the literature. Significant structural variations have been observed between acetylcholine (2) and acetylthiolcholine (3), but the accuracy of these structures does not permit a detailed comparison of the valence states about the respective ester linkages. In an attempt to obtain more definitive information about the resonance in thiolesters the crystal structure of thiolphthalide has been completed.

EXPERIMENTAL

Elongated colorless prisms obtained by sublimation were used, and the unit cell dimensions for these crystals were measured on a General Electric XRD-6 diffractometer with Ni filtered Cu $K\alpha$ radiation. They were found to be a = 4.104 ± 0.001 Å., b = 11.835 ± 0.003 Å., c = 14.602 ± 0.007 Å., and $\alpha = \beta = \gamma = 90.0°$. The systematic absences of the $h\,0\,0$ ($h = 2n + 1$), $0\,k\,0$ ($k = 2n + 1$), and $0\,0\,e$ ($e = 2n + 1$) reflections indicated the space group P $2_12_12_1$. The density calculated from the X-ray data is 1.42 Gm./cm.^{3} (assuming 4 molecules in the unit cell). Attempts were made to measure the density of the material in potassium iodide solutions, but an accurate value was not obtained.

The intensity data were collected by the stationary counter-stationary crystal technique with balanced Ni-Co filters. The mounted crystal had to be coated with petroleum jelly in order to retard its sublimation. Even though it was so covered, a 20% decrease in intensity was observed over the whole data collection period. A correction for this effect was applied to the intensities. Lorentz and polarization factors were applied to the data as well as an adjustment for the anisotropy of transmission about the ϕ axis. A correction for the α_1-α_2 splitting was also made using a correction similiar to that of Tulinsky *et al.* (4). In the 2θ range of the data collection (0–120°), 640 reflections out of a total possible number of 660 had intensities significantly greater than their background counts.

The Patterson function revealed the sulfur position and from subsequent Fourier syntheses the locations of the other atoms were obtained. The positional and thermal parameters were refined by least squares using a block diagonal matrix approximation. A weighting of $1/f_c$, where f_c is the scattering factor for carbon, was utilized in the least squares analysis. This weighting is approximately equivalent to differential synthesis weighting. The 20 unobserved reflections were given zero weight. In the later stages of refinement the hydrogen atoms were located from an electron density difference Fourier synthesis (see Fig. 1)[1] and included in the final cycles of least squares. The final R value was 0.070 (including the 20 unobserved reflections which were given half the minimum observable intensity). The atomic form factors used in all the above calculations were those tabulated by Cromer and Waber (5).

The atomic positional and thermal parameters for the atoms together with their estimated standard deviations are given in Table I. A list of the observed and calculated structure factors amplitudes will be supplied upon request.

RESULTS AND DISCUSSION

The intramolecular bond distances and angles for the molecule are shown in Fig. 2. These values were not corrected for the thermal libration of the molecule. The mean standard deviation of the intramolecular bond lengths and angles for the nonhydrogen atoms are 0.01 Å. and 0.6°. The average error for the C—H bonds is 0.10 Å.

The two C—S bonds differ significantly in their bond lengths. The C(8)—S distance of 1.83 Å. agrees well with the "commonly" accepted C—S single bond length of 1.82 Å. (6), while the C(7)—S bond is significantly shorter than this value. The latter bond appears to have approximately 35% double bond character (estimated from the data presented in *Reference 6*). The C—O— bonds in various lactones (7–10) also show an analogous difference in their molecular structures. It is worthy to note that the bond length of the carbonyl group is quite similar to the average value found for the same group in the two γ-lactone moieties of anemonin (7), where the value is 1.19 Å. In comparing the thiol-lactone portion of this molecule to anemonin, a most striking difference is observed between the C—S—C and C—O—C angles, which 94.5 and 110° (mean value), respectively, this

The author is indebted to Professor David Harker, Roswell Park Memorial Institute, for the use of his facilities, to the Computing Center of this University for a generous gift of computing time, and especially to Professor Henry G. Mautner, School of Medicine, Yale University, for his interest, and for the elongated colorless prisms which he so kindly furnished.

The *Chemical Abstracts* nomenclature for this compound is benzo(*c*)-thiophen-1-(3*H*)-one.

Note Added in Proof—Recent calculations by G. Edwin Wilson, Jr. [*Tetrahedron Letters*, **21**, 2007(1967), and personal communication] are consistent with the findings in this paper. He also suggested the possibility that the smaller C—S—C angle may also be due to the larger 3 p orbital of sulfur.

[a] The estimated standard deviations are given in parentheses × 10^4 except those for the isotropic temperature factors of the hydrogens, which have an average error of ±2.0 Å.^{2}. The anisotropic temperature factor is of the form: $T = \exp. -(B_{11}h^2 + B_{22}k^2 + B_{33}\ell^2 + B_{12}hk + B_{13}h\ell + B_{23}k\ell)$.

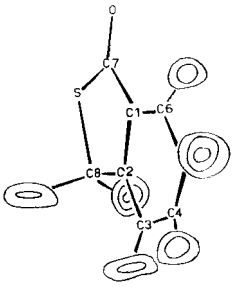

Fig. 1—Hydrogen atom electron density contours in a difference Fourier synthesis computed at the conclusion of the refinement. Contour levels at 0.1 eÅ.$^{-3}$, starting at 0.1 eÅ.$^{-3}$.

difference may be indicative of the ability of the sulfur atom to use its *d* orbitals in this bonding situation.

Within experimental error the other bond lengths and angles of the molecule agree favorably with their expected values.

The 10 nonhydrogen atoms comprising the molecule are essentially planar. The least squares equation of the plane through these atoms is:

$$-0.8897\ X - 0.0358\ Y + 0.4552\ Z = -0.9511 \text{ Å}.$$

where X, Y, and Z are the coordinates in Å. measured along a, b, and c, respectively. The root mean square deviation of the 10 atoms from this plane is 0.001 Å.

The packing arrangement of the molecules in the crystal lattice is shown in Fig. 3. The shortest intermolecular contacts are represented as dashed lines. With the exception of the C(8)—H2...O intermolecular contact, all the distances appear to be normal van der Waals contacts. Even though the estimated standard deviation for the C(8)H2...O distance is 0.12 Å., the contact is substantially smaller than the sum of the van der Waals radii between the respective atoms [1.2Å.(H) + 1.4 Å.(O)]. C—H...O hydrogen bonds have been found in a number of heterocyclic structures (11).

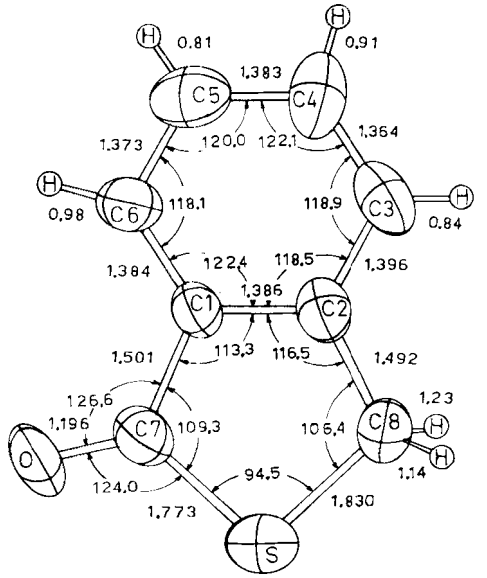

Fig. 2—The intramolecular bond distances and angles in thiolphthalide. The thermal ellipsoids are also shown.

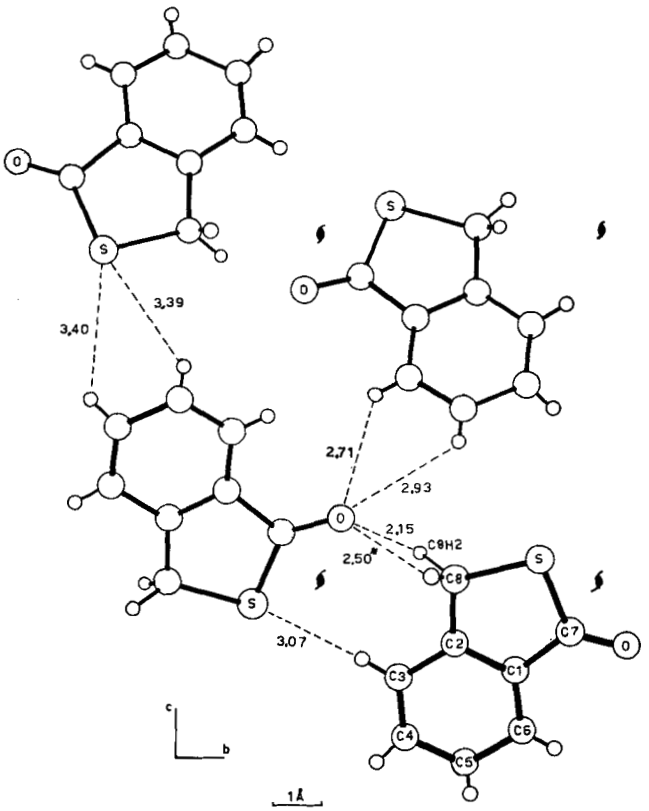

Fig. 3—The arrangement of the molecules as viewed down the a-axis. Dashed lines show shortest intermolecular contacts.

Interaction of a Photosensitizer with Dipalmitoyl Lecithin

By R. SCHAUBMAN and A. FELMEISTER*

Monomolecular films of lecithin spread on aqueous subphases containing chlorpromazine hydrochloride were studied. The effects of ultraviolet irradiation and pH were determined. The degree of penetration of the chlorpromazine into the lecithin film was found to be dependent on surface pressure, pH, and ultraviolet irradiation. The biological significance of the data is discussed in relationship to a mechanism for photosensitization.

OVER 70 years ago Raab (1) reported the first photosensitized reaction in a biological system, noting that the killing power of acridine on paramecium was markedly increased in the presence of light. Since that time numerous other compounds have been implicated as photosensitizers, including such modern medicinal agents as the sulfonamides, phenothiazines, tetracyclines, and salicylanilides (2). While a number of theories have been advanced to explain this phenomenon (1–3), neither the exact mechanism of photosensitization nor the cellular constituents involved have been clearly established (4). The following fundamental steps, though, are generally assumed to occur: absorption of light by the photosensitizing agent; a photochemical reaction involving the photosensitizing agent, oxygen, and some cellular component; and development of increased cell permeability, probably as a result of the interaction of the photo-produced species with the constituents necessary for maintaining cellular integrity. The resultant clinical developments *i.e.*, erythema, wealing, edema, and in more drastic situations, hemorrhage and irreversible cell damage, are apparently then a consequence of increased cell permeability.

It is reasonable to postulate that this increased cell permeability involves interactions of the photo-produced species with the phospholipids or sterols of the membrane. These components are the principal structural elements which make up the membranes of the epidermal and dermal cells (5), and it would be expected that changes in their structure or orientation might lead to increased cell permeability or lysis.

A number of *in vivo* and *in vitro* models have been employed to study the photosensitization process, including erythrocytes, protozoa, and the skin of test animals (4, 6, 7). While all of these models are useful in assessing the damage produced by the photosensitization process, none of them serve to establish the particular cellular components involved in the reaction. The work of Allison *et al.* (4), however, did indicate that disruption of the membranes of lysosomes and mast cells might be the primary event in photosensitization.

It is the purpose of this work to investigate the usefulness of monomolecular films as models for studying photosensitized reactions with cell membrane constituents. For this initial phase, a spread film of L-α-dipalmitoyl phosphatidylcholine (lecithin) was selected, since it has been reported to be the principal phospholipid of epidermal cells (5). Chlorpromazine hydrochloride (CPZ) was selected as the photosensitizer because of the large number of cases of photosensitization reported implicating this drug (8), and because there is extensive information available concerning the photo-properties of CPZ (8–11).

EXPERIMENTAL

Materials—The L-α-dipalmitoyl phosphatidylcholine (lecithin) was obtained, chromatographically pure, from Mann Chemical Co., New York, N. Y. Chlorpromazine hydrochloride (CPZ), obtained from Smith Kline & French Laboratories, Philadelphia, Pa., was used without further purification. The water used was first deionized with a mixed resin bed, and then double distilled from alkaline permanganate using all glass equipment. All other chemicals were reagent grade.

Equipment and General Methods—Surface tension was measured by means of a Rosano tensiometer (12) using a thin roughened platinum plate. Films were spread on a 900-ml. capacity Langmuir-type trough equipped with a movable Teflon barrier. The trough temperature was maintained constant at 25° ± 0.1 by circulating water from a constant-temperature water bath. The edges of the trough were lightly coated with paraffin to prevent wetting. Ultraviolet irradiation of the films was accomplished by means of a Mineralite model V-41 UV lamp[1] fitted with a filter to screen out radiation below 270 mμ. The lamp was positioned about 50 mm. above the trough. The lecithin was dissolved in hexane–ethanol (95%:5% v/v) and spread on the aqueous subphase using an Agla micrometer syringe.[2] Measurements of pH and absorbance were made with a Beckman Zeromatic pH meter and a Beckman DB spectrophotometer, respectively.

Studies of Nonirradiated Films—The surface pressure (surface tension of the subphase minus the surface tension of the subphase in the presence of the film) of the lecithin film was determined at different areas per molecule on a subphase containing CPZ ($1 \times 10^{-4} M$) at pH values of 3.0 and 6.0. The subphase was adjusted to pH 3.0 and 6.0 with 0.001 *M* HCl and sodium acetate–acetic acid buffer (0.1 *M*), respectively. The ionic strength of the HCl solution was adjusted to 0.1 with sodium chloride. Surface pressure was also determined in the absence of CPZ for comparison.

Studies of Irradiated Films—Films were spread under the same conditions as used for the nonirradiated studies. Irradiation was initiated with the films at zero surface pressure and continued for 2 min. The surface pressure–surface area (π-A) curves were determined either immediately or 5 min. after irradiation.

Pure lecithin films, *i.e.*, in the absence of CPZ, were irradiated for 30 min. to determine their ultraviolet stability.

To determine the effect of initial pressure, films were irradiated for extended periods of time at two different initial film pressures.

RESULTS AND DISCUSSION

Irradiation of pure lecithin film at pH 3.0 and 6.0 for 30 min. showed no change in surface pressure, demonstrating the stability of these films to the ultraviolet radiation. Irradiation of the pH 3.0 subphase containing 1×10^{-4} *M* CPZ in the absence of the film also produced no change in surface pressure, though some decomposition did occur as evidenced by formation of color and changes in absorbance spectrum. However, at pH 6.0 an increase in surface pressure was observed even in the absence of the lecithin film. This increase in surface pressure apparently was due to the formation of an insoluble film, whose π-*A* characteristics were markedly dependent on rate of compression.

The π-*A* curves for the lecithin on a 1×10^{-4} *M* CPZ subphase at pH 3.0 and 6.0 were the same (Fig. 1). A π-*A* curve for pure lecithin (*i.e.*, in the absence of CPZ) is included for comparison. It is clear that film pressure develops at much larger lecithin areas when CPZ is included in the subphase. This apparently is the result of penetration of the CPZ molecule into the lecithin film leading to the formation of a mixed film. On continued compression of the nonirradiated film it can be seen that the π-*A* curves for both the lecithin and lecithin–CPZ monolayers become identical, due to the ejection of CPZ from the film at about 31 dynes/cm.

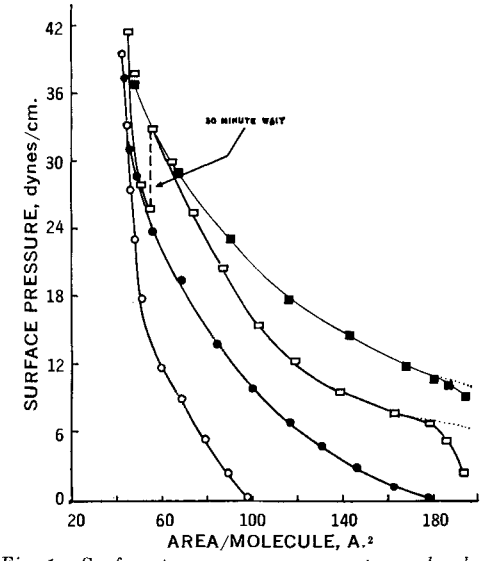

Fig. 1—Surface pressure versus *area per molecule for L-α-dipalmitoyl phosphatidylcholine at pH 3.0 and 6.0, 25°, and ionic strength 0.1. Key:* ○, *zero chlorpromazine HCl at pH 3.0 and 6.0;* ●, 1×10^{-4} M *chlorpromazine HCl at pH 3.0 and 6.0;* □, 1×10^{-4} M *chlorpromazine HCl at pH 3.0 irradiated for 2 min. at zero initial pressure;* ■, 1×10^{-4} M *chlorpromazine HCl at pH 6.0 irradiated for 2 min. at zero initial pressure; dotted lines indicate the curve that results if the readings are initiated 5 min. after the termination of the irradiation rather than immediately after.*

pressure. Similar results have been reported by Zografi *et al.* (13).

At both pH values irradiation results in significantly higher pressure at all areas as compared to the corresponding nonirradiated films. The rapid rise in surface pressure seen in the initial part of the π-*A* curves was observed consistently when the surface tension readings were begun immediately after the end of the irradiation. If, instead, the readings were begun 5 min. after the end of the irradiation, this sharp rise was not observed. The initial part of the curves then started at a higher pressure as indicated by the dotted lines (Fig. 1). The remainder of the curves were the same under both conditions. Thus it appears that changes occur, possibly in the composition of the photospecies, its orientation, or its interaction with the film or other components of the system, for a short period after the irradiation has ceased. However, apparently, after this initial period no further changes occur in the photoproduced species over the time of observation. At very high pressures it appears that the π-*A* curves of the irradiated films approach that of the pure lecithin. This suggests that the irradiated component as well as the nonirradiated CPZ is ejected from the film at very high pressures. Because of the uncertainty of the data at pressures very near the collapse pressure, it was not established whether the curves do eventually coincide and whether all of the irradiated components are ejected.

If the compression of the irradiated film on the pH 3.0 subphase was stopped on reaching an area of about 60Å² (33 dynes/cm. pressure) and maintained at this area for 30 min., the pressure gradually decreased to the value previously recorded for the nonirradiated film. Further compression then showed the same π-A characteristics as did the nonirradiated film (Fig. 1). When the compression was stopped at an area of 100Å.² or greater (*i.e.*, an area at which the pressure is about 17 dynes/cm. or less) and maintained at that area for 30 min., no change in surface pressure with time was observed. Thus it appears that the decrease in surface pressure with time, observed at the smaller area/molecule, was the result of a gradual ejection of the photo-produced species from the film rather than any change in the properties of the species itself.

At pH 6.0 the π-*A* curve after irradiation was shifted considerably to the right of that obtained at pH 3.0 (Fig. 1). However, if the surface pressure at each area developed from the irradiation of CPZ at pH 6.0 in the absence of the lecithin was subtracted from this curve, the resultant curve appeared to qualitatively follow that obtained at pH 3.0. Thus it appears that the differences observed at the two pH values are at least in part due to the increase in surface activity which results from irradiation of CPZ alone at pH 6.0. In addition, at pH 6.0 the change in π that resulted after a 2 min. irradiation decreased with increasing film pressure beyond 4 dynes/cm. The opposite effect was noted above an initial pressure of 8 dynes/cm. when the film was irradiated at pH 3.0 (Fig. 2). The reason for these differences was not determined, but they might be due to a number of factors, including the formation of different photo species at each pH value as well as the influence of pH on the rate of the photo reaction and on the photo species–film interaction.

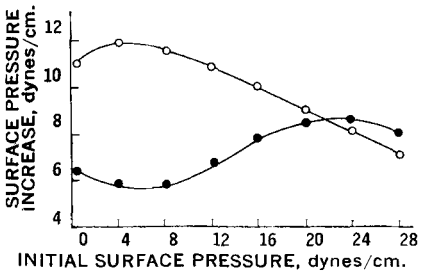

Fig. 2—The increase in surface pressure at various initial surface pressures for L-α-dipalmitoyl phosphatidylcholine at 25°, ionic strength 0.1, and 1 × 10^{-4} M chlorpromazine HCl following ultraviolet irradiation of the film at zero surface pressure for 2 min. Key: ●, pH 3.0; ○, pH 6.0.

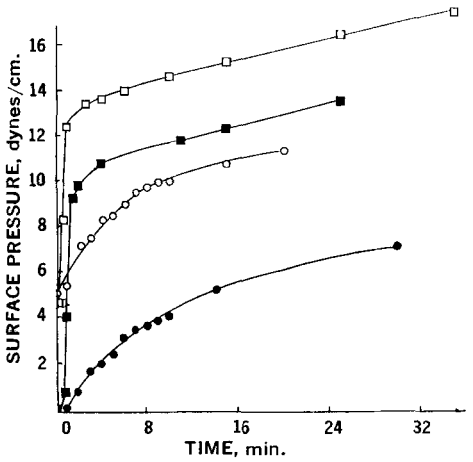

Fig. 3—Surface pressure versus *time of ultraviolet irradiation for L-α-dipalmitoyl phosphatidylcholine at 25°, ionic strength 0.1, and 1 × 10^{-4} M chlorpromazine HCl. At pH 3.0 irradiation started at zero surface pressure (●), and at 5.1 dynes/cm. surface pressure (○); at pH 6.0 irradiation started at zero pressure (■), and at 4.9 dynes/cm. surface pressure (□).*

When irradiation at pH 3.0 was extended beyond 2 min., it was noted that the rate of increase in surface pressure was fairly rapid during the first 7 to 8 min., after which the rate tailed off (Fig. 3). To determine whether this change in rate was a direct result of the increase in pressure that accompanied irradiation, and thus possibly a change in concentration and/or orientation of CPZ in the film, the effect of compression prior to irradiation was studied. The lecithin film, spread on a subphase containing 1 × 10^{-4} *M* CPZ at pH 3.0 was compressed to 5.1 dynes/cm. prior to the start of irradiation. The same rapid increase in pressure was noted, followed by tailing off after about 7–8 min. (Fig. 3). At pH 6.0 the increase in pressure developed much more rapidly and reached a higher pressure before leveling off (Fig 3). However, at both pH values the initial pressure (within the limited range studied) seemed to have no significant influence on either the rate of increase or total increase of surface pressure which resulted from irradiation. Thus it appears that the surface pressure which develops during the course of irradiation does not influence the photo reaction.

To determine whether the irradiated interaction was dependent on the presence of the film, the subphase at pH 3.0 was irradiated for 2 min. prior to spreading of the lecithin. The π-*A* curve of the lecithin film spread on this pre irradiated subphase was not significantly different from that obtained in previous experiments when the film was spread first and then irradiated for 2 min. at zero initial pressure.

CONCLUSION

Seeman *et al.* (14) have shown that CPZ penetrates the membrane of erythrocytes *in vitro*, producing membrane stabilization at concentrations of 10^{-4} *M* or lower, and lysis at concentration above 10^{-4} *M*. These effects have been related to the surface activity and the ability of this drug to penetrate spread monolayers (14). In view of this, and the results of this preliminary study, it appears that in CPZ mediated photosensitized reactions this drug may first penetrate the membranes of the cells of the dermis or basal layers of the epidermis at levels sufficient to stabilize these cell membranes. This is quite reasonable since plasma and tissue levels of CPZ are normally well below 10^{-4} *M*. Subsequent irradiation would tend to increase the pressure within the cell membranes until it reaches a level equivalent to that produced by lytic concentrations of CPZ. The result would be increased cell permeability, with its subsequent clinical effects.

It appears that a monomolecular lecithin film is a useful model to study the interactions of photosensitizing agents at cell membranes. Additional work is currently in progress to determine the effects of other photosensitizing agents on this model as well as the influence of antioxidants and ultraviolet absorbers.

Some Effects of Humidity and Heat on the Tableting Properties of Microcrystalline Cellulose Formulations I

By MUHAMMAD A. SHAH and ROBERT G. WILSON

Microcrystalline cellulose was exposed to the atmosphere of the tableting room. It was found that this exposed material did not tablet as well as material taken from the original, sealed container. Heating of the exposed material improved its tableting characteristics as was shown by increases in the weight and hardness of the tablets produced. Lubrication of the exposed material served to increase tablet weight, but this was accompanied by a decrease in the hardness of the tablets. The combination of heat and lubrication also gave heavier tablets, but again at a sacrifice in hardness.

MICROCRYSTALLINE CELLULOSE is a comparatively new material for use in the manufacture of pharmaceutical tablets. Its significance to the pharmaceutical industry is indicated by its recent inclusion in the "National Formulary" (1) as a pharmaceutic aid (tablet diluent). Several groups of investigators have reported on research work involving this new material. Among them, Lee *et al.* (2) studied the effect of water vapor pressure on the moisture sorption and stability characteristics of microcrystalline cellulose based tablets. Reier and Shangraw (3) found that microcrystalline cellulose-containing tablets swelled, gained in weight, and lost in hardness when exposed to humid conditions. The effect was shown to be a reversible phenomenon.

During preliminary work, it was observed that microcrystalline cellulose which had been exposed to the normal atmospheric conditions of the tableting room did not perform as well in tableting as did material of the same batch which was drawn from the original, closed container. The problem seemed to lie in the flow of material from the feed hopper of the tableting press. Several methods were suggested for improving the performance of the exposed material and experiments were carried out to test the effects of heat and/or lubricant upon the exposed microcrystalline cellulose. The results of two of these experiments are reported here.

MATERIALS AND EQUIPMENT

The microcrystalline cellulose,[1] as supplied was packed in a polyethylene bag contained in a standard cylindrical fiber drum. The magnesium stearate[2] was of USP quality.

All tablets were compressed on a single-punch Stokes model B tablet machine, using $^3/_8$ in. standard concave punches and die. The die fill adjustment and upper punch movement were set so they would remain essentially constant throughout any one part of the investigation. The tablets were compressed at the rate of 70 tablets per minute. Tablet weights were measured with an analytical balance. Tablet hardness was determined using a Pfizer hardness tester. The USP disintegration test, using distilled water, and the Roche Friabilator were used to test disintegration and friability, respectively. Where it was necessary to heat the microcrystalline cellulose, a bacteriological incubator was used in which the temperature could be held to $\pm 2°$.

Received June 9, 1967, from the College of Pharmacy, University of Houston, Houston, TX 77004

Accepted for publication August 10, 1967.

EXPERIMENTAL

A—Nonlubricated Microcrystalline Cellulose—In one part of the experimental work, microcrystalline cellulose was removed from the original container and exposed to the uncontrolled atmosphere of the tableting room for a 3-week period. During this time the temperature ranged from 10–28°, at a relative humidity of 50–80%. An amount of exposed material sufficient for a 60-min. tableting run was divided into three portions. One of these was placed in an oven at 37° for 16 hr., while the other two were held under ambient room conditions. The tableting press was adjusted, and all three batches were then run consecutively, starting with a room temperature batch, continuing with the heated batch, and then finishing the run with the second batch of material at room temperature. This design served two purposes: (*a*) by running the room temperature microcrystalline cellulose before and after the heated batch, it could be shown that the press settings would remain essentially constant throughout the entire run; and (*b*) it was possible to compare the tableting properties of the heated and unheated portions of the exposed material. The tablets were collected in a predetermined pattern so as to avoid any variation due to the start-up of the press or shifts from one material to another in the course of the tableting run. The results obtained are shown in Table I.

There was but a slight variation in tablet weight or in tablet hardness between tablets made from the same portion and no significant difference between the two batches of room temperature material compressed before and after the heated batch. This indicates that the press settings remained constant, and the powder flowed at uniform rates during these two parts of the experiment. There was, however, a marked and statistically significant difference between the exposed unheated, and the exposed heated, portions of the material. Heating the exposed microcrystalline cellulose caused it to fill the die cavity to a greater extent and thus to produce a heavier, harder tablet. This was accomplished without a sacrifice in the disintegration characteristics of the tablets and with what appeared to be a slight improvement in tablet friability.

B—Lubricated Microcrystalline Cellulose—In another part of the work, microcrystalline cellulose was exposed for a 3-week period and again divided

TABLE I—EFFECT OF MICROCRYSTALLINE CELLULOSE ON TABLETS

Property	Microcrystalline Cellulose—Room Temp., Compressed Before Heated Portion	Microcrystalline Cellulose—Heated 16 hr. at 37°
Av. tablet wt. (100 tablets)	220.8 mg.	240.8 mg.
S. D. in av. tablet wt.	1.7 mg.	1.3 mg.
Av. tablet hardness (20 tablets)	10.6 lb.	14.5 lb.
S. D. in av. tablet hardness	0.6 lb.	0.6 lb.
Disintegration time (USP test)	Practically instantaneous	Practically instantaneous
Friability (Roche Friabilator)	0.15% loss in wt.	0.11% loss in wt.

into three parts. One part was held as an untreated control. The other two parts were lubricated with magnesium stearate at a concentration of 1% by weight. One of these lubricated portions was then heated in an oven at 37° for 16 hr., while the other was held under room conditions. The press was set, and the three portions were processed in sequence through the tableting machine. The results obtained are shown in Table II. The data on the tablets produced from the plain, unlubricated microcrystalline cellulose show that the tablets of part *B* were lighter than those of part *A*, *i.e.*, a different press setting, as well as having been treated at a different temperature level. The results of the two parts of the experiment are not to be compared against each other. Considering part *B*, alone, it is evident that the addition of magnesium stearate gave a marked and significant improvement in average tablet weight, and that an even further and again statistically significant improvement was obtained by heating the lubricated material for 16 hr. at 37° prior to tableting. However, these significant increases in the average weights of the tablets produced were accompanied by important decreases in tablet hardness and friability. In addition it was observed that the lubricated microcrystalline cellulose seemed to give tablets with imperfect surfaces, and ones which would presumably be too soft for most commercial purposes. Further studies would be required before a definite decision could be reached on this point.

TABLE II—EFFECT OF MAGNESIUM STEARATE ON MICROCRYSTALLINE CELLULOSE TABLETS

Disintegration time (USP test method)	Practically instantaneous	Practically instantaneous	Practically instantaneous
Friability (Roche Friabilator)	0.18% loss in wt.	0.92% loss in wt.	0.87% loss in wt.

SUMMARY

Microcrystalline cellulose was used in direct compression tableting studies. It was observed that the tableting characteristics of the material changed with time during exposure to the atmosphere of the tableting room. Three procedures were suggested as possible ways to improve the performance of the exposed material. These were: (*a*) to heat the exposed material, (*b*) to add magnesium stearate as a lubricant, and (*c*) to combine the effects of heat and lubrication.

An analysis of variance, using the F ratio, was applied to the data from each of the experimental runs. It was found that heating the exposed microcrystalline cellulose prior to its direct compression gave a statistically significant ($P < 0.01$) increase in both the weight and hardness of the finished tablets. The use of magnesium stearate as a lubricant also increased the tablet weight significantly ($P < 0.01$), but there was an undesirable decrease in the hardness of the finished tablets. The combined use of heat and lubricant gave an increase in average tablet weight over that obtained with lubricant alone, but the hardness of the tablets was still at a low and unsatisfactory level. Futher studies are being conducted on the effects of exposure upon the tableting characteristics of microcrystalline cellulose. More should be known about the underlying reasons for the changes that have been observed.

Effect of Molecular Conformation on Interaction of Organic Species in Water. Benzamides and Anisamides with Theophylline and Riboflavin

By MASAHIRO NAKANO* and TAKERU HIGUCHI†

Complexing tendencies of *N,N*-dimethylbenzamide and *N,N*-dimethylanisamide toward theophylline and riboflavin in water were found to be significantly less than those of *N*-substituted and *N*-monomethyl analogs. It is suggested that rotation of *N,N*-dimethylamide group about the benzene ring-carbonyl carbon bond may inhibit formation of such complexes. *N,N*-Dimethylcinnamamide whose *N,N*-dimethylamide group can lie on the same plane as the styrene group was shown to be as good an interactant as the unsubstituted cinnamamide.

HIGUCHI AND PISANO (1) and Nakano with Higuchi (2) have observed that some *ortho*-substituted benzoate ions other than hydroxy were generally much weaker binding agents than the unsubstituted and the corresponding *meta*- or *para*-substituted benzoate ions. In these systems the observed effect was attributed to steric interferences by groups in the *ortho* position.

The present report is concerned with a similar observation resulting from a substitution in a side chain. *N,N*-Dimethylbenzamide was found to be a significantly weaker interactant toward theophylline and riboflavin than unsubstituted and *N*-monosubstituted benzamide. Measurements were also carried out on anisamides and cinnamamides.

EXPERIMENTAL

Materials—Benzamide (Eastman), anisamide (Aldrich), and cinnamamide (Aldrich) were recrystallized from water, m.p. 128°, 166°, 147°, respectively. *N*-Methylbenzamide, *N*-methylanisamide, *N,N*-dimethylbenzamide, *N,N*-dimethylanisamide, and *N,N*-dimethylcinnamamide were synthesized from their acid chlorides (Aldrich) and gaseous monomethylamine or dimethylamine in ether and purified by vacuum distillation or by recrystallization from water, m.p. 80°, m.p. 116°, b.p. 132° at 15 mm., m.p. 42°, and m.p. 103°, respectively. The PMR spectrum of each compound was also checked on a Varian A-60A spectrometer. Theophylline (m.p. 272°) and riboflavin were of NF and USP grade, respectively, and were used without further purification.

Solubility Studies—For benzamide–theophylline systems, increasing amounts of benzamide solution ($0–3 \times 10^{-1}$ *M*) were pipeted into vials and the solutions were brought to a constant final volume (10 ml.) in presence of fixed, excess amount of solid theophylline. For cinnamamide–theophylline systems, increasing amounts of theophylline solution ($0–3 \times 10^{-2}$ *M*) were pipeted into vials and excess amounts of cinnamamides were added. Equilibration was effected by rotation of the vials in a water bath thermostated at 25.0 ± 0.1° for 48 hr.

After equilibration, an aliquot of the supernatant liquid was withdrawn and analyzed spectrophotometrically after dilution with methanol. Wavelengths chosen were 282 mμ for benzamide–theophylline systems and 290 mμ for cinnamamide–theophylline systems. Small absorption due to the known amount of benzamides for the former systems and that of theophylline for the latter systems were substracted from the total observed absorbance. Apparent 1:1 stability constants were computed according to the phase-solubility technique (3).

Spectrophotometric Studies—Stability constants for riboflavin complexes were evaluated from spectroscopic measurements. Volumetric flasks, each containing 4×10^{-5} *M* riboflavin and varying amount of benzamides or anisamides ($0–5 \times 10^{-2}$ *M*), were equilibrated in a 25° water bath. These solutions were brought to final equilibrium in a Cary 15 spectrophotometer cell compartment kept at 25°. The absorbance was measured at 490 mμ and the Foster *et al.* method (4) was employed for the computation of stability constants.

PMR Studies—Proton magnetic resonance (PMR) spectrum of *N,N*-dimethylbenzamide (5×10^{-2} *M*) in water at 25° was recorded on a Varian A-60A spectrometer with a V-6057 variable temperature accessory. PMR spectra of anisamides (3×10^{-2} *M*) in deuterium oxide were recorded on the same spectrometer at temperature of the probe (38°). DSS was used as an internal reference.

RESULTS AND DISCUSSION

Experimentally observed apparent stability constants of benzamide and substituted benzamides interacting with theophylline as determined by the solubility method are shown in Table I. It is probable that these values reflect, to a limited degree, contributions from species other than 1:1;

both systems it would appear that a single *N* substitution produced a small but a definite increase in binding tendencies. *N,N*-Dimethyl series, however, exhibit in every case a dramatic drop-off in their associative ability. It is suggested that this situation may arise as a result of the difference in the steric conformation of the disubstituted amides as compared to the others. Benzamides and *N*-methylbenzamides can have completely planar structures which would permit maximum conjugation between the amide groupings and the benzene rings. These have, as expected, closely similar spectra (5). With *N,N*-dimethylbenzamides, on the other hand, a completely planar structure is impossible because of the interference between the methyl groups and the *ortho* hydrogen atoms (5). The interference can be relieved by rotation about the Ph—CO bond or the CO—NMe_2 bond. It is more likely that the amide group remains planar because of its high resonance energy (6), and that rotation takes place about the Ph—CO bond. The ultraviolet spectrum of *N,N*-dimethylbenzamide in water, furthermore, has no peak above 220 mμ, a situation characteristic of nonplanar molecules (7). The PMR spectrum of *N,N*-dimethylbenzamide at 25° in water, moreover, was observed to have 2 peaks, separated by 7 c.p.s. from each other, corresponding to 2 different methyl groups with respect to carbonyl group. This effect is most likely due to hindered rotation about the CO—NMe_2 bond. The relative PMR chemical shifts of the *ortho* and *meta* hydrogens in anisamides shown in Fig. 1 also appear to reflect the effects of *N* methylation.

The complexing tendency toward theophylline of *N, N*-dimethylcinnamamide, whose amide group is sufficiently removed from the benzene ring for steric hindrance to planarity to be absent, was also examined and the results are shown in Table III.

Unlike the benzamide *N, N*-dimethylcinnamamide

appears to be almost as good an interactant as the unsubstituted cinnamamide and has essentially the same absorption as the latter when account is taken of the bathochromic effect of the methyl groups (5).

It is believed that the interactions of aromatic molecules in water are likely plane to plane stacking (2). If this is true, the observed poor complexing tendencies of *N, N*-dimethylbenzamides are possibly due to prevention of approaching molecules from coming closer to the aromatic ring. The decreased interactive tendencies of the dialkyl derivatives, on the other hand, may also arise in part from the reduction in resonance caused by the steric effect.

Method for Determining Ethchlorvynol in Urine and Serum by Gas Chromatography

By DON W. ROBINSON

A new gas chromatographic technique for the identification and quantitative determination of ethchlorvynol in urine and serum is described. The method was developed because of the need for a rapid analysis of the drug in cases of suspected overdosage. The procedure was tested at concentrations of 3 to 100 mcg./ml.

PREVIOUS METHODS (1, 2) for the determination of ethchlorvynol,[1] a nonbarbiturate hypnotic, in biological fluids have involved distillations and chemical reactions. The procedure described is specific and does not require altering the ethchlorvynol molecule.

In developing a gas chromatographic method, it was noted that the presence of alcohol in urine would interfere with the ethchlorvynol peak. The syringe and injector become clogged when serum was injected directly. These problems were solved by the addition of an extraction step.

Two drugs of similar structure, ethinamate[2] and methylparafynol,[3] were found not to interfere. Kazyak and Knoblock have also shown different retention times for these compounds on a silicone column (3).

Recovery of therapeutic and overdoses of ethchlorvynol using chemical methods have been reported in the literature (1, 2).

EXPERIMENTAL

Method and Materials—*Instrument*—A gas chromatograph equipped with a flame ionization detector. A 5 ft. by $^1/_8$ in. outside diameter stainless steel column packed with Silicone L-46[4] 20% on acid washed Chromosorb W 80 to 100 mesh.[5] The liquid phase was applied by the evaporation technique. The column should be conditioned at 225° for 24 hr. prior to use. A Hamilton microliter syringe equipped with a Chaney adapter set to deliver 5 μl.

Instrument Conditions—Column temperature, 125°; injector temperature, 150°; nitrogen carrier gas, 22 ml./min.; electrometer, maximum sensitivity; and attenuator, 1.

Reagents and Solutions—Carbon disulfide analytical reagent.[6] Urine and serum from a subject who has not recently ingested ethchlorvynol and which does not produce an ethchlorvynol response after extraction and injection into the chromatograph.

Procedure—Weigh accurately 0.1 Gm. of ethchlorvynol into a 100-ml. volumetric flask. Bring to volume with urine or serum which does not contain the drug. This solution contains 1000 mcg./ml. and is used for making further dilutions. The solution may be frozen and used at a later date.

Urine Analysis—Using a separator, extract 50 ml. of urine with two portions of carbon disulfide, 30 and 20 ml. Inject 5 μl. of the carbon disulfide layer and measure the area of the ethchlorvynol peak. Extract a standard of ethchlorvynol in urine at the suspected concentration in exactly the same manner. Inject 5 μl. of the standard extract and measure the peak area.

Serum Analysis—The extraction procedure for serum must be modified because of the usually small volume available. Pipet 5 ml. of serum along with 5 ml. of carbon disulfide into a glass-stoppered centrifuge tube. Shake gently for 2 min. Care must be taken to prevent formation of an emulsion which cannot be broken. Centrifuge at 2000 r.p.m. for 15 min. Inject 5 μl. of the carbon disulfide layer and measure the peak area. Treat a standard of ethychlorvynol in serum at the suspected concentration in exactly the same manner.

Under the conditions described, the ethchlorvynol should be eluted in 3 to 4 min. A chromatogram is shown in Fig. 1. Using toluene as the reference standard, the relative retention time is 3.0:

Calculation—

$$\frac{\text{area sample peak}}{\text{area std. peak}} \times \text{concn. of std., mcg./ml.} = \text{sample concn., mcg./ml.}$$

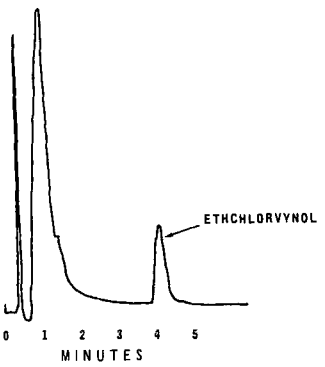

Fig. 1—Chromatogram of carbon disulfide extract from human serum containing 18 mcg./ml. ethchlorvynol. Five foot × $^1/_8$ in. stainless steel column packed with 20% Silicon L-46 on Chromosorb W 80 to 100 mesh. Temperature 125°; nitrogen at 22 ml./min.

DISCUSSION

Carbon disulfide was chosen as the extracting solvent because of its good solvent properties and because of the low response it produces on the flame ionization detector (4).

Received May 15, 1967, from the Analytical Research Department, Abbott Laboratories, North Chicago, IL 60064
Accepted for publication August 8, 1967.

[3] Marketed as Dormison by Schering Corp., Union, N. J.
[4] Silicone Division, Union Carbide Corp.
[5] Johns-Manville Corp.
[6] Mallinckrodt No. 4352. Purification is not necessary.

The standard extracts are stable and may be tightly sealed and stored at low temperature for use at a later date.

To further confirm the presence of ethchlorvynol, the extract can be chromatographed on a column of different polarity. A 5 ft. by $^1/_8$ in. outside diameter stainless steel column packed with diethylene glycol succinate 20% on Gas-Pack W[7] 60/80 gives good separation. When operated under the same conditions employed with the Silicone L-46 and using benzyl alcohol as the reference standard, the relative retention time for ethchlorvynol is 0.54.

To establish the linearity of the method, standard curves were prepared for both urine and serum. Concentrations of 5, 10, 25, 50, and 100 mcg./ml. were prepared and extracted. The curves are shown in Figs. 2 and 3. The ability of the procedure to recover the drug quantitatively from urine and serum was tested. The results were obtained by comparing the sample to a standard of similar concentration. Two of the urine samples also contained 0.2% ethanol to check for possible interferences. The results are in Tables I and II.

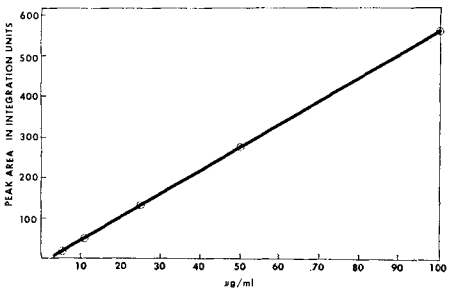

Fig. 2—Standards of 5, 10, 25, 50, and 100 mcg./ml. ethchlorvynol in urine extracted with CS_2.

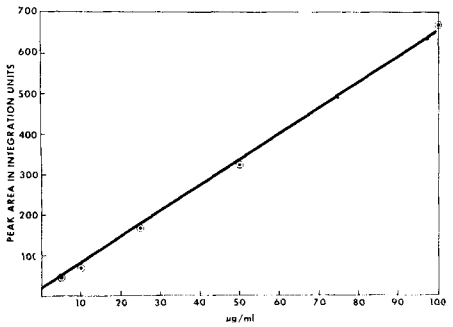

Fig. 3—Standards of 5, 10, 25, 50, and 100 mcg./ml. ethchlorvynol in serum extracted with CS_2.

The method can be performed in approximately 1 hr. and used to confirm suspected misuse of the drug.

Mechanism of Action of Starch as a Tablet Disintegrant II Effect of Pepsin and Surfactants on Swelling of Starch Grains at 37°

By JAMES T. INGRAM and WERNER LOWENTHAL

The study of the effects of the individual components of simulated gastric fluid USP on starch grain swelling is completed. There is no statistically significant swelling demonstrated by pepsin in the submersion medium when compared to simulated gastric fluid and distilled water. Surfactants demonstrated no significant effect on starch grain swelling over that of distilled water. Apparent effectiveness of surfactants in improving tablet disintegration in some cases is postulated as being due to an increase in the rate of wetting. In the same experiment, the significant differences observed between corn and amioca starches and the moisture contents of these two starches are postulated as being due to the initial size differences of the grains being maintained during the experiment.

It does not seem probable that untreated or unmodified starch will swell sufficiently at 37° to cause tablet disintegration. If swelling is the primary mechanism whereby starch exerts its disintegrant effect, then this property must be imparted to the starch by the environmental conditions. The minimal effects of acid and salts in the submersion medium were demonstrated previously (1). Changes in pH had little effect on swelling; however, evidence was obtained to show that starch grains may swell more at a pH of 5.3 than in lower pH media. Salts did effect increased swelling, and the results indicated that salts of polyvalent cations produced more swelling than the salts of monovalent cations. Ionic concentration did not show an effect on swelling.

In order to complete the study of the effects of the individual components of simulated gastric fluid USP (SGF) on starch swelling, pepsin is included as a submersion medium in the present study.

Since surfactants have been shown to be effective in certain cases in improving tablet disintegration (2, 3), an experiment is included to determine their effect on starch swelling. Surfactants, when sprayed onto granulations containing starch, were shown by Cooper and Brecht (2) to be generally effective in improving tablet disintegration. A total of 21 surfactants, representing anionic, cationic, and nonionic classifications as well as a wide range of chemical and physical properties, were incorporated into calcium lactate tablets containing starch. Disintegration tests on these tablets revealed that the four surfactants that were most efficient in improving disintegration time were anionic in ionization, waxy solids, and structurally related to sulfosuccinic acid.

Aradi (3) also studied the influence of surfactants on disintegration and found a positive relationship between surfactants and improvement of disintegration time.

Gray and Schoch (4) studied the effect of various surfactants on the swelling behavior of several typical starches. Viscosity measurements on aqueous solutions of the starches heated above the pasting range were used as a measure of swelling. It was reasoned that if the surfactant complexes strongly with the linear fraction of the starch, it should restrict swelling. If no such complex is formed or if a waxy starch is used, the surfactant should act as a wetting agent and assist hydration of the starch molecules with subsequent swelling of the starch grains. Results of the study show that polar surfactants which complex strongly with the linear fraction restricted the swelling and solubilization of corn, potato, and even waxy sorghum starches. Cationic quaternary ammonium surfactants anomalously increased the hydration of corn and waxy sorghum starches, but drastically reduced the swelling and solubilization of potato starch.

EXPERIMENTAL

The study was planned to determine the effect of pepsin and surfactants on starch grain swelling. The swelling of starch grains was determined microscopically by measurement of the individual grain diameters using the procedure described previously (1). Two full factorial experimental designs were used and analyses of variance were calculated to determine the effects of pepsin and surfactants with various starches. Two types of starches at two moisture contents were used to determine if the type of starch and moisture content would have any effect on swelling in the submersion media used and to give more sensitive experimental design.

Commercial grades of corn and amioca (waxy corn) starches were chosen for the investigation. For the high moisture content, the commercially available starches[1] were used. For the low moisture content cornstarch, a commercial redried cornstarch[2] (P825) containing 1.5% maximum moisture was used. For the low moisture content amioca starch, the commercially available amioca starch was dried at 93° to a constant moisture content of 2.88% w/w.

RESULTS AND DISCUSSION

To investigate the effect of pepsin on swelling of starch grains, a $2 \times 2 \times 3$ full factorial experimental design was used. A 0.32% w/w aqueous solution of pepsin, distilled water, and SGF were used as submersion media. It was previously shown that there is no significant difference between distilled

[a] Unsubmerged. [b] Mean grain sizes in scale divisions; one scale division = 1.8 μ.

water and SGF as submersion media, and that the significance of the time effect was due to the difference in grain diameters between unsubmerged starch (0 time) and submerged starch (1). For these reasons, the time effect was not investigated. Distilled water and SGF were included as a basis of comparison.

The starches were slurried in the submersion media at 37° and the mean grain diameters were determined after submersion for 5 min. Table I shows the mean grain sizes and the variables investigated. In the analysis of variance, interactions were not significant and were combined with the error term. There was no significant difference demonstrated among any of the variables investigated.

The effectiveness of surfactants in improving tablet disintegration may be due to the fact that surfactants increase the rate of starch grain wetting. Nogami, Nagai, and Uchida (5) state that immersional wetting might be a controlling factor in disintegration of tablets made under low compressional force. In order to investigate the possibility that surfactants improve tablet disintegration by increasing the swelling capability of the starch grains, a 4 × 2 × 2 × 2 factorial experimental design was used.

Table II shows the variables studied and the mean grain sizes. Polysorbate 80 (P80), benzalkonium chloride (BzC), and sodium lauryl sulfate (NaLS) were selected as the surfactants because they represent each of the ionic classifications—nonionic, cationic, and anionic, respectively. Aqueous solutions containing 1% surfactant were used as submersion media and distilled water was included as a control. Due to the high mobility of the starch grains in the surfactant solutions, measurement of the grain diameters was almost impossible when the slides were prepared directly from the surfactant slurry. To overcome this difficulty, the sample removed from each slurry was mixed with glycerin, which does not affect the swelling of starch grains (6). This increased the viscosity sufficiently to fix the grains and allow measurement of the diameters. In the analysis of variance, the three-factor interactions were not significant and were combined with the error term. The type of starch × time interaction was significant. Type of starch and moisture content were significant at the 0.5% level. These differences are probably due to maintenance of the initial grains size difference for the duration of the experiment. Significant differences among the surfactants and distilled water were not demonstrated.

SUMMARY AND CONCLUSIONS

Previous work on the effect of environmental conditions on starch grain swelling is reviewed and determination of the effects of the individual components of simulated gastric fluid USP was completed. There was no statistically significant swelling demonstrated by pepsin in the submersion medium when compared to simulated gastric fluid and distilled water.

Surfactants did not significantly affect starch swelling when compared to distilled water. Surfactant effectiveness in occasionally improving tablet disintegration is apparently not due to any effect on starch grain swelling, but is more likely due to an increase in the wetting rate of the tablet resulting from the decrease in surface tension.

The study of the effects of tableting procedure on starch grain swelling and tablet disintegration is being completed.

Phosphorus–Nitrogen Compounds VII. Urethan Derivatives

By L. A. CATES and J. A. NELSON

A series of phosphorylated urethans was synthesized for antitumor screening. Results indicate that the P(O)NHC(O)OEt moiety does not contribute directly to an oncolytic effect against lymphoid leukemia.

BIS(1-AZIRIDINYL)PHOSPHINYL CARBAMATES have been extensively investigated as potential anticancer drugs (1–4); these derivatives being synthesized specifically to incorporate two biologically active groups into a single molecule, *i.e.*, the so-called "dual antagonist." Papanastassiou and Bardos (2) prepared a phosphorylated urethan lacking an aziridine group to support their premise that for a dual antagonist "each synergistic component should be present in the molecule in such form (chemical linkage) that it can exert its biological activity." This "open-chain" analog, *N,N,N′,N′*-tetraethyl-*N″*-carbethoxyphosphoramide, was inactive in Walker carcinosarcoma 256 but equal to urethan against adenocarcinoma 755 in mice. The difficulty these investigators encountered in the synthesis of this compound involved ammonolysis of the labile ester group and separation of the desired carbamate from the corresponding carbamide.

In view of the antileukemic activity of urethan it was considered advisable to prepare further *N*-phosphorylated derivatives (Table I) for testing against this tumor system. None of the phosphorylated urethans (compounds I–V, VII, and IX, Table II) exhibited significant oncolytic properties. These results indicate that previously reported (1) superior activities of bis(1-aziridinyl)phosphinyl carbamates over nitrogen mustards against leukemia may be due to the effect of the carbamate portion on some other factor, such as distribution, absorption, or elimination.[1]

It has been reported that urethan is *N*-hydroxylated *in vivo* and the resulting *N*-hydroxyurethan may be the active metabolite which is responsible for its radio-mimetic effects (5). Also, Skipper *et al.* (6, 7) observed reduced antileukemic activity in *N*-alkyl derivatives of urethan. It is possible, therefore, that *N*-substitution, such as phosphorylation, may interfere with hydroxylation, and thus with the oncolytic activity, of urethan.

Previous studies (8, 9) have indicated that direct phosphorylation of physiologically active amines results in a reduction of activity and toxicity, whereas separation of phosphorus and nitrogen atoms by a carbamoyl group has afforded derivatives with some degree of antitumor activity (10). VIII represents a ureido separation of these atoms and a comparison of its activity with that of VII may provide a basis for the study of related derivatives. A future paper in this series describes the synthesis of phosphoric triamides incorporating urethan and methoxyurea moieties.

The phosphinylcarbamates herein reported were prepared *via* the reaction between dichlorophosphinylurethan and various amines or ammonia. Ammonolysis of carbamate to carbamide was shown, by means of elemental microanalyses and infrared absorption in the 1660 cm.$^{-1}$ (ureas) instead of the 1700–1735 cm.$^{-1}$ range (urethanes) (11), to occur in only one case (IX). The low yield of VI may be accounted for on this basis although no corresponding carbamide was isolated. A high yield of III was obtained despite the use of a strong base which would expectedly result in ammonolysis. VII and VIII were prepared in good yield by condensing phosphinylidynetris isocyanate with ethanol or ethyl carbazate, respectively.

Compounds II–V and IX were incidentally screened for antimalarial activity.[2] None of these derivatives extended survival time of mice infected with lethal doses of *Plasmodium berghei*.

EXPERIMENTAL

Ethyl Bis(diaminophosphinyl) Carbamates[3] (I–VI)—Dichlorophosphinylurethan (2) (0.1 mole) in toluene or benzene (100 ml.) was added to aniline, *p*-toluidine, cyclohexylamine, 2-aminopyridine, or phenylhydrazine (0.4 mole) in toluene or benzene (100 ml.) with stirring and <50°. The reaction mixtures were allowed to remain overnight and filtered, and the residues were washed with water and recrystallized once or twice from the appropriate solvent. In the case of II, the reaction mixture filtrate was spin-evaporated to yield a dark oil which was dissolved in dilute NaOH, treated with charcoal, filtered, and acidified with concentrated HCl. Recrystallization of the resulting white precipitate from ether gave the product. I and IV were similarly dissolved in alkali and precipitated with acid as a purification step. VI was prepared by passing dry ammonia into an ethereal solution of dichlorophosphinylurethan (0.2 mole) for 5 min. with stirring and isolating the product from the precipitate.

Triethyl Phosphenylidynetris Carbamate (VII) and Triethyl 3, 3′, 3″-[phosphinylidynetris (iminocarbonyl)] tricarbazate (VIII)—Ethanol or ethyl carbazate (0.1 mole) in acetonitrile (50 ml.) was added to phosphinylidynetris isocyanate (0.03 mole) (phosphoryl isocyanate, Alfa Inorganics, Inc.) in ether or acetonitrile (200 ml.) with stirring and 5–10°. After remaining overnight, the precipitates were collected, washed with ether, and dried *in vacuo*. Neither product showed absorption in the 2250–2275 cm.$^{-1}$ region (isocyanates).

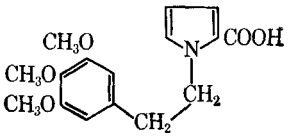
Peyote Alkaloids IV. Structure of Peyonine, Novel β-Phenethylpyrrole from *Lophophora williamsii*

Sir:

In a recent study on the peyote alkaloids, we reported (1, 2) isolation of five crystalline quaternary bases, four of which were identified. A sixth quaternary base was obtained in a purified form and a seventh crystalline compound was a nonalkaloidal substance. Further work on the peyote constituents resulted in an isolation of an eighth new compound designated peyonine.[1] Structural study on peyonine is the subject of this communication and has revealed that this is a novel β-phenethylpyrrole.

Peyonine, m.p. 131–133.5°, isolated from purified methanolic extracts of *Lophophora williamsii* (Lem.) Coult., shows a positive Ehrlich reaction, indicating the presence of an indole, a pyrrole, or a phenolic compound (3, 4). The mass spectrum (Fig. 1) is characterized by peaks at *m/e* 305 (parent), 261 (loss of a carbon dioxide), and 181 (base, evidently the trimethoxybenzyl ion, see below). The IR spectrum revealed a broad hydroxyl peak at 3600–2500 cm.$^{-1}$, a carbonyl peak at 1670, and aromatic peaks at 1595, 820, and 750 cm.$^{-1}$ The ultraviolet absorption spectrum in methanol showed a maximum at 261 mμ (ε10,000) which base shifted to 257 (9700), and acid shifted to 266 (10,700). The NMR spectrum ($CDCl_3$, TMS = 0) revealed a broad peak at 10.70 p.p.m. (1 H, COOH), 6.32 (2 H singlet, polyoxygenated aromatic), 4.35 and 2.98 (2 H each, triplets, A_2X_2, $ArCH_2CH_2$), and 3.85 (9 H, singlet, aromatic OCH_3); in benzene this last peak appeared as two singlets, 3.63 (6 H) and 3.85 [3 H, *o,o'* disubstituted aromatic methoxyl (6)]. Multiplets at 7.15, 6.70, and 6.12 (1 H each) are assigned to the protons of an *N*-substituted pyrrole-2-carboxylic acid. The spectral properties of pyrrole-2-carboxylic acid substantiated this assignment. IR (KBr) carbonyl: 1660; aromatic 1550; 750 cm.$^{-1}$; UV, $\lambda_{max.}^{MeOH}$ 261 mμ(ε 13,200) (8), shifted by base to 254 (12,000) and by acid to 263 (14,700). The spectral data and the biogenetic considerations suggested that peyonine was most likely 1-(β-3′, 4′, 5′-trimethoxyphenylethyl)-pyrrole-2-carboxylic acid (I).



I

The assigned structure I was confirmed by the synthesis of peyonine. Treatment of mescaline with methyl 2,5-dimethoxytetrahydro-2-furoate (9) in refluxing glacial acetic acid produced peyonine methyl ester. Saponification furnished crystalline peyonine identical (TLC, GLC, UV, IR, NMR, and mixed m.p. undepressed) with the isolated compound.

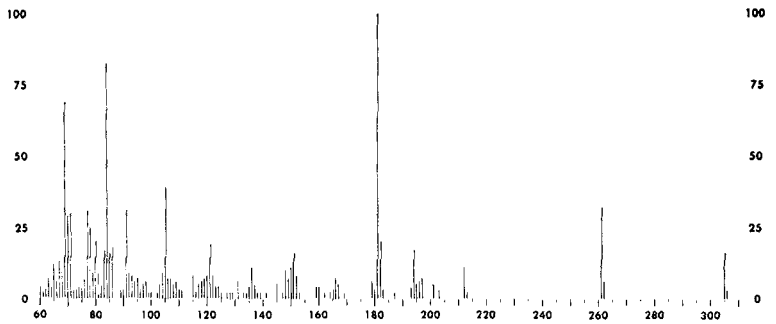


Fig. 1—Mass spectrum of peyonine.

Although proline (2-pyrrolidinecarboxylic acid) is an amino acid of wide natural occurrence, peyonine appears to be the first simple pyrrole-2-carboxylic acid derivative isolated from natural source, its structure elucidated, and the assigned structure proven by a synthesis.

It seems reasonable to speculate that the pyrrole ring of peyonine is produced in the plant by condensation of a 1,4-dicarbonyl compound such as an α-ketoglutaric acid derivative or its equivalent with mescaline or its precursors. The biosynthesis of peyonine, the preparation of com-

[1] Isolation and synthesis of peyonine have been separately reported. (See *Reference 7* for the published abstract.)

pounds related to the isolated β-phenylethylpyrrole, and pharmacological studies of peyonine and related compounds are currently being investigated.

Remarks on Synthesis of Benzofurans

Sir:

A recent note in this Journal by P. K. Sharma *et al.* (1) reported the synthesis of several substituted benzofurans. It appears, however, that there are some discrepancies in this report worthy of further mention.

The authors describe the reaction of benzyl bromide with hydroxymethyl propiophenone,[1] and *p*-nitrobenzyl bromide with 2-hydroxypropiophenone and 2-hydroxy-3-aceto-6-methylpropiophenone to yield, respectively, 4-methyl-6-phenylbenzofuran, 2-(*p*-nitrophenyl)benzofuran, and 2-aceto-5-methyl-7-nitrophenylbenzofuran. The products to be expected (2) in the first two cases, respectively, are 2-phenyl-3-ethyl-5-methylbenzofuran and 2-(*p*-nitrophenyl)-3-ethylbenzofuran, while in the third case the product might be expected to be 2-(*p*-nitrophenyl)-3-ethyl-4-methyl-7-acetylbenzofuran and/or 2-(*p*-nitrophenyl)-3,6-dimethyl-7-propionylbenzofuran. On first consideration the discrepancies appear to be one of nomenclature (2, 3), but additional contemplation reveals the problem to be an error on the part of the authors. Utilizing the reactants and conditions stated it is impossible to obtain the products alleged. Since the authors offer no analytical data or spectra to substantiate their claims, it is doubtful as to the true nature of the products. For example, the authors report the melting point of their alleged 2-(*p*-nitrophenyl)benzofuran to be 193°, while the literature value (4), substantiated by a good carbon–hydrogen analysis, is 182°. Indeed, in view of the same literature report (4), the reaction between benzyl bromide and hydroxymethyl propiophenone might *not* be expected to proceed under the *mild* conditions described, but might terminate at the benzyloxy stage.[2] Finally, the structure depicted for their alleged compound 2-aceto-5-methyl-7-nitrophenylbenzofuran is actually 1-methyl-4-acetyl-8-nitro*di*benzofuran (2).

[1] Private communication from P. K. Sharma, reveals that 2-hydroxy-5-methyl propiophenone is the "hydroxymethyl propiophenone" described.

Remarks on Synthesis of Benzofurans

Sir:

A recent note in this Journal by P. K. Sharma *et al.* (1) reported the synthesis of several substituted benzofurans. It appears, however, that there are some discrepancies in this report worthy of further mention.

The authors describe the reaction of benzyl bromide with hydroxymethyl propiophenone,[1] and *p*-nitrobenzyl bromide with 2-hydroxypropiophenone and 2-hydroxy-3-aceto-6-methylpropiophenone to yield, respectively, 4-methyl-6-phenylbenzofuran, 2-(*p*-nitrophenyl)benzofuran, and 2-aceto-5-methyl-7-nitrophenylbenzofuran. The products to be expected (2) in the first two cases, respectively, are 2-phenyl-3-ethyl-5-methylbenzofuran and 2-(*p*-nitrophenyl)-3-ethylbenzofuran, while in the third case the product might be expected to be 2-(*p*-nitrophenyl)-3-ethyl-4-methyl-7-acetylbenzofuran and/or 2-(*p*-nitrophenyl)-3,6-dimethyl-7-propionylbenzofuran. On first consideration the discrepancies appear to be one of nomenclature (2, 3), but additional contemplation reveals the problem to be an error on the part of the authors. Utilizing the reactants and conditions stated it is impossible to obtain the products alleged. Since the authors offer no analytical data or spectra to substantiate their claims, it is doubtful as to the true nature of the products. For example, the authors report the melting point of their alleged 2-(*p*-nitrophenyl)benzofuran to be 193°, while the literature value (4), substantiated by a good carbon–hydrogen analysis, is 182°. Indeed, in view of the same literature report (4), the reaction between benzyl bromide and hydroxymethyl propiophenone might *not* be expected to proceed under the *mild* conditions described, but might terminate at the benzyloxy stage.[2] Finally, the structure depicted for their alleged compound 2-aceto-5-methyl-7-nitrophenylbenzofuran is actually 1-methyl-4-acetyl-8-nitro*di*benzofuran (2).

[1] Private communication from P. K. Sharma, reveals that 2-hydroxy-5-methyl propiophenone is the "hydroxymethyl propiophenone" described.

REVIEWS

Design of Active-Site-Directed Irreversible Enzyme Inhibitors. By B. R. BAKER. John Wiley & Sons, Inc., 605 Third Ave., New York, NY 10016, 1967. xiii + 325 pp. 15.5 × 23.5 cm. Price $13.50.

Professor Baker has written an interesting book about the work he has been doing for the last six years on the design, synthesis, and evaluation of what he calls "active-site-directed irreversible inhibitors." The book itself deals primarily with design of these inhibitors.

Dr. Baker's ideas initially were based largely on the established mechanism of action of azaserine, which is known to combine, because of its similarity to glutamine, reversibly at the active site of phosphoribosylformylgycineamidine synthetase using the glutamine binding points, and then irreversibly inactivate the enzyme by reaction of its diazomethyl group with a thiol group in the active site. The design of such inhibitors, which have been termed endo-alkylating agents, is severely limited because of the steric requirements of the active site. On the other hand, Professor Baker has found that an inhibitor can be designed to fit an enzyme active site and at the same time bear a group capable of reacting with a functional group on the enzyme surface but outside the active site. This concept of an exo-alkylating agent has two advantages. First, the *position* of the change made in a metabolite to give an antimetabolite becomes more important than the nature or size of the change. Second, and more important ultimately, such an inhibitor has an extra dimension of specificity, since even closely related isozymes differ in their secondary and tertiary structure.

Professor Baker uses the "6-mercaptopurine story" to illustrate the parameters involved in the use of enzyme inhibitors as chemotherapeutic agents. He then discusses the development of his exo-mechanism concept. Chapter 2 is devoted to a general discussion of the forces involved in the reversible binding of substrates to enzymes. Chapters 3–5 deal with the mode of binding to specific enzymes. Chapter 6 is concerned with the types of changes in the structure of a metabolite that can be expected to produce inhibitors and the types of changes that may lead to modified substrates, while Chapter 7 discusses bulk tolerance in enzyme–inhibitor complexes. Chapter 8 details the kinetic parameters important to active-site-directed irreversible inhibition and studies, other than the author's, on this type of inhibition. Chapters 9–12 are devoted to the details of the *modus operandi* developed by Professor Baker in his studies of lactic and glutamic dehydrogenases, dihydrofolic reductase, and other folate cofactor area enzymes, while Chapter 12 describes the work of other investigators on adenosine deaminase. Unexpectedly, the last chapter is devoted to enzyme-specific columns, but the relationship of this subject to the author's interests is obvious.

This book should be studied by any serious student of medicinal chemistry. I would agree with the author's statement "Although these active-site-directed irreversible inhibitors have not yet led to useful chemotherapeutic agents, the future for such discoveries appears based on scientifically sound premises." That is a lot more than can be said for much of the work being carried out today on the design and synthesis of potentially useful medicinals.

Topics in Medicinal Chemistry. Vol. 1. Edited by J. L. RABINOWITZ and R. M. MYERSON. Interscience Publishers, Inc., 605 Third Ave., New York, NY 10016, 1967. xi + 453 pp. 15 × 23 cm. Price $17.75.

This volume is the first in a new series that will deal with the biomedical aspects of drugs, or groups of drugs. It draws from a wide source of authors, especially from industry. In general presentation and format it resembles the chapters in the various Annual Reviews that started the now essential function of regularly reviewing the literature with the "Annual Review of Biochemistry" 35 years ago.

In the first chapter, Litwack, in discussing the mechanism of action of cortisol, comes to the obviously reluctant conclusion that direct effect on the genetic apparatus of the cell is probably not the essential mechanism, at least in liver cells. In the chapter on anti-inflammatory agents, Shen describes the increase in knowledge of the nature of the inflammatory process and the difficulties of associating them with immunological disease. The series, analgesics to anti-immune agents, runs from the salicylates through phenylbutazone, corticosteroids, antimalarial, and gold salts to indomethacin and mefenamic acid and, for general usefulness, back to the salicylates again. Shimkin, in his usual clear fashion, classifies the chemotherapeutic agents against cancer that are turned to when surgery and irradiation are not effective or not applicable. For only a very few tumors, notably choriocarcinoma, can chemotherapy compare with optimal use of the scalpel, but Shimkin feels that this situation will inevitably change. Osden in a review on antiviral agents shows that despite an immense amount of work no agents are available against systemic disease therapeutically in man, as opposed to prophylactically. However, the effectiveness of agents in simple *in vitro* settings, as with cancer chemotherapy, holds the interest and hope of workers in the field. Childress shows how far chemists have gone from original antibiotic structures by chemical modification. Nature's contribution was unique, but

Separation Techniques in Chemistry and Biochemistry. Edited by ROY A. KELLER. Marcel Dekker, Inc., 95 Madison Ave., New York, NY 10016, 1967. xvi + 415 pp. 16 × 23 cm. Price $12.75.

In June 1966, a symposium on analytical chemistry was held at the University of Alberta, Edmonton, Alberta, Canada. Separation techniques presented at the symposium have been collected in this single volume. Gas-liquid chromatography and thin-layer chromatography comprise a substantial portion of the separation techniques. Applications of GLC include adrenocortical steroids and protein amino acids, while TLC is represented by separations of *N*-substituted maleimides on alumina. One section of the book is devoted to criteria of identity and purity in chromatographic separations. Specialized topics in gas chromatography include ultra high pressure to 2000 atmospheres, indeterminate errors in the measurement of chromatographic peaks, behavior of pretreated silica gels, support-coated open tubular columns, and nonlinear distribution coefficients. A theoretical aspect of TLC is noted in a chapter on observed plate height.

Newer separation techniques discussed are continuous particle electrophoresis for fractionating and studying particles of biological interest, gel chromatography for separating molecules by means of solvent-swollen gels, and liquid chromatography. A comparison of mobile-phase peak dispersion in gas and liquid chromatography is offered in this volume.

Statistical Techniques for Collaborative Tests. By W. J. YOUDEN. The Association of Official Analytical Chemists, Box 540, Benjamin Franklin Station, Washington, DC 20044, 1967. ix + 60 pp. 17 × 26 cm. Price $2.00. Paperbound.

This brief paper-covered book sums up the ideas and experience of Dr. W. J. Youden, who recently retired from the National Bureau of Standards. It was written, not so much with the statistician in mind, but rather the nonstatistician or management-oriented chemist. Over the years, Dr. Youden has developed methods of presenting data in tabular and graphic form, which, from a statistical sense, are readily understandable and usable by the bench chemist. Dr. Youden has repeatedly urged that collaborative tests be run using few tests per laboratory but many laboratories. This book sums up his thoughts on the subject.

One of the highlights of his discussion is that on "systematic error," *e.g.*, an inherent error in the analytical method. The average pharmaceutical laboratory talks about systematic error but seldom routinely evaluates quantitatively the degree to which it exists or creeps into the test over a period of time. The only time a chemist might detect he has added systematic error to a test is when he gets a bad lot of material to test, the formula of the product has been changed, he compares a series of past results on a control chart and finds them predominantly high or low, or when he is setting up a new test involving knowns and the results are uniformly high or low.

The reading of this book is a good review for the chemist, because, being written in lecture style, Dr. Youden takes the reader through a series of eight chapters and tells him what he should keep in mind during his everyday work in addition to the occasional collaborative testing he may do. This book is not a textbook on statistics nor is it meant to be such. It deals with the application of a limited set of statistical techniques and the inherent problems in their use. The logic and methodology contained herein could be used as the basis on which collaborative testing for official compendia and intra-industry test development is undertaken.

Review Article

Spectroscopy of Amines of Pharmaceutical Interest

By I. B. EISDORFER, R. J. WARREN, and J. E. ZAREMBO

ALTHOUGH THE USE of alkaloidal amines of plant origin as therapeutic agents extends well back into the history of mankind, it was not until the advent of synthetic organic chemistry in the 19th century that the first successful attempts were made to simulate and improve upon nature. Early in this century it was discovered that many body substances either are amines, are metabolized to amines, or can be simulated by amines. Certainly by its brilliant work elucidating the structure and function of epinephrine (1), norepinephrine (2), ephedrine (3), and the other sympathomimetic amines now so widely used in medicine, pharmaceutical chemistry has to a great extent been amine chemistry.

Amines are, of course, basic nitrogen-containing groups derived from ammonia. Amino groups can be found or placed on aromatic as well as aliphatic skeletons; they can be fused into alicyclic rings, be attached to atoms other than carbon, be quaternized to increase their basicity, or be located adjacent to other functional groups that make them neutral or even acidic. It is not the purpose of this review to cover all possible amino group combinations. For the purpose of this review we will restrict our discussion to basic amino-containing compounds in which the amino group is attached directly to an aliphatic carbon with no other substitution on the nitrogen other than alkyl groups or hydrogens. There may of course, be aromatic, or heteroatom-containing groups elsewhere in the molecule.

Received from the Research and Development Division, Smith Kline & French Laboratories, Philadelphia, PA 19130

The various forms of spectroscopy, UV, IR, NMR, Raman, mass, *etc.*, are all well-established techniques for elucidating gross and fine structure of organic compounds, for evaluating compound interactions, and under appropriate circumstances for quantitatively determining compounds in mixtures. It is the purpose of this paper to review specific applications of the various forms of spectroscopy for amine-containing compounds that have been or are likely to be of interest to people working in the field of pharmaceutical chemistry. Our primary purpose is to describe how spectroscopy can help elucidate the amine function but secondarily also to attempt to relate spectroscopy to the whole molecule.

Of the various spectroscopic techniques covered here, ultraviolet and infrared absorption are best known and most widely applied in structure identification and quantitative analysis. Nuclear magnetic resonance is now perhaps the most useful and most rapidly growing branch of spectroscopy for gross and fine structure determination. Mass spectroscopy shows great promise for rapidly unraveling difficult structures particularly when only small sample sizes are available, as for example, in the effluent from a gas chromatograph. Raman spectroscopy has much promise for structure assignment work, but it still awaits development of simple inexpensive equipment before its potential can be adequately realized. The most promising of all developments in organic structure identification is the combined use of all spectroscopic techniques to attack a single problem (4, 5). This very powerful pro-

cedure can become even more so when applied in conjunction with an interpretive computer. This certainly is the direction of future development in this field.

There are a number of good review articles and books that have been published on the use of the various spectroscopic techniques in analyzing amine-containing organic structures (6–8). Previous reviews in this journal have covered certain aspects of the subject quite adequately and should be referred to for further information on the subject.

NUCLEAR MAGNETIC RESONANCE

To attempt to review all of the literature for every report of nuclear magnetic resonance data on amines would be an impossible task. The number of scientific papers including NMR data has increased at an almost unbelieveable rate. Five years ago 12% of the reports in the *Journal of Organic Chemistry* contained NMR data either as the major topic of discussion or as supporting data for structure assignment. Today, it would be safe to say that no more than 12% do not contain NMR data. It has been reported (9) that in 1964 NMR was mentioned in every sixth paper appearing in the chemical literature of the United States. In other words, every journal reporting synthesis or structure elucidation of organic compounds serves as a repository for NMR data. Realizing the difficulties inherent in undertaking a search of such dimensions and the practical limits of time and space allotted here, this reviewer has chosen to present a broad review of the techniques developed specifically for amines. These data will be supplemented with references to pharmaceutical and biologically important amines.

The use of nuclear magnetic resonance in the elucidation of the structure of amines has found wide application. The identification of *N*-alkyl groups by NMR has been described by several workers (10–13), and the technique has largely replaced other methods for identifying *N*-alkyl groups. Ma and Warnhoff (14) and others (15–18) have discussed the application of NMR for detection of *N*-methyl groups in particular. The NMR method for *N*-methyl analysis is described as being dependent on a pronounced downfield shift of the resonance peak of basic *N*-methyl groups in solvents of increasing acidity. The effect is due to the decreased shielding of the methyl protons of the positively charged ion relative to those of the free amine. This has also been mentioned by earlier investigators (17–19). Ma and Warnhoff have presented the NMR spectral data on a series of 116 compounds containing *N*-methyl and/or other methyl groups and have recorded the spectra in deuterochloroform, perdeuteroacetic acid, and trifluoroacetic acid. *N*-Methyl protons in secondary amines (aliphatic) have been found to be decidedly less deshielded in strong acid than *N*-methyl groups in tertiary amines. The explanation offered for this behavior is that the charge on the protonated secondary amine is more dispersed (20), and therefore, the smaller charge has a smaller deshielding effect on the *N*-methyl protons. A large number of chemical shift values and spin-spin splitting constants was given.

An extension of the method to the identification of primary, secondary, and tertiary aliphatic amines has also been reported (16, 21). Once again it is found that the effects of strongly acidic solvents on the chemical shift and spin-spin splitting constants of the protons α to the amine ion are characteristic for the particular functional group. The protons adjacent to the primary amine ion, NH_3^+, are split into a quartet; those adjacent to secondary ion, NH_2^+, into a triplet, and those adjacent to tertiary ion, NH^+, into a doublet. This phenomenon is also reported by Loewenstein and Meiboom (22) and Jackman (23). The nuclear magnetic resonance spectra of amino acids have been reported. Among the more interesting studies that have been reported are those on the correlation of NMR spectra with the L- and *meso* structures of cystine (24) and of the effect of optical activity of amino acids on their NMR spectra (25). There have been comprehensive analyses of many specific amino acid spectra using NMR (26–29); much detail on the spectra of the individual acids is given. In addition, Thompson *et al.* (21) have shown that spectra of *N*-substituted amino acids examined in alkaline deuterium oxide and in trifluoroacetic acid show chemical shifts and first-order spin-spin splitting patterns that are useful for identification of *N*-methyl, *N*-methylene, *N*-phenyl, and other groups attached to the nitrogen of an amino acid.

Data on aromatic amines are not as plentiful as those on aliphatic amines unless one wishes to consider the spectra of individual amines reported in the literature. The spectrum and chemical shift of the aromatic protons in aniline have been reported (30), and Ma *et al.* (14) have included data on 13 aromatic and *N*-heterocyclic amines in their work. Identification of *N*-phenyl amines by acidic solvent effects on the chemical shift and spin-spin splitting constants of the phenyl protons were reported (31) to provide the basis for the identification of the *N*-phenyl groups

in primary, secondary, and tertiary amines.

In addition to these rather general techniques for identification of amines, there have been collections and compilations of NMR data on nitrogen-containing compounds. One of the most recent and extensive papers is presented by Slomp and Lindberg (32), in which the structural and chemical shift data for 2306 hydrogens influenced by nitrogen in a variety of ways have been correlated and charted. There are also publications on specific classes of nitrogen-containing compounds such as the alkaloids (33). Other heterocyclic systems which have been recorded and analyzed are the pteridines (34), pyridines (35), piperidines (36), purines (37), pyrrolines (38). A general treatment of heterocyclics by NMR is also available (39). Reports on pharmaceutical applications of NMR have been presented (40), and Jardetzky and Jardetzky (41) give many examples from the biological field.

For those who have found that trying to keep abreast of all the current NMR literature is impossible, but who would like to stay up to date, there remains the abstract services (42, 43).

Techniques

Spin-Decoupling—Equipment is commercially available for heteronuclear spin-decoupling and has been used with success. Anderson and Silverstein (16) have described the decoupling of the NH^+ protons from the nitrogen in amine salts. The actual performance of a spin-decoupling experiment is straightforward, and an experienced operator can accomplish it in a relatively short time. For a complete and, excellent review of spin-decoupling see Baldeschwieler and Randall (44). Heteronuclear spin-decoupling equipment can be purchased either from the various instrument manufacturers or from Nuclear Magnetic Resonance Specialties, Inc., New Kensington, Pa.

Micro Sampling—Most instrumental techniques are taxed to the limit of sensitivity in the pharmaceutical and biological areas where a constant problem is paucity of sample. In the study and identification of metabolites, for instance, frequently there is an insufficient amount of sample to obtain spectral data by routine methods. This is especially true in NMR work, but the use of a CAT (computer of average transients) has eliminated much of the problem of small sample sizes. A spectrum, is scanned repeatedly a preselected number of times. The signal output from the spectrometer is stored and accumulated by the computer which presents a final spectrum with a total signal proportional to the number of passes through the spectrum and with the noise accumulated as the square root of the number of passes. This gain in signal to noise ratio and the buildup of sample signal allows one to obtain an NMR spectrum on microgram quantities of sample. Applications of the technique to biological systems have been reported (45).

INFRARED SPECTROSCOPY

An earlier review in this Journal by Carol (46) presented the fundamental theoretical concepts and techniques of infrared spectrophotometry as applied to pharmaceutical analyses. In the present report we shall confine our interest to the relatively narrow range of amines. The areas of interest in the infrared spectra of amines concern themselves primarily with the stretching and bending or deformation vibrations of the amine function. These regions have been assigned (47–49) as follows: N—H stretching region for primary and secondary amines from 3500–3300 cm.$^{-1}$; NH_2 bending or deformation approximately 1650 cm.$^{-1}$. Primary amines are identified by two absorption bands in the 3500–3300 cm.$^{-1}$ region (47–52). A third band is often found at slightly lower frequency due to hydrogen bonding. This third band is generally broader than the two bands at higher frequency (53). The 1650 cm.$^{-1}$ region is also useful in identifying primary amines in that it contains the NH_2 deformation band. This absorption band is usually broad and of medium intensity (47, 54) and shifts to higher frequency on hydrogen bonding in a similar manner as the NH_2 stretching vibration (53). Because of its location, the absorption band can often be assigned only with difficulty when the complexity of the molecule increases, and aromatic and other functional groups such as secondary amides are present. In such cases a variety of techniques may be brought to bear on the problem. The two techniques most commonly used are deuteration of the NH_2 groups (55, 56) and/or formation of an amine salt (57). Deuteration causes a shift of the NH_2 absorption to lower frequency, and salt formation involves a shift to lower frequencies as well as other changes in the absorption bands. Although for secondary amines one might expect only one absorption band in the 3500–3300 cm.$^{-1}$ range, there are often two bands observed due to association (53). The band from the associated NH is broader than that of the free NH, just as in the case of the associated NH_2 band. However, the integrated absorption intensity of the absorption bands of primary amines is approximately double that for secondary amines.

Tertiary amines, lacking the NH function, offer no absorption bands in the areas 3500–3300 or 1650 cm.$^{-1}$. They are difficult if not impossible to identify as free bases by infrared spectroscopy. There exists the possibility of identifying the group attached to the nitrogen atom, *i.e.*, CH_3N, C_2H_5N, *etc.*, but in the final analysis it would appear that the best method of identification by infrared would be to form a derivative of the amine.

From what has been said thus far, one might get the impression that differentiation of primary, secondary, and tertiary amines could be made quite simply. However, such is not always the case. Duval (58) describes how various factors such as molecular association, interactions with solvents, and poor dispersion in some instruments make identification and differentiation of amine classes an extremely difficult proposition.

A great amount of effort has been exerted in the study of inter- and intramolecular interactions of amines (53, 59). The conclusion reached almost unanimously is that spectra, to be compared qualitatively or quantitatively, should be measured in the same solvent under the same conditions.

For positive identification of amines it has been found useful in many cases to form an amine salt. This is particularly true of pharmaceutical amines which are generally administered in the form of a salt. The formation of the NH_3^+, NH_2^+, and NH^+ ions results in a shift of the amine absorption band to lower frequency. The wavenumbers at which the resulting absorption bands occur are specific for each class of amine. Primary amine salts have been reported to show a series of weak peaks with a broad absorption band of medium to weak intensity located between 1960 and 2080 cm.$^{-1}$. Secondary amine salts have been found to have a series of three bands between 2860 and 2040 cm.$^{-1}$; splitting of one or more of these bands has been observed in some cases. Tertiary amine salts, which are by far the most common class of amines used pharmacologically, have the simplest absorption spectra since they contain only one hydrogen on the nitrogen. The distinguishing feature of NH^+ spectra is a broad and intense peak located in the range of 2770–2380 cm.$^{-1}$. The exact location of the absorption band depends on whether the molecule contains water of hydration (64). There is of course strong hydrogen bonding in all of the crystalline amine salts and very little absorption found at the normal N—H frequency range 3500–3300 cm.$^{-1}$.

One thing to be remembered in dealing with amine salts is to avoid preparation of alkali halide disks whenever possible. Changes in spectra arising from hydrogen bonding and interaction with halide disks have been reported (65).

Near IR—Near infrared spectrophotometry in this discussion refers to the area of the spectrum between 1.0 and 2.5 μ. We are eliminating the fundamental N—H region because it has been adequately covered in the preceding section. The area deals largely with stretching vibrations involving hydrogen bound to a variety of other atoms. The absorption bands in this region are overtones or combination bands of vibrations originating in the fundamental region. The principal use of the area is in quantitative analysis; however, it is possible to differentiate primary, secondary, and tertiary amines on the basis of their absorption here. In addition to other absorptions, primary amines have a peak at about 2.0 μ, which is due to a combination band resulting from N—H bending and stretching vibrations in the fundamental region (66). Secondary and tertiary amines lack the 2.0 μ band, but secondary amines have an absorption in the first overtone region which is located at about 1.5 μ. Tertiary amines have no absorption due to NH and contribute nothing to this area of the spectrum as free bases.

The area of the combination band (1.95–2.0 μ) has great quantitative value in determining primary amines alone or in combination with secondary and tertiary amines (67, 68). The chief disadvantages to more extensive use of this region of the spectrum is the increased sample size required for significant absorption in the overtone region and the lack of suitable solvents. Carbon tetrachloride is the only solvent transparent in the region from 1.0 to 3.0 μ. Carbon disulfide has only one peak in the area of 2.2 μ, which makes this a useful solvent also. However, because of solubility problems on one hand and possible solvent interaction on the other, it is sometimes difficult to operate under the most desirable conditions. Whetsel *et al.* (53), in describing solvent and concentration effects on the near infrared NH bands of primary amines state that the absorption bands tend to broaden and shift to longer wavelength with increasing concentrations. Intensities and band widths vary markedly from solvent to solvent and great care should be exercised in comparing qualitative as well as quantitative data on the same material unless the data have been collected under similar conditions.

The spectroscopy of amine salts in the near infrared region has recently been described (69). A technique using samples in the solid state is described by which qualitative and quantitative

data on the salts were obtained. Primary amine salts were distinguished from secondary and tertiary amine salts on the basis of the presence of a band at 2.18 μ and the absence of a band at 2.05 μ.

For a review of near infrared spectrophotometry in general, the reader is referred to the chapter by Goddu in "Advances in Analytical Chemistry" (75).

Far IR—During the last few years instrumentation extending beyond the 650 cm.$^{-1}$ region has become commercially available, and many laboratories have begun investigating the range of 700–200 cm.$^{-1}$ for potential application. The techniques and methods of analysis used in the 4000–7500 cm.$^{-1}$ region are generally applicable to the far infrared. Window materials and solvents are not used interchangeably from one region to another, but there is an adequate supply of these for both regions. For example, the range to 400 cm.$^{-1}$ can be covered with potassium bromide cell windows and disks, while cesium bromide and cesium iodide transmit reasonably well to about 300 cm.$^{-1}$. Polyethylene has been shown (76) to be a useful window material for far infrared work. Good solvents for the far infrared are available although not as common as those available for the infrared region. Wyss *et al.* (77) have published a collection of 12 organic solvents for possible use in the far infrared.

For solid state samples the common alkali halide disks have been found to be most useful. Cesium iodide has also been used to press disks. Polyethylene and hydrocarbon wax have also been suggested as possible disk matrices (78). The information obtained in this range of the spectrum is related to the skeletal vibrations in the amines. Although the amount of information available on amines in this range is small relative to the 4000–7500 cm.$^{-1}$ range, some work has been reported on NH_2 vibrations (70). Tsuboi *et al.* (71) and Fukushima (72) have investigated amino acids in some detail in this region and have reported on NH_2, ND_2, and NH_3^+ vibrations. While the potential of the far infrared for providing a wealth of information for routine analysis is low, the area will undoubtedly provide more supplementary information that will aid in identifying molecular vibrations.

Attenuated Total Reflectance—The technique of attenuated total reflectance should be mentioned in this review of pharmaceutical amines because of its ability to obtain spectra with relative ease on samples which would ordinarily be difficult or impossible to handle. While the technique of ATR is known principally for its application to surfaces, it is also extremely useful in obtaining spectra on small amounts of sample. Microgram quantities of sample spread out as a thin film on an ATR sample plate or crystal yield spectra of excellent quality. The practical applications of the technique include analysis of metabolites isolated from biological systems and fractions from thin-layer and gas–liquid chromatograms, in amounts that heretofore would have precluded any attempt at identification by infrared spectra.

The principles of attenuated total reflectance have been set forth by Fahrenfort (73) and Harrick (74). The equipment in the form of attachments for present infrared spectrometers is available commercially from several manufacturers, including Wilks Scientific, the Perkin-Elmer Corp., and Barnes Engineering Co.

ULTRAVIOLET SPECTROPHOTOMETRY

Ultraviolet spectrophotometry has become an established, fundamental technique in pharmaceutical research and analysis as well as in the broad area of organic and inorganic analysis. Its widespread use and acceptance is such that for a general review of theory and techniques the reader is referred to several recent texts and not necessarily to papers appearing in current journals. The possible exception to this statement is the review of ultraviolet spectrometry appearing biannually in *Analytical Chemistry*. The theory and applications of ultraviolet spectrometry have been treated in detail in such recent books as "Absorption Spectroscopy," by Bauman (79), "Theory and Applications of Ultraviolet Spectroscopy," by Jaffe and Orchin (80), "Molecular Spectroscopy: Methods and Applications in Chemistry" (81), "Ultraviolet and Visible Spectroscopy: Chemical Applications" (82), "Advances in Analytical Chemistry and Instrumentation" (83). Special topics have been covered in other volumes such as "Interpretation of the Ultraviolet Spectra of Natural Products" (84), "Spectrophotometric Analysis of Drugs" (85), and a review and tabulation of the ultraviolet spectra of alkaloids (86). The latter review is especially useful since it contains all the available ultraviolet data on alkaloids up to and including 1964. The data are arranged according to structural type for more convenient study.

There are several collections of spectra and spectral data available which provide quantitative as well as qualitative data on amines as well as other organic classes. Perhaps the most useful of these is the four-volume work "Organic Electronic Spectral Data" (87). This collection

provides qualitative and quantitative data, often in several solvents, for each compound. The data are derived from a literature search involving some 69 journals. It is probably the most comprehensive work of its kind.

Ultraviolet spectrometry has found application in the study of aromatic amines in many areas of pharmaceutical analysis. The technique has been used in organic analysis and structure elucidation as well as to study stability, kinetics, ionization constants, mixtures, drug levels, and metabolites.

Organic Analysis—It has been mentioned previously that ultraviolet spectrophotometry is an established, fundamental technique in pharmaceutical analysis. Because of its general use in all phases of analysis it is often shunted aside and neglected in one of its most basic applications—structure elucidation. Many people bypass ultraviolet spectra completely in favor of the latest or what they consider to be more sophisticated techniques in the solution of organic structure problems. While other, newer techniques undoubtedly make important contributions in structural analyses, ultraviolet spectra can give much in the way of complementary or supplementary evidence for a specific structure proof. As a matter of fact, the determination of small amounts of organic material is very often done more conveniently by ultraviolet spectrometry than by any other method. Recent examples of the use of ultraviolet spectra in structural analysis are described in the work of Kamlet, Adolph, and Hofsommer (88) who showed that comparison spectra of 2,4-dinitroaniline and its *N*-alkyl and *N,N*-dialkyl derivatives permit discernment of the spectral effects of steric enhancement and inhibition of resonance. Baker *et al.* (89) have shown that it is possible to identify positional isomers in *N*-substituted uracils containing additional substituents in the 5- and 6-positions. Ultraviolet spectra taken in neutral and 0.1 *N* alkaline solvents show that substitution in the N-1 position results in a shift of less than 2 mμ. Substitution in the N-3 position results in a shift of 24–36 mμ.

In the quantitative analysis of aromatic amines, ultraviolet spectrometry plays a major role. Standard methods of analyses of aromatic amines invariably include UV as one of the methods of choice. Recent reports of the use of the technique include a spectrophotometric method for the determination of poldine methylsulfate (90), phenethanolamine after oxidation with periodate to benzaldehyde (91), and ephedrine, phenylpropanolamine, phenyramidol, and phenylephrine (92). In addition, Brandstaetter-Kuhnert *et al.* (93) have described a combination thermomicroscopic and ultraviolet spectrophotometric method for the qualitative determination of a series of antihistamines. Determination of thiobarbiturates by simultaneous recording of two spectra of the same material, differentiated by a spectrum shift due to regulated acidification of an alkaline solution of the thiobarbiturate, has been reported by Williams *et al.* (94). This use of differential UV spectrophotometry allows determination without interference from regular barbiturates. Needless to say it would be impossible to include here all of the articles and papers relating to the UV spectra of amines. For methods and applications for specific amines, the reader may consult the applications review articles in *Analytical Chemistry* or *Chemical Abstracts.*

Kinetics—Reaction rates and mechanisms of reactions in solution are conveniently followed by ultraviolet spectroscopy. An added advantage of following reactions this way is the detection and identification of intermediates and/or other unexpected products. Repetitive scans of the spectra of reaction mixtures at fixed time intervals permit observation and calculation of the amount of product as it is formed. The method, of course, is dependent on either formation of a new absorption band, which increases with time, or the decrease in intensity of the band of the starting material as it reacts to form a product. This method has been used by Eisenthal and Katritsky (95) to measure the rate of hydrolysis of 1-methoxypyridinium salts. A study involving oxidation and bromination of phenothiazine showed that the phenothiazine sulfoxide was the first stable product formed (96).

Szulczewski, Shearer, and Aguiar (97) studied the kinetics and mechanism of isomerization and hydrolysis of 4,6-diamino-1-(3,5)-dichlorophenyl-1,2-dihydro-2,2-dimethyl-1,3,5-triazine in dilute aqueous solution. In this study, which may be considered a typical kinetic study involving UV spectroscopy, a standard solution was prepared and diluted into various buffers held at the temperature of the run. Samples of the thermostated solutions were withdrawn periodically, and the ultraviolet spectrum of the intact starting material was obtained. The absorbance of the solution was read and the amount of unchanged material was calculated from a standard plot of the starting material.

Stability—The method for stability studies is the same as that used for kinetic work. The method provides stability data in a relatively short space of time, and the stability of the

material in question can be checked under a variety of conditions, *e.g.*, heat, light, time, *etc.* Recent applications of this method are reported by Garrett and Schraeder (98) and Simpson and Zappala (99). Riegelman and Fisher (100) have used the method to measure the stability of epinephrine. UV may also be used in stability studies in conjunction with thin-layer chromatography where decomposition products are isolated and determined by UV.

Amine Complexes—The formation of amine complexes showing absorption in the UV range has been used in the determination of amines. A number of articles describing formation of these UV-absorbing complexes have appeared recently. Ferric chloride has been found to complex with pyridine (101). The complexes of mercury and aniline have been studied (102), and the interaction of mercuric acetate with indole derivatives has been reported (103). Iodine has been found to complex with aniline (104), tertiary amine *N*-oxides (105), and 2,2-bipyridines (106). In a report by Lim *et al.* (107), a study of the solubilization and stabilization of phenobarbital by aminoalcohols is described. The increased solubility of phenobarbital by aminoalcohols is attributed to the formation of a "complex" or salt. An ultraviolet method for quantitative analysis of phenobarbital was used throughout the study.

Ionization Constants—The changes in the spectra of aromatic amines brought about by change of the pH of the solution reflect the changes in electronic state in going from free base to ion. These spectral changes are useful in studying tautomeric equilibria and for determining ionization constants of amines. The procedure generally followed in determining pKa values is to obtain the absorption spectra of the amine in basic solution, the amine ion in acidic solutions, and mixtures of the two forms in suitable buffer solution. The pH of the buffer solution is measured, and this in addition to the absorbance values at a given wavelength permits calculation of the pKa value from the following relationship:

$$\mathrm{pKa} = \mathrm{pH} + \log \frac{A_B - A_{OH^-}}{A_{H^+} - A_B} + \log \gamma^+$$

where A_B, A_{OH^-}, and A_{H^+} are the absorbance in the buffer, basic, and acidic solutions, respectively, and γ^+ is the activity coefficient of the ion in the buffer solution. This procedure or variations and modifications of it have been used to calculate the pKa values of many aromatic amines. For ultraviolet or pKa data on individual amines, the reader is referred to *Chemical Abstracts.* Recently pKa values of 2-(2′-thienyl)-pyridine and of methyl-2-picolyl sulfide were determined by Kahmann, Sigel, and Erlenmeyer (108) and of the dichloroanilines by Robinson (109). Apparent dissociation constants of some phenolic amines reported also (110), and there are reports of special techniques for individual amines and/or circumstances. For instance, determination of ionization constants on submilligram amounts of sample has been reported by Rinehart and Stafford (111).

Mixtures—Ultraviolet spectrophotometric analysis of mixtures is carried out routinely on two- and three-component systems. This is made possible, of course, by the fact that absorbance is linear with concentration and that the absorbances of various components in a mixture are additive. This concept is treated extensively in the text by Bauman (79) and others. Examples of its practical applications are found in the recent literature. Endriz (112) has described an ultraviolet spectrophotometric determination of heroin hydrochloride, methapyrilene hydrochloride, and quinine hydrochloride mixtures. The spectra for heroin, methapyrilene, and quinine show points of maximum absorption at 280 mμ, 313 mμ, and 348 mμ, respectively. Methapyrilene and quinine do not seriously interfere with the heroin maximum, and methapyrilene in dilute acid solution absorbs only slightly at the quinine maximum of 348 mμ. The procedure is fast and accurate enough for forensic purposes.

Analyses of chloramphenicol and tetracycline hydrochloride mixtures (113) and phenobarbital and pentobarbital in pharmaceutical mixtures (114) are further examples of the utility of UV spectrophotometry in this area.

Metabolite and Drug Levels—Because of the sensitivity of the ultraviolet method, the amount of sample required for spectral identification is very small; drug levels and metabolites have been determined in biological tissues and fluids after separation and extraction. The method is used extensively and routinely. Since most materials are not photosensitive, the technique is nondestructive, and the metabolite or drug can be recovered for further testing. Reports have been published for most pharmaceutical amines whose metabolites have been investigated discussing the UV spectra of starting material and metabolites. For UV data on specific metabolites, once again the reader is referred to *Chemical Abstracts* data on the specific parent amine.

RAMAN SPECTROSCOPY

Raman spectroscopy is presently undergoing a revitalization after years of relative inactivity. After the discovery of Raman spectroscopy in 1928, a wealth of information regarding molecular structure of organic and inorganic compounds was obtained. A large number of scientific papers was presented and published in the 1930's dealing with the analysis of molecular vibration by Raman techniques. Subsequently, however, infrared spectroscopy eclipsed Raman and took the lead in widespread use and application in industrial laboratories. The principal difficulty with Raman technique was the great care and time-consuming aspects associated with obtaining good data. In spite of the fact that good, reliable, and revealing information could be obtained with Raman, the experimental difficulties were too great for most people. Industrial chemists, especially, were reluctant to contend with the weak lines produced by Raman scatter, which took hours to produce a photographic spectrum of sufficient intensity, when they could prepare and obtain an infrared spectrum in a few minutes. Cost of equipment was also a factor which limited its use in most laboratories. The result of these experimental and cost disadvantages was the decline and overshadowing of Raman by infrared.

The development of the continuous laser as a source for Raman spectroscopy has revived and stimulated new interest in this technique. The laser, by increasing the intensity of the Raman scatter lines, has once more made the technique attractive. The additional development of electronic devices has made possible photoelectric readout and in a few minutes a complete vibrational spectrum from 4000–50 cm.$^{-1}$ can be recorded. The spectrum is recorded as intensity *versus* wavelength, and since the intensity is directly proportional to the concentration, the technique lends itself very well to quantitative analysis. Other advantages of laser-Raman are that the scatter lines produced by a laser source are sharper and easier to read than those from other sources. Focusing and collimating are simplified. Ultraviolet radiations from conventional sources which cause photodecomposition of some molecules is eliminated. Use of the ionized noble gas laser allows different laser lines of excitation to be used, and in some cases this eliminates the problem of fluorescence which often prevents obtaining a spectrum when a conventional Hg lamp is used. A sample containing water, which would obscure a good part of the infrared spectrum, can be run successfully by the Raman technique because the spectrum of water is weak in the Raman. The whole range from 4000–50 cm.$^{-1}$ can be seen without instrumental changeover (prisms, gratings, *etc.*). Selection rules for the Raman effect permit observations of some vibrations which do not make themselves known in infrared spectroscopy. For example, rotational transitions of molecules are observed for molecules which do not possess a permanent dipole moment. Vibrations involving groups such as $R_1R_2C{=}CR_1R_2$ which have very weak infrared absorptions at best can be seen clearly with Raman. The advent of the laser source has not only stimulated interest in academic and industrial scientists but has stirred the commercial world as well. With low-cost equipment available and more research on low-cost instrumentation promised, the outlook for increased use of Raman spectroscopy is very favorable.

For the best comprehensive summary of Raman spectroscopy up to 1960, see Brandmuller and Moser (115). Other review articles on the subject are those by R. N. Jones and M. K. Jones (116), A. C. Jones (117), and Green (118). A number of books devoted in whole or in part to Raman have appeared recently (119–122). The recent impetus given to Raman is indicated not only in the increased number of publications covering the subject but also in the beginnings of a shift of Raman from the academic laboratories exclusively to more industrial laboratories. The use of Raman to provide information on the C—C, C=C, and C—H skeletal bands of complex molecules will provide more information leading to the elucidation of structures. If the recent interest in Raman can be sustained and nurtured by more organic and analytical chemists, the amount of information involving group frequency-structure correlations in Raman will assume an importance on a par with infrared correlations used routinely in nearly every organic and analytical laboratory.

The principal applications of Raman in the area of organic chemistry have been in the field of hydrocarbons and amino acids. Studies have been made on glycine (123, 124), diglycine barium chloride monohydrate (125), and triglycine selenate (123). Stretching frequencies of N—H hydrogen bonding of these compounds have been investigated and reported by the same authors. Raman spectra of glycine have also been reported by Ghazanfar (126). Methyl, ethyl, and propylamine have been studied by Wolff and Staschewski (127). A number of other molecules have been investigated singly or in conjunction with infrared studies on the same molecule. It is often difficult to locate the

Raman spectra of the material in such cases because the spectra are often listed under infrared headings with little or no attention given to the Raman data in the journal index. In addition to this more recent data, there are, of course, data on individual amines listed in collections such as the Landolt–Bornstein (128) tables which include assignments for spectra. There are many amines and nitrogen-containing heterocyclics which are included in this collection. While the collection and accumulation of this data were slow and painstaking over the years, the data and assignments are of good quality and can be of great service not only in Raman work but in infrared as well.

MASS SPECTROMETRY

Introduction—The history of structural organic chemistry is filled with methods used to resolve complex molecules by breaking them into small pieces, which can be easily and unambiguously identified, and then assembling these pieces in a logical sequence to determine the original compound. Obviously as molecules become larger and more complex the task becomes more formidable. This differs in principle from infrared spectroscopy where functional groups present in the molecule can be identified and the positions of the groupings in respect to one another obtained. Isolated nuclear magnetic resonance data also provide fragmentary data and, if unsupported, does not permit unambiguous identification of many chemical species.

Just as NMR has become a valuable tool to provide unique structural information about unknown molecules and to complement infrared spectroscopy, mass spectrometry has also become a valuable complementary technique to provide additional unique information about molecules, and to facilitate the assignment and verification of chemical structures. Unlike ultraviolet, nuclear magnetic resonance, and infrared spectroscopy where compounds are recovered after analysis, mass spectrometry is a destructive technique; however, one might be consoled in knowing that fractional parts of a microgram of sample, which otherwise might be insufficient for other instrumental methods, are sufficiently large to obtain a perfectly good mass spectrum. Another important feature of mass spectrometry, in addition to its sensitivity is the fact that, even though a sample is impure, considerable structural information can be obtained, and although the sample is destroyed, a permanent record of the data can be obtained in an extremely short period of time. Scans of masses up to approximately 500 atomic mass units can be made in a matter of seconds.

There has been an aura of mystery associated with mass spectrometry because of the complex nature of a mass spectrum which can comprise a hundred or more peaks, and the lack of a simplified theoretical approach for interpreting these data. In spite of the immensity of data provided by a mass spectrometer, this technique has come of age and has become an equally important partner of the other spectroscopic techniques. This rise in importance and popularity is due, for the most part, to the efforts of such men as Professor F. McLafferty, Purdue, Dr. Klaus Biemann, M.I.T., Dr. R. I. Reed, Glasgow University in Scotland, Professor Carl Djerassi and his co-workers, Stanford, Professor Einar Stenhagen, Dr. Raynor Ryhage, Dr. J. H. Beynon, Dr. J. S. Shannon, and several others who have contributed significant data to the literature of this subject.

Mass spectra of compounds containing the amine function have been studied extensively (7, 129–136, 138). In the work of Gohlke and McLafferty (132), 67 aliphatic amines were studied, fragmentation patterns were presented, and methods for identifying amines were given. Collin (129) reported on the mass spectra of aliphatic amines including appearance potential data, likely structure, and additional mass spectral correlation data. Judson and Struck (153) have also correlated mass spectral data on aliphatic amines. The theory of unimolecular decomposition as applied to mass spectra electron bombardment of aliphatic amines has been discussed by Hurzeler, Ingraham, and Morrison (154). Budzikiewicz and co-workers (7) have discussed the mass spectra of aliphatic, cycloalkyl, aromatic, and steroidal amines as well as other nitrogen functions in their book and publications. A correlation of the mass spectral data of alicyclic amines has been reported by Saunders and Williams (155). This class of amines has been studied by several other investigators (155–159). The fragmentation process of some cyclic amines (158) and the location of the rearranging atom in some alicyclic amines (156) was established by deuterium labeling. The usefulness of dimethylamine derivatives in the study of steroidal fragmentation was presented by Pelah and co-workers (160). Geminal amine mass spectra (134), derivatives of amines (161, 162), and the mass spectra of amino acids (163–167) and derivatives (164) of amino acids have been studied extensively. Aromatic amines (140–143) and heteroaromatic *N*-containing compounds (168) have been studied extensively because of their significance in the pharmaceutical industry.

A discussion of all the above aspects of amine mass spectrometry is a formidable and quite impractical plan in this type of report; however, this is an attempt to present a practical coverage of pharmaceutically important amine-type functions, the factors that have provided the basis of mass spectral study of these compounds, and an understanding of the factors involved in using mass spectrometry for further study and future research in these areas.

In its most simplified version, mass spectrometry of organic molecules involves the bombardment of a hypothetical molecule, ABCD, in the vapor state with a high energy electron beam. If the ionization potential of the molecule is less than the energy of the electron bombardment, a single electron will be expelled from the molecule and a molecular ion ($ABCD^{+\cdot}$) is produced (*A*):

$$ABCD + e^- \longrightarrow ABCD^{+\cdot} + 2\,e^- \quad (A)$$

If this ion ($ABCD^{+\cdot}$) is accelerated without further breakdown and deflected in the magnetic field of the mass spectrometer, it will be collected at a radius that corresponds to the molecular weight. This, in fact, is the basis of molecular weight determinations by mass spectrometry. Further and more intense electron bombardment will break bonds and produce additional ions and smaller fragments of the original molecule. As more bonds are broken a multiple stepwise process will occur, producing one positively charged ion and additional neutral species:

Fragmentation:
$$ABCD^{+\cdot} \longrightarrow ABC^+ + D\cdot \quad (B)$$
$$ABC^+ \longrightarrow BC^+ + A\cdot \quad (C)$$
$$BC^+ \longrightarrow B^+ + C\cdot \quad (D)$$
$$BC^+ \longrightarrow C^+ + B\cdot \quad (E)$$

Rearrangement:
$$ABCD^{+\cdot} \longrightarrow AD^+ + BC\cdot$$
$$ABCD^{+\cdot} \longrightarrow AC^+ + BD\cdot$$

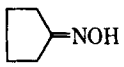
Ionization:
$$ABCD \longrightarrow ABCD^+ + 2\,e^-$$
$$ABCD \longrightarrow ABCD^{2+} + 4\,e^- \quad \text{(multiple ionization)}$$

The ions and fragments which form will depend upon the bond broken, its dissociation energy, and the stability of the charged and neutral species formed. This formation of a charged particle is analogous to carbonium ion and multiple bond formation, with the consequent stabilization of the ion by formation of positively charged particles having considerable stability, such as tropylium, azatropylium, acylium, oxonium, and ammonium ions.

$R'-CH=\overset{+}{O}H$ (oxonium)

$R-C\equiv O^+$ (acylium)

(tropylium)

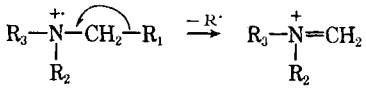


(cyclic oxonium)

$$R'-CR''-NH_2^{+\cdot} \longrightarrow R'-CR=NH_2^+$$

(ammonium)

In general, the stability of a molecular ion will be enhanced by any structural feature which permits spreading of the odd electron charge over the molecular ion rather than concentrating it at any one atom. Thus charge delocalization leads to greater stability. In aromatic compounds, conjugated unsaturated systems, and functional groups having unsaturated groups, stable bonds are produced. In alicyclic systems where two bonds have to be broken to produce a fragment, additional stability is encountered. In amine compounds with which we are concerned here, the most easily removed electron in the ionization process is from the lone pair (nonbonding) electrons of the nitrogen atom. The process may be represented as in Scheme I.



Scheme I

[Homolytic processes will be indicated by a fishook (↷) which implies a one-electron shift, whereas an arrow (↷) represents a heterolytic (two-electron shift) (7).]

In dealing with the mass spectra of amine compounds we are dealing with a molecule having a nitrogen atom which provides more information than a nonnitrogen-containing molecule. In compounds having an odd number of nitrogen atoms, the molecular weight is odd, and in those having an even number of nitrogens, the molecular weight is even. In organic molecules containing carbon, hydrogen, and oxygen, fragments arising from the cleavage of *one bond* without hydrogen, transfer will always appear at odd mass numbers. The reverse of this occurs in compounds with an odd number of nitrogens, *e.g.*, one-bond fission of an odd nitrogen-containing compound will produce an even fragment. Elimination of neutral stable molecules is a frequent fragmentation mechanism. Nitrogen forms such stable species as HCN and NH_3 which are removed from amine-containing compounds. Amines frequently constitute a more volatile group than other nitrogen species, *e.g.*, NO_2^-, amido, *etc.*, and conversion to an amine permits easy handling and specific fragmentation,

which permits facile identification of unknown species. Deuteration of amino nitrogens also permits convenient study of reaction pathways and rearrangement processes. These points will be elaborated in the context of this paper.

The principles of mass spectrometry are dealt with in great detail in several textbooks (7, 169–174) and will be summarized here only briefly. To record the mass spectrum of a compound the sample has to be admitted into the ionization chamber of a mass spectrometer at pressures of 10^{-6} to 10^{-8} torr. For easily volatile materials this is done by placing the sample in a reservoir of the inlet system either as a gas or vapor at pressures of about 10^{-2} torr. and allowing it to "leak" through a very small orifice into the ionization chamber where it is bombarded with a high energy electron stream having a potential of about 10 to 100 e.v. (usually 70). The pressure in the chamber is kept low by a series of mercury diffusion pumps. Both positively and negatively charged particles and neutral fragments are produced. Only the positively charged particles are accelerated in the chamber, where the ion beam is focused magnetically and electrostatically (only in double focusing instruments) into a circular path. The radius of this path depends upon the ratio of the mass to charge of the cations (m/e). This radius is related to the accelerating voltage, V, and the magnetic field by the expression: $R = (2mV/eH^2)^{1/2}$. The mass spectrometer is designed so that only particles which describe a radius R will pass through the exit slit and be recorded by the ion collector. The current of the particles is of the order of 10^{-15} to 10^{-8} amps. This current is amplified and recorded *via* an electrometer and recording galvanometer which produces signals according to the relative abundance of the ions. The m/e value of the collected ions will be $R^2H^2/2V$ and will depend upon instrument design and applied electrical and magnetic field. The complete m/e spectrum is obtained by changing either the magnetic field, H, or the accelerating voltage, V, during the recording of a spectrum. It should be noted that mass spectra are recordings of discontinuous signals, unlike the continuous recordings in the infrared or ultraviolet region, since atomic masses vary in integral units. The units of m/e of atomic mass to charge in units of electric charge are termed "mass number" or atomic mass units (a.m.u.).

Instrumentation—The recent availability of moderately priced mass spectrometers (about $25,000) has permitted many smaller pharmaceutical laboratories and universities with limited budgets to enter the mass spectrometric field. As a result of this interest and activity, current literature on this subject has increased logarithmically in the number of published articles over the last few years and has significantly advanced the science. The lower priced instruments have resolutions of 500–850 with a 10% valley over the 1–300 mass range (Perkin-Elmer model 270) and up to 2500–3000 (AEI Model 15 and the Hitachi Model RMU6E).

High resolution instruments with a capability of 1 part in 30,000 or better are much more expensive ($80,000+). These instruments permit the analysis of fragments of about 5 p.p.m. or better. To be considered as high resolution, an instrument must have the capability of making mass measurements with a resolving power ($m/\Delta m$) of 10,000 or better with a 10% valley definition and at the same time have a precision of better than ± 10 p.p.m. measuring capability.

Much of our present mass spectrometric instrumentation is designed for use in qualitative organic structural analysis, and differs from earlier instrumentation which was used for the determination of isotope masses and, later, for relative abundances of these masses. These very early instruments were developed in the 1930's into precision equipment for mass/charge determinations which led to exhaustive studies using stable isotope tracers. About 1940 commercial instrumentation was first placed on the market.

There are two major types of commercially available high resolution mass spectrometers, the Mattauch-Herzog and the Nier-Johnson type. In both of these instruments there is an electrostatic field used as an energy selector, which controls the energy spread in the ion beam produced by the initial kinetic energy of the ions. The differences are in the methods of focusing the ions. In the Mattauch-Herzog system all the ions are focused simultaneously in one plane, and a collector slit can, therefore, be placed along any point in the plane. By scanning the magnetic field a complete mass spectrum of the ions can be obtained. This can be displayed either on a photographic plate or a high speed recorder. These, of course are permanent high resolution mass spectrum recordings. For very high precision mass determination of peaks, a peak matching procedure is used incorporating an oscilloscopic screen. In the Nier-Johnson type system the ion beam is refocused at a single point, and it is at this point where the collector slit is placed. In either system, of course, a complete mass spectrum can be recorded within a fraction of a second to a few minutes, depending upon the resolution desired and also on the particular spectrum being

obtained. A third type of instrument, the "time of flight" mass spectrometer, works on a different ion separation principle. Here a pulse of ions which has been produced by the ion bombardment is accelerated down a straight evacuated tube. In the course of their flight, the ions are separated according to the momentum they have received during their acceleration. These ions arrive at the ion collecter plate in order of increasing mass, the lightest arriving first and the higher ones follow in increasing order of mass. An instrument with capabilities of unit mass resolution of 700 ($m/\Delta m$) can be used for general organic structural analysis and identification. It has the advantage of attaining high scan speeds of a few milliseconds and is useful for thermodynamic, combustion, and fast reaction studies. It does not, however, meet the requirements for high resolution work.

The newest entry into the mass spectrometer field is the double focusing cycloidal medium resolution mass spectrometer (Varian Associates) which produces a cycloidal ion trajectory in which focusing depends only on the m/e of the ion and not on the direction or velocity of the charged particle.

Gas chromatograph attachment to the mass spectrometer permits mixtures to be separated and analyzed while the chromatograph is being run without the need for collecting individual peaks. This aspect will be discussed more fully later. Many instruments are equipped with detection systems which allow detection of negative ions produced in the fragmentation process. All the instruments mentioned here are suitable for use with pharmaceutical amines.

Sample Requirements and Manipulation—Boiling points and volatilities of organic amines range from the low boiling liquid to solid. Many of the amines are conveniently isolated and recrystallized as salts. Introduction of these materials into a mass spectrometer involves injection *via* a gas chromatograph, a gas inlet system, or a solid direct insertion probe. Modification by derivatization as silyl derivatives, trifluoroacetyl, or acetyl derivatives also provides convenient procedures for volatilizing the more intractable or heat-sensitive compounds. Probably the most elegant feature of the mass spectrometric method is the sensitivity of the instrument; submicrogram quantities of sample are sufficient for a mass spectrum (176). Biemann (175) has used 0.25 mcg. (1.5×10^{-9} moles) of phenylalanine and was able to get unambiguous identification of the compound. Elliot and co-workers (176) have obtained excellent accuracy of mass measurements with as little as 0.005 mcg. (5×10^{-9} Gm.) of ibogaine.

It is obvious, of course, but important that pure uncontaminated samples be used for the most valuable retrievable information. This presumes the use of high purity and sufficiently volatile solvents, which can be pumped out of the instrument before volatilization of the sample, when a direct sample insertion technique is used or when samples are being isolated from mixtures for insertion as liquids. This precaution is usually not necessary when good separation is possible *via* a gas chromatographic sample separation and insertion technique. Occasionally when an amine sample does not give a good molecular ion, introduction of a salt will help. If this is a hydrochloride it presents other problems by corroding equipment and being difficult to pump out completely. Nonvolatile compounds may sometimes be safely placed directly in the ion beam where, under the effect of high vacuum and temperature, small amounts are flaked off into the ion beam to produce a good spectrum. When a smoke or aerosol can be created in the ion source, highly intractable compounds inert to chemical modification are frequently analyzed successfully.

Molecular Weight—The molecular ion of amine compounds can be obtained if the compounds do not decompose under the influence of heat and electron bombardment at the low pressures (about 10^{-6}–10^{-8} torr.) that they will experience in the sample chamber of the mass spectrometer. In cases where decomposition does take place, more stable derivatives may be prepared by silylation, acetylation, trifluoroacetylation, *etc.* (discussed later). In most cases with amines, as with other compounds the "parent" or "molecular" ion may be found in the normal fragmentation pattern. It usually appears as the largest peak of the highest molecular weight multiplet of peaks in the mass spectrum, and represents a single electron removed by electron bombardment of the original compound: $M \rightarrow M^+ + e$.

McLafferty (132) examined the spectra of 67 aliphatic amines and found that the molecular ion was present, although in small relative abundance, in amines containing up to 16 carbon atoms. With primary amines the molecular ion intensity reaches a minimum (about 0.2–0.4%) in the region of nine to 12 carbon atoms. When the α-carbon atom is substituted, the molecular ion intensity is greatly diminished. McLafferty points out that in α-substituted primary amines containing four or more carbon atoms, the molecular ion is useless for analytical purposes; whereas, with α-substituted secondary amines, the molec-

ular ion is indistinguishable when there is a total of approximately eight carbon atoms. In cases where the longest chain of an α-substituted amine has more than four carbon atoms, the molecular ion cannot be used for molecular weight determinations.

In compounds where the amine function is attached or is part of an aromatic or alicyclic system, there is greater ion stability (177) and the molecular ion abundance increases significantly.

As the intensity of the parent peak of higher molecular weight amine compounds becomes indistinguishable precluding its use for determining molecular weight, there is increased possibility of observing the ion occurring at a molecular weight + 1, $(M + 1)^+$. This, of course, is now an even mass ion for compounds containing an odd number of nitrogen atoms, and as such is a diagnostic device, which helps to pick out this ion. This anamolous type of ion can also be found in alcohols, ethers, sulfides, glycols, and nitriles and is due to a bimolecular reaction which occurs in the ion stream. A striking feature of this ion which makes it useful for analytical purposes is the fact that it is pressure sensitive. The relative abundance of this $(M+1)^+$ peak increases with increased sample pressure and with decreased ion repeller potential. This peak is especially valuable with high molecular weight amines, and its presence can be demonstrated by rescanning the spectrum of these compounds at the higher mass range after reducing the repeller potential, thereby allowing longer ion residence time in the ion stream for reaction to occur. Increasing the sample pressure by adding another organic compound will also increase the relative amount of this peak. Munson and Field (178) have used chemical ionization mass spectrometry for certain amines and indicate that the ions in the ionization chamber of the mass spectrometer will produce a spectrum, which is more useful for determining the structure and the molecular ion for certain amines, and they indicate that the ions in the mass spectrum are predominantly high molecular weight fragments; whereas, the converse is true for electron impact spectra. Since the ionization potentials of primary aliphatic amines are greater than 8.5 v. and between 7 and 8 v. for tertiary aliphatic amines, the authors point out the differences indicated for the parent ion of these types of compounds are sufficiently different to allow isomers to be distinguished by this technique.

The $M+1$ ion indicated above was first reported by Wertzeler and Kinder (135) and later work (129) by Collin indicates that the $M+1$ ions arise from a reaction such as the following:

$$RNH_2 + RNH_2 \longrightarrow RNH_3^+ + RNH$$

To recognize the molecular ion in amines, certain tests may be applied to the highest mass peak that can help to distinguish whether this ion is not the molecular ion. These tests cannot determine if the converse is true.

Where the possibility exists that impurities are present, contributions from background or other artifacts, suitable steps such as partial ionization, examination of the compounds by thin-layer chromatography or gas chromatography should be used to complement these data. A combination of gas chromatography and mass spectrometry (discussed later) may provide a suitable system for obtaining a meaningful mass spectrum of the compound.

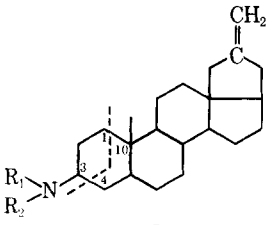
Since the molecular ion is produced by electron impact and the loss of one electron from the molecule, the ion produced must be an odd-electron ion, M^+, and appear at an odd mass. An even electron ion, M^+, appearing at high mass at an even mass number is usually the molecular ion. For an even mass ion to be a molecular ion it must contain an odd number of nitrogen atoms. In cases where major ions appear at positions separated from the highest mass ion by anomolous mass values or elemental composition by high resolution, mass measurement is illogical; the molecular ion is probably not the molecular ion or else there probably is an impurity in the sample. Mass losses of 3 to 14, 21 to 25, 33, 37, and 38 are highly improbable, and an examination of the masses compiled by McLafferty (179) in his mass spectral correlations will help to establish whether such an ion is probable. To prevent possible mistakes in considering the molecular weight of compounds, which have atoms where isotopes are naturally present, such as with bromine or chlorine, the mass should be calculated on the basis of the lower mass of the two isotopes. Low energy bombardment may also help to establish the identity of the molecular ion. Since the molecular ion is the precursor ion, it requires less energy for its formation, and as the electron energy is lowered, it should be the last one to disappear. In the case of some amines this would be difficult because of the low abundance of the molecular ion, but for derivatives, this should be suitable. An ion with the lowest appearance potential is not necessarily the molecular ion; only the converse would be true. Empirical formulas can frequently be determined from the two small peaks at $(M+1)^+$ and $(M+2)^+$, which are due to the isotopes of C, H, O, N, Cl, Br, S, *etc.*, present in the compound. If an illogical mass is obtained,

further investigation of other peaks, sample purification, *etc.*, are in order. Molecular weight determinations may also be field ionization (180) and rate of effusion techniques. Once the molecular ion has been identified, interpretation of the remainder of the spectrum can start.

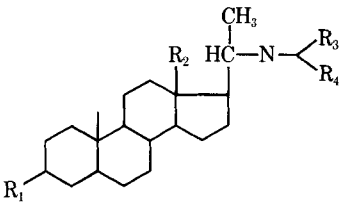
Use of Isotopes—Radioactive and stable isotope use in chemical, biochemical, and physiological fields has increased over the years very markedly. The availability of ^{18}O, deuterium, ^{13}C, and ^{15}N has provided the stimulus for research in biological and chemical fields where only small amounts of isolated compounds are available for study, and where incorporation of these materials into a molecule provides an elegant way to determine the mode of action, as well as to provide a means of following the compound in a living system. It is, therefore, not unusual to incorporate a stable isotope in a drug and use the mass spectrometer to assist in identifying and following the metabolic fate of the drug in an animal or microbial system. Because many pharmaceutical compounds have an amine function associated with them, it is not uncommon to exchange the active hydrogen atoms attached to a nitrogen with deuterium or to synthesize an amine or other nitrogen-containing pharmaceutical with ^{15}N.

Mechanisms (7, 158) of mass spectral fragmentation have been studied *via* deuterium exchange in many phases. The replacement of —N—H with N—D or NH_2 with —ND_2 leads to fragment ions of one and two atomic mass units greater than the parent; however, in the case of tertiary amines there is no exchange, and hence no effect.

Deuteration is achieved readily by equilibration of the sample with deuterium oxide. Deuteration has been useful to study fragmentation patterns, to determine structure, to examine ionization potentials. After deuteration of an amine, comparison of the fragments and the molecular ion permits identification of the fragments which have the nitrogen containing the deuterium. In cases where there are two nitrogens present in the molecule, the procedure becomes particularly useful. Systematic studies have been made by Pelah *et al.* (147) upon the migration mechanisms of hydrogen migration in amides and amines, and for the selective replacement of certain hydrogen atoms in *N*-acetylcyclohexylamine. Fragmentation of steroidal amines was also studied after deuteration. Incorporation of deuterium in the amine nitrogen of *Holarrhea* alkaloids of types I and II by Dolejs *et al.* (181) permitted these workers to ascertain the number of methyl groups bound to the individual nitrogen atoms.

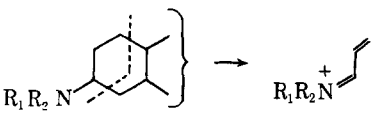


I



II

By the fragmentation process in Scheme II, cleavage in these molecules was shown to occur by rupturing of the C_3—C_4 bond (β-bond to the nitrogen atom) and the C_{1-10} to give fragments as those in the scheme. The nitrogen ion which was formed was stabilized by splitting off or transfer of hydrogen atoms. Adequate metastable peaks in sufficient abundance were also found to verify the fragmentation. Where R_1 and R_2 are methyl the inductive effect of the methyl group stabilizes the positive charge on the nitrogen atom (*Reference 175*, p. 88) and produces high abundance fragments. Additional studies on the structure and stereochemical relationships of steroidal dimethylamines (152) done by Pelah and co-workers supported these studies by deuterium labeling experiments. This work showed the most abundant ion in the fragmentation of steroidal dimethylamines corresponds to the immonium ion (III) and they predicted this



m/e = 56
70

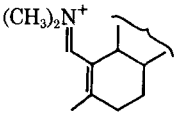
Scheme II



III

species in terms of charge localization on the nitrogen of the molecular ion and subsequent fragmentation by rational bond homolysis and hydrogen transfer. They also showed in their studies that dimethylamino compounds were desirable derivatives for mass spectral purposes.

The exchange of active hydrogen for deuterium in amines can very conveniently be carried out by injection of D_2O into a gas chromatograph, and then immediate injection of the amine with the replaceable hydrogen. Alternatively, this can be done with the sample in contact with D_2O in the heated inlet system of the mass spectrometer.

Ambiguities arising from the splitting out, for example, of an M-28 peak, which could be due to the loss of H_2CN, CO, C_2H_4, or the appearance of a M-27 peak due to the loss of C_2H_3 or HCN, can be resolved in many cases with deuterium labeling.

Aside from the labeling aspect of isotope mass spectral data, the isotope peaks $M+1$ and $M+2$ can be used to calcuate the molecular formula of a compound. Details may be found in the textbooks mentioned above (170–175).

Elemental Analysis and High Resolution Mass Spectrometry—In addition to the information obtained from the molecular ion determination, information on molecular structure is obtained from an elemental analysis of secondary ions which provides information on the arrangements of the atoms in the molecule. Compounds which contain several isotopic elements (polyisotopic) provide unique peak abundances in proportion to the abundance of the isotopes normally associated with an element. These data are useful both qualitatively as well as quantitatively. They not only indicate the presence of these elements but often tell how many of the atoms are present in the molecule. The monoisotopic elements found with organic compounds include fluorine, phosphorus, and iodine. These are also useful in studying fragmentation mechanisms and compound structures. Perfluorokerosene, for example, is one of the most widely used internal standards for peak identification and peak matching to obtain very accurate mass values.

Microcombustion analysis for the elements, because of its inherent errors, falls short of the capabilities of the mass spectrometer; however, the data provided by such determinations very often complements mass spectrometric data and also provides information on the compound such as inorganic ash content, compound stability, nature and ease of compound decomposition, volatility, ease of sublimation, *etc.* Many researchers use combustion data to verify or support their mass spectral findings. One must, however, recognize that unit mass measurements with low as well as high resolution instruments provide accurate means for establishing exact molecular formulas. Because of this high degree of accuracy, high resolution mass spectral determination has removed the ambiguities that arise from combustion analysis data and has simplified this aspect of structural elucidation problems. This has been extremely useful in pharmaceutical applications for high molecular weight amine compounds, alkaloids, polypeptides, *etc.* (151), which differ from other possible structures by mass units less than one. Microelemental analysis would have been completely inadequate to assign exact empirical formulas for such compounds. Another advantage with mass data of this type is for determining molecular formulas of mixtures of compounds, if there is supporting additional information available on a sample. When molecular species present or suspected as being pressed in a sample have sufficiently different masses, they can often be recognized and determined because of unusual fragment ions which are not present in normal fragmentations. By changing parameters on the instrument such as ionization voltages to below ionization potentials of some of the compounds present in a mixture, distinction can be made between several compounds; by changing temperature, a fractionation is often possible; or by coupling a gas chromatograph, separate compounds in a mixture can be determined as they elute from a column. These are discussed later.

High resolution mass spectrometers which use both electrostatic and magnetic focusing systems are capable of determining and distinguishing between molecular formulas of monoisotopic molecular weights to values of less than a few parts per million of the actual mass on as little as 0.2 mcg. of sample. The modern approach to determining elemental formulas for all the ions in a mass spectrum with high resolution mass spectrometers was introduced by Biemann and co-workers (182). High resolution mass spectra may be recorded on magnetic tape, photographic plates, recorder charts, or obtained by peak matching techniques using an oscilloscope (171), or by combinations of all these techniques. These data may be fed into a computer (184), and the information may be displayed as an "elemental map" containing all the ion species arranged in columns according to mass, elemental composition, intensity of peaks, and elemental combinations (183). Element mapping makes use of all the peaks in a mass spectrum, unlike

that in normal spectra where many of the low abundance peaks are disregarded. These lesser abundance peaks very often provide much of the information, which allows a complete structure determination, that otherwise would either be impossible or extremely time consuming to obtain. Biemann (185, 186) has provided several examples of this "elemental map" technique for the analysis of high resolution mass spectra of alkaloids, steroids, amines, and many other compounds. Powers and Wolstenholme (183) used element mapping to determine the structure of linear peptides, cyclic peptides, and cyclodepsipeptides. They report that computer interpretation of the high resolution mass spectra of peptides completely removes the necessity for quantitative amino acid analysis. For linear peptides, acylation provides sufficient information for the computer to identify all the peaks by their atomic composition. Spectra at a resolution of 10,000 can be run in as little as 10-sec. intervals thereby permitting this technique to be used simultaneously with gas chromatography. The result is that unambiguous assignments of atomic composition of molecular and fragment ions are possible even in complex mixtures.

The accuracy of measurement is limited to the capability of the instrument to resolve very close peaks, and this determines, to a large extent, how unique a differentiation can be made to select two or more possible elemental combinations to fit an empirical formula. In cases where it is necessary to determine the differences in mass of a compound containing a CH_4 (m/e = 16.031300) or an oxygen (15.994915) where the difference in mass is (0.036385) or 36.4 micro mass units (m.m.u.) it would require an instrument with a resolving power ($m/\Delta m$) = 16/0.036385 = 440. If this difference existed in a molecule with a mass of 160, an instrument with a resolution of 4400 would be required (*e.g.*, 160/0.036385 = 4400), and, as the case may very well be with pharmaceutical compounds, a mass twice this amount, *e.g.*, 320, would not be unusual. This, of course, would require a resolution of 8,800 or very nearly 10,000 which approaches the resolution limits for many "high resolution" instruments. For a compound containing C, H, N where a distinction between CH_2 *versus* N is required (Δm = 12.6 m.m.u.) an instrument with a resolving capability of ±5 m.m.u. would be necessary. Other more demanding resolution capability (±1 m.m.u.) would not be unusual.

Biemann (186) has reported many of the techniques where high resolution mass spectrometry can be used. The voluminous data accumulated from mass measurements have made element mapping a very desirable technique and have made interpretation of spectral data an attractive technique. Suitable computer programs (183, 184) have been developed to handle such mass spectrometric data, and frequently when such data are presented, interpretation may be made by use of a few significant peaks which show the parent ion, the important fragments, and the fragmentation process with reasonable certainty. Many aliphatic amines (187) are determined this way. Several approaches to the interpretation of high resolution spectra have been reported and should be consulted for more details and the rationale used. The usefulness of high resolution mass spectrometery used in conjunction with element mapping or exact fragment determination has been reported in several reviews (188–194).

Sample Modification—*Derivatives*—Incorporation of stable and radioactive isotopes in compounds for mass spectral analysis was described earlier. Amine compounds very often can be successfully analyzed by means of their more stable derivatives. These compounds may be acetylated with acetic anhydride or other suitable anhydride, trifluoroacetylated, or converted into silyl derivatives (195).

Many easily obtainable and efficient silylating reagents such as bis-trimethylsilyl, acetamide (BSA), hexamethyldisilizane, trimethylchorosilane, bromomethyldimethylchlorosilane (197), and chloromethyldimethylchlorosilane may be used. The halogenated compounds are useful for work at low concentrations of sample, using gas chromatographs incorporating electron capture detectors at low or only moderate temperatures. Amino acids (198,199) are readily converted into volatile, stable derivatives with BSA, *N*-trimethylsilydiethylamine, *N*-trimethylsilydiethylamine.

Hill (170) and Reed (169) give detailed instructions on the utilization of chemical reactions to convert many compounds to amines to obtain characteristic fragmentation patterns for structural elucidation. They give examples for converting amides and nitro compounds to amines, nitriles to primary amines, isonitriles to secondary amines, *etc.*, to assist in characterizing them. Thus treatment of primary aromatic amines with nitrous acid and heat converts them to phenols, secondary amines to N-nitroso and tertiary amines to C-nitroso derivatives. The mass spectra of these compounds are usually quite easily distinguished because of characteristic peaks. In the case of C-nitroso *versus* *N*-nitroso compounds,

the *N*-nitroso compound should lose NO (M-30) easily. Reed (169) has treated the subject of distinguishing compounds containing one, two, or more nitrogens adequately. Budzikiewicz, Djerassi, and Williams (7) have illustrated the usefulness of the information in compound identification and reaction mechanisms of fragmentation patterns. They have also shown the utility of using stable isotopes in such studies. Several reviews on this subject are also available (131, 188).

Gas Chromatography–Mass Spectrometry—Resolution of many of the difficult problems associated with isolation of components in a mixture, especially when they are present in trace amounts, has been greatly facilitated when the advantages of a gas chromatograph have been combined with those of a mass spectrometer. The capability of rapid scanning of peaks emerging from a gas chromatograph, even those small trace peaks or peaks which have shoulders or tails, has provided information which previously has been extremely difficult and time consuming to obtain. Because of the speed at which a spectrum can be obtained on a mass spectrometer, a peak appearing in the gas chromatographic recording can frequently be scanned several times to determine if it is, indeed, a single component, or whether it is an unresolved mixture. It is easy, of course, to see the potentialities of this technique for studying the reaction products of an organic synthesis, microbiological transformation, metabolic transformation, or identification of the components in a simple mixture. Reaction mechanisms and much of the physical chemistry of compounds may be deduced by the procedure. Because mass spectrometers handle small samples (as little as 0.2 mcg.) with relative ease, the high plate efficiency of capillary gas chromatographic columns can be exploited. Thus, materials obtained from human, animal, or agricultural isolations can be examined easily. Research in the study of drug metabolites of chlorpromazine found in human blood (200) have been monitored by Holmstedt, Hammar, and Ryhage, Karolinska Institute. Their studies have indicated that chlorpromazine disappears from the blood in about 4 hr., but the drug metabolites continue to circulate for an indefinite time, and rather significant to medical and pharmaceutical scientists is the fact that breakdown products differ from person to person.

In addition to the advantages described above, the gas chromatograph provides a convenient way to introduce volatile gases, liquids, and volatile solids into the mass spectrometer. Rapid volatilization and hence low residence times at high temperatures often permit heat-sensitive compounds, such as steroids and their derivatives, to be examined without thermal decomposition.

In the past few years mass spectrometer–gas chromatographic combination instruments have become available commercially. These instruments couple gas chromatographs to a mass spectrometer by three popular separators (201), the Biemann-Watson, the Becher-Ryhage (202), and the Llewelyn types (203). The first two are based on the concept of sample enrichment by gas diffusion, whereas the Llewelyn, a two-stage separator, is based on the use of a permeable barrier separation where an elastomer barrier sets up a condition somewhat similar to the liquid phase of a gas chromatographic column. The gas not being very soluble does not permeate the barrier greatly, whereas the organic liquid, on the other hand, does. The result is an enriched gas on the opposite side of the barrier to the one in which the gas passes. For additional enrichment a two-stage separator is used. These elastomeric membranes are made of silicone rubber and permit very rapid organic liquid permeability while enriching the gas at the same time. Since permeation of different organic materials varies considerably, the gas chromatograph–separator cannot be used strictly as a quantitative tool; however, the gas chromatograph itself should be considered the quantitative tool (see above), and as such, does not affect the utility of the system. The operating parameters in using fast scanning, high resolution mass spectrometry in tandem with gas chromatography have been reported by McMurray, Greene, and Lipsky (204), by Watson and Biemann (205), and many others (206-208). A direct application for the separation and identification of optically resolved amino acids is reported in the work by Halpern and coworkers (209).

Quantitative Analysis—Quantitative mass spectral analysis was pioneered and certainly exploited by the petroleum industry. While many of the applications of mass spectrometery are for qualitative analysis or structural elucidation, quantitative mass spectrometric analysis of a 30-component mixture can be done rapidly and accurately ($\pm 1\%$) (210). The method used in quantitative mass spectrometric analysis is similar to that in infrared or ultraviolet spectrometry. Peaks are chosen from the spectrum of pure compounds and used for calibration. Ideal peaks are those which have high intensity and freedom from interference from other components in the mixture being analyzed. After choosing these peaks, measure-

ments are made for all the compounds present in the mixture and a calibration curve is prepared. Simultaneous linear equations are set up, one for each compound. Thus, a 30-component mixture would require 30 × 30 sets of equations (211). These are best handled using an inverse matrix and a computer program (213). A desk calculator is quite satisfactory for small systems once a matrix has been set up (175). Where occasional analyses, say a few a week, are required, mass spectrometry would probably be impractical; however, in cases where hundreds of analyses on multicomponent systems are needed, the mass spectrometer is a very efficient technique. Calculations for quantitative analysis are detailed in texts on mass spectrometry (169, 212, 213).

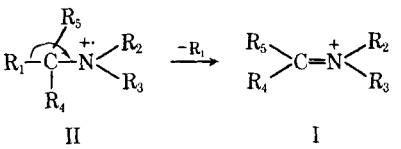
When mass spectrometry is combined with gas chromatography, the mass spectrometer sees only fractional parts of the sample because of the variances due to separator efficiencies and varying efficiencies of ion collection. This is due to the fact that ions pass through a variety of electrical and magnetic fields before reaching the collector. Exact conditions, careful control of temperature, and careful calibration are necessary for good mass spectral quantitative data. It is much more reasonable to use the gas chromatographic data for quantitative analysis and the mass spectrometer for the qualitative identification of the components present in the mixture.

Interpretation of Mass Spectra of Amines—After the molecular ion of a compound has been located and an empirical formula established from the mass spectral evidence, identification of structure begins. This involves the assemblage of the spectral fragments, a rational picture of the elements, functional groups, and other structural features into a chemical structure which will stand the tests of all or any other evidence that is presented, *e.g.*, spectral or chemical. The whole sequence of events involved in breaking down a molecule into smaller, more simple fragments must, in effect, be reversed. An understanding of these fragmentation processes has been the subject of extensive investigation by many serious individuals (145, 148, 154, 196, 214–218), but their work, for the most part, has been limited to practical, mechanistic, and semiempirical approaches. Their efforts, on the other hand, have permitted a logical interpretation of compounds based on spectral evidence. There has, however, been only limited effort made on the development of the theoretical aspects of mass spectrometry.

Many of the relationships in the fragmentation of simple amine structures may be extended to more complex pharmaceutical amine compounds, and an understanding of these will help to identify the structure of the more complex pharmaceutical amine structures. These structural features which appear in the mass spectra of amines are considered below on an individual basis. It should be remembered that identification and interpretation of mass spectral data is much easier and more meaningful if the data are plotted under high resolution conditions, and the formula of each peak determined from accurate mass measurement or an element map is prepared. Lacking such capabilities, much structural evidence may be gleaned from low (unit) or medium resolution instruments (231).

Aliphatic Amines—In considering the spectra of aliphatic amines, considerable information about the fragmentation processes may be deduced by a comparison with the spectra of known ethers and alcohol compounds (133). It might well be imagined that the spectra of amines would be more complex because of the nature of a nitrogen-containing molecule where there exists the possibility of three rather than two side chains. Primary aliphatic amines (129–133, 214) fragment by a C—C cleavage at the bond β to the nitrogen, by alpha cleavage, and by rearrangement and cleavage. Many examples of this type of fragmentation are found in the references given earlier (129–134). Rules regarding the fragmentation of aliphatic amines are included which were derived from a large number of amine compounds, many of which had been tagged with deuterium.

Important in the primary fragmentation process of an aliphatic amine (132) is the removal of the lone pair of electrons of the heteroatom, followed by cleavage of the carbon-carbon bond adjacent to the nitrogen atom (α-cleavage) to give a positive ion (I) and an alkyl fragment (R_1) (Scheme III).



II I

Scheme III

Ion I is the most intense peak in the spectra of primary, secondary, and tertiary alkyl amines (II, $R_4 = R_3 = H$) and α-mono- and α-disubstituted primary amines (II, $R_2 = R_3 = H$, R_4 = alkyl or H). When R_3 and/or $R_4 = H$, an M-1 peak is usually visible. The largest alkyl group is lost preferentially and hydrogen is eliminated only when no other alternative exists. Since the

amino group usually directs the fragmentation process (215) in preference to other functional groups because of the ease with which it loses an electron and because of the stronger resonance stabilization of the ion fragment, the only structural information available is that from the low mass region.

Examples of the fragmentation which occur in several amines of biological importance were reported by Beckett and co-workers (136) and by others (137) and are shown in Scheme IV. This information has been proposed to aid in the identification of metabolites as well as parent compounds in the urine of dosed individuals.

One mass unit differences in possible fragments differentiate between these two isomers (137).

Amino Acid Esters—Fragmentation of α-amino acid esters (217–223) occurs according to the general Scheme V, where β-cleavage is the preferred mode of fragmentation. The charge is carried on the amine fragment as expected. If the ester is an ethyl, the ester fragment will have a mass of 102 and can be used to identify the NH_2 position in other amino acid esters. From the molecular weight, the amine fragment, as well as the ester fragment, any substitution in the α-carbon position readily can be deduced.

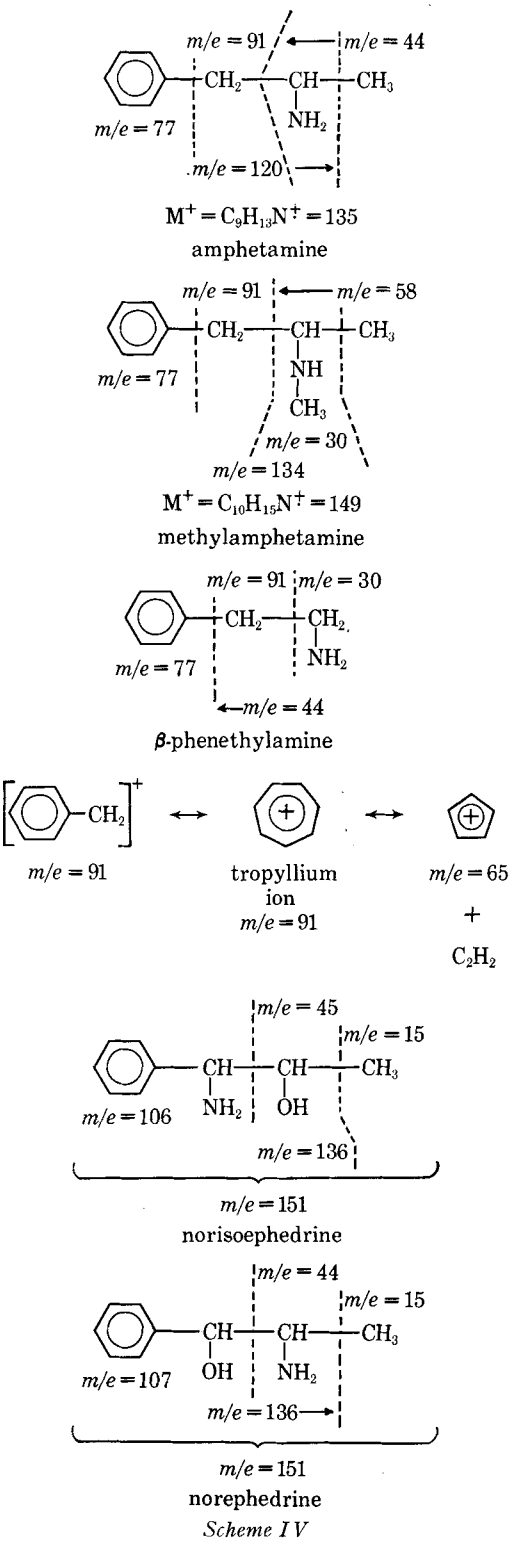
Just as in the aliphatic amine compounds, many amino acid esters have weak molecular ions but do have a characteristic M+1 peak detected by changes in pressure (*vide supra*).

Using the information obtained by studying known amino acid structures, it is possible to assign structures to new amino acids. Thus, Biemann *et al.* (224, 225) established the structure of lysopine, the lysine analog of octapine, which contains an arginine moiety. The processes leading up to the identification of new amino acids by mass spectrometry are elegantly described by Biemann (139).

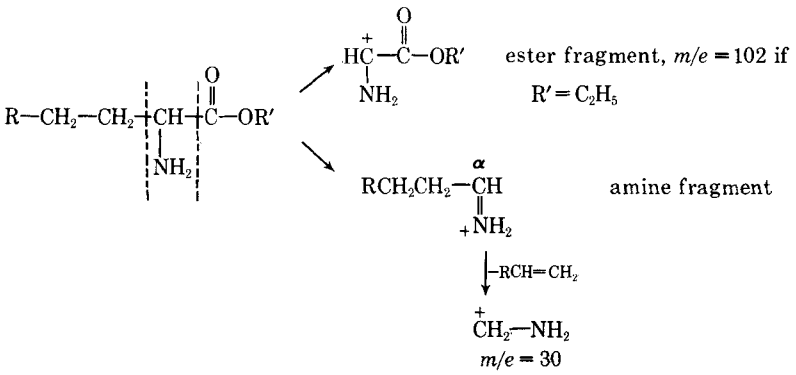
Aromatic Amines—The mass spectra of primary aromatic amines show that there are no bonds which are easily broken, therefore aniline loses one of the amine hydrogen atoms to give a moderately strong peak at M-1, also a peak in which HCN is lost. *N*-Alkyl anilines decompose by cleavage of a C—C bond next to a nitrogen to give an ion fragment of *m/e* = 106 (Scheme VI).

The mass spectra of aromatic amines have been reported by several authors (226–229).

Other Amine Structures—Reports on the mass spectra of cyclic amines include the work of Duffield and co-workers (230) and Gallegos and Kiser (231). Geminal amines (134) are described by Kostyanovskii and Pan'shin. Mass spectrometry has been successfully used to determine the amino acid sequence in oligopeptide methyl esters (146) and has proved ex-



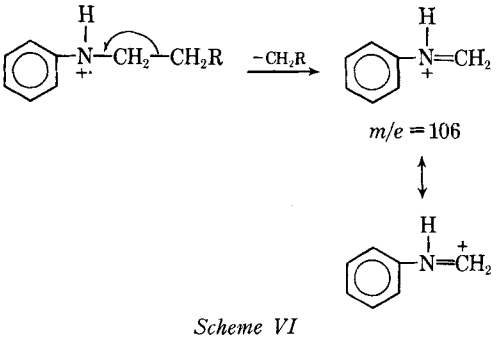
Scheme IV



Scheme V

tremely useful in structural and stereochemical problems of steroidal dimethylamines (147). Nitrogen in a steroid very strongly and consistently directs the mass spectral fragmentation, so it is very desirable to use mass spectrometry for the study of many steroidal amines to complement other spectral techniques. The fragments have diagnostic value for determining both the size and number of alkyl groups attached to nitrogen and also the nature of carbons in other functional groups in related molecules. Smith and Grostic (230) have described a procedure for mass spectrometric identification of the metabolites of an orally active diuretic agent, methyl *N*-(*o*-aminophenyl)-*N*-(3-dimethylaminopropyl) anthranilate. The mass spectra of enamines (149), and acetylene-amine adducts (150) have been studied. The recent review by Spiteller (216) on the mass spectrometry of heterocyclic compounds includes information on many amine-containing alkaloids, heterocyclic, and other compounds and should be consulted for an excellent description of the uses to which mass spectrometry may be put in the study of many biologically related compounds. Rearrangements (133) and hydrogen transfer reactions (132) in amides and amines are also reported.

In the field of pharmaceutical chemistry mass spectrometry has made a significant and important impact in the last 10 years and it promises



Scheme VI

to pioneer even greater pathways in the future. It should contribute much understanding of the processes involved in microbial as well as animal metabolism, and potentially supply valuable information for the development and advancement of new drug designs by providing the means for identification and elucidation of new structures of matter.

SUMMARY

The various branches of spectroscopy hold much promise for organic amine structure elucidation and analysis. Procedures and techniques for deducing information about these compounds are now quite well established, although new approaches are being developed daily. Future developments in this field are likely to include development of new sophisticated techniques and equipment, simplification of known techniques and equipment, and, most of all, wider use of computers to allow the research worker to learn more with less effort.

Role of Wetting on the Rate of Drug Release from Inert Matrices

By PARVINDER SINGH*, SAURABH J. DESAI*, ANTHONY P. SIMONELLI, and WILLIAM I. HIGUCHI

This investigation has shown that matrix permeability and rates of permeation of the matrix by the solvent can individually limit drug release rates. This was found to be a function of the pore size distribution of the matrix and the permeation pressure of the release media defined by its surface tension and contact angle. Methods useful in separating the various roles of the above were developed and are presented. They include the correlation and use of external pressure, vacuum techniques, surface tension and contact angle measurements, and porosimeter data. The results have been used to develop models to illustrate the possible systems that can be encountered. Concepts such as rates of pore permeation, varying solubility dependence, and tortuosity are developed and applied to these models.

PREVIOUS release studies have indicated that the polyethylene matrix gave excellent results in the presence of surfactant (1). The experiments in water, however, gave comparatively poor results as release rates were very slow and apparent tortuosities very high. It was speculated at that time that polyethylene was hydrophobic in nature and that wetting was not fully achieved.

Studies involving the effect of increasing concentrations of dibasic potassium phosphate on salicylic acid release from polyethylene matrices surprisingly showed no rate increase due to potassium phosphate even though the solubility increased by a factor of 45. There was, however, a dramatic rate increase in the presence of surfactant, even though the solubility remained constant.

These studies prompted this investigation in order to further clarify the possible mechanisms which can be operative under various conditions.

EXPERIMENTAL

Release Rate Determinations—The general procedure used for investigating the release rates has been previously described (2). It was necessary, however, to redesign the apparatus to allow the pressure to be kept constant at different pressures, as illustrated in Fig. 1.

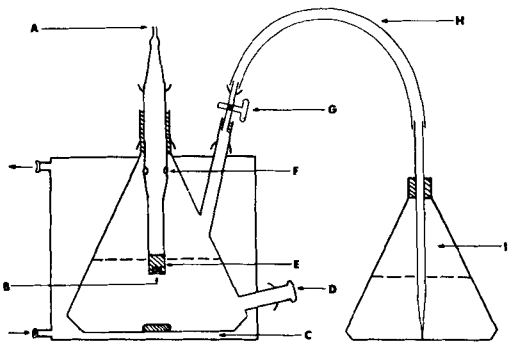

Fig. 1—Schematic diagram of the apparatus used to study release rates under positive net pressures.

side arms was used for these experiments. The tablet was mounted on a holder with a ground-glass joint to fit into the ground-glass necked conical flask. The lower part of the tube (E) was sealed to prevent hydrodynamic flow during the pressure experiments. The holder (A) was designed so that vacuum or pressure could be applied to its upper end and transmitted to the surface of the solvent by means of the lower openings (F).

Pressure was applied and maintained at a constant level by utilizing a tank of compressed nitrogen. To maintain a closed system when it was charged with solvent under vacuum conditions, the side arm (G) was connected by means of a tube (H) to a flask containing the solvent. Before vacuum was applied, the connecting tube (H) and stopcock bore (G) were completely flushed with the solvent to remove any entrapped air. A vacuum pressure of less than 0.1 mm. Hg was obtained to make certain all air was removed from the matrix before the solvent from the flask (I) was allowed to flow into the apparatus. The length of the tablet holder was sufficient to ensure that the tablet was not exposed to air, but was completely immersed in solvent prior to the release of the vacuum.

It should be emphasized that once the matrix is immersed in solvent, air can no longer enter the matrix, and a pressure differential of 1 Atm. remains on the system even though the vacuum is eliminated. Since this net solvent pressure of penetration is given by $P_{net} = P_{vacuum} + P_{external}$ it can be readily seen that each specific pressure can be achieved by many combinations of the above. For obvious technical reasons, however, the vacuum contribution was restricted to 1 Atm. pressure.

Samples were withdrawn using a 10-ml. syringe which was injected through a self-sealing multidose vial stopper (D). The sample outlet was placed so that it was always below the solvent level to prevent a change in pressure due to loss or addition of air to the system whenever fluid was removed or added.

Contact Angle Measurements—Contact angle measurements were made for all experiments reported in this study. The solutions used were made by dissolving enough drug in the solvent to provide a concentration equivalent to approximately 95% of its solubility in order to approximate the conditions existing in the matrix at the solvent front boundary.

The tablet was placed on an adjustable platform kept perfectly horizontal by means of a leveling device. A small drop of the test solution was placed on the tablet surface, and the contact angle was measured using a Gaertner[1] telemicroscope fitted with a protractor eyepiece and an objective lens (magnification 5×). The entire unit was mounted on an adjustable stand. The hairline of the protractor eyepiece was adjusted to coincide with the flat surface of the tablet, and the intersection of the two hairlines was fixed at the solid–liquid–air triple interface. With this baseline adjustment made, the reading on the protractor eyepiece was recorded. The eyepiece was then rotated until the horizontal hairline was made tangent to the liquid–air interface at the table surface. The angle difference between these two readings was equal to the contact angle used in these studies. These contact angles are not the contact angles in the classical sense because of the presence of capillaries and other heterogeneities on the surface. It should therefore be noted that the term contact angle, as referred to in the text, is in reality only an apparent value. However, it should also be emphasized that these measurements, and not the classical ones, are valid and provide a useful method of comparing the wetting tendencies of the different systems studied.

Other Parameters—The solubilities and diffusion coefficients were measured using methods reported earlier (3). The surface tension measurements were carried out using the Wilhelmy plate method (4). The solutions used were again made by dissolving enough drug in the solvent to provide a concentration equivalent to approximately 95% of its solubility.

RESULTS AND DISCUSSION

Water and Surfactant Data—As mentioned in the introduction, the release profile of salicylic acid from the polyethylene matrix was studied utilizing a wide range of dibasic potassium phosphate concentrations, thereby providing increasing solubilities. The results of these studies, along with the apparent solution–tablet contact angles, are presented in Table I. The expected slopes listed in the last column of Table I have been calculated using the 0.01 *M* K_2HPO_4 slope as the reference, and then calculating the release rates for the dibasic potassium phosphate systems based on the predicted square root of solubility dependence (2). It is clear that this dependence is not observed, as the experimental rates for the various systems studied are relatively constant and do not show the predicted five- to six-fold increase. This strongly indicates that the diffusion model is not applicable under the above conditions.

Examination of Table I further shows that for all these dibasic potassium phosphate solutions, the contact angles are extremely high (>90°), and reflect a nonwetting solid–liquid interface. This suggests that drug release may possibly be controlled by the rate of solvent penetration.

If this is true, the release rates should be considerably increased by reducing the contact angle to below 90°. Studies in water and 0.01% dioctyl

sodium sulfosuccinate[2] (AOT) confirmed this. Release rate studies of 20% salicylic acid from a polyethylene matrix were then carried out in varying concentrations of dibasic potassium phosphate solutions containing 0.01% AOT.

Examination of the 0.01% AOT results shown in Table II demonstrate the desired increase in rates with increasing solubility. The rate shown by the solvent not containing any dibasic potassium phosphate, however, was considerably lower than expected. At the same time there was a seemingly concomitant higher contact angle and surface tension.

To investigate this effect further, the above studies were repeated using 0.05% AOT, and these results are also tabulated in Table II. Interestingly, the rates in dibasic potassium phosphate solutions did not change, but the water data show a dramatic increase. A comparison of the rates and their corresponding contact angles and surface tensions clearly shows a strong relationship. The rate was greatly increased when the contact angle was lowered from a value greater than 90° to either 56° or 31°. The surface tensions were also correspondingly lowered. The slope was not changed, however, when the angle was lowered from 31° to essentially 0°, but dramatically increased when the angle was lowered from 56°. At the same time the surface tension also remained constant when the contact angle was lowered from 31°, but decreased when the angle was lowered from 56° to 0°. This implies that the rate is either controlled by the surface tension or that an effective maximum wetting effect is achieved at a contact angle between 31° and 56°. This observation is also implied by the fact that only the solutions of contact angles equal to or greater than 56° significantly show slower rates. Lastly, the apparent tortuosity values also are reasonable for all solutions but those showing contact angles of 56° or greater, as seen by the water data showing values of 107, 25, and 3.3.

The nonsurfactant solutions of Table I, on the other hand, had high contact angles and surface tensions, indicating that in those systems solvent penetration into the matrix may have been the reason for nonconformity to the diffusion model.

It would be highly desirable at this point to determine the individual roles that surface tension and contact angles play in this regard. A study in which contact angle can be continuously varied while a relatively constant surface tension is maintained could shed light on these roles, and in this way the two effects could be separated. Polysorbate 80[3] provided such a system. A series of varying concentrations of polysorbate 80 was selected so that the contact angle decreased from 97° to 46° with little change in surface tension, with the hope of obtaining a varying rate of solvent penetration. Table III shows that the release rates of salicylic acid considerably increase with increasing concentration of polysorbate 80. Figure 2 and Table III indicate that the experimental rates show a strong relationship with the corresponding contact angle, but are relatively independent of the surface tension. A large effect is also demonstrated regarding the apparent tortuosities which decrease exponentially.

This strongly suggests that the contact angle or degree of wetting is more important than surface

tension in determining solvent penetration. In these studies, however, the surface tension was already considerably lower (40 dynes/cm.). The studies in water, listed in Table I, on the other hand, are involved with a high surface tension in addition to a high contact angle, and in this situation the contact angle may not be the more important factor. The contact angle effect, independent of the surface tension effect, can be studied by using a matrix which shows a moderate contact angle in water. It was found that a matrix made of 70% polyvinyl chloride (PVC) and 30% polyethylene satisfied these requirements, as it exhibited a wetting contact angle (~70°) in the presence of nonsurfactant solutions. The study of Table I, *i.e.*, by varying the solubility using dibasic sodium phosphate, was then repeated using this matrix. The data are tabulated in Table IV and show that despite the presence of high surface tension of a nonsurfactant solution, the rate is increased with increasing solubility, and low tortuosity values are obtained. This shows that the degree of wetting is the important factor controlling matrix permeability and is the reason that the solubility effect was not observed in the experiments of Table I.

Pressure Studies as a Function of Solubility—The question of whether the apparent wetting dependence is an all-or-nothing effect or whether it is a rate effect, however, has yet to be answered.

These roles of solvent penetration can be further investigated by applying external pressure to the system as its permeation rate will increase with an increase of external pressure on the solvent. In this way the role of the rate of solvent penetration can be illustrated.

With the above in mind, experiments utilizing water as the release medium were carried out. The results tabulated in Table V show the feasibility of this method as the rates indeed are significantly increased and the apparent tortuosities decreased by an increase in pressure, despite a constant solubility, surface tension, and contact angle. As a matter of fact, the release rates and tortuosities obtained at higher pressures were comparable to those obtained from the same system (no K_2HPO_4) in the presence of surfactant (see Table II), and

suggest that at higher pressures a solubility effect should be observed.

This was substantiated by obtaining the release rates of salicylic acid in a series of release media at 40 p.s.i. external pressure. Data presented in the lowest row of Table VI show that the rate is increased with an increasing concentration of dibasic potassium phosphate, and thereby show that the solubility dependence is observed when 40 p.s.i. is applied to the aqueous system but is not observed at atmospheric pressure (Table I).

At this point it may be worthwhile to try to delineate the role played by solvent penetration in eliminating the solubility effect in terms of a hypothetical model utilizing an increasing net permeation pressure. This net permeation pressure, P_n, is defined as

$$P_n = P_p - P_i \qquad \text{(Eq. 1)}$$

where P_i is the internal pressure resisting solvent penetration, P_p is the permeability pressure $= P_w + P_e$; P_w is the pressure due to wetting, and P_e is the external pressure applied to the system.

In this model, the net permeation pressure is initially negative. This can be done by applying vacuum to a system previously loaded with solvent under atmospheric pressure. The entrapped air then causes an internal pressure which pushes solvent out of the matrix. This prevents solvent penetration and yields no drug release (see Fig. 3, top left).

This condition will persist until the net pressure is positive, at which point solvent will begin to penetrate (Fig. 3, bottom left). At low positive net pressures, however, the solvent rate of contact with solid drug is slower than the rate of drug diffusion, resulting in a subsaturated solution at the moving solvent boundary. As long as this condition persists, the release rate of the drug will

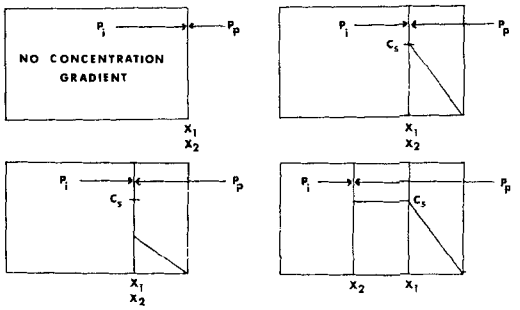

Fig. 3—Hypothetical model describing the conditions existing under a varying net pressure on the system.

be independent of the solubility. As the net positive pressure is further increased, the condition will be reached when the solvent rate of contact with solid drug becomes equal to the rate of drug diffusion (Fig. 3, top right). At this point no further increase in the rate of drug release will occur with further increase in net pressure. The solvent front, however, must continue to penetrate the matrix at a proportionally higher rate (Fig. 3, bottom right). This means that two boundaries must exist at net pressures above the minimum critical value—a solvent boundary, and a solid drug boundary, enclosing a region containing a saturated solution in equilibrium with its solid drug.

This model can be further clarified by exploiting the expression for the steady state at the solid drug–liquid interface, as the rate of drug solution must be equivalent to the rate of drug diffusion. The rate of solution is given by the amount of drug per unit volume of tablet, A, times the rate of the solid drug–liquid boundary movement, dx_1/dt. The rate of diffusion is given by the effective diffusion coefficient, $D\epsilon/\tau$, times the concentration gradient, dC/dx or Cx_1/x_1, where Cx_1 is the concentration of drug at the solid drug boundary. Then:

$$A \frac{dx_1}{dt} = \frac{D\epsilon}{\tau} \frac{Cx_1}{x_1}$$

(See Fig. 3, bottom right.) For the diffusion model to be operative the rate of permeation of the solvent must be equal to or greater than the rate of solid drug boundary movement, and permit a buildup of Cx_1 to the solubility level. The above equation can be rearranged to yield:

$$\frac{dx_1}{dt} = \frac{D\epsilon}{A\tau} \cdot \frac{Cs}{x_1} = \text{min. solvent permeation rate} \qquad \text{(Eq. 2)}$$

This shows that the minimum rate of penetration must increase as the porosity, the diffusion coefficient, or solubility of drug is increased, but it may permeate more slowly with a higher tortuosity, higher percentage of drug embedded in the matrix, and as penetration proceeds.

In an effort to verify the requirements of an increasing permeation rate with increasing solubility, the experiment conducted at 40 p.s.i. was repeated as a function of lower pressures, and the results are tabulated in Table VI and plotted in Fig. 4. Each curve seems to support the previous discussion as the rates of drug release appear to increase and

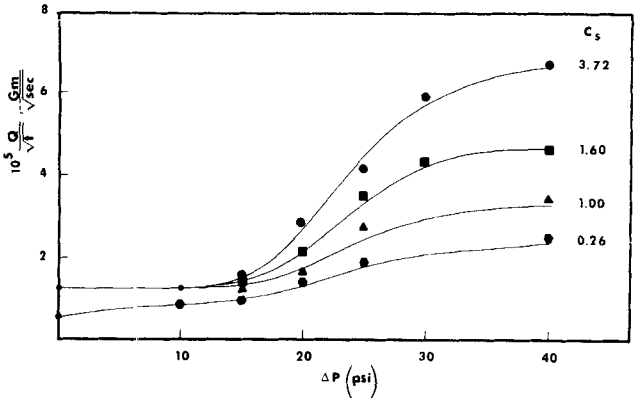

Fig. 4—Comparison of the effect of pressure on the release rates of the salicylic acid–polyethylene system as a function of solubility in water. Solubility is expressed in Gm./ml. × 10^2. (See Table VI.)

then plateau with an increased rate of solvent penetration. Furthermore, the plateau appears to require a higher rate of solvent penetration as drug solubility increases.

The family of curves in Fig. 4, however, also displays characteristics not predicted by the previous discussion. The rates of drug release do not increase with increasing solvent penetration rates until a net pressure of about 15 p.s.i. is reached, although the previous discussion indicated that this should begin at 0 p.s.i. This implies that an all-or-nothing effect is predominant below 15 p.s.i., but that above 15 p.s.i. the rate of penetration is controlling.

Pore Size Distribution—The initial plateau region of Fig. 4 displaying the all-or-nothing pressure effect can be explained if one includes the pore size distribution in the proposed model. This can be done by using the Washburn equation (5) which relates pore diameter to the solvent pressure required to initiate its penetration. Then,

$$P_i = -\left(\frac{4}{d_i}\right)\gamma \cos\theta \qquad \text{(Eq. 3)}$$

where P_i is the minimum net pressure required to achieve penetration, γ is the surface tension of the solvent, θ is the contact angle of the solid–solvent interface, and d_i is the minimum pore diameter penetrated by solvent at pressure P_i.

The above equation is valid only for contact angles greater than 90° (which is true of the system under consideration) and indicates that the all-or-nothing effect may be due to solvent impenetrability of certain pores present in the matrix which are below minimum diameter. This equation indicates that the pressure opposing solvent penetration is proportional to the product of the surface tension and the cosine of the wetting angle. Examination of this product, listed in Table I, indicates that all solutions are under the influence of a force opposing solvent penetration. Examination of Table II shows, however, that there is a positive permeation force manifested. More enlightening, on the other hand, is a re-examination of Table III, which shows that the above product ranges from an opposing penetration force to one of strong permeation. The plot in Fig. 2 strongly suggests the possibility that the presence of a restrictive pore distribution is operative in Fig. 4.

Figure 4 shows that the range of critical pressures begins at 20 p.s.i. and continues to a point past 40 p.s.i., indicating that there is a range of pore size which are not penetrated at a lower pressure. The distribution of pore sizes limiting penetration corresponding to the above range of critical pressures was calculated using the Washburn equation and found to range from 0.32 μ down to a value less than 0.12 μ. The average pore size of the above distribution was estimated to be 0.24 μ, using 25 p.s.i. as its critical pressure, which corresponds to the average point of inflection on the rising portions of all Fig. 4 curves. Porosimeter (6) data were obtained and indicated that the pore size distribution ranged from 40 μ down to below 0.06 μ. There was, however, a sharp peak beginning at 2 μ extending to 0.3 μ with its maximum at 0.8 μ. It was felt that this was in very good agreement with the hypothesis, if one considers that first, the porosimeter yields essentially data at equilibrium, whereas the pressure studies are rate data. One would therefore expect that the critical pressure would be increased, and therefore its apparent pore size distribution would be exhibited at lower pore sizes. Second, there may be distortion of the pores due to compression of preceding empty lumen occurring with the porosimeter at the higher pressures used. Last, the effective diameter (7) of a tortuous pipe will be less than the true diameter when considering hydraulic flow.

To further investigate the phenomenon, 0.005% polysorbate was added to the release media and release studies were again made as a function of the pressure. The contact angle for this system decreased from 98° to 93°, and the surface tension from 59 dynes/cm. to 44 dynes/cm. This means that the critical pressure should be lowered by a large factor of 0.6 (from the Washburn equation). The results of these studies are presented in Table VII and Fig. 5, and a large shift is seen supporting

Table VII—Comparison of the Effects of Pressure on the Release Rates of the Salicylic Acid–Polyethylene System as a Function of Solubility in 0.005% Polysorbate 80 Solution

[a] Solubility in Gm./ml. × 10^2.

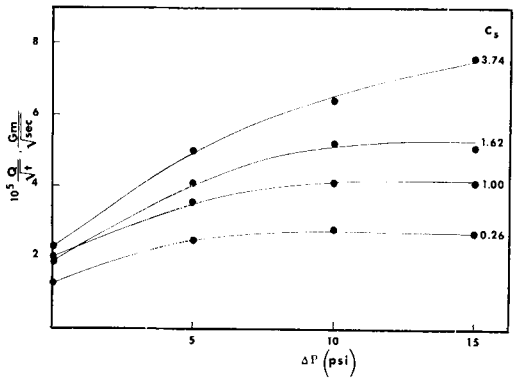

Fig. 5—Comparison of the effects of pressure on the release rates of the salicylic acid–polyethylene system as a function of solubility in 0.005% polysorbate solutions. Solubility is expressed in Gm./ml. × 10^2. (See Table VII.)

the previous discussion. Comparable release rates are seen in Figs. 4 and 5, although for the system containing polysorbate they occur at about 15 p.s.i. lower than in the absence of polysorbate. This implies that the addition of 0.005% polysorbate is equivalent to an application of 15 p.s.i.

This above observation can be quantitated by using the Washburn equation (Eq. 3) to determine the external pressure required for penetration under both water and surfactant conditions. Obviously, the difference will yield the contribution due to the addition of 0.005% polysorbate to the solution. Then,

$$P_{\text{polysorbate contribution}} = P_{\text{polysorbate}} - P_{\text{water}} = -\frac{4}{d}(\gamma_{PSO}\cos\theta_{PSO} - \gamma_{H_2O}\cos\theta_{H_2O})$$

and this yields a value of 10 p.s.i., which agrees very well with the above value.

The degree of the solubility dependence as a function of the pressure exhibited in Figs. 4 and 5 prior to the maximum plateau can be determined from a plot of the rate of drug release *versus* the square root of solubility. For better comparison, however, the ordinate and abscissa can be normalized by using the release rates and the corresponding solubility value in 0.25 *M* K_2HPO_4 solution for each pressure. Ideally, all curves should be superimposable with a slope of one, as the effect of all other factors (such as porosity, tortuosity, drug percent, and diffusion coefficient) are eliminated by taking a ratio, yet Figs. 6 and 7 show that the slopes are less than one and increase with an increasing rate of solvent penetration. Drug unavailability cannot be used to explain the results as the total amount of drug released showed that there was enough drug present to produce a saturated solution in the matrix. This indicates that there are complicating kinetic factors involved.

The Effect of Pressure Variation Under Wetting Conditions—If these factors are not dynamic in nature, there should not be pressure dependence of the release rates exhibited under wetting conditions. To test this point, two series of experiments were performed, one at a relatively high constant solubility level, 1.62 Gm./100 ml. (0.1 *M* K_2HPO_4), using a varying concentration of polysorbate solutions; and another at a relatively low constant solubility level, 0.26 Gm./100 ml. (H_2O), using a varying concentration of AOT solutions. The results of these experiments are tabulated in Tables VIII and IX, and are plotted in Figs. 8 and 9, respectively.

Both curves show that the release rates are not independent of pressure under these conditions. In addition, the application of external pressure and the permeation pressure due to wetting are evidently complementary, since with an increase in the permeation pressure (by increasing the wetting power of the release medium), less external pressure must be applied to achieve the maximum rate. In fact, the release rates no longer are dependent on the external pressure if the wetting power is sufficiently increased. The persistent pressure effect, even under wetting conditions, strongly reinforces the possibility that the partial solublity. dependence is due to complicating kinetic factiors These kinetic factors can be brought about by the presence of a complex distribution of pore sizes of which porosimeter data only showed two distri-

butions. Since all of the porosity was not accounted for, it is very likely that the unaccounted for porosity is composed of pores whose size distribution is so small it would require prohibitive pressures to detect. The higher resistance of these pores to flow, however, can greatly affect the rates of permeation and diffusion. These rates can also be complicated by other factors such as microenvironmental heterogeneities and contact angles which can exist throughout the matrix porosity.

Model Defining the Role of Solvent Penetration—It would be useful at this time to review the techniques and concepts that have been developed in this study, and show how they may be used to characterize various matrix systems.

It would appear, first of all, that one must consider kinetic as well as static factors. These include the degree of possible penetration which can range from matrix impermeability to one of complete permeability. The rate of permeation, on the other hand, can also be very important, and can be rate determining if too slow.

If one wishes to apply the results of this investigation to a particular inert matrix, however, one must be able to characterize each system, so that the variables can be identified which must be altered to obtain a desired drug release profile. The following discussion considers the different systems that can exist with the above in mind.

If incomplete penetration of the matrix occurs, the porosities used in the theoretical equations will obviously be too large, and consequently will yield

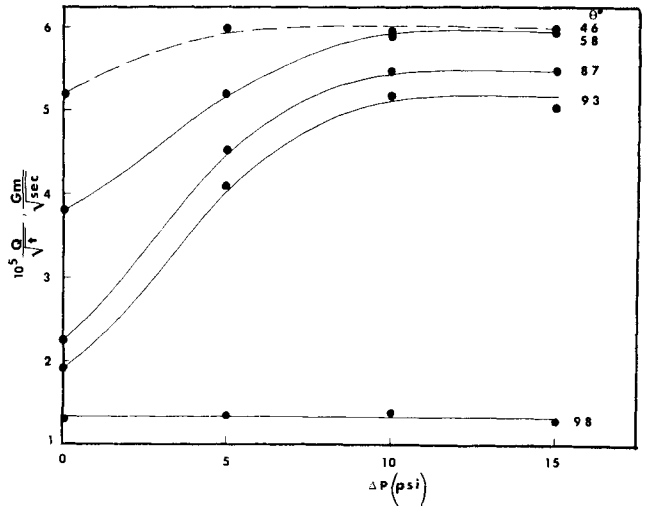

Fig. 8—Comparison of the effects of pressure on the release rates of the salicylic acid–polyethylene system as a function of the contact angle in polysorbate solutions. Solubility maintained constant at 1.6 × 10^{-2} Gm./ml. (See Table VIII.)

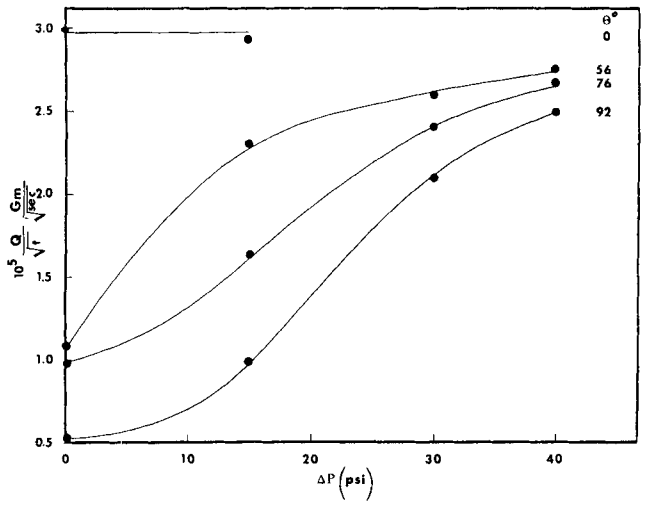

Fig. 9—Comparison of the effects of pressure in the release rates of the salicylic acid–polyethylene system as a function of the contact angle in AOT solutions. Solubility maintained constant at 2.6 × 10^{-3} Gm./ml. (See Table IX.)

abnormally high tortuosities. The rate of solvent penetration will strongly influence the characteristics exhibited by this system. For example, if the permeation rate is too slow, the release rate will be increased by either an increase in pressure or on addition of surfactant. The effect of pressure, however, may not be evident until a critical pressure is applied. This system is also characterized by an absence of a solubility dependence effect. These characteristics describe the salicylic acid release in water as shown by the effects of pressure and surfactant, tabulated in Tables II, III, V, and VI, and the solubility effect shown in Table I.

If the permeation rates, on the other hand, are sufficiently rapid, a solubility dependence will be exhibited. There also will be a concomitant decrease in the apparent tortuosity to an intermediate value. The pressure and surfactant studies will reveal the same behavior as the first case. These characteristics describe the salicylic acid release in 0.005% polysorbate solution as shown by the effects of pressure and surfactant in Table VIII and the solubility effect in Table VII. The appplication of a critical pressure was not necessary in this system.

If complete penetration of the matrix is accomplished, needless to say, only the rate of permeation of the solvent can be limiting. If it is too slow, no solubility dependence is found, both pressure and surfactant effects can be observed, and high apparent tortuosities will be present. This condition can be achieved if one utilizes a highly soluble drug in too low a percent in the tablet.

The rate of permeation, however, can be sufficiently rapid to manifest a solubility dependence, but not rapid enough to demonstrate it to the maximum. This system will be characterized by pressure and surfactant effects with intermediate values of apparent tortuosities. This description would appear to describe the salicylic acid release in 0.005% polysorbate solution, but this possibility is easily eliminated due to the high nonwetting contact angle. These characteristics, however, can be used to describe the release of salicylic acid in 0.005% AOT. The pressure and surfactant effects are shown in Table IX. The solubility dependence was not determined for this system, but examination of Fig. 9 leaves little doubt that a partial solubility dependence would be observed.

The ideal situation of complete penetration and

sufficiently rapid permeation rates, needless to say, will exhibit no pressure or surfactant effects, and yield a maximum solubility dependence with low tortuosities. These characteristics apply very well to salicylic acid release in 0.05% AOT as shown by Table II and Fig. 9.

It appears that the techniques developed and presented here lend themselves very well to a definitive description and characterization of the particular matrix system one is dealing with, and in particular, permit the selection of the proper variables to alter in order to remedy nonideal matrix systems to provide the desired release profiles.

Use of the Overturn End Point for the Estimation of Absorption and Elimination Kinetics in Goldfish

By MILO GIBALDI and CHARLES H. NIGHTINGALE

The advantages of overturn time as a pharmacologic end point for studies of biologic membrane permeation in goldfish are presented. Studies with both pentobarbital and ethanol showed good reproducibility. Redeterminations of overturn time after 18 hr. provided excellent agreement with initial determinations with both drugs. Evidence is presented to suggest a complex mechanism of action of ethanol in goldfish. A kinetic model is derived which relates overturn time and recovery time and permits the estimation of an elimination rate constant from pharmacologic response data alone.

Fish, particularly goldfish, have been used since 1867 as test animals for determining the toxicity of various substances, and a number of techniques have been developed for this purpose (1). A useful approach has been measurement of the time required to produce a well-marked stage of toxicity such as death.

Powers (2), after an extensive series of experiments with goldfish using a variety of drugs and chemicals, concluded that for every toxic substance, over a certain concentration range, the survival time is inversely related to the concentration. For many years the idea prevailed that the magnitude of the slope of a reciprocal time of death-concentration plot was indicative of intrinsic toxicity (1). Recently, Levy and Gucinski (3) have demonstrated that the slope of such a plot is actually a complex function of both the intrinsic toxicity and the absorption rate of the drug. Furthermore, these workers proposed that the reciprocal time of occurrence of any suitable pharmacologic response for a given drug will be directly proportional to the absorption rate of the drug under certain specified conditions (*viz.*, absorption occurs by passive diffusion, drug concentration gradient across the absorbing membranes remains essentially constant, drug metabolism in the fish is negligible, and the pharmacologic end point occurs without significant delay after a given amount of drug is absorbed). Knowledge of the amount of drug in the goldfish body required to induce a pharmacologic response permits the calculation of the absorption rate constant from reciprocal time of response-concentration plots. Even in the absence of such knowledge, relative absorption rates of a single drug under different experimental conditions may be assessed from the slopes of reciprocal time-concentration plots (3).

logic response that has been used in the goldfish is the so-called overturn time (1). The overturn end point marks the time, after exposure to a given substance, at which the fish appear to lose their sense of balance and float on their side or upside-down. This end point seems somewhat analogous to the loss of righting reflex in the rat.

Use of the overturn time rather than time of death as a pharmacologic end point offers certain advantages in that the fish survive the study and may, after a suitable period of time, be used again in other experiments. In well-designed experiments a fish or a group of fish may serve as its own control, thereby affording a decided statistical advantage. Furthermore, the ability to reuse fish in a series of experiments allows conservation of test animals which minimizes the problems of lot-to-lot variation (3). In certain toxicity studies the overturn time end point has been claimed to be better defined than the time of death end point since with some drugs the fish enter a deep anesthetic stage which may be mistaken as death (1).

A further advantage of the use of overturn time as a pharmacologic criterion of drug absorption is that the duration of pharmacologic response may be determined. The duration of response should be related to the body drug levels in the fish as well as the rate of drug elimination from the fish.

It is the purpose of the present report to demonstrate the utility of the overturn time end point for the determination of drug absorption and exsorption rates in the goldfish.

EXPERIMENTAL

Goldfish, *Carassius auratus*, common variety, weighing from 5 to 10 Gm. were used. All fish utilized in a given experiment were from the same lot. Three different lots were used during the study. Solutions were prepared daily, as required, from reagent grade or USP materials. The test drugs, ethanol and sodium pentobarbital, were dissolved in 0.05 *M* phosphate buffer, adjusted to pH 6.1.

Evaluation of Pharmacologic Response—All measurements of overturn time (T_0) and duration of effect (T_R) were made at 24–26°. The overturn time was taken as the time required for the fish to lose the ability to maintain itself upright after immersion in drug solution. When the first signs of overturn were observed the end point was tested by attempting to turn the fish on its side with a stirring rod. Unaffected fish will either not allow themselves to be placed on their side or will immediately right themselves. The end point was judged as the time when a fish placed on its side did not right itself immediately. The parameter T_R was defined as the time required (from $t = T_0$) for a fish to regain the ability to right itself immediately after being placed on its side.

The determination of T_0 was carried out with individual fish in 200 ml. of drug solution in 250-ml. beakers. At $t = T_0$ the fish was immediately (or after a timed interval of 2 or 4 min.) placed in approximately 5 gal. of distilled water. The time required from immersion of the fish in the reservoir to recovery of righting reflex is T_R.

At one concentration with each drug the fish were removed from the drug solution after determination of T_0 and placed in a holding tank containing 10 gal. of distilled water. These fish were restudied under identical conditions after 18 hr.

RESULTS AND DISCUSSION

It was found in preliminary experiments that immersion of goldfish in the buffer solution for 24 hr. had no apparent effect on the fish. In addition the overturn time found in 3% ethanol solutions with and without buffer was virtually identical. Hence, it was concluded that the buffer system had no direct effects on pharmacologic response.

According to the model proposed by Levy and Gucinski (3), the time required for a pharmacologic response (T) is related to drug concentration (C) in the following manner:

$$1/T = KC \qquad \text{(Eq. 1)}$$

where $K = ka/A_B$. The term ka is the apparent absorption rate constant (which includes the absorptive surface area) and the term A_B is the amount of drug required in the fish to elicit the pharmacologic response. The requisite assumptions for Eq. 1 have been detailed (3).

Levy and Miller (4) have found that the relationship between time of death and concentration of various barbiturates including pentobarbital and various alcohols is in agreement with Eq. 1. The results of the present study with pentobarbital (shown in Fig. 1) using overturn time as the pharmacologic end point rather than time of death are also in good agreement with the biologic model. A plot of $1/T_0$ as a function of concentration demonstrated linearity over a concentration range from 10 to 50 mg.%. The significance of a least-squares treatment on a reciprocal plot, without appropriate weighting factors, is questionable. Accordingly, the

[a] A total of 5 fish was studied but one fish showed no response over a 2-hr. period and was not included in the calculation.

data in Fig. 1 were fitted by eye and the resulting line appears to approximate the origin. The mean data obtained at each concentration of pentobarbital along with standard error calculations are summarized in Table I.

The results of retesting a group of fish after exposure to 3% ethanol or 50 mg.% pentobarbital are shown in Table II. The excellent agreement of the mean values, range, and standard errors between the initial study and the second study, conducted 18 hr. later, indicates clearly the statistical advantages to be gained by the use of a pharmacologic end point other than time of death.

The results of the overturn time–ethanol concentration studies are shown in Table III. The reciprocal time-concentration plot shown in Fig. 2 clearly indicates that the data do not adhere to the theoretical model. Although a linear relationship exists between $1/T_0$ and ethanol concentrations between 1.5 and 4.0% (v/v), a clearly defined intercept is observed at a concentration of about 1%. These findings are similar to those reported recently by Hall and Hayton (5) using overturn time of goldfish and guppies in ethanol solutions.

The model proposed by Levy and Gucinski (3) requires conditions where the fish body functions as an infinite sink, *i.e.*, drug concentration in the fish never exceeds 10 to 20% of drug concentration in the bathing solution. Accordingly, if the concentration required to elicit a pharmacologic response in the fish is $1/5$ to $1/10$ the concentration of the drug

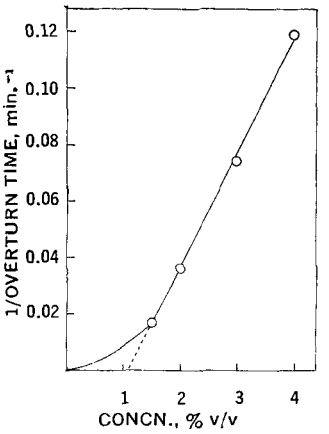

Fig. 2—Reciprocal time of overturn of goldfish as a function of ethanol concentration. Data suggest a concentration intercept of 1% (v/v).

solution, one would anticipate a change in the order of absorption kinetics and a lack of agreement with Eq. 1 at these low concentrations.

On the basis of the present findings it would appear that the minimum body level of ethanol required to elicit overturn in the goldfish is in the order of 150 to 300 mg. %. Interestingly, this estimate approximates the toxicity level of ethanol in man. Sollmann (6) reports that an ethanol blood level of 300 mg. % is required to induce a stuporous condition or sedation in man.

An alternative possibility to explain the intercept is that the fish is capable of metabolizing ethanol. If this were the case, the minimum body level of ethanol required to induce overturn may be significantly lower than 150 mg. % and one would still observe a concentration intercept of approximately 1%.

The ethanol studies also indicated lack of agreement with the biologic model at concentrations above 4% (v/v). Experiments conducted at 5% and 7.5% ethanol gave reciprocal times of overturn that were significantly higher than those predicted by extrapolating the results in Fig. 2. These tentative findings suggested a change in the mechanism of penetration or pharmacologic effect of ethanol in the goldfish as a function of concentration.

On the basis of these findings, it was decided to restudy a second lot of fish and to determine overturn times over a 2 to 8% concentration range at 1% intervals.[1] The results of this second study are shown in Table IV and Fig. 3. Once again a concentration intercept was noted at about 1%. In this particular lot of fish a linear relationship between $1/T_0$ and concentration was found from 2 to 5% ethanol.

The data in Fig. 3 clearly indicate a discontinuous increase in $1/T_0$ above 5% ethanol, *i.e.*, time of overturn is significantly shorter than can be predicted from the low concentration data. The present results suggest the absence of a concentration intercept if high ethanol concentration data are extrapolated to zero concentration. This finding is in agreement with that of Levy and Miller (4).

[1] Concentrations above 8% ethanol gave rise to T_0 values of less than 1 min. and corresponding $1/T_0$ values are subject to large errors.

extracted with portions of methanol. The methanolic extracts (2 L.) were concentrated to about 50 ml. and passed through 20 Gm. Amberlite IRA 400 (OH) resin column. The resin was washed with 150 ml. 50% aqueous methanol. The effluents were evaporated to yield 123 mg. of choline. The base was identified by converting it to picrate and crystallizing the product from absolute ethanol. The melting point of the picrate, 242–244°, was not depressed by mixing the compound with reference choline picrate and IR spectra of the two samples were identical.

The unidentified polar base, which had zero R_f value on the preparative paper chromatograms, was isolated by extracting the corresponding band with 50% aqueous methanol acidified with formic acid. The product obtained after evaporation was saved.

DISCUSSION

An investigation of *Lophophora williamsii* constituents resulted in isolation and identification of four crystalline compounds. Three bases, which were new peyote alkaloids, were designated—anhalotine, lophotine, and peyotine—and were identified as metho derivatives corresponding to anhalidine, lophophorine, and pellotine, respectively. A fourth base which was obtained as a picrate was identified as choline.

Of the three quaternary tetrahydroisoquinolines isolated and identified, lophotine and peyotine are expected to be optically active. Since only small amounts of the two compounds were available, the optical rotations of the compounds could not be determined. However, the melting points of lophotine iodide isolated and that of the methiodide prepared from the natural lophophorine were the same and the mixed melting point of the two showed no depression. This suggested that the isolated compound was identical with the prepared.

The melting point of crystalline peyotine iodide was lower than the melting point of the methiodide prepared from *dl*-pellotine. The isolated compound softened at 114° and thereafter solidified and then melted at 185–186°. It is possible that the isolated compound is an optically active substance or that the compound in part may have racemized during the isolation. According to Spaeth and Kesztler (18) pellotine base itself undergoes racemization and this had led the authors to suggest that the optically active base is present in the plant; the compound is racemized during extraction or aging of the drug. As indicated earlier, small amounts of peyotine iodide isolated did not permit any further work. The R_f values, IR, and UV spectra of the isolated and prepared compounds were, however, identical.

With the isolation and identification of anhalotine, lophotine, and peyotine the expected occurrence of the quaternary bases corresponding to the known peyote secondary and tertiary bases—namely, anhalamine, anhalidine, anhalonine, lophophorine, anhalonidine, and pellotine—is realized. However, the isolated quaternary bases—namely, the three tetrahydroisoquinolines, choline, and the other two unidentified basic compounds—occur only as minor constituents of peyote.

The quaternary compound corresponding to mescaline, the major and important peyote base, appears not to be present in a detectable amount in the plant. In connection with this, it may be indicated that *N*-methylmescaline has been isolated as a minor alkaloid of peyote (19) and *N*,*N*-dimethylmescaline (≡ tricocereine) which though known to be present in the cactus plant, *Trichocereus terscheckii* (Perm.) (20), has not yet been isolated from the mescal buttons.

As indicated earlier in a recent study thin-layer chromatographic identification of candicine has been reported (5) from peyote quaternary base fraction. In connection with the identification of this compound, the following may be noted.

In Table I are listed the R_f values of anhalotine, lophotine, and peyotine iodides and choline chloride. For comparison R_f values of candicine iodide have also been given. The results recorded in the table indicate that the R_f values of candicine iodide are either too close to or the same as that of the quaternary alkaloids which have been isolated in our studies. Even on alumina G plate and the solvent system carbon tetrachloride-methanol-glacial acetic acid (12:28:1) used (5), candicine iodide has the same R_f value as peyotine iodide. Wagner's reagent a nonspecific reagent, was used for location of the quaternary bases on the chromatogram by these authors. Therefore, distinction of the compound(s) present on the spot having an R_f value same as candicine iodide, into phenolic and nonphenolic quaternary bases, could not be made. In this study tetrazotized di-*o*-anisidine was used for the location of the phenolic bases. The nonphenolic and the phenolic quaternary bases were further detected and distinguished by the use of the modified Dragendorff's reagent. The former agent yielded distinct violet colored spots with the phenolic tetrahydroisoquinoline bases anhalotine, peyotine, and also other nonquaternary phenolic bases anhalamine, anhalidine, anhalonidine, and pellotine. On the other hand candicine, a phenolic quaternary β-phenylethylamine and other related compounds namely, tyramine, *N*-methyltyramine, and hordenine, gave yellow colored spots. In the chromatographic examination of the quaternary base fraction of peyote, no yellow colored spot at the candicine R_f location was observed. This observation and the fact that the R_f values of candicine iodide are the same as, or too close to, other quaternary bases, suggest that the candicine cannot be identified by the method reported and its occurrence in peyote has not been proven.

In the present studies, in addition to the quaternary bases, the known peyote alkaloids namely, lophophorine, pellotine, and anhalonine were obtained by a method differing from that reported previously (8–11). The modified method is based on the fact that from an aqueous extract acidified with hydrochloric acid, the three known bases can be extracted as hydrochlorides with chloroform. Inasmuch as the isolation of the three compounds is accomplished in earlier stages of extraction, the modified method reported herein can be considered as a convenient procedure for the isolation of at least lophophorine and pellotine.

One noteworthy point regarding isolation of pellotine that needs to be pointed out is that, even though this is a phenolic alkaloid, it can be extracted from an aqueous potassium hydroxide

solution with chloroform and ether. Spaeth and Becke (8) also have reported such a behavior for the peyote phenolic alkaloids. According to them, these compounds were at least in part extracted with ether from an aqueous potassium hydroxide solution even though they used concentrated solution (50%) of aqueous potassium hydroxide.

In conclusion, it may be indicated that although the β-phenylethylamine quaternary alkaloids, candicine and coryneine (≡ 3-hydroxycandicine), have been isolated from some cacti (1,20), *Lophophora williamsii* appears to be the first cactus plant from which simple quaternary tetrahydroisoquinolines have been isolated and identified. Occurrence of such compounds in other cacti could be expected, and as in peyote, these compounds may be present at least as minor basic constituents.

Thalictrum Alkaloids V

Isolation

By MAURICE SHAMMA and BERNARD S. DUDOCK

The experimental procedure which led to the isolation of the new alkaloids thalifendlerine (I), thalifendine (II), thalidastine (III), thaliporphine (IV), preocoteine (V), and thalidezine (VI), from *Thalictrum fendleri* is described in detail. Known alkaloids also found in *T. fendleri* are berberine (VII), jatrorrhizine (VIII), glaucine (IX), magnoflorine (X), ocoteine (XI), hernandezine (XII), and thalicarpine (XIII). A completely new dimeric aporphinebenzylisoquinoline alkaloid of only partially elucidated structure is thaldimerine (XIV). A novel procedure for the separation of tertiary alkaloids consists of partition chromatography of the mixture of hydrochloride salts using a cellulose column in the system methyl ethyl ketone–water.

THE STRUCTURAL ELUCIDATION of a variety of new isoquinoline-type alkaloids from *Thalictrum fendleri* has previously been reported. The alkaloids involved were thalifendlerine (I), thalifendine (II), thalidastine (III), thaliporphine (IV), preocoteine (V), and thalidezine (VI) (1–4). In addition, the presence of the following known alkaloids in *T. fendleri* was indicated: berberine (VII), jatrorrhizine (VIII), glaucine (IX), magnoflorine (X), ocoteine (XI), hernandezine (XII) (3), and thalicarpine (XIII). The purpose of the present paper is to describe the isolation procedure employed to obtain these 13 compounds. Additionally, the isolation of the completely new alkaloid thaldimerine (XIV) will also be discussed, although lack of sufficient material has so far precluded the complete structural elucidation.

Coarsely ground *T. fendleri* was extracted with methanol and the solvent was evaporated. The oily residue obtained was taken up in dilute acetic acid and filtered. The filtrate was extracted with chloroform and ether to remove acidic and neutral components. The aqueous acidic layer was then made just basic with concentrated ammonium

solution with chloroform and ether. Spaeth and Becke (8) also have reported such a behavior for the peyote phenolic alkaloids. According to them, these compounds were at least in part extracted with ether from an aqueous potassium hydroxide solution even though they used concentrated solution (50%) of aqueous potassium hydroxide.

In conclusion, it may be indicated that although the β-phenylethylamine quaternary alkaloids, candicine and coryneine (≡ 3-hydroxycandicine), have been isolated from some cacti (1,20), *Lophophora williamsii* appears to be the first cactus plant from which simple quaternary tetrahydroisoquinolines have been isolated and identified. Occurrence of such compounds in other cacti could be expected, and as in peyote, these compounds may be present at least as minor basic constituents.

Thalictrum Alkaloids V

Isolation

By MAURICE SHAMMA and BERNARD S. DUDOCK

The experimental procedure which led to the isolation of the new alkaloids thalifendlerine (I), thalifendine (II), thalidastine (III), thaliporphine (IV), preocoteine (V), and thalidezine (VI), from *Thalictrum fendleri* is described in detail. Known alkaloids also found in *T. fendleri* are berberine (VII), jatrorrhizine (VIII), glaucine (IX), magnoflorine (X), ocoteine (XI), hernandezine (XII), and thalicarpine (XIII). A completely new dimeric aporphinebenzylisoquinoline alkaloid of only partially elucidated structure is thaldimerine (XIV). A novel procedure for the separation of tertiary alkaloids consists of partition chromatography of the mixture of hydrochloride salts using a cellulose column in the system methyl ethyl ketone–water.

THE STRUCTURAL ELUCIDATION of a variety of new isoquinoline-type alkaloids from *Thalictrum fendleri* has previously been reported. The alkaloids involved were thalifendlerine (I), thalifendine (II), thalidastine (III), thaliporphine (IV), preocoteine (V), and thalidezine (VI) (1–4). In addition, the presence of the following known alkaloids in *T. fendleri* was indicated: berberine (VII), jatrorrhizine (VIII), glaucine (IX), magnoflorine (X), ocoteine (XI), hernandezine (XII) (3), and thalicarpine (XIII). The purpose of the present paper is to describe the isolation procedure employed to obtain these 13 compounds. Additionally, the isolation of the completely new alkaloid thaldimerine (XIV) will also be discussed, although lack of sufficient material has so far precluded the complete structural elucidation.

Coarsely ground *T. fendleri* was extracted with methanol and the solvent was evaporated. The oily residue obtained was taken up in dilute acetic acid and filtered. The filtrate was extracted with chloroform and ether to remove acidic and neutral components. The aqueous acidic layer was then made just basic with concentrated ammonium

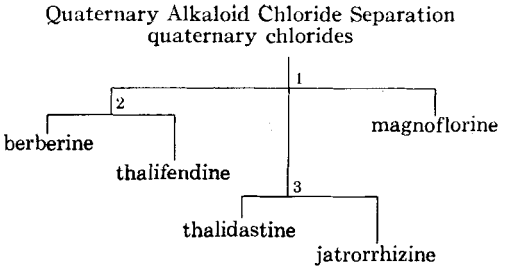
hydroxide, and reextracted with chloroform and ether to remove the tertiary alkaloids. The aqueous solution was acidified and the quaternary alkaloids were precipitated as their reineckate salts, which were then converted to the alkaloid chloride salts by ion exchange.

Quaternary Alkaloid Chloride Separation



1, partition chromatography
2, alumina chromatography
3, preparative TLC

Scheme I

Preliminary attempts to fractionate the quaternary alkaloid chloride mixture, employing fractional crystallization and adsorption chromatography on columns of alumina, silica gel, and magnesium silicate,[1] gave relatively poor separations. Partition chromatography, previously shown to be successful in fractionating highly complex quaternary alkaloid mixtures (5), was therefore employed. Methyl ethyl ketone saturated with water was chosen as the partition system for the large-scale column chromatography on cellulose. This solvent combination gave a good separation, and had the advantage of being fast running, reasonably stable, and odorless, and low boiling so that it could easily be removed without alkaloid decomposition.

The partition column used cellulose powder as the inert support. The cellulose was first saturated with the stationary phase (water saturated with methyl ethyl ketone) then "dry-packed" (6) into the column and finally equilibrated with the mobile phase. The quaternary chloride mixture, dissolved in the stationary phase bound to the cellulose powder, was then added to the top of the equilibrated column and the separation was begun by allowing the mobile phase to slowly flow down the column. Efforts were made to control the temperature, and the packing and drip-rate fluctuations. The complete procedure is described in detail under *Experimental.*

The quaternary alkaloid mixture was thus separated into distinct fractions as summarized in Scheme I. Fractions were combined on the basis of their paper and thin-layer chromatographic pattern, and usually further purified by adsorption chromatography on alumina or preparative thin-layer chromatography (TLC).

Due to the success of partition chromatography in fractionating the quaternary alkaloids, the same procedure was employed to separate the

TABLE I—FRACTIONATION OF TERTIARY ALKALOIDS BY PARTITION CHROMATOGRAPHY[a]

Fractions	Flasks[b]	Alkaloids isolated
1	1–6	No well-defined alkaloids isolated
2	7–15	Thalifendlerine (I), 3 Gm.[c]
3	16–20	Thalifendlerine (I), 200 mg. Ocoteine (XI), 200 mg. Glaucine (IX), 5 mg. Preocoteine (V), 60 mg.
4	21–28	Thaliporphine (IV), 70 mg.
5	29–35	Thaliporphine (IV) 30 mg. and other minor alkaloids
6	36–55	Not investigated to date[d]
7	56–61	
8	62–89	
9	90–105	
10	106–115	
11	Methanol washing	Hernandezine (XII), 50 mg. Thalicarpine (XIII), 20 mg. Thaldimerine (XIV), 20 mg Thalidezine (VI), 300 mg.

[a] The column was 180 cm. in height, 10 cm. wide, and contained 1,500 Gm. of cellulose powder. [b] Each flask contained about 100 ml. of solution. [c] The weight refers to the alkaloid free base obtained from 15 Kg. of dried plant. [d] TLC revealed the presence of hernandezine and thalicarpine.

tertiary bases. The total tertiary alkaloid mixture, which was only half as prevalent as the quaternary alkaloid fraction, was converted to hydrochloride salts and fractionated on large cellulose columns with methyl ethyl ketone saturated with water, in the same manner as previously described. To our knowledge, this is the first time such an isolation procedure has been employed for the fractionation of tertiary alkaloids. Upon completion of the partition chromatography, the column was washed thoroughly with methanol to insure complete removal of the alkaloids. Similar fractions were combined on the basis of their TLC patterns. This procedure gave 11 fractions which are indicated in Table I.

The general procedure for separating the components of each fraction was to convert the tertiary alkaloid salts back to the free bases, and then to employ adsorption chromatography on neutral alumina with chloroform, containing increasing amounts of methanol, as solvent. The fractions from this chromatographic separation were further purified by preparative TLC.

It was repeatedly found in the course of the present investigation that the true complexity of the crude alkaloid mixtures could not be determined prior to the large-scale partition chromatography on cellulose. It is therefore felt that the use of large partition columns as the first step in alkaloid fractionation is decidedly advantageous, and facilitates the isolation of minor alkaloids.

The new tertiary alkaloid thaldimerine (XIV) which has not previously been described was obtained as a transparent light brown oil which was homogeneous by TLC. The UV spectrum with $\lambda_{max.}^{EtOH}$ 303 and 283 mμ showed a marked bathochromic shift upon the addition of base, so that the alkaloid must be phenolic. The NMR spectrum of a deuteriochloroform solution exhibited two *N*-methyl groups superimposed at 2.48δ (six protons), and six *O*-methyls at 3.57 (three protons), 3.79 (nine protons), and 3.92δ (six protons), underscoring the fact that the alkaloid must be dimeric. The mass spectrum with a molecular ion at *m/e* 699 pointed to the formula $C_{40}H_{46}O_9N_2$, indicating the alkaloid to be an aporphine-benzylisoquinoline dimer. The base peak at *m/e* 206 represents the moiety XV. Other intense peaks were situated at *m/e* 491, 411, 397, 340, 222, and 192. It is quite tempting to present a complete structural expression for thaldimerine on the basis of these data. The authors shall refrain, however, from doing so, pending the isolation of additional thaldimerine for further study.

EXPERIMENTAL

All melting points were taken on a block manufactured by the Nalge Co. and are uncorrected. Infrared spectra were taken on a Beckman IR-5 spectrophotometer, and the ultraviolet spectra were measured in distilled 95% EtOH on a Cary model 14 spectrophotometer. The nuclear magnetic resonance spectra were taken on a Varian Associates A-60 instrument unless indicated otherwise, in deuteriochloroform or trifluoroacetic acid with tetramethylsilane as internal standard.

Mass spectra were obtained with a Nuclide 12-90-G1.1 mass spectrometer using the following procedure. The sample was placed into the heated inlet and the temperature was gradually raised until a sufficient ion current was obtained. The probe was then removed, thoroughly cleaned, and a fresh alkaloid sample added. It was then placed into the heated inlet at the previously determined temperature and the spectrum was taken immediately after a sufficient ion current was reached. In no case was a spectrum used after the sample had been in the heated inlet for more than 2 min. because of rapid alkaloid decomposition at the extreme temperatures employed.

Thin-layer chromatography was performed on a purified silica gel.[2] Preparative TLC was run on plates 8 × 8 in., (20 × 20 cm.) coated with a 1-mm.-thick adsorbent layer. Paper chromatography was performed by the descending procedure on Whatman No. 1 paper. Cellulose powder refers to Whatman ashless grade.[3] The ion-exchange resin[4] was chromatographic grade, 100–200 mesh, chloride form. Methyl ethyl ketone (MEK) was purchased from Eastman Organic Chemicals and purified by refluxing in Zn dust for 8 hr., followed by distillation from Zn dust. Ammonium reineckate was purchased from Matheson, Coleman and Bell and dissolved in water only prior to immediate use.

The following procedures were strictly adhered to:

[2] Adsorbosil I. Applied Science Laboratories, State College, Pa.
[3] Chromedia CF 11.
[4] Amberlite CG 400. Matheson, Coleman and Bell.

(*a*) solvent evaporations were performed below 60°, either at reduced pressure or under a nitrogen stream, (*b*) samples were stored under nitrogen in the dark, (*c*) compounds were removed from the preparative TLC adsorbent as soon as the solvent had evaporated, (*d*) quaternary alkaloid reineckate salts were converted to their chloride form within 4 hr. of their preparation, (*e*) after use, all chromatographic columns were washed with methanol to insure complete alkaloid removal.

Plant Extraction and Preliminary Separation—The *T. fendleri* samples used in this research were harvested during three consecutive summers in the area surrounding Tabiona, Utah. They were air dried and shipped to State College, Pa. The plant material (a total of 40 Kg. was used for this investigation) was ground to a fine powder and extracted in a Soxhlet extractor with MeOH, until the MeOH was clear and gave a negative Mayer's test (7) (usually 3–5 days). The extracts, upon evaporation of the MeOH, gave a thick, viscous residue which was dissolved as much as possible in dilute (3–5%) HOAc and filtered with the aid of Filtercel. Approximately 1 L. of acid solution was used to dissolve the extract from each 1 Kg. of dried plant. The solution was then extracted with an equal volume of $CHCl_3$ to remove nonalkaloidal components. The aqueous layer was basified (pH 8) with concentrated NH_4OH, and reextracted with an equal amount of $CHCl_3$, followed by an equal amount of Et_2O. The $CHCl_3$ and Et_2O layers were combined and the solvent was removed to give a black oil containing the total tertiary alkaloid mixture. It was found preferable not to keep alkaloids in $CHCl_3$ solution due to slow decomposition.

The aqueous layer was now freed of organic solvent at reduced pressure, and acidified (pH 2) with concentrated HCl. Freshly prepared, warm (50–60°), aqueous ammonium reineckate solution was added until the alkaloids were completely precipitated. After cooling to 0°, the precipitate was removed by suction filtration. It was immediately dissolved in acetone giving a deep red solution. This solution was diluted with an equal volume of MeOH and the alkaloids were converted to the chloride form by ion exchange as described below. Slight differences in relative alkaloid concentrations were noted in plant batches of different years.

Ion-Exchange Conversion of Alkaloid Reineckates to Chlorides—The yellow ion-exchange resin was completely converted to the chloride form by soaking in 1 *N* aqueous HCl for 10 min. and drying by suction filtration. It was then washed once in distilled water and redried. The resin was now washed three times with acetone–MeOH (1:1) and finally suspended in acetone–MeOH (1:1) for 30 min., with occasional stirring. This mixture was stirred to form a slurry which was poured slowly into a chromatographic column containing a glass wool plug. After the resin had settled (30 min.) the stopcock was opened, and the resin was washed repeatedly with acetone–MeOH (1:1) until the eluate was clean and gave no residue upon evaporation of 25 ml. of eluant. The deep red alkaloid reineckate solution in acetone–MeOH (1:1) was now placed on the column. A successful conversion was indicated by a yellow effluent of alkaloidal chlorides if concentrations are low, or more generally by a deep red band at the top of the column. The completeness of the conversion could also be checked by the disappearance of the 310 mμ reineckate anion peak (8) in the effluent. The longer alkaloid reineckate solutions were permitted to stand, the poorer was the subsequent conversion to the chloride form.

Chromatography—*Adsorption Chromatography*—All adsorption chromatography columns were prepared as a slurry. Alumina, which was found to be superior to other adsorbents, was Baker neutral alumina, 100–200 mesh, slurry pH 6–8. It was stored tightly sealed and was not activated before use. Silica gel and magnesium silicate were found to give poorer results due to the difficulty of desorbing some of the alkaloids from their surface.

Partition Chromatography—The large partition columns of cellulose, which were the major means of fractionation employed in this study, were carefully prepared and equilibrated prior to use. They were packed dry using a procedure modified from Kupchan (6) as follows.

Dry cellulose powder (500 Gm.) was placed in a 5-L. round-bottom flask equipped with a tight-fitting stopper covered with aluminum foil. Water saturated with MEK (250 ml.) (the lower phase of the MEK–H_2O system, *i.e.*, the stationary phase) was added, and the mixture was shaken vigorously to break up all lumps. The cellulose powder, appearing dry at this stage, had now been impregnated with the stationary phase. Approximately 10 Gm. of this cellulose powder was placed into the chromatography column and tamped down lightly. This procedure was repeated usually 20–30 times, until the proper size column was built. The cellulose powder was now topped with 3 or 4 filter paper disks cut to fit. Care was taken so that at no stage was the cellulose powder exposed to the air for more than a few minutes because the stationary phase impregnated on it could easily evaporate.

After the column had been built, a large amount of mobile phase, MEK–H_2O (MEK–H_2O = methyl ethyl ketone saturated with water), was added and allowed to run through. This washing and equilibration was continued for at least 8–48 hr., whereby the pressure ridges became less pronounced. A successfully equilibrated column gives a clear eluate, a cloudy eluate indicating incomplete equilibration. The equilibration of the column can be destroyed by even moderate temperature fluctuations, in which case it has to be reequilibrated prior to use.

The placing of the sample on the column was usually the most critical step in the chromatographic separation. Since alkaloid salts are generally only slightly soluble in the mobile phase (MEK–H_2O), the following procedure was used to place them on the column.

The alkaloid chlorides (5 Gm.) were dissolved in 10 ml. of stationary phase (water saturated with methyl ethyl ketone) and the solution was added to 20 Gm. of dry cellulose powder and shaken vigorously to break up all lumps. This cellulose powder was then carefully placed on the top of the previously prepared and equilibrated column, and tamped down lightly. This was topped with 3 or 4 filter paper disks, and the chromatography was started by the addition of the mobile phase.

In general, 1 Gm. of crude alkaloid chloride per 100 Gm. of dry cellulose powder was used to insure an optimum separation. The large cellulose columns employed contained 1,500 Gm. of cellulose and

TABLE II—INITIAL QUATERNARY ALKALOID SEPARATION

Fraction	Alkaloids Isolated[a]
I	Berberine chloride (VII), 1 Gm.
	Thalifendine chloride (II), 200 mg.
II	Jatrorrhizine chloride (VIII), 150 mg.
	Thalidastine chloride (III), 700 mg.
III	Magnoflorine chloride (X) 10 Gm.[b]

[a] The weight refers to the amount of alkaloid, in the chloride form, that was obtained from 15 Kg. of dried plant. [b] This weight is approximate since only a small fraction of the crude magnoflorine chloride was purified.

TABLE III—ALUMINA COLUMN CHROMATOGRAPHY OF FRACTION I (TABLE II)

Solvent	Alkaloids Present
Acetone–methanol (9:1)	Berberine
Acetone–methanol (1:1)	Uncharacterized alkaloid
Methanol	Thalifendine

were 180 cm. in height and 10 cm. wide, and a maximum of 50 Gm. of alkaloid chloride was added at one time. No column was used twice to insure against cross-contamination of alkaloid fractions.

Occasionally another procedure of sample application was employed for the separation of protoberberine alkaloids. In this case the column was prepared and equilibrated as previously described. Solid crude quaternary chlorides were now added to a 250-ml. conical flask containing 100 ml. of the mobile phase (MEK–H_2O). The flask was stoppered tightly and shaken vigorously. After 2 hr. the mobile phase was decanted off and 100 ml. of fresh mobile phase was added and the procedure was repeated until the desired amount of quaternary chloride was dissolved. This mobile phase saturated with alkaloids, sometimes amounting to 2 L. in volume, was now added to the column and the separation was begun. Despite the large volume used in the sample application, an excellent separation of protoberberine alkaloids could be achieved. This procedure was not tried with other complex quaternary mixtures.

Fractionation of Quaternary Alkaloids—The quaternary alkaloid chloride mixture was first separated on a large partition column in MEK–H_2O as previously described. The eluate was separated into three fractions, the first two of which were bright yellow and were shown by TLC in MeOH to contain three alkaloids each. The final fraction was colorless, exhibited a brilliant blue-white fluorescence under UV light, and consisted of primarily one component. Table II summarizes the alkaloids isolated from these three fractions.

Fraction I (see Table II) upon evaporation of the MEK–H_2O gave a yellow oil showing a number of spots on thin-layer chromatography. A neutral alumina column was prepared as a slurry in the solvent acetone–methanol (9:1). The yellow oil was dissolved in acetone–methanol (1:2), carefully placed on the alumina column, and elution was begun with acetone–methanol (9:1), which brought down the first yellow band. Elution was continued with acetone–methanol (1:1), which brought down another yellow band, and was completed with pure methanol, which brought down the final, yellow-orange band. The results of this alumina column are summarized in Table III.

Berberine (VII)—Upon evaporation of the acetone–methanol (9:1), the residue crystallized readily from methanol and was shown to be identical to authentic berberine chloride in terms of melting point; found 205°, reported 205° (9), mixed m.p. 205°, superimposable IR spectra (KBr pellet and Nujol mull), NMR spectra in trifluoroacetic acid and UV spectra. TLC and paper chromatography confirmed the identity of the isolated berberine chloride with authentic material.

Thalifendine (II)—Upon elution of the alumina column containing fraction I with methanol, an orange and very diffuse band emerged. Since this band had no sharply defined boundaries, a large volume of methanol was used to insure complete elution. After evaporation of the solvent, an orange solid remained. This solid showed only one spot on TLC and was converted to a yellow solid by addition of dilute hydrochloric acid. The yellow solid crystallized readily from methanol, and was recrystallized to give fine yellow needles sintering above 230°. The structural elucidation of thalifendine has been reported (1).

Thalidastine (III)—The second fraction obtained from the large cellulose column, fraction II (see Table II), gave a yellow viscous oil upon evaporation of the solvent. This oil gave three spots on TLC, all of which appeared to be protoberberine-like from their yellow-orange color. The oil was separated by preparative TLC in methanol into two easily distinguishable bands as follows: top band, R_f 0.4–0.5 thalidastine; bottom band R_f 0.0–0.1 jatrorrhizine and uncharacterized yellow alkaloid.

Both bands were eluted from the TLC plate with methanol which also dissolved some of the adsorbent. The alkaloids were freed of this impurity by alumina column chromatography with absolute ethanol. On evaporation of the ethanol, thalidastine appeared as an orange oil and jatrorrhizine and the uncharacterized yellow alkaloid as a yellow-orange oil.

The orange oil from the top band mentioned above was dissolved in methanol, aqueous HCl was added until the solution turned yellow, and upon evaporation of the solvent yellow crystalline thalidastine chloride was obtained. The structural study of this alkaloid has been described (2).

Jatrorrhizine (VIII)—Fraction II (see Table II), in addition to containing the previously mentioned thalidastine, also contained two other protoberberine alkaloids, the known alkaloid jatrorrhizine and a yellow uncharacterized salt. These two alkaloids were easily separated from thalidastine by preparative TLC in methanol, but it was found very difficult to separate them from each other. After repeated failures it was decided to employ a magnesium silicate column from which jatrorrhizine could be eluted, but not the uncharacterized salt. Using this column with acetone–methanol (1:1) as solvent, pure jatrorrhizine (one spot on TLC) was obtained as a red-brown oil. This oil was dissolved in methanol, hydrochloric acid was added until the color turned yellow, and upon evaporation jatrorrhizine chloride crystallized as fine needles.

The isolated material was shown to be identical with authentic jatrorrhizine chloride by comparison

of NMR spectra in trifluoroacetic acid and UV spectra, both of which were superimposable. Additionally TLC and paper chromatography confirmed the identity of the two samples. The isolated material was reduced in a microhydrogenator with Adams catalyst in methanol for 24 hr. A white crystalline reduction product was obtained in quantitative yield. This was shown to be identical to authentic tetrahydrojatrorrhizine by melting point comparison; found 210°, reported 216° (10) mixed m.p. 210°, practically superimposable IR ($CHCl_3$) and mass spectra, and TLC R_f values in several solvent systems.

Magnoflorine (X)—Fraction III (see Table II) was the last and largest fraction eluted from the large cellulose column. Upon evaporation of the solvent a thick brown oil was obtained. This oil gave one spot on TLC and paper chromatography, with very few minor spots also present. A small amount of this oil was rechromatographed on a long thin cellulose column with MEK–H_2O as solvent. Part of the eluate from this column crystallized upon evaporation of solvent.

The isolated material and magnoflorine chloride were shown to be identical through IR (Nujol mull) and UV spectral comparisons. Additional TLC and paper chromatography confirmed the spectral results. Magnoflorine is the most prevalent alkaloid in *T. fendleri*.

Preliminary Separation of the Crude Tertiary Alkaloids—The solid crude tertiary alkaloids (50 Gm.) were dissolved in 50 ml. of 2 *N* methanolic HCl, the pH being kept highly acidic by dropwise addition of concentrated HCl when needed. The MeOH and excess acid were removed very thoroughly under a nitrogen steam and *in vacuo*. The tertiary hydrochloride salts were then subjected to partition chromatography (1,500 Gm. cellulose powder) in the same manner as described above for the quaternary chloride salts. Upon elution from the column and combination of like fractions the solvent was removed and the tertiary hydrochloride salts were converted back to their free bases. This was done by dissolving the salts in 10–20 ml. of water followed by dropwise addition of concentrated NH_4OH until the solution was just basic and then repeated extraction with $CHCl_3$. The $CHCl_3$ layer was removed, dried with Na_2SO_4, filtered, and evaporated to dryness. All adsorption chromatography and structural elucidation was done on the tertiary free bases. The large partition separation of the tertiary hydrochloride mixture is summarized in Table I.

Thalifendlerine (I)—Fraction 2 (see Table I) gave a light brown oil upon evaporation of the solvent. This oil, showing one spot on TLC, crystallized upon the addition of methanol. After several recrystallizations from the same solvent and then from acetonitrile, large white rods were obtained. The chemistry of this interesting benzylisoquinoline alkaloid has been described (1).

Separation of Tertiary Alkaloid Fractions 3 and 4—Fraction 3 (see Table I) gave a brown oil upon evaporation of the solvent. TLC showed it to be a highly complex mixture composed of at least 10 alkaloids, although some were present to only a minor extent. TLC also indicated that many components of this fraction were present in the succeeding fraction, designated fraction 4. Fraction 4 was further purified in the same manner as will be described for fraction 3, and will therefore not be discussed in detail.

TABLE IV—SEPARATION OF FRACTION 3

Flasks	Solvents	Alkaloids
1–9	$CHCl_3$	Ocoteine (XI), glaucine (IX)

36–39	3% MeOH	Preocoteine (V), thaliporphine (IV)
40–44	3% MeOH	Thaliporphine (IV), thalifendlerine (I)
44–53	5% MeOH	Thalifendlerine (I), plus other alkaloids
54–64	10% MeOH	Several alkaloids present

The brown oily fraction 3 (1.2 Gm.) was dissolved in chloroform, filtered, and chromatographed on a neutral alumina column (90 Gm.) prepared as a slurry in chloroform. After the addition of 400 ml. of chloroform, methanol was added in increasing increments (gradient elution chromatography) until a 10% methanol solution in chloroform was reached. The results of this adsorption chromatography are given in Table IV.

Flasks 1–27 contained 25 ml. each and 28–64 ml. each of solvent.

Flasks 1–9 (see Table IV) were combined and evaporated to dryness, giving a light yellow oil which failed to crystallize. TLC showed this oil to be composed of at least three components which were easily separated by preparative TLC in acetone. The top band was not characterized, the middle band was identified as ocoteine (XI), and the lower band corresponded to glaucine (VII).

Ocoteine (XI)—The middle band from the preparative TLC, gave a UV spectrum with $\lambda_{max.}^{EtOH}$ 314, 302, 283, and 232 mμ (log ε 4.1, 4.2, 4.2, and 4.4). The NMR spectrum showed one *N*-methyl at 2.54 δ, three *O*-methyl groups at 4.01 (three protons) and 3.92 δ (six protons), one methylenedioxy as two doublets at 6.05 and 5.92 δ (J = 1.5 c.p.s.), and two aromatic protons at 6.78 and 7.62 δ. The UV and NMR spectra were practically superimposable with those of an authentic sample of known ocoteine. TLC confirmed the identity of the two samples. In addition, the mass spectrum of the isolated alkaloid showed a molecular ion (M^+) at m/e 369 ($C_{21}H_{23}NO_5$) and other large peaks at 354 (M-15), 338 (M-31), and 326 (M-43), all characteristic of aporphine alkaloids, and in agreement with the reported structural assignment (11).

Glaucine (IX)—The lower band from the preparative TLC gave a colorless oil, λ_{max}^{EtOH} 300, 280, and 218 mμ, showing no shift on addition of base. This UV spectrum indicated the isolated alkaloid to be a 1, 2, 9,10- substituted, nonphenolic aporphine, and strongly suggested the alkaloid was glaucine (12). This assumption was strengthened by the mass spectrum, which showed a large molecular ion (M^+) at m/e 355 ($C_{21}H_{25}NO_4$), and the other expected peaks at 340 (M-15), 324 (M-31), and 312 (M-43) (11). The isolated alkaloid was then shown to be the known base glaucine by means of a direct comparison with an authentic sample in terms of UV and mass spectral comparisons and TLC R_f values. The structural assignment was performed on less than 5 mg. of isolated material.

Preocoteine (V)—Flasks 28–35 (Table IV) were combined and upon evaporation of the solvent gave a light green oil. This oil was shown by TLC to contain some nonalkaloidal material, and this impurity was separated by preparative TLC in methanol–acetone (5:3). The alkaloid moved to the middle of the plate and the impurity was located at the solvent front. Upon removal from the plate with chloroform–methanol (9:1), preocoteine exhibited $\lambda_{max.}^{EtOH}$ 314, 304, 279, and 222 mμ, with a marked bathochromic shift upon addition of base. The NMR spectrum in deuteriochloroform at 100 Mc. showed the presence of one *N*-methyl at 2.52 δ, four *O*-methyl groups at 3.92 δ (six protons), and 3.88 δ (six protons), and two aromatic protons, one downfield at 7.99 δ characteristic of a C-11 proton, and the other at 6.74 δ (12). The absence of a relatively upfield methoxyl indicates the phenolic function is at C-1 (12). The UV spectrum of preocoteine strongly resembles that of ocoteine (XI). The structural elucidation of preocoteine has been recorded (4).

Thaliporphine (IV)—Flasks 36–39 (see Table IV) were combined and upon solvent evaporation gave an oil showing two spots on TLC. These two components were easily separated by preparative TLC in chloroform–methanol (19:2). The top band proved to be preocoteine (V). The lower band was eluted from the purified silica gel with chloroform–methanol (9:1), and crystallized with difficulty from methanol. The chemistry of this new aporphine alkaloid, designated thaliporphine, has been discussed (4).

Flasks 40–44 (see Table IV) were combined and the solvent removed. TLC showed it to contain thaliporphine (IV) and thalifendlerine (I). These two alkaloids were separated by preparative TLC in methanol–chloroform (2:19), the top band being thaliporphine, and the bottom band thalifendlerine.

Flasks 44–53 and 54–64 (see Table IV) after combination and solvent evaporation were shown to be complex mixtures of at least eight components each by TLC in methanol–chloroform (1:1). Preparative TLC in this system allowed the isolation of some thalifendlerine from flasks 44–53. The other components of both fractions were present in too small amounts to be isolated.

Fractions 5 and 6 were chromatographed on a column of neutral alumina, using chloroform with increasing amounts of methanol as the eluent. Additional quantities of thaliporphine were isolated from this procedure together with other minor alkaloids which were not characterized.

Hernandezine (XII) and Thalicarpine (XIII)—The methanol washing from the large cellulose column (see Table I) proved to be rich in alkaloids. After solvent evaporation the oily residue was dissolved in chloroform and chromatographed on a neutral alumina column. The solvent polarity was gradually increased by the addition of methanol, until pure methanol was used. Fractions were combined on the basis of their TLC patterns in methanol–acetone (5:3). This chromatographic procedure gave two distinct fractions: an early fraction eluted with pure chloroform, and a late fraction eluted with chloroform–methanol. The results of this chromatographic procedure are summarized in Table V.

Table V—Separation of Methanol Washing

Early fraction (eluted with chloroform)	Hernandezine (VIII) Thalicarpine (XIII)
Late fraction (eluted with chloroform containing methanol)	Thaldimerine (XIV) Thalidezine (II)

The early fraction showed three spots on TLC either in methanol–acetone (5:3) or in methanol–chloroform (1:1). Preparative TLC in these solvents was used to separate these three components. The top band was identified as the known alkaloid hernandezine (VIII), the middle band was shown, by comparative TLC to be thalicarpine (XIII), and the bottom band was present in too small amounts to be investigated.

Hernandezine, m.p. 158° (MeOH), was obtained upon washing the purified silica gel with methanol–chloroform (1:9). A direct comparison of the isolated material with an authentic sample showed the two materials to be identical in terms of IR (chloroform), UV, and mass spectral comparisons, and TLC R_f values. A structural reevaluation of hernandezine has been reported (3).

Thalicarpine (XIII) obtained by washing the purified silica gel with methanol–chloroform (1:9) was identified by spectral comparison with an authentic sample, and comparative TLC.

Thaldimerine (XIV)—The late fraction (see Table V) showed two spots on TLC in methanol–acetone (5:3). After many trials it was decided that methanol–ether (7:3) was a suitable solvent combination for preparative TLC. A complete separation of the two alkaloids was achieved only after repeated use of preparative TLC. The upper band proved to be a new alkaloid, designated thalidezine (VI). The lower band, which was oily and turned brown on exposure to iodine vapor, was also a new alkaloid and was named thaldimerine (XIV).

Thalidezine (VI)—The new bisbenzylisoquinoline alkaloid thalidezine (Table V) was obtained in crystalline form by repeated preparative TLC separations from the crude thaldimerine fraction above. Recrystallization from acetone gave 300 mg. of white needles, m.p. 158–159°. The structural elucidation of thalidezine has been reported (4).

Inhibitors of Monoamine Oxidase

Influence of Methyl Substitution on the Inhibitory Activity of β-Carbolines

By BENG T. HO, WILLIAM M. MCISAAC, KENNETH E. WALKER, and VICENTE ESTEVEZ

A number of tetrahydro and aromatic β-carbolines, mostly with a methyl substituent at various positions, were synthesized and their *in vitro* inhibitory activities on monoamine oxidase evaluated. Substitution of a methyl group at the N-9 nitrogen of tetrahydro-β-carboline gave a potent competitive inhibitor of the enzyme. Methyl groups at C-1 of both tetrahydro and aromatic β-carbolines generally reduced the potency, whereas introduction of a methyl group at the N-2 nitrogen of tetrahydro-β-carboline gave a compound of equal activity.

FOR MANY YEARS, since the discovery of iproniazid, inhibitors of the enzyme monoamine oxidase have been used as chemotherapeutic agents for the treatment of depression. However, the many potent antidepressants of the hydrazine class are hepatotoxic, and for this reason have fallen into disuse. Attempts, therefore, have been made to search for other antidepressants with more rapid onset and lower toxicity.

A number of β-carbolines have been found to be potent inhibitors of monoamine oxidase (1–3), yet little is known about the way these compounds bind to the enzyme. In this phase of these studies, a number of tetrahydro and aromatic β-carbolines, mostly with methyl substituents at various positions, were synthesized and their *in vitro* inhibitory activities evaluated. Information on the mode of binding of these compounds to the enzyme will be useful in the design and synthesis of more potent inhibitors which may become useful in the treatment of depression.

DISCUSSION

A fivefold decrease in inhibitory activity was observed when a methyl group was placed on C-1 of the tetrahydro-β-carbolines I and IV (Table I) and the aromatic β-carboline (XX)(Table II) to give II, V, and XXI, respectively. Ethyl substitution on C-1 of I and XX resulted in an even greater decrease in activity; III was seven times less active as an inhibitor than I, and XIII was 16 times less than XX. This loss of inhibitory activity could be attributed to steric hindrance by the bulk of the alkyl group. When a larger group such as COOH was substituted on C-1 of tetrahydro-β-carbolines, an even greater loss of activity occurred; the activity of XV was about 18 times less than I and four times less than II. However, the possibility of a repulsion between COO^- of XV and an anion site on the enzyme could not be entirely ruled out. Likewise, a methyl substituent on C-3 caused a threefold decrease in activity when I was compared with XVII. A COOH group on C-3 gave an inactive compound (XVIII).

Introduction of a methoxy group to C-6 of the ring decreased the inhibitory activity; a fourfold loss in activity was observed in both cases when I was converted into IV, or II into V. An eightfold decrease in activity was observed when 1,9-dimethyl-β-carboline (XII) was compared to its 6-methoxy derivative (XIII). If the indole nucleus binds as an electron donor to an electron-poor locus of the enzyme in a charge-transfer complex (4), the electron-donating methoxy group should make IV and V bind better. Thus, the decreased activity of 6-methoxytetrahydro-β-carbolines can be attributed either to the bulk of the methoxy group or to its polar nature, which is unfavorable for the binding. Studies to obtain greater binding of the indole nucleus by other substituents are in progress.

Neither methyl nor propyl substitution on N-2 of II affected the inhibitory activity; VI and VII were equally as active as II, indicating that a long alkyl

chain like propyl can be tolerated by the enzyme provided the basicity of the N-2 nitrogen is not appreciably decreased. That a basic N-2 nitrogen is required for the binding of the β-carbolines to the enzyme is indicated by the fact that the acetyl derivatives (VIII and IX) of II and V show a marked decrease in activity. This was further observed in XIX where the basicity of the N-2 nitrogen was abolished by formation of a lactam linkage. Other evidence is seen from the work of McIsaac and Estevez (3), who found that replacement of the N-2 nitrogen of β-carbolines by CH completely abolished monoamine oxidase inhibitory activity.

An increase of 35-fold in inhibitory activity was observed in XI by the introduction of a methyl group at N-9 nitrogen of I. Only an eighteenfold increase was observed when a methyl group was placed at N-9 nitrogen of II; this difference is probably due to the steric interaction between the two adjacent methyl groups in XII. The effect of substitution on N-9, however, is not as great in the aromatic series. For example, the introduction of an N-9 methyl group to XX (Table II) resulted in XXIII which is only three times as active as XX.

In summary, tetrahydro-β-carbolines in general are not as good inhibitors of monoamine oxidase as aromatic β-carbolines *in vitro;* an approximately tenfold difference in inhibitory activity between these two series can be seen when I is compared to XX, and II to XXI. However, by substituting a methyl group at the N-9 nitrogen of the tetrahydro-β-carboline (I) a 35-fold increase in activity occurs, and the resulting XI becomes as potent as the aromatic β-carboline (XXIII). From the assay, XI appears to be three times more active than iproniazid (Table I). A Lineweaver-Burk plot showed that XI was a competitive inhibitor of the monoamine oxidase $Km = 8.1 \times 10^{-6}$ M and $Ki = 7.4 \times 10^{-6}$ M (Fig. 1). To our knowledge XI is so far the only

tetrahydro-β-carboline whose inhibitory activity is comparable to the most potent of the aromatic β-carbolines. There is no obvious explanation for the greater inhibitory activity of XI other than that the methyl group on N-9 makes the indole nucleus bind strongly to the enzyme. This methyl group may itself bind to the monoamine oxidase by a combination of van der Waals forces and hydrophobic bonding. However, the maximum increase in binding expected for one methyl group from both hydrophobic bonding and van der Waals forces would be only tenfold (5). Studies of the effect of other substituents of N-9 and N-2 of β-carbolines on inhibitory activity are in progress.

CHEMISTRY

Three tetrahydro-β-carbolines (IV, XI, and XVII, Table III) were synthesized from the condensation of the appropriate indolealkylamine with glyoxylic acid, followed by decarboxylation of the intermediates (XVI, XIV, and XXIV). Compound XVII prepared according to this method had a melting point of 240–241°, whereas 201–203° was recorded for this compound prepared by reacting α-methyltryptamine with formaldehyde (6). The synthesis of I by this route has been reported (7). The starting material for XIV, 1-methyltryptamine, was prepared according to the method of Potts and Saxton (8). In our preparation this oily amine was converted to its hydrochloride salt, m.p. 174–175°, in 42% yield. The melting point (239.5–240.5°) of the picrate of XI agreed with that in the literature (9) prepared by reduction of the 1-oxo derivative. Although the preparation of IV (10) and XI have been reported, our procedure seems to be more convenient than the reported method *via* the Na–BuOH reduction of the corresponding 1-oxo derivatives. At pH 4, 1-carboxytetrahydro-β-carboline precipitated, while glyoxylic acid and the salt of the unreacted tryptamine remained in the aqueous solution. In the next decarboxylation step, the product was obtained by precipitation from the basic medium in which unreacted amphoteric starting material, if any, was soluble in basic medium. Thus, in both steps the product can be obtained in a reasonably pure state and subsequent recrystallization should not be necessary. The decarboxylation was performed at 65–70° for 45 min. However, in a later run comparable yields were obtained when the decarboxylation was carried out at reflux temperature for only 30 min.

The condensation of tryptamine with propionaldehyde in aqueous acid medium was carried out at reflux temperature. 1-Ethyltetrahydro-β-carboline (III) was isolated as its hydrochloride salt.

The preparation of 1-ethyl-β-carboline (XXII) started from the acylation of tryptophan with propionyl chloride. Cyclization and subsequent decarboxylation of the resulting *N*-propionyltryptophan with $POCl_3$ and polyphosphoric acid gave XXII in a low yield of 7.2%. No attempt was made to improve the yield.

Alkylation of the sodium salts of 1-methyl-1,2,3,4-tetrahydro-β-carboline and its 2-methyl derivative with methyl iodide gave XII and X, respectively. 9-Methyl-β-carboline (XXIII) was prepared in the similar manner. An attempt was made to prepare X from XII. Treatment of XII with formaldehyde and formic acid did not give the desired product. Since the hydrochloride salts of both X and XII as well as the sulfate salt of X were hygroscopic, these two compounds were characterized as their picrate salts (Schemes I and II).

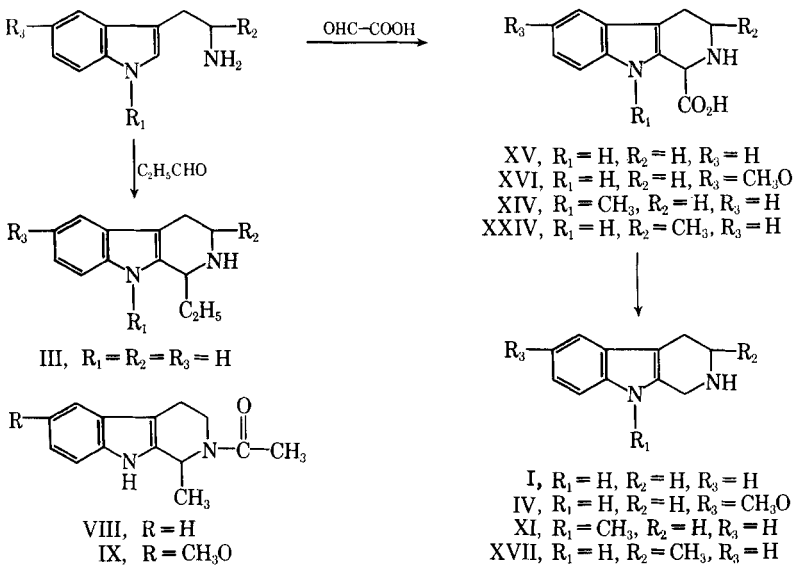
EXPERIMENTAL

Melting points were taken on a Fisher-Johns apparatus and are corrected.

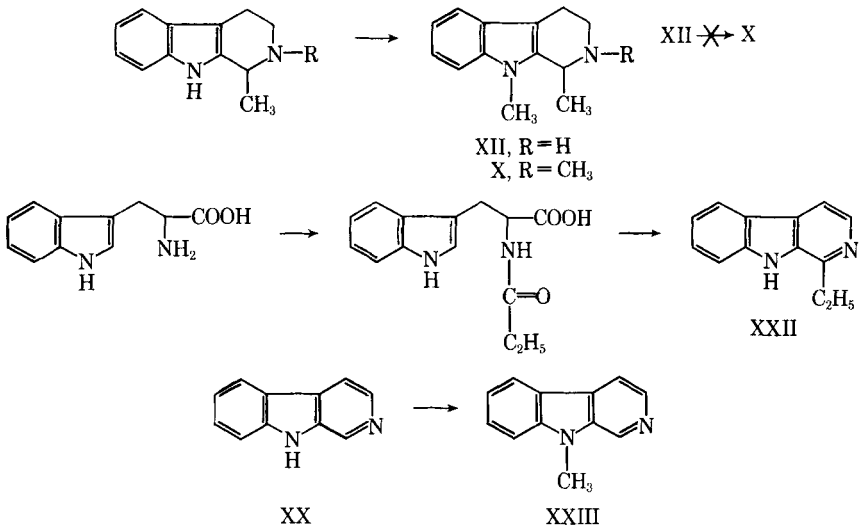
Synthesis

1-Ethyl-1,2,3,4-tetrahydro-β-carboline(III)—To a stirred suspension of 2.0 Gm. (12.5 mmoles) of tryptamine in 50 ml. of water was added 10% H_2SO_4 until the pH of the solution reached between 2–3. A stream of helium was flushed over the surface while the solution was heated to reflux. Propionaldehyde (3 ml., 40 mmoles) was added and the solution was allowed to stand for 30 min. without further heating. The condenser was removed and the solution was heated to boiling for an additional 30 min. It was made strongly basic with 10% KOH and extracted with ether (3 × 50 ml.). The ethereal extracts were combined and dried with anhydrous Na_2SO_4. Anhydrous hydrogen chloride was passed into the ethereal solution to precipitate the hydrochloride; yield, 2.2 Gm. (76%).

Thin-layer chromatography on silica using *n*-



Scheme I



Scheme II

propanol–concentrated NH_4OH (95:5) showed contamination of the product by tryptamine. One recrystallization from absolute ethanol–ether gave 1.3 Gm. (45%) of solid, m.p. 261–262°, which was free of starting material. $\nu_{max.}$ (KBr) 3240 (NH); 2950, 2900, 2760, 2670, 2620, 2575, 2480, 2380, 2290 (CH, NH^+); 1620, 1590 (C=C, NH^+); 745 cm.$^{-1}$ (indole CH). (See Table III for analytical data.)

6-Methoxy-1,2,3,4-tetrahydro-β-carboline-1-carboxylic acid (XVI)—A solution of 400 mg. (4 mmoles) of glyoxylic acid monohydrate in 22 ml. of water was added with magnetic stirring to a solution of 1 Gm. (4 mmoles) of 5-methoxytryptamine hydrochloride in 8 ml. of water. The mixture was adjusted to pH 4 with 10% KOH and the product precipitated after a short time. After being stirred for 5 hr. at room temperature, the solid was collected on a filter and washed several times with small amounts of water; yield, 450 mg. (50%), m.p. 224–226°, with evolution of CO_2. $\nu_{max.}$ (KBr) 3300 (NH) 2900–2875, 2790, 2530 (CH, NH^+); 1645, 1590, 1570 cm.$^{-1}$ (COO^-, NH^+, C=C); $\lambda_{max.}$ (1% HCl) 220, 273, 293 (s), 367 mμ. (See Table III for analytical data.)

6-Methoxy-1,2,3,4-tetrahydro-β-carboline (IV)—A mixture of 400 mg. (1.7 mmoles) of XVI and 3 ml. of concentrated hydrochloric acid in 10 ml. of water was heated at 65–70° for 45 min., during which time a white solid deposited in the solution. Just enough water was added to dissolve the solid and the product was precipitated by adding excess of 10% KOH; yield, 276 mg. (87%), m.p. 216–218°. $\nu_{max.}$ (KBr) 3270 (NH); 1625, 1590, 1560 cm.$^{-1}$ (C=C); $\lambda_{max.}$ (EtOH) 220, 273, 293 (s), 362 mμ.

A melting point of 220–223° has been recorded for this compound prepared by reduction of 6-methoxy-1-oxo-1,2,3,4-tetrahydro-β-carboline (10).

For analysis this product was converted to the

hydrochloride salt, m.p. 268–269° dec.; $\nu_{max.}$ (KBr) 3190 (NH); 2900–2880, 2780–2740, 2640, 2570, 2560, 2500, 2440 (CH, NH^+); 1620, 1590, 1580, 1565 $cm.^{-1}$ (NH^+, C=C). (See Table III for analytical data.)

1-Ethyl-β-carboline (XXII)—To a solution of 5 Gm. (24.5 mmoles) of tryptophan in 200 ml. of ice cold 10% KOH was added a solution of 20 ml. of propionyl chloride in 200 ml. of benzene and the mixture was stirred vigorously. An additional small amount of solid KOH plus crushed ice was added to make the aqueous solution strongly basic; this was followed by addition of 5 ml. of propionyl chloride. This procedure was repeated once more. The aqueous layer, after being made strongly basic with solid KOH, was separated. It was then acidified with concentrated HCl to about pH 1 and extracted with chloroform (3 × 200 ml.). The combined chloroform extracts were dried with Na_2SO_4 and the product was precipitated by adding 1 L. of petroleum ether (b.p. 60–110°); yield, 4.3 Gm. (67%), m.p. 161–161.5°. $\nu_{max.}$ (KBr) 1715 (acid C=O); 1615, 1540 $cm.^{-1}$ (amide C=O and NH).

A vigorously stirred mixture of 4.2 Gm. (16 mmoles) of the above *N*-propionyltryptophan, 42 Gm. of polyphosphoric acid, and 9 ml. of $POCl_3$ was heated at 125° for 45 min., then poured onto 100 Gm. of crushed ice. After removal of the resinous material by filtration, the solution was made strongly basic with 10% KOH and extracted with ether (3 × 15 ml.). The ethereal extracts were combined and dried with anhydrous Na_2SO_4. Anhydrous hydrogen chloride was passed into the ethereal solution to precipitate the hydrochloride; yield, 1.2 Gm. (32%), m.p. 135–145°. This crude product was recrystallized several times from absolute ethanol–ether then from ethanol–heptane giving 270 mg. (7.2%) of beige solid, m.p. 218–219°, which was chromatographically pure [solvent, *n*-propanol–concentrated NH_4OH (95:5)]. $\nu_{max.}$ (KBr) 3340 (NH); 3125, 3040, 2950, 2900, 2850, 2800, 2750 (CH, NH^+); 1630, 1620, 1570, 1525, 1505 (C=C, NH^+); 820 (pyridine CH); 755 $cm.^{-1}$ (indole CH); $\lambda_{max.}$ (H_2O) 212, 233, 250 (s), 280 (s), 287, 335, 347. (See Table III for analytical data.)

1,9-Dimethyl-1,2,3,4-tetrahydro-β-carboline (XII)—1-Methyl-1,2,3,4-tetrahydro-β-carboline (1.86 Gm., 0.01 mole) was added slowly with stirring to a sodamide solution prepared by reacting 0.25 Gm. (0.011 mole) of Na with 60–70 ml. of liquid ammonia in the presence of a catalytic amount of ferric nitrate. After all the amine had dissolved (about 15 min.), 1.56 Gm. (0.011 mole) of methyl iodide in 20 ml. of ether was added slowly over a period of 30 min. Stirring was continued for an additional 20 min. The volatile solvents were removed by a stream of helium while the flask was immersed in hot water. The residue was extracted with benzene (3 × 5 ml.) and the combined extracts dried with anhydrous Na_2SO_4. An excess amount of 5% methanolic H_2SO_4 was added to the benzene solution and the sulfate salt solidified upon addition of ether. It was collected on a filter, washed with ether, and dried *in vacuo;* yield, 1.7 Gm. (63%), m.p. 239–242° dec.. $\nu_{max.}$ (KBr), 3350, 3275, 3225, 3200, 3000, 2930, 2890, 2850, 2800 (NH, CH, NH^+); 1600, 1555 (C=C); 745 $cm.^{-1}$ (indole CH); $\lambda_{max.}$ (1% HCl) 222, 274, 281, 288 mμ. For analysis the sulfate was converted to the monopicrate which was purified by recrystallization from absolute ethanol. (See Table III for analytical data.)

9-Methyl-β-carboline (XXIII)—β-Carboline (800 mg., 4.6 mmoles) was treated with a mixture of 114 mg. (5 mmoles) of sodium in liquid ammonia and 468 mg. (6.6 mmoles) of methyl iodide as in the preparation of 1,9-dimethyl-1,2,3,4-tetrahydro-β-carboline. The reaction residue was extracted with benzene, evaporated, and the residue dissolved in the minimum amount of petroleum ether (b.p. 30–60°). After removal of the insoluble starting material by filtration, the petroleum ether was evaporated *in vacuo* leaving a white solid. Recrystallization from heptane gave 434 mg. (52%) of product, m.p. 108–109°; $\nu_{max.}$ (KBr) 1620, 1595, 1555, 1495 (C=N, C=C); $\lambda_{max.}$ (EtOH) 216, 236, 241 (s), 251 (s), 264 (s), 284, 290, 346, 357 mμ. (See Table III for analytical data.)

A m.p. of 107° (12) and 109° (13) has been recorded for this compound prepared by the treatment of 9-methyl-1-oxo-β-carboline with $POCl_3$.

Assay

Beef liver was homogenized in 10 vol. of 0.25 *M* sucrose and the cell debris was removed by centrifugation. The supernatant was centrifuged at 13,000×g for 90 min. to sediment the mitochondrial pellet which was then suspended in 0.01 *M* phosphate buffer pH 7.6 and subjected to sonication at 20 kc./sec. for 20 min. The sonicated preparation was then centrifuged at 100,000×g for 60 min., and the supernatant containing monoamine oxidase (340 mμmole/hr./mg. protein) was used as the enzyme source. This procedure gives approximately sevenfold purification.

All the stock solutions of the hydrochloride salts of inhibitors were prepared in water and the solutions of free amines in 0.01 *N* HCl. Compound VIII was dissolved in dimethylsulfoxide, IX and XIX in 50% aqueous dimethylsulfoxide, XIV in 0.01 *N* NaOH, and XVI and XVIII in 0.05 *N* NaOH. Incubation was carried out at 37° for 30 min. in a solution containing 60 mμmoles of the substrate, tryptamine-2-^{14}C hydrochloride, varying amounts of inhibitor, 20 μl. of enzyme, phosphate buffer pH 7.4, and water to make a final volume of 1 ml. The product, a mixture of indoleacetaldehyde and indoleacetic acid, was extracted with ether in strong acidic medium. After the removal of solvent, the product was assayed for ^{14}C in a liquid scintillation spectrometer and the concentration of inhibitor at which enzyme activity was 50% inhibited was determined.

Drug Release from Wax Matrices I

Analysis of Data with First-Order Kinetics and with the Diffusion-Controlled Model

By JOSEPH B. SCHWARTZ, ANTHONY P. SIMONELLI, and WILLIAM I. HIGUCHI

The release of drug into aqueous media from wax matrices has been investigated using benzoic acid and salicylic acid as the active ingredients. The data have been examined from the viewpoint of the first-order kinetic theory and that of a diffusion-controlled process. It was found that the experimental data are best analyzed using a diffusion-controlled model and square root of time release profiles. Parameters controlling the release are presented.

SEVERAL WORKERS (1–4) have recently reported the results of investigations regarding the factors influencing drug release from inert, insoluble matrices. Matrices composed of plastic polymers have been shown to exhibit release profiles which are best described by the linear square root of time dependence indicating that a diffusion-controlled mechanism is operative (2). Waxes, on the other hand, present a much more complicated system, both experimentally and theoretically, due to various physical-chemical factors and properties not present in the plastic systems.

As a result, the mechanism of release from wax matrices has not been as firmly established. In view of the large number of patents issued in this area, it would be highly desirable that the release rates from these systems also be quantitated by use of the diffusion model and the determination of the necessary controlling parameters made.

Theoretical treatment has shown that drug release from an insoluble, inert matrix is described by the T. Higuchi equation (5) if the rate-determining process is diffusion; and this is given by:

$$Q = \sqrt{\frac{D\epsilon}{\tau}(2A - \epsilon C_s)C_s t} \qquad \text{(Eq. 1)}$$

where Q is the amount of drug released per unit area of the disk exposed to the solvent; D is the diffusion coefficient of the drug in the solvent; ϵ is the porosity of the matrix; τ is the tortuosity of the matrix; A is the concentration of solid drug in the matrix; C_s is the solubility of the drug in the solvent; and t is time. Each of the above variables lends itself to experimental determination. Any units may be used for the above variables and constants, provided they are mutually consistent.

It was the purpose of this study to establish the applicability of the diffusion model to wax systems and to determine the controlling variables.

EXPERIMENTAL

Tablets composed of a drug homogeneously distributed throughout a wax matrix were prepared by the following method. The drug was suspended or dissolved in the melted waxes contained in an evaporating dish. Following the removal of heat, continual stirring until complete solidification had

Drug Release from Wax Matrices I

Analysis of Data with First-Order Kinetics and with the Diffusion-Controlled Model

By JOSEPH B. SCHWARTZ, ANTHONY P. SIMONELLI, and WILLIAM I. HIGUCHI

The release of drug into aqueous media from wax matrices has been investigated using benzoic acid and salicylic acid as the active ingredients. The data have been examined from the viewpoint of the first-order kinetic theory and that of a diffusion-controlled process. It was found that the experimental data are best analyzed using a diffusion-controlled model and square root of time release profiles. Parameters controlling the release are presented.

SEVERAL WORKERS (1–4) have recently reported the results of investigations regarding the factors influencing drug release from inert, insoluble matrices. Matrices composed of plastic polymers have been shown to exhibit release profiles which are best described by the linear square root of time dependence indicating that a diffusion-controlled mechanism is operative (2). Waxes, on the other hand, present a much more complicated system, both experimentally and theoretically, due to various physical-chemical factors and properties not present in the plastic systems.

As a result, the mechanism of release from wax matrices has not been as firmly established. In view of the large number of patents issued in this area, it would be highly desirable that the release rates from these systems also be quantitated by use of the diffusion model and the determination of the necessary controlling parameters made.

Theoretical treatment has shown that drug release from an insoluble, inert matrix is described by the T. Higuchi equation (5) if the rate-determining process is diffusion; and this is given by:

$$Q = \sqrt{\frac{D\epsilon}{\tau}(2A - \epsilon C_s)C_s t} \qquad \text{(Eq. 1)}$$

where Q is the amount of drug released per unit area of the disk exposed to the solvent; D is the diffusion coefficient of the drug in the solvent; ϵ is the porosity of the matrix; τ is the tortuosity of the matrix; A is the concentration of solid drug in the matrix; C_s is the solubility of the drug in the solvent; and t is time. Each of the above variables lends itself to experimental determination. Any units may be used for the above variables and constants, provided they are mutually consistent.

It was the purpose of this study to establish the applicability of the diffusion model to wax systems and to determine the controlling variables.

EXPERIMENTAL

Tablets composed of a drug homogeneously distributed throughout a wax matrix were prepared by the following method. The drug was suspended or dissolved in the melted waxes contained in an evaporating dish. Following the removal of heat, continual stirring until complete solidification had

occurred prevented any separation of drug and wax. To facilitate compression, this solid was then granulated by means of a 16-mesh screen and a spatula. Tablets of approximately 250 mg. with a $^3/_8$-in. diameter were compressed from this granulation using a Carver press at a compressional force of 5,000 lb.

To measure release rate, a volumetric flask (250 ml.) containing a tablet was filled with 100 ml. of the solvent and was placed in a shaking water bath maintained at 30°. Aliquot samples were withdrawn at various times and replaced with fresh solvent. After proper dilution with water, these samples were assayed using a Beckman DU spectrophotometer (salicylic acid, 294 mμ; benzoic acid, 259 mμ).

RESULTS AND DISCUSSION

Preliminary investigations were carried out with several waxes and their combinations. The matrix chosen for these studies was composed of PGMS[1] and hydrogenated castor oil[2] in a 1:1 ratio. It was observed that either wax, when used alone, had disadvantages which disappeared when the two were combined. Tablets of PGMS exhibited relatively rapid release rates but showed a tendency to flake when run for any length of time under experimental conditions. Tablets of hydrogenated castor oil did not flake but gave an extremely slow release. The 1:1 ratio provided the optimum matrix.

Tablets containing either salicylic or benzoic acid were studied. Figures 1 and 2 show linear square root of time plots indicating that these systems are diffusion controlled. Average slopes (3 or more runs) of these curves, listed in Table I, are proportional to the concentration of drug in the tablet as predicted by Eq. 1 and support the above mechanism.

Interestingly, the data also yielded an apparently straight line when the log of the drug left in the matrix was plotted as a function of time as predicted by first-order release:

$$\log W = \frac{kt}{2.303} + \log W_0 \qquad \text{(Eq. 2)}$$

where W = amount of drug left in tablet,
W_0 = initial amount of drug in tablet,
k = first-order rate constant,
t = time.

Figure 3 illustrates the release profiles of the salicylic acid data when plotted this way. The initial curvature can be attributed to the presence of surface drug and can be ignored. This same figure shows that the rate constant appears to remain relatively constant with a change in concentration of the drug in the tablet; this fact is in agreement with a first-order analysis.

Since both first-order and square root of time plots are acceptably linear, a more stringent test was developed to distinguish between the mechanisms. The use of the predicted rate equations corresponding to Eqs. 1 and 2 can be used for this purpose as shown by the following treatment.

Equation 1 can be reduced to the following:

$$Q' = KSt^{1/2} \qquad \text{(Eq. 3)}$$

where Q' = amount released = $Q \times S$,
S = surface area of tablet,
$K = \left[\frac{D\epsilon}{\tau}(2A - \epsilon C_s)\, C_s\right]^{1/2}$

By differentiation of the above reduced equation and appropriate substitution, Eq. 4 can be obtained:

$$\frac{dQ'}{dt} = \text{rate} = \frac{K^2S^2}{2Q'} \qquad \text{(Eq. 4)}$$

which indicates that the rate will be inversely proportional to the amount of drug released, Q'.

The rate predicted by first-order kinetics, however, is given by the following relationship:

$$\frac{dQ'}{dt} = \text{rate} = kW_0 - kQ' \qquad \text{(Eq. 5)}$$

since

$$-\frac{dW}{dt} = \frac{dQ'}{dt} = kW \qquad \text{(Eq. 6)}$$

TABLE II—VALUES FOR RATE, AMOUNT RELEASED, AND THE CORRESPONDING RECIPROCAL FOR THE RELEASE OF 5% SALICYLIC ACID

Rate = dQ'/dt	Q'(mg.)	$1/Q'$(mg.)
0.3400	0.480	2.083
0.2250	0.700	1.429
0.1670	0.850	1.176
0.1185	1.105	0.905
0.0940	1.520	0.658
0.0650	2.350	0.426
0.0400	3.520	0.284
0.0290	4.670	0.214
0.0225	5.580	0.179
0.0215	6.180	0.162

and

$$W = W_0 - Q' \qquad \text{(Eq. 7)}$$

which indicates that the rate is proportional to Q' rather than inversely proportional as predicted by the diffusion model.

The rates of release were determined by obtaining slopes of a Q' *versus* time plot (see Fig. 4). These values are tabulated along with Q' and reciprocal Q' values in Table II.

By comparison of Eqs. 4 and 5, it is clear that the first predicts a linear plot when *rate* is plotted as a function of $1/Q'$ and that the second predicts a linear plot when *rate* is plotted as a function of Q'. Figures 5 and 6 show that the two mechanisms can indeed be differentiated by this rate treatment as only Fig. 5 is linear indicating a diffusion-controlled mechanism. In addition, it should be noted that the slope of the line in Fig. 5 was found to be equal to $K^2S^2/2$ as predicted by Eq. 4.

This conclusion can be further confirmed by the use of Eq. 8, which is obtained by taking logs of Eq. 3:

$$\log Q = \log K + {}^1/_2 \log t \qquad \text{(Eq. 8)}$$

This predicts that a plot of log Q *versus* log t must not only give a straight line, but must have a slope

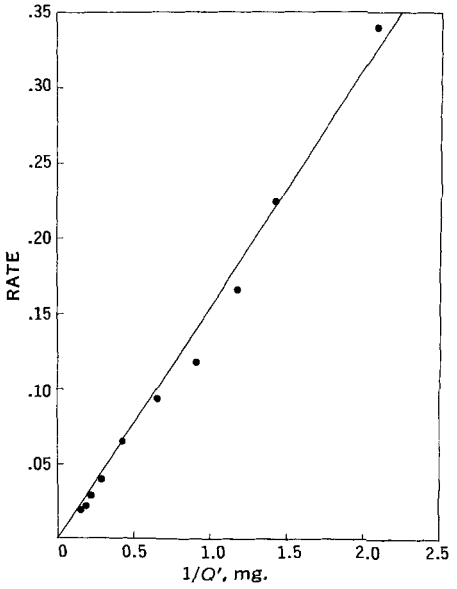

Fig. 5—Rate as a function of reciprocal drug released for 5% salicylic acid.

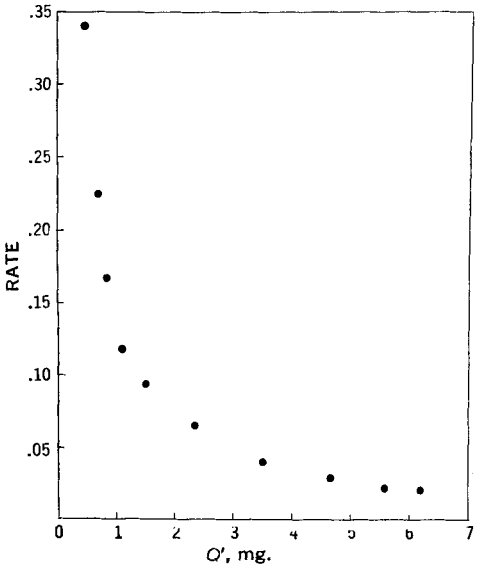

Fig. 6—Rate as a function of amount of drug released for 5% salicylic acid.

of $^1/_2$. This was found to be true and is illustrated by Fig. 7.

In addition, the various parameters for all systems were calculated by use of methods previously reported (6, 7) and are presented in Table I. The values for tortuosity, τ, are relatively constant and reasonable, as one would expect slightly higher τ values when the matrix components are relatively plastic and easily distorted.

CONCLUSIONS

Although the systems studied demonstrated apparently linear semilog plots with slopes that were apparently independent of the concentration of drug embedded in the wax matrix, more stringent tests clearly showed that the diffusion-controlled mechanism was operative and that a first-order release was incorrect.

It should be noted that one must use studies which are sufficiently long to properly evaluate matrix systems. First-order processes demand three or more half-life intervals, and the diffusion model requires an exponential increase in time with each successive sample due to the $t^{1/2}$ dependence. These studies utilized a minimum of 6 days and yet only 50 to 60% was released and can account for the linear semilog plots. This also explains the lack of significant curvature predicted in the latter points of the $t^{1/2}$ plots due to finite changes in the effective area of drug release of a whole tablet since these do not occur until greater than 60 to 70% is released.

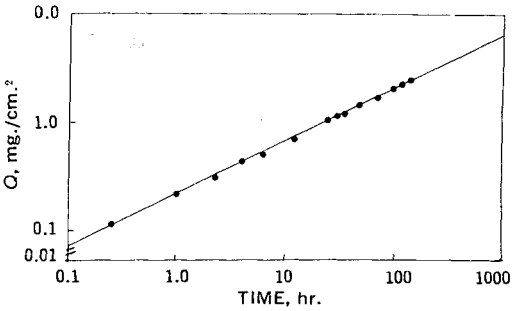

Fig. 7—Plot of the log of the amount of drug released per unit surface area against the log of time for 5% salicylic acid.

Drug Release from Wax Matrices II

Application of a Mixture Theory to the Sulfanilamide–Wax System

By JOSEPH B. SCHWARTZ, ANTHONY P. SIMONELLI, and WILLIAM I. HIGUCHI

Using the T. Higuchi relationship for the release of a drug from a solid matrix, a hydrogenated castor oil–propylene glycol monostearate–sulfanilamide system has been investigated. Plots of the amount of drug released per unit of tablet surface area exposed as a function of the square root of time enabled comparison of the release for various concentrations of drug, and the calculation of the apparent tortuosity values. A model based on the Bruggeman mixture relationship for a two-phase system has been used and equations were derived for the prediction of theoretical tortuosity values as a function of porosity due to drug. These theoretical values for tortuosity appear to follow a skewed convex parabolic function. The experimental results obtained compared well with the theoretical predictions.

THE APPLICABILITY of applying the basic T. Higuchi relationship (2) for systems incorporating drug in a wax matrix has been previously considered (1). This relationship is given by:

$$Q = \sqrt{\frac{D\epsilon}{\tau}(2A - \epsilon C_s)\,C_s t} \qquad \text{(Eq. 1)}$$

where Q is the amount of drug released per unit area of the tablet exposed to the solvent; D is the diffusion coefficient of the drug in the solvent; ϵ is the porosity of the matrix; τ is the tortuosity of the matrix; A is the concentration of solid drug in the matrix; C_s is the solubility of the drug in the solvent; and t is time. Equation 1 predicts a linear relationship between Q and the square root of time. Each of the above variables may be determined experimentally, and these have been reported for two drug–wax systems (1).

In the present communication, a drug–wax system is described in which the drug release behavior is relatively complex. Over one range of drug–wax composition the rate appears to be diffusion controlled through the aqueous pores, but the tortuosity values are extremely high. In the second range (high drug concentrations in the tablet) the mechanism appears to change to one in which the rate is not solute diffusion controlled in the aqueous pores. A quantitative physical model is presented that appears to satisfactorily describe the data in the low drug concentration range.

THEORY

Before a theory can be developed, it is essential to first consider the various possible physical arrangements of drug and matrix and their corresponding tortuosity values. If the matrix is composed of nearly spherical particles, such as one would have in a bed of spheres, the τ values should range between about 1.5 to 3 (2, 3). On the other hand, if the matrix material is less spherical, either because the initial particles are nonspherical or because during preparation of the matrix the particles become distorted (4), then greater τ values would be expected. However, even under extreme conditions, it is difficult to imagine τ values much greater than 10 or 20 when the simple concept (2, 3) underlying the meaning of tortuosity is used.

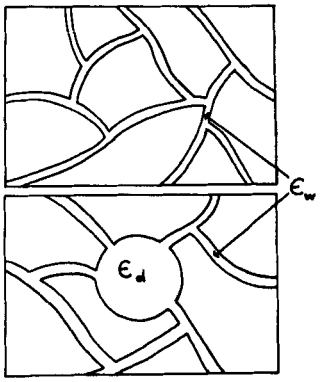

Fig. 1—Schematic diagram of proposed tablet model with air channels through the wax represented by ϵ_w and drug represented by ϵ_d.

As will be seen later, apparent τ values greater than 1,000 have been observed with compressed tablets made of drug–wax combinations. In order to explain such results the following model is proposed.

It is assumed that the drug particles are isolated in a sea of wax. This should be a reasonable approximation at low drug concentrations, since most waxes are extremely soft (plastic) and should flow around the drug particles during compression. Figure 1 schematically illustrates this model. The important feature of this situation is that diffusion is most difficult in the wax regions connecting the pores (left behind after the drug is leached) rather than in the pores themselves as might be generally assumed (2, 5). Thus the permeability of the drug is largely determined by the permeability characteristics of the wax matrix itself.

One equation which gives the permeability char-

Previous paper: Schwartz, J. B., Simonelli, A. P., and Higuchi, W. I., *J. Pharm. Sci.*, **57**, 274 (1968).

acteristics of a two-phase system is the Bruggeman equation (3, 6).

$$\frac{P_2 - P_e}{P_2 - P_1} = V_1 \left(\frac{P_e}{P_1}\right)^{1/3} \quad \text{(Eq. 2)}$$

where P = permeability,
P_e = permeability of the total system,
V = volume fraction,
1 = external phase,
2 = internal phase.

In a diffusion-controlled system, permeability may be defined as:

$$P = \frac{D\epsilon}{\tau} = KD \quad \text{(Eq. 3)}$$

where $K = \epsilon/\tau$ and where all symbols have been previously defined and all are effective quantities.

The Bruggeman equation (Eq. 2) may be applied to the present system by regarding the matrix "phase" as the external phase. Then the pores left by the leached drug in the tablet constitute the internal phase of the system.

The following relationships are then known for the system:

$$D_2 = D_s \quad \text{(Eq. 4)}$$
$$\therefore P_2 = D_s$$
$$V_1 = (1 - \epsilon_d)$$

where D_2 = diffusion coefficient of internal phase,
D_s = diffusion coefficient of the drug in the solvent,
P_2 = permeability of the internal phase,
V_1 = volume fraction of the external phase,
ϵ_d = porosity due to drug.

Substituting into Eq. 2:

$$\frac{D_s - P_e}{D_s - P_1} = (1 - \epsilon_d)\left(\frac{P_e}{P_1}\right)^{1/3} \quad \text{(Eq. 5)}$$

From Eq. 3 the following relationships may be obtained:

$$P_e = \left(\frac{\epsilon_d + \epsilon_w}{\tau}\right) D_s \quad \text{(Eq. 6)}$$

since the total porosity of the system, ϵ, is composed of that porosity due to drug, ϵ_d, plus that due to air, ϵ_w; and τ is the apparent overall tortuosity.

$$P_1 = \left(\frac{\epsilon_w}{\tau_w}\right) D_s \quad \text{(Eq. 7)}$$

$$\frac{D_s - \frac{(\epsilon_d + \epsilon_w)}{\tau} D_s}{D_s - \left(\frac{\epsilon_w}{\tau_w}\right) D_s} = (1 - \epsilon_d)\left[\frac{\left(\frac{\epsilon_d + \epsilon_w}{\tau}\right) D_s}{\left(\frac{\epsilon_w}{\tau_w}\right) D_s}\right]^{1/3} \quad \text{(Eq. 8)}$$

$$\frac{1 - \left(\frac{\epsilon_d + \epsilon_w}{\tau}\right)}{\left(\frac{\epsilon_d + \epsilon_w}{\tau}\right)^{1/3}} = (1 - \epsilon_d)\frac{\left(1 - \frac{\epsilon_w}{\tau_w}\right)}{\left(\frac{\epsilon_w}{\tau_w}\right)^{1/3}} \quad \text{(Eq. 9)}$$

Letting

$$\theta = \frac{\left(1 - \frac{\epsilon_w}{\tau_w}\right)}{\left(\frac{\epsilon_w}{\tau_w}\right)^{1/3}}$$

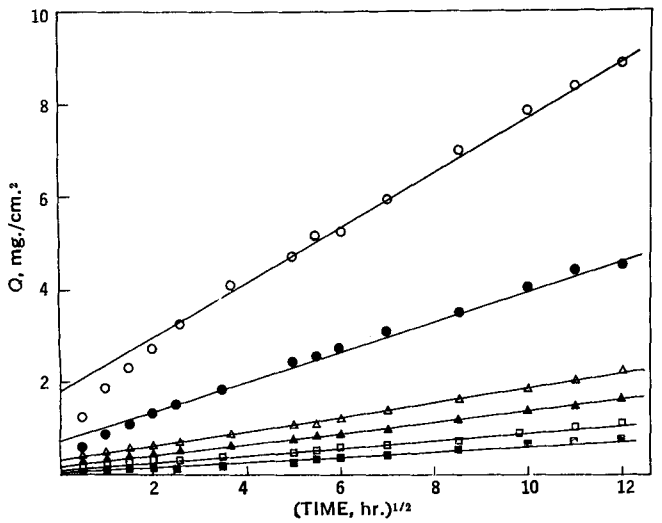

Fig. 2—Q versus $t^{1/2}$ plots for tablets with varying concentrations of drug released in distilled water. Key: ■, 5%; □, 10%; ▲, 15%; △, 20%; ●, 35%; ○, 50%.

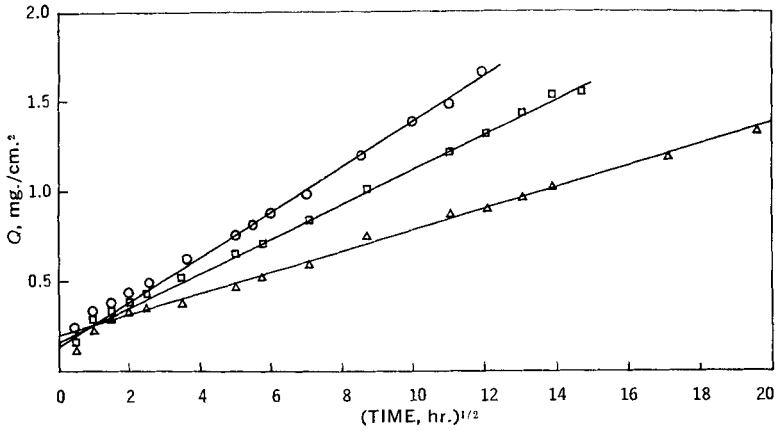

Fig. 3—Comparison of released profiles for 15% sulfanilamide released in different solvents. Key: ○, distilled water; □, 0.5 M NaCl; △, 5.0 M NaCl.

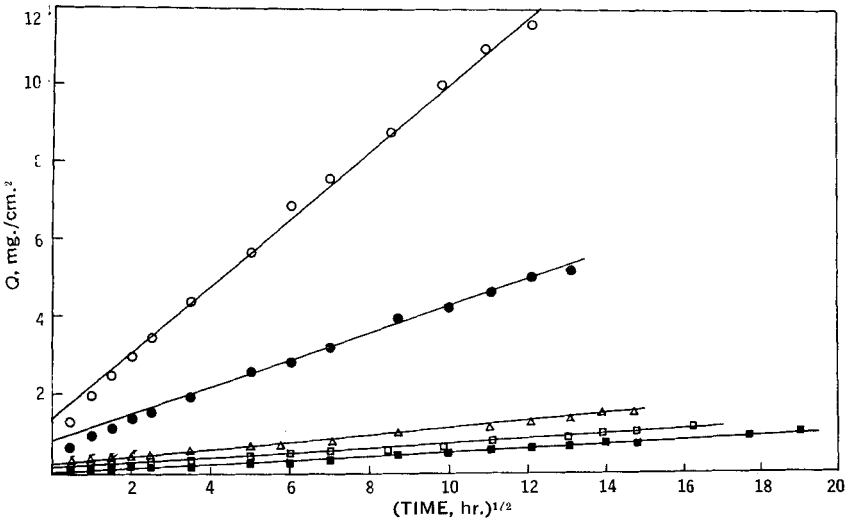

Fig. 4—Q versus $t^{1/2}$ plots for tablets with varying concentrations of drug released in 0.5 M NaCl. Key: ■, 5%; □, 10%; △, 15%; ●, 35%; ○, 50%.

$$\frac{[\tau - (\epsilon_d + \epsilon_w)]\tau^{1/3}}{\tau(\epsilon_d + \epsilon_w)^{1/3}} = (1 - \epsilon_d)\,\theta \quad \text{(Eq. 10)}$$

$$\tau^{2/3}[\tau - (\epsilon_d + \epsilon_w)] = \theta\,(1 - \epsilon_d)(\epsilon_d + \epsilon_w)^{1/3} \quad \text{(Eq. 11)}$$

If it is assumed that $\tau \gg \epsilon_d + \epsilon_w$, then the following relationship holds:

$$\tau^{1/3} = \theta\,(1 - \epsilon_d)(\epsilon_d + \epsilon_w)^{1/3} \quad \text{(Eq. 12)}$$

$$\tau = \theta^3\,(1 - \epsilon_d)^3(\epsilon_d + \epsilon_w) \quad \text{(Eq. 13)}$$

Thus, the apparent tortuosity of the system is given theoretically as a function of the permeability factors of the matrix alone, θ; the porosity due to drug, ϵ_d; and the porosity due to air, ϵ_w. It should be noted that the apparent tortuosity is independent of the diffusion coefficient of the drug in the solvent.

EXPERIMENTAL

The procedure used for these experiments is essentially the same as that presented in a previous paper in this series (1). The same components, PGMS[1] and hydrogenated castor oil,[2] were used as the matrix material and in the same 1:1 ratio. The drug used in this study was sulfanilamide which was spectrophotometrically assayed in the UV region. In addition to the usual solvent, distilled water, varying concentrations of sodium chloride solution were used to test the C_s effect.

RESULTS AND DISCUSSION

Figure 2 shows the release profiles of the tablets in water for various concentrations of sulfanilamide as a function of the square root of time. It is noted that the initial points appear to deviate from linearity, and we have tentatively attributed this to the release of surface drug before the matrix diffusion model takes control. To analyze the data, the best straight lines were drawn through the points after $t^{1/2} = 3$. The experiments had been carried out for much longer periods of time. Based on the observed slopes, the apparent values for tortuosity, τ, were calculated according to Eq. 1, these are listed in Table I along with several other parameters for the system.

Because of the surprisingly high values obtained for τ, it was decided to see whether diffusion in the aqueous phase was rate determining. This was done by changing the C_s factor (see Eq. 1). Tablets were run in NaCl solutions instead of water; because of the salting out effect, the solubility of sulfanilamide

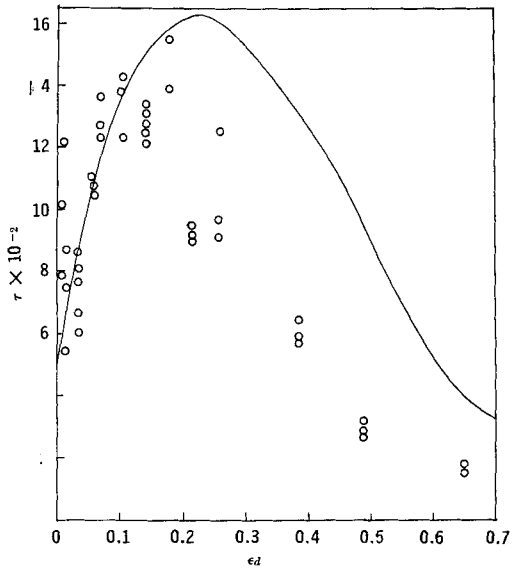

Fig. 6—Comparison of experimental values with the theoretical curve obtained by applying the Bruggeman theory.

is reduced appreciably by high concentrations of NaCl The reduced solubility was expected to reduce the slope of the *Q versus* $t^{1/2}$ plots in accordance with the predictions of Eq. 1. As can be seen in Fig. 3 and also by comparing Fig. 2 with Figs. 4 and 5, this effect was seen for those experiments at low drug concentrations.

The salt effects were not observed, however, with the tablets containing high concentrations ($\gtrsim$35%) of drug. This suggests a basic change in the mechanism of release at the high drug concentrations. Thus the proposed model would be expected to hold only at drug concentrations of less than about 35%.

Table II shows the slopes obtained in the various solvents and the slopes normalized to the distilled water values. According to the Stokes-Einstein equation, the diffusion coefficient, D, is affected by the viscosity of the solvent. Therefore, both the effect of the salt upon D and the effect upon C_s were taken into account in Table II. While the agreement is not exactly quantitative, the comparison strongly supports the diffusion-controlled concept for the low drug concentration cases.

Figure 6 shows the comparison of the experimental τ values with the Bruggeman relationship (Eq. 13). An experimentally determined (1) value for ϵ_w = .0374 was used and a τ_w value of 500 was used to give the fit as shown. A different choice of τ_w would only raise or lower the theoretical curve in Fig. 6; the shape would remain unchanged. Differentiation with respect to ϵ_d and proper analysis of Eq. 13 reveals that the maximum, calculated at 0.222, is independent of τ_w. Treatment of the second derivative, moreover, showed an inflection point at ϵ_d = 0.481 which gives the theoretical curve (see Fig. 6) a skewed convex parabolic shape.

The good agreement of the data with the theory at the lower ($\lesssim$20%) drug concentrations strongly

supports the proposed model in this concentration range. The large deviations from the theory at high drug concentration are consistent with the idea that a more rapid process takes over that does not appear to be aqueous diffusion controlled. More work is needed to explain the latter behavior.

Alpha-Chymotrypsin-Catalyzed Hydrolysis of Some Carbonate Esters

By ATUL A. SHAH* and KENNETH A. CONNORS

The kinetics of the α-chymotrypsin-catalyzed hydrolysis of several carbonate diesters, ROCOOR′, can be described by the Michaelis-Menten equation. *p*-Acetamidophenyltrichloroethyl carbonate shows a sigmoid pH-rate curve with a kinetic dependence on an enzyme function of pKa 7.2. The limiting values of the catalytic rate constant at high pH are, for *p*-acetamidophenyltrichloroethyl carbonate, 8.0×10^{-2} sec.$^{-1}$; for *p*-nitrophenyltrichloroethyl carbonate, 8.2×10^{-2} sec.$^{-1}$; for *p*-nitrophenylethyl carbonate, 0.2×10^{-2} sec.$^{-1}$. The evidence is consistent with the intermediate formation of an alkyl enzyme carbonate, the hydrolysis of which is rate controlling.

CARBONATE DIESTERS are derivatives of carbonic acid, the two hydrogens of the acid being formally replaced by alkyl or aryl groups to give the general structure ROCOOR′. The suggestion has recently been made (1) that such esters may be useful "prodrugs" because they may possess desirable pharmaceutical properties and can release the parent pharmacologically active compounds (ROH and R′OH) upon hydrolysis in the body. The mechanism of enzymatic hydrolysis of carbonate esters is therefore of pharmaceutical interest.

The enzymatic hydrolysis of carbonate esters is also of considerable fundamental importance. α-Chymotrypsin has been selected as the enzyme in the present study because it is commercially available in crystalline form, a good assay method is known, and especially because more is known about the catalytic behavior of chymotrypsin than of any other enzyme. Chymotrypsin is a member of a group of related enzymes known as the serine hydrolases; these enzymes catalyze the hydrolysis of proteins, peptides, amides, and esters. It is now well established that chymotrypsin (and probably other closely related enzymes) functions catalytically by a double displacement type of reaction. With an ester substrate, for example, the reaction may be written as shown in Scheme I.

$$\text{En—OH} + \text{RCOOR}' \rightleftarrows \text{En—OH}\cdot\text{RCOOR}'$$

$$\text{En—OH}\cdot\text{RCOOR}' \xrightarrow{\text{acylation}} \text{EnOCOR} + \text{R}'\text{OH}$$

$$\text{EnOCOR} + \text{H}_2\text{O} \xrightarrow{\text{deacylation}} \text{En—OH} + \text{RCOOH}$$

Scheme I

Here En—OH represents the enzyme, with a serine hydroxyl group specifically indicated. En—OH · RCOOR′ is the enzyme–substrate complex. In the acylation step, the enzyme is acylated with the release of the alcohol portion of the substrate. Deacylation involves hydrolysis of the acyl–enzyme intermediate EnOCOR to give the carboxylic acid portion of the substrate and to regenerate the enzyme. The evidence supporting this interpretation of chymotrypsin-catalyzed reactions has recently been reviewed by Bruice and Benkovic (2). It is now of interest to consider the possible mode of action of chymotrypsin when the substrate is a carbonate ester, ROCOOR′. It is obvious that two possible

"acyl–enzymes" can be formed from this substrate. The simplest representation of the reaction may therefore be written as shown in Scheme II.

The deacylation must be more complicated than is implied by Scheme II. The relative rates of formation of the two possible intermediates and their rates of hydrolysis will depend upon the structures R and R'. Structural variation in the substrate should therefore provide useful information on the mechanism of this reaction.

EXPERIMENTAL

Materials—*N-trans*-Cinnamoylimidazole was prepared according to Schonbaum, Zerner, and Bender (3). It was recrystallized twice from cyclohexane, m.p. 133°. [Lit. (3) m.p. 133–135°.] *p*-Nitrophenyl acetate (*p*-NPA) was prepared by the method of Chattaway (4). The crude product was recrystallized twice from Skellysolve B, m.p. 80°. [Lit. (5) m.p. 80°.] *p*-Acetamidophenyl-2,2,2-trichloroethyl carbonate (1) (*p*-APTC), m.p. 153°; *p*-acetaminophenol, m.p. 169–170°; these products were generously supplied by Smith Kline & French Laboratories. *p*-Nitrophenylethyl carbonate (*p*-NPEC): 2.8 Gm. (0.02 mole) of *p*-nitrophenol was dissolved in 20 ml. of pyridine. The solution was cooled in an ice bath and with continuous stirring 2.5 ml. (0.025 mole) of ethyl chloroformate (Aldrich Chemical Co.) was added dropwise. The mixture was allowed to stand 15 min. The pyridine was removed by evaporation under reduced pressure. The oily brown residue was recrystallized twice from methanol–water, m.p. 66°. [Lit. (5) m.p. 67–68°.]

p-Nitrophenyl-2,2,2-trichloroethyl carbonate (*p*-NPTC): to a solution of 120 ml. of toluene and 8.2 ml. of pyridine, cooled to −10°, was added 43 ml. (3.5 mole) of phosgene solution in toluene during about 90 min. Cooling was effected in dry ice–isopropyl alcohol. The reaction mixture was allowed to reach 0°, at which time the addition of 15 ml. (0.1 mole) of trichloroethanol was initiated. This addition required 40 min., and the final temperature was 10°. The mixture was stirred at room temperature for 2 hr. and then 30 ml. of cold water was cautiously added. Considerable CO_2 gas was evolved. The solution was washed with four more 30-ml. portions of water and dried over anhydrous magnesium sulfate. The dry solution was filtered.

Seventy-five milliliters of filtrate was added to a mixture of 4.5 ml. of pyridine, 30 ml. of toluene, and 7.5 Gm. of *p*-nitrophenol; the addition required 1 hr. The mixture was stirred for 90 min. and 0.9 ml. of pyridine was added, followed by 0.5 ml. of pyridine 30 min. later. The mixture was then cooled to 5°, 75 ml. of water was added, and it was stirred for 15 min. The toluene layer was separated and dried over magnesium sulfate. The solvent was removed by reduced pressure and the yellow residue was recrystallized three times from Skellysolve B. Pale yellow needles were obtained, m.p. 58°.

Anal.—Calcd. for $C_9H_6Cl_3NO_5$: C, 34.34; H, 1.91, Cl, 34.97; N, 4.45. Found: C, 34.31; H, 1.85; Cl, 34.85; N, 4.44.

The infrared spectrum showed peaks at 5.65 μ (OCOO), 6.2 and 6.4 μ (aromatic), 8.2 μ (COOR), 9.9, 10.5, and 12.3 μ (*p*-disubstituted phenyl ring), 13 μ (C—Cl), 6.6 and 7.4 μ (aromatic nitro). The nuclear magnetic resonance spectrum yielded τ 5.05 (methyl protons) and 2.5 and 1.67 (aromatic protons). The integrated spectrum gave 1:1:1 ratio for the three types of protons.

α-Chymotrypsin, three times recrystallized, was a Worthington product. The purity of the Worthington chymotrypsin was consistently found to be 84–86% by titration against *N-trans*-cinnamoylimidazole, following the procedure of Schonbaum *et al.* (3).

Acetonitrile (Eastman Kodak technical grade) was refluxed over phosphorus pentoxide and distilled twice from P_2O_5, b.p. 81°. Tris(hydroxymethyl)aminomethane (Tris) (Sigma Chemical Co.) was recrystallized from 95% ethanol. Pentaerythritol (Aldrich Chemical Co.) and *n*-butyl alcohol (Mallinckrodt A.R.) were used directly. Buffer chemicals were reagent grade. All water was redistilled from alkaline permanganate in an all-glass still. Buffers were prepared according to published formulas (6, 7). Ionic strength was maintained constant by addition of potassium chloride.

Apparatus—pH was measured with a Radiometer model 25 SE pH meter or with a Sargent model DR pH meter. The meters were standardized against the standard buffers recommended by Bates (8).

Spectral measurements were made with a Cary model 14 recording spectrophotometer equipped with a thermostated cell compartment that maintained temperature to ±0.1°. The absorbance scale was checked against the alkaline chromate solution described by Haupt (9).

Procedures—Reactions were followed by continuous spectrophotometric monitoring at a constant wavelength, which was 240 mμ for *p*-APTC and 400 mμ for *p*-NPA, *p*-NPEC, and *p*-NPTC. The temperature was 25 ± 0.1° in all experiments. Ionic strength was 0.2 *M*, and pH was held constant with buffers. The substrate concentration was much larger than the enzyme concentration. The analysis of the operational normality of the chymotrypsin was made during the same time period as the kinetic measurements.

A typical experiment was conducted as follows. One-centimeter cells, each containing 3.0 ml. of

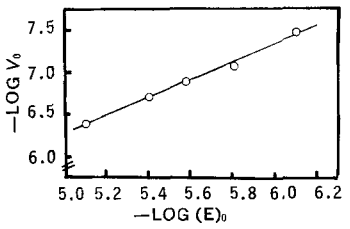

Fig. 1—Plot of $-\log v_0$ against $-\log [E]_0$ for the chymotrypsin-catalyzed hydrolysis of p-*APTC; pH = 7.54, $[S] = 1.13 \times 10^{-4}$ M, $[E]_0 = 7.8 \times 10^{-7}$ to 7.8×10^{-6} M.*

buffer solution, were placed in the reference and sample compartments of the spectrophotometer and were allowed to reach temperature equilibrium. The spectrophotometer signal was balanced and then 50 μl. of substrate stock solution (in acetonitrile) was introduced to the sample cell by means of a glass stirring rod. This was followed by 50 μl. of aqueous enzyme solution. Recording was initiated within 5–10 sec. When rates of nonenzymatic hydrolysis were significant, the enzyme solution was added prior to the substrate. Net enzymatic initial velocities were obtained by subtracting nonenzymatic initial velocities from total initial velocities.

Initial velocities were obtained from the initial zero-order portion of the absorbance-time tracing. The conversion of this quantity, $v_0' = dA/dt$ (initial velocity in absorbance units per second) to $v_0 = dc/dt$ (initial velocity in moles per liter per second) is readily accomplished through application of Beer's law to the substrate and product; the equation obtained is:

$$v_0 = v_0'/b(\epsilon_S - \epsilon_P)$$

where b is the path length, ϵ_S is the molar absorptivity of the substrate, and ϵ_P is the molar absorptivity of the product.

Beer's law is followed, at constant pH, by all substrates and products studied. The molar absorptivity of *p*-APTC at 240 mμ was 1.46×10^4 in the pH range 6.5 to 10.0. For *p*-nitrophenol the molar absorptivity at 400 mμ was 9.52×10^3, 1.75×10^4, and 1.90×10^4 at pH 7.02, 7.84, and 8.91, respectively.

RESULTS[1]

Order with Respect to Enzyme—Because carbonate esters are unusual substrates for chymotrypsin, it was considered important to investigate the validity of the usual rate relationships. When the logarithm of the initial velocity of the chymotrypsin-catalyzed hydrolysis of *p*-APTC was plotted against the logarithm of the enzyme concentration at constant substrate concentration, straight lines of unit slope were obtained. Figure 1 and Table I show these results. It can be concluded that under these conditions the chymotrypsin-catalyzed hydrolysis of *p*-APTC is first order with respect to the enzyme.

Stoichiometry—Hartley and Kilby (10, 11) studied the chymotrypsin-catalyzed hydrolysis of *p*-NPA and *p*-NPEC. They observed, with both of these substrates, an initial rapid release of *p*-nitrophenol (the "burst effect") followed by a slower, zero-order production of *p*-nitrophenol. These experiments have been repeated, with identical results. Extrapolation of the linear portions of the plot of *p*-nitrophenol concentration *versus* time to zero time gave finite intercepts. When these intercept values (expressed as molar concentration of product) are plotted against the molar concentration of enzyme, straight lines of unit slope are obtained (12). The stoichiometry of the reactions between chymotrypsin and *p*-NPA or *p*-NPEC is therefore 1:1.

The manifestation of the burst effect by *p*-NPEC is pertinent in the present study because it suggests similar mechanisms for the chymotrypsin-catalyzed hydrolyses of *p*-NPEC and *p*-NPA.

Kinetic Behavior—The adherence of carbonate ester systems to the Michaelis-Menten kinetic scheme was investigated. Plots of initial velocity against substrate concentration show the characteristic "saturation" effect (Fig. 2). Linear Lineweaver-Burk plots of $1/v_0$ *versus* $1/[S]$ were obtained, and it was from these plots that the kinetic parameters were determined. The kinetic scheme is:

$$E + S \underset{k_{-1}}{\overset{k_{+1}}{\rightleftarrows}} ES \xrightarrow{k_{cat.}} \text{products} \qquad \text{(Eq. 1)}$$

where ES is the enzyme–substrate complex. From the Lineweaver-Burk plots can be obtained the quantities $V_{max.}$ and $K_{m(app.)}$, where:

$$V_{max.} = k_{cat.}[E]_0 \qquad \text{(Eq. 2)}$$

$$K_{m(app.)} = \frac{k_{-1} + k_{cat.}}{k_{+1}} \qquad \text{(Eq. 3)}$$

Since the enzyme concentration is known, $k_{cat.}$ can be calculated.

Table II gives values of $k_{cat.}$ and $K_{m(app.)}$ for the chymotrypsin-catalyzed hydrolysis of *p*-APTC

over the pH range 6.5 to 9.8. The rate constant $k_{cat.}$ shows a sigmoid dependence on pH (the values above pH 9 are not considered as reliable as the others). If the enzyme is treated as a monobasic acid with characteristic dissociation constant, K_a, and the catalytic activity of the enzyme is assigned solely to its basic form, it is easily shown that $k_{cat.}$ is related to the pH through the equation:

$$k_{cat.} = \frac{k' K_a}{[H^+] + K_a} \qquad \text{(Eq. 4)}$$

where k' is a rate constant that is independent of pH. Figure 3 shows the data of Table II with a smooth curve calculated with Eq. 4 and the values pKa = 7.2 and $k' = 8.0 \times 10^{-2}$ sec.$^{-1}$.

The hydrolysis of *p*-NPEC and of *p*-NPTC were studied at several pH's. These results are given in Tables III and IV. It is seen that $k_{cat.}$ increases with pH in much the same manner as is observed with *p*-APTC. *p*-NPTC and *p*-APTC constitute an interesting pair of substrates because they contain the common trichloroethyl group. It is noted that the limiting value of $k_{cat.}$ (that is, the value at high pH) is 8.2×10^{-2} sec.$^{-1}$ for *p*-NPTC; this value is essentially the same as the limiting value of 8.0×10^{-2} sec.$^{-1}$ found for *p*-APTC. *p*-NPEC and *p*-NPTC are also a pair of substrates with a common group; the limiting rate constants are quite different for these compounds. The consequences of these comparisons will be discussed later.

Effects of Additives—During the pH-dependence study of the chymotrypsin–*p*-APTC system an unusual acceleration effect was observed in 0.05 M Tris buffers of pH 8 to 9. Values of $k_{cat.}$ were found to be about threefold greater in the presence of Tris than were values observed in other buffers. Figure 4 shows this effect; the constants observed in Tris buffers are plotted with the normal pH-rate profile. In attempting to account for this acceleration, some structurally related compounds were investigated as additives in the chymotrypsin–*p*-APTC system. The additives used were: (*a*) pH 8.15 ammonia buffer; (*b*) 0.15 M methanol; (*c*) pH 8.15 ammonia buffer and 0.15 M methanol; (*d*) pH 8.03 0.1 M glycine–NaOH buffer; (*e*) pH 8.0 0.1 M imidazole–HCl buffer; (*f*) 0.01 M pentaerythritol; (*g*) 0.15 M *n*-butyl alcohol. Only *n*-butyl alcohol caused an acceleration of the enzymatic reaction, but it was not nearly as effective as was Tris. Studies were carried out to evaluate $k_{cat.}$ and $K_{m(app.)}$ at several values of *n*-butyl alcohol concentration; both quantities increased with increase in the alcohol concentration (12). *p*-NPA was found to be a competitive inhibitor of the chymotrypsin-catalyzed hydrolysis of *p*-APTC. Since *p*-NPA is known to be

a normal substrate of chymotrypsin, this result implies that the hydrolysis of *p*-APTC is also catalyzed in a normal manner.

DISCUSSION

The conventional Michaelis-Menten kinetic scheme is represented by Eq. 1. It has been shown above that the chymotrypsin-catalyzed hydrolysis of several carbonate diesters can be accounted for by this overall scheme, and the enzymatic behavior of these substrates is therefore normal. The relationship between initial velocity and substrate concentration is the well-known Michaelis-Menten equation, Eq. 5:

$$v_0 = \frac{k_{cat.}[S][E]_0}{K_{m(app.)} + [S]} \qquad \text{(Eq. 5)}$$

where $K_{m(app.)}$ is defined in Eq. 3.

If the reaction proceeds through an acyl–enzyme intermediate, as with ester and amide substrates of chymotrypsin, $k_{cat.}$ may be a complex constant. The reaction then becomes Scheme III.

It can be shown (2, 12, 13) that the $k_{cat.}$ of Eq. 1 is related to the constants of Scheme III by $k_{cat.} = k_{+2}k_{+3}/(k_{+2} + k_{+3})$, and the implications of this relationship for chymotrypsin reactions have been discussed in detail (14).

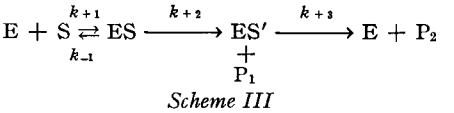
The situation is more complicated with carbonate diesters. Now the kinetic scheme is shown in Scheme IV.

Application of the steady-state approximation to ES, ES′, and ES″ (where ES′ and ES″ are the two possible "acyl–enzyme" intermediates) leads to an equation of the same form as Eq. 5, and comparison shows that the experimental $k_{cat.}$ can be expressed by Eq. 6:

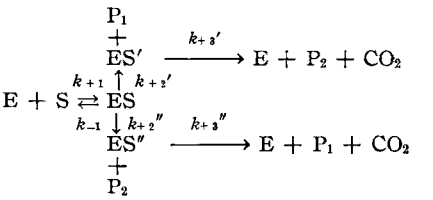
$$k_{cat.} = \frac{k'_{+3}k_{+3}''(k_{+2}' + k_{+2}'')}{k_{+2}'k_{+3}'' + k_{+2}''k_{+3}' + k_{+3}'k_{+3}''} \qquad \text{(Eq. 6)}$$

It is therefore clear that $k_{cat.}$ cannot, in general, be given a simple interpretation. If, however, one of the possible pathways in Scheme IV is greatly favored (*e.g.*, let $k_{+2}' \rangle\rangle\rangle k_{+2}''$), then Eq. 6 simplifies to $k_{cat.} = k_{+2}'k_{+3}'/(k_{+2}' + k_{+3}')$, which is identical with the corresponding equation for Scheme III. If this condition holds and, in addition, the deacylation of ES′ is rate determining (*i.e.*, $k_{+2}' \rangle\rangle\rangle k_{+3}'$) then $k_{cat.} = k_{+3}'$.

The similar behavior of *p*-NPA and *p*-NPEC suggests very strongly that the carbonate ester is



Scheme III



Scheme IV

TABLE V—LIMITING $k_{cat.}$ VALUES

Substrate	$10^2k_{cat.}$(sec.$^{-1}$)
p-APTC	8.0
p-NPTC	8.2
p-NPEC	0.2

hydrolyzed by the same overall reaction path as the carboxylic ester. Each substrate exhibits a rapid "burst" release of a stoichiometric amount of *p*-nitrophenol, which is followed by a steady-state zero-order production of *p*-nitrophenol. This behavior is consistent with Scheme III, where P_1 = *p*-nitrophenol and ES′ = $EnOCOCH_3$ (for *p*-NPA) or $EnOCOOCH_2CH_3$ (for *p*-NPEC).

The limiting $k_{cat.}$ values for *p*-APTC, *p*-NPTC, and *p*-NPEC provide the interesting comparison shown in Table V.

These relative rates can be accounted for with the assumptions that Scheme IV is the pertinent reaction scheme, that formation of the alkyl enzyme–carbonate is greatly favored over the aryl enzyme–carbonate, and that deacylation is rate controlling. Then, as shown above, $k_{cat.} = k_{+3}'$. The essential identity of $k_{cat.}$ for *p*-APTC and *p*-NPTC leads to these assumptions, for this identity is readily explicable on the basis that $k_{cat.}$ is a measure of the reaction rate of an intermediate common to the two substrates; this intermediate would be $EnOCOOCH_2CCl_3$. This interpretation is consistent with the fortyfold greater value of $k_{cat.}$ for *p*-NPTC relative to *p*-NPEC.

Because of the greater complexity of Scheme IV compared with Scheme III, the argument presented in the preceding paragraph, implicating a common intermediate, is not so compelling as it is for the carboxylic acid derivatives. However, the greatly different chemical natures of the R and R′ groups in these ROCOOR′ substrates probably favor a considerable disparity in the rate constants k_{+2}' and k_{+2}'' in Scheme IV. If R and R′ were similar (both aryl groups, for example) it is possible that very complex kinetics might be observed, and that $k_{cat.}$ could only be interpreted in terms of Eq. 6.

Effect of Certain Drugs on Perfused Human Placenta VIII

Angiotensin-II Antagonists

By CHARLES O. WARD and RONALD F. GAUTIERI

The majority of the drugs tested as angiotensin antagonists in this investigation were from two pharmacologic classes: negative musculotropic agents (papaverine, sodium cobaltinitrite, isosorbide dinitrate, nitroglycerin, sodium nitrite, and dipyridamole) and agents which selectively block α-adrenergic receptors (dibenamine, phentolamine, tolazoline, and hydralazine). Of the direct smooth muscle depressants, sodium nitrite and dipyridamole were the most effective; dibenamine and phentolamine were the most potent adrenergic blocking agents employed. Atropine, cocaine, and cyproheptadine were also tested as antagonists of the pressor effect of angiotensin and exhibited only moderate effectiveness. Lidoflazine, a specific angiotensin antagonist, was the most potent compound tested in this study; the degree of antagonism exhibited by it, however, was only slightly greater than either dibenamine or phentolamine. The results indicate that the pressor effect of angiotensin in the perfused human placenta is primarily the result of a direct stimulation of vascular smooth muscle and secondarily to a stimulation of α-adrenergic receptors.

WHILE RESEARCH with angiotensin in the last two decades has dealt principally with its effects on innervated preparations, there still exists in the literature a paucity of information on the actions of this polypeptide in the more common nerve-free preparations, the perfused human placenta and umbilical cord. Eliasson and Astrom (1) could detect only moderate increases in perfusion pressure using angiotensin in the former preparation; others have reported little or no effect with angiotensin on either the perfused umbilical cord (2) or helical strips of both the human umbilical artery and vein (3). In contrast to these investigations, Gautieri and Mancini (4) recently reported an increase in perfusion pressure of the human placenta that ranged from 11 to 51 mm. Hg; this response to angiotensin was reduced but not completely blocked by either 3-or 6-mg. doses of phentolamine.

In addition to the effects of angiotensin on the above isolated preparations, many recent investigations have linked abnormally high blood levels of angiotensin and renin with the pathogenesis of the toxemias of pregnancy (5–8). The symptomology of clinical toxemia has been mimicked by the injection of renin-containing renal extracts into rats made hypertensive by the administration of desoxycorticosterone (DCA); renal damage similar to that of toxemia as well as convulsions, anasarca, oliguria or anuria, sodium retention, and increased blood urea nitrogen were reported (5). Also, an increased pressor response to angiotensin administration was found by Chesley (6) in women with pre-eclampsia. However, a decreased sensitivity to this autocoid was observed in normal pregnancy when this group was compared with

The authors express sincere thanks to the Obstetrical Staff, Temple University Hospital, for the generous supply of placentas, to Dr. David E. Mann, Jr., for his valuable suggestions and discussions, and to Mr. James C. Tatnall for his technical assistance.
Previous paper: Gautieri, R. F., and Mancini, R. T., *J. Pharm. Sci.*, **56**, 296 (1967).

nonpregnant controls. Dexter and Haynes (7) found higher than normal concentrations of renin in the blood of patients with eclampsia and pre-eclampsia and Landesman *et al.* (8) reported increased blood levels of angiotensinase in toxic women when compared with nontoxic, pregnant controls. When high doses of renin and angiotensin were administered to the pregnant rat, a drop in placental blood pressure was noted by Burlingame *et al.* (9). Injections of renin into the rat placenta itself produced consistent increases in perfusion pressures.

Thus, because angiotensin may be involved in the etiology of the toxemias of human pregnancy and because a previous study in this laboratory (4) has shown that angiotensin exerts its pressor action on perfused human placental vessels by both a stimulation of α-adrenergic receptors and also a direct stimulation of vascular smooth muscle, it was the purpose of this investigation to screen compounds that would selectively modify the mechanisms whereby angiotensin produces vasoconstriction in these vessels, in order not only to identify angiotensin antagonists, but also to more clearly elucidate its vasopressor action in this system.

MATERIALS AND METHODS

Full-term human placentas, obtained from the hospital 15 to 20 min. after normal delivery, were used throughout this investigation. Each was transported to the laboratory in a light-resistant glass container filled with approximately 1 L. of Tyrode's solution preheated to 38°.

The apparatus used and the procedures employed in the preparation and perfusion of the placentas, in recording and maintaining the perfusion pressure, and in measuring the inflow and outflow volumes of the perfusate have been described in previous papers (10, 11). In 38 successful placental preparations, each lasting 1–4 hr., a total of 106 studies was conducted. The results from 4 placentas were discarded because the response to a test dose of angiotensin was erratic.

Throughout this investigation the agonist, angiotensin, was administered before the various antagonists for the purpose of establishing a standard response to its vasoconstrictor effect; the antagonists were then administered 2–3 min. after the pressor response to angiotensin subsided. Subsequent responses to angiotensin, at 4–6-min. intervals after the pressor or depressor effect of the various antagonists subsided, were then compared to the initial standard. The mean pressure change at maximal antagonism of the pressor effect of angiotensin, as well as the mean onset of maximal antagonism in minutes, were used as bases for comparing the relative potencies of the various antagonists. The pressor dose of angiotensin used throughout this investigation was kept at 50.0 mcg. and was based on that used in a previous investigation (4). This dose of angiotensin produced a mean increase in perfusion pressure of 20.3 mm. Hg (range 10.6–34.0 and S. D. ±6.6).

The doses of the antagonists were determined by trial and error and were kept as low as possible, yet sufficient to exhibit angiotensin antagonism. However, in the case of the α-adrenergic blocking agents, their doses were based on those used to antagonize the constrictor effect of 40-mcg. doses of norepinephrine in a previous study with this preparation (11).

The following drugs were injected into the rubber tubing, prior to entering the pump, in a volume of distilled water not exceeding 5.0 ml., except where noted: angiotensin-II,[1] 0.01%; cyproheptadine hydrochloride,[2] 0.01%; papaverine hydrochloride USP, 1.0%; sodium cobaltinitrite, 0.4%; nitroglycerin USP, 0.1%; isosorbide dinitrate,[3] 0.4%; sodium nitrite, 0.4%; dipyridamole,[4] 0.5% in 1.0 ml. of an aqueous solution containing polyethylene glycol 600, 50 mg., and tartaric acid, 2 mg.; dibenamine hydrochloride,[5] 0.1% and 0.2% in 95% ethyl alcohol USP; phentolamine methanesulfonate,[6] 0.1%; tolazoline hydrochloride,[7] 0.1%; hydralazine hydrochloride,[8] 0.1%; lidoflazine,[9] 0.25% in 0.17 *M* acetic acid; atropine sulfate, 0.1%; cocaine hydrochloride USP, 1.0%. In addition, the appropriate amounts of 95% ethyl alcohol USP, 0.17 *M* acetic acid, and an aqueous solution containing 50 mg. of polyethylene glycol 600 and 2 mg. of tartaric acid per 1.0 ml. were injected to observe their effects on the placental vessels and the normal pressor response to angiotensin.

RESULTS

The following results, which are summarized in Table I, were obtained on the vasculature of full-term human placentas perfused at pressures between 70 and 120 mm. Hg. This range of perfusion pressures corresponds to inflow rates of 17 to 62 ml. of perfusion fluid (Tyrode's solution modified by the addition of 0.525% polyvinylpyrrolidone[10] per minute.

Cyproheptadine—In a dose of 100.0 mcg. cyproheptadine produced a mean pressure decrease of 3.32 mm. Hg (range 0.4 to 6.6) in the subsequent pressor responses to the standard 50.0-mcg. dose of angiotensin. In the five experiments performed, the maximum antagonism occurred an average of 24.4 min. (range 16.0 to 30.0) after the administration of the antagonist. The 200.0-mcg. dose of cyproheptadine produced a mean decrease of 3.6 mm. Hg (range 2.2 to 7.0) in perfusion pressure at maximum effectiveness. The onset of maximum antagonism

TABLE I—COMPARISON OF ANGIOTENSIN ANTAGONISM BY SEVERAL COMPOUNDS IN PERFUSED HUMAN PLACENTAL VESSELS

Drug	Dose[a]	No. of Exp.	Av. Max. Antagonism, min.	Mean Pressure Decrease, mm. Hg	S.E.M.[b]	P Value[a]
Cyproheptadine	100.0 mcg.	5	24.4	3.32	±1.10	0.025
Cyproheptadine	200.0 mcg.	5	18.4	3.60	±1.31	0.050
Papaverine	5.0 mg.	5	19.0	2.88	±1.18	0.050
Papaverine	10.0 mg.	5	8.6	3.28	±0.74	0.010
Sodium cobaltinitrite	2.0 mg.	5	20.6	2.00	±0.53	0.010
Isosorbide dinitrate	2.0 mg.	5	25.6	1.36	±0.50	0.050
Nitroglycerin	2.0 mg.	5	18.4	3.12	±1.08	0.025
Sodium Nitrite	2.0 mg.	6	19.5	6.66	±2.11	0.025
Dipyridamole	5.0 mg.	5	14.4	5.16	±0.76	0.005
Dibenamine	2.0 mg.	5	16.2	2.08	±1.57	0.150[c]
Dibenamine	4.0 mg.	5	20.2	7.72	±1.29	0.005
Phentolamine	3.0 mg.	5	14.1	7.74	±2.32	0.025
Tolazoline	5.0 mg.	5	15.4	4.90	±1.56	0.025
Hydralazine	4.0 mg.	5	17.6	2.24	±0.43	0.005
Atropine	1.0 mg.	5	17.4	2.50	±0.50	0.005
Cocaine	2.0 mg.	6	13.3	1.73	±1.36	0.150[c]
Lidoflazine	5.0 mg.	5	17.4	8.86	±3.33	0.050

[a] P value calculated from "paired t test" (17). [b] S.E.M. = standard error of the mean. [c] P value >0.050 not significant.

occurred at about 18.4 min. (range 4.0 to 32.0) after 200.0 mcg. of cyproheptadine had been administered. In one of the five preparations the 200.0-mcg. dose of the antagonist resulted in a mild increase (0.4 mm. Hg) in the pressor response to subsequent doses of angiotensin. In 7 of the 10 experiments performed, using both doses of cyproheptadine, the antagonist itself produced an increase in perfusion pressure ranging from 1.0 to 9.2 mm. Hg; in the other three experiments no pressure change was noted immediately following the administration of the antagonist.

Papaverine—In a total of 5 experiments, a 5.0-mg. dose of papaverine produced an average decrease in the pressor response to angiotensin of 2.88 mm. Hg (range 2.8 to 6.2). In one instance a 1.2 mm. Hg increase in perfusion pressure, rather than a decrease, was noted when angiotensin was given following papaverine administration. The maximum decrease in the pressor response to subsequent doses of angiotensin occurred an average of 19.0 (range 7.0 to 52.0) min. after administration of the antagonist. In two cases the antagonist produced a decrease in perfusion pressure itself; an increase was noted immediately following the administration of the antagonist in one experiment; and no change was produced by papaverine itself in the remaining two experiments. In a dose of 10.0 mg. papaverine always produced a decrease in pressure by itself of 2.0 to 6.2 mm. Hg and the mean pressure decrease at maximum angiotensin antagonism was 3.28 mm. Hg (range 1.4 to 5.4) in the five experiments performed at this dosage. The greatest degree of antagonism occurred an average of 8.6 min. (range 5.0 to 14.0) after the higher dose of papaverine had been administered.

Sodium Cobaltinitrite—Sodium cobaltinitrite, in a dose of 2.0 mg., produced a mean decrease in the pressor response to subsequent doses of angiotensin of 2.0 mm. Hg (range 0.6 to 3.6) at maximum effectiveness. In the five experiments performed the maximum degree of angiotensin antagonism occurred an average of 20.6 min. (range 16.0 to 37.0) after administration of the antagonist. In all of the experiments performed, sodium cobaltinitrite produced a decrease in perfusion pressure itself of 0.8 to 6.6 mm. Hg.

Isosorbide Dinitrate—In a dose of 2.0 mg. isosorbide dinitrate reduced the pressor response to 50.0 mcg. of angiotensin an average of 1.36 mm. Hg (range 1.6 to 2.2) at maximal antagonism. In one of the five experiments performed the pressor response to angiotensin was increased 0.6 mm. Hg when compared to the original test dose of the agonist. An average of 25.6 min. (range 15.0 to 44.0) elapsed before the maximum effect of isosorbide dinitrate was noted; each administration of the antagonist was followed by a decrease in the perfusion pressure that ranged from 1.4 to 5.2 mm. Hg.

Nitroglycerin—In a total of five experiments 2.0 mg. of nitroglycerin produced an average decrease in the pressor response to subsequent angiotensin administration of 3.12 mm. Hg (range 2.4 to 5.0). The maximal efficacy of the antagonist was noted an average of 18.4 min. (range 14.0 to 25.0) after administration. In four instances the antagonist itself produced a decrease in perfusion pressure ranging from 1.4 to 14.4 mm. Hg.

Sodium Nitrite—Sodium nitrite, in a dose of 2.0 mg., produced a mean decrease in perfusion pressure of 6.66 mm. Hg (range 2.2 to 13.7) at maximum angiotensin antagonism. In one case a 1.6 mm. Hg increase in perfusion pressure was noted following angiotensin administration, when compared to the test dose of the agonist, after sodium nitrite had been given. In the six experiments performed the maximal antagonism of angiotensin occurred an average of 19.5 min. (range 11.0 to 38.0) after administration of the antagonist. In each case sodium nitrite itself produced a decrease in perfusion pressure of 1.0 to 5.2 mm. Hg.

Dipyridamole—In a total of five experiments 5.0 mg. of dipyridamole produced an average decrease in the pressor response to subsequent angiotensin administration of 5.16 mm. Hg (range 3.5 to 7.5). The maximum effect of the antagonist was noted an average of 14.4 min. (range 8.0 to 19.0) after administration. In each instance the antagonist itself produced a decrease in perfusion pressure of 2.0 to 5.2 mm. Hg immediately following its administra-

tion. A decrease in perfusion pressure (1.0 to 3.0 mm. Hg) was also noted when 1.0 ml. of an aqueous solution containing 50.0 mg. of polyethylene glycol 600 and 2.0 mg. of tartaric acid (equivalent to the vehicle for the 5.0-mg. dose of dipyridamole) was tested in four separate experiments.

Dibenamine—In a dose of 2.0 mg. dibenamine produced a mean pressure decrease of 2.08 mm. Hg (range 0.6 to 7.6) in the pressor response to the standard 50.0-mcg. dose of angiotensin. In the five experiments performed, the greatest decrease in the pressor response to angiotensin occurred an average of 16.2 min. (range 12.0 to 24.0) after the 2.0-mg dose of dibenamine had been given. In five separate experiments of 4.0-mg. dose of dibenamine produced a mean decrease of 7.72 mm. Hg (range 3.8 to 11.2 in the pressor response to subsequent doses of angiotensin at maximum effectiveness. The onset of maximal antagonism occurred at about 20.2 min. (range 11.0 to 28.0) after dibenamine had been given. The administration of 2.0 mg. of dibenamine produced an increase of 1.8 mm. Hg in the pressor response to subsequent doses of angiotensin in one preparation. In 9 of the 10 experiments performed, using both the 2.0- and 4.0-mg. doses of dibenamine, the antagonist itself produced an increase in perfusion pressure ranging from 1.6 to 27.0 mm. Hg. The administration of 1.0 ml. of 95% ethyl alcohol, equal to the amount used to dissolve the 2.0-mg. dose of dibenamine, resulted in a comparable increase in perfusion pressure (2.6 to 2.40 mm. Hg) in four separate experiments. Also, when 4.0 ml. of 95% ethyl alcohol, equivalent to the amount used to dissolve the 4.0-mg. dose of the antagonist, were tested in four experiments, an increase in perfusion pressure of 14.0 to 26.0 mm. Hg was observed.

Phentolamine—In a total of five experiments, a 3.0-mg. dose of phentolamine produced an average decrease in the pressor response to angiotensin of 7.74 mm. Hg (range 4.0 to 16.7). The maximum decrease in the pressor response to subsequent doses of angiotensin occurred an average of 14.1 min. (range 7.5 to 18.5) after the administration of the antagonist. In three cases the antagonist itself produced an increase in perfusion pressure ranging from 1.2 to 2.2 mm. Hg.

Tolazoline—Tolazoline, in a dose of 5.0 mg., produced a mean decrease in the pressor response to subsequent doses of angiotensin of 4.90 mm. Hg (range 4.0 to 8.8) at maximal antagonism. In one experiment tolazoline had no effect on the pressor response to angiotensin. In the five experiments performed the maximum degree of angiotensin antagonism occurred an average of 15.4 min. (range 11.0 to 23.0) after administration of tolazoline. In four of the experiments tolazoline itself produced an increase in perfusion pressure of 1.8 to 4.4 mm. Hg; in the one remaining instance a decrease in perfusion pressure (2.6 mm. Hg) was noted immediately after tolazoline had been given.

Hydralazine—In a dose of 4.0 mg. hydralazine reduced the pressor response to a standard 50.0-mcg. dose of angiotensin an average of 2.24 mm. Hg (range 1.0 to 4.4) at maximal antagonism. An average of 17.6 min. elapsed (range 13.0 to 23.0) before maximum the effect of hydralazine was noted. In each of the five experiments performed hydralazine administration was followed by an increase in perfusion pressure of 0.14 to 2.6 mm. Hg.

Atropine—Atropine, in a dose of 1.0 mg., produced a mean decrease in perfusion pressure of 2.50 mm. Hg (range 1.6 to 4.4) at maximum angiotensin antagonism. In the five experiments performed, the greatest decrease in the pressor response to angiotensin occurred an average of 17.4 min. (range 7.5 to 26.0) after the antagonist was administered. Atropine, itself, had no effect on perfusion pressure in any of the placentas studied.

Cocaine—In a dose of 2.0 mg. cocaine reduced the pressor response to a standard 50.0-mcg. dose of angiotensin an average of 1.73 mm. Hg (range 2.0 to 6.4) at maximal antagonism. An average of 13.33 min. elapsed (range 6.0 to 33.0) before the maximum effect of cocaine was noted. Cocaine itself had no effect on perfusion pressure in three experiments; in one case a decrease in perfusion pressure was noted; in the remaining two instances an increase in perfusion pressure was noted immediately after the antagonist was given. In only four of the six experiments performed did cocaine show an antagonism of the pressor effect of angiotensin; in the other two placentas increases in the pressor response to angiotensin (1.4 and 2.6 mm. Hg) were observed.

Lidoflazine—In a total of five experiments, 5.0 mg. of lidoflazine produced an average decrease in the pressor response to angiotensin of 8.86 mm. Hg (range 2.6 to 21.4). The maximum effect of the antagonist occurred an average of 17.4 min. (range 11.0 to 28.0) after administration. In each instance the antagonist itself produced a decrease in perfusion pressure of 2.6 to 8.0 mm. Hg immediately following its administration. The administration of an amount of 0.17 *M* acetic acid (2.0 ml.) equal to that used to dissolve the 5.0-mg. dose of lidoflazine produced a decrease (1.6 to 4.0 mm. Hg) in the perfusion pressure itself in three separate experiments; in another case it had no effect on perfusion pressure alone.

Polyethylene Glycol 600 and Tartaric Acid—The administration of 1.0 ml. of an aqueous solution, containing 50.0 mg. of polyethylene glycol 600 and 2.0 mg. of tartaric acid, slightly decreased thd pressor response to subsequent doses of angiotensin (0.2 mm. Hg) in one experiment. In three other experiments, however, an increase in the pressor response to the agonist (0.6 to 4.0 mm. Hg) was observed after injection of this solution.

Ethyl Alcohol—The administration of both 1.0 and 4.0 ml. of 95% ethyl alcohol caused no perceptible effect on the pressor responses of the placenta to subsequent doses of angiotensin in eight separate experiments.

Acetic Acid—A dose of 2.0 ml. of 0.17 *M* acetic acid in three experiments caused a small decrease (0.4 to 0.8 mm. Hg) in the pressor response to subsequent doses of angiotensin; in one other experiment an increase (1.0 mm. Hg) in the pressor response to angiotensin was observed.

DISCUSSION

Because a previous investigation in this labora-

tory (4) had demonstrated that the vasoconstrictor effect of angiotensin in the perfused human placenta was primarily the result of a direct stimulation of vascular smooth muscle and only partially due to a stimulant effect on α-adrenergic receptors, the majority of the drugs tested as antagonists in this investigation were chosen from two pharmacologic classes: negative musculotropic agents (papaverine, sodium cobaltinitrite, isosorbide dinitrate, nitroglycerin, sodium nitrite, and dipyridamole) and compounds that selectively block α-adrenergic receptors (dibenamine, phentolamine, tolazoline, and hydralazine).

Among the direct-acting smooth muscle depressants, sodium nitrite and dipyridamole were the most potent angiotensin antagonists and exhibited a mean pressure decrease at maximum antagonism of 6.66 mm. Hg and 5.16 mm. Hg, respectively. Isosorbide dinitrate, whose depressant effect on the placental vasculature has been shown to be due to the nitrate moiety (12), proved to be the weakest antagonist in this class (mean pressure decrease of 1.36 mm. Hg). However, its onset of action was longest, averaging 25.6 min. Each of the drugs in this category produced a mild and transient decrease in perfusion pressure which always subsided before its antagonistic effect on the pressor response to angiotensin was noted.

When 1.0 ml. of the vehicle used to dissolve dipyridamole (an aqueous solution containing 50.0 mg. of polyethylene glycol 600 and 2.0 mg. of tartaric acid per 1.0 ml.) was tested as an angiotensin antagonist, a slight increase (0.6 to 4.0 mm. Hg) in the pressor response to subsequent doses of angiotensin was observed in three experiments and a small decrease (0.2 mm. Hg) was noted in another. Thus it is reasonable to assume that the antagonistic ability of dipyridamole observed in this study is due entirely to the chemical itself, and not to the solvent employed.

Since previous investigations in this laboratory have shown that angiotensin and serotonin share similar mechanisms in producing a pressor effect on the vasculature of the perfused human placenta (4), and because cyproheptadine was shown to be a potent serotonin antagonist when tested in this preparation (13), this compound was evaluated as an angiotensin antagonist in this investigation. Only moderate angiotensin antagonism was recorded when cyproheptadine was tested in this study (mean pressure decreases of 3.32 mm. Hg with the 100.0-mcg. dose and 3.60 mm. Hg decrease with 200.0 mcg.). Cyproheptadine administration was followed by an immediate rise in perfusion pressure (range 1.0 to 9.2 mm. Hg) in this investigation whereas Gokhale *et al.* (2) observed no effect with this compound on the perfusion pressure of the human umbilical artery; yet they recorded a significant decrease, as in this study, in perfusion pressure immediately after administration of papaverine and sodium nitrite. In view of the above results, the negative musculotropic action for cyproheptadine, suggested as an additional mechanism of action by Ward and Gautieri (13), does not appear to be involved with its ability to antagonize the pressor effect of angiotensin in this preparation.

Dibenamine (mean pressure decrease of 7.72 mm. Hg in a dose of 4.0 mg.) and phentolamine (mean pressure decrease of 7.74 mm. Hg) were the most effective α-adrenergic receptor blocking agents employed in this study. In our results, the mean difference between the pressor effect of angiotensin before and after the administration of the 2.0-mg. dose of dibenamine was not statistically significant when the 0.050 level of probability was chosen after computation of the paired t test (17). Our results with the 3.0-mg. dose of phentolamine agree remarkably well with those of Gautieri and Mancini (4), who used a similar dose of this agent as an angiotensin antagonist in this preparation; they found, however, that doubling the dose of phentolamine did not increase its antagonistic ability. Our results with hydralazine (mean pressure decrease of 2.24 mm. Hg), in antagonizing the pressor effect of angiotensin in this isolated organ preparation, differ from those of Page and McCubbin (14) and Gross and Turrian (15), who could detect no antagonism of the pressor effect of angiotensin in the intact dog. Meier *et al.* (16), in contrast, have reported that hydralazine, but not phentolamine, reduced the pressor response to angiotensin in the perfused vasculature of the rabbit hind leg.

Although it was observed that the immediate increase in perfusion pressure of the human placenta, after the administraton of dibenamine, was due to the 95% ethyl alcohol used as the solvent, no angiotensin antagonism could be attributed to this vehicle when appropriate amounts were tested in eight separate experiments.

The foregoing results, therefore, indicate that the negative musculotropic agents employed produced the most predictable and consistent results of all the antagonists utilized. We are, then, in agreement with Gautieri and Mancini (4) who postulated that the pressor effect of angiotensin in the perfused human placental vessels was due primarily to a direct stimulation of vascular smooth muscle and only secondarily to a stimulation of α-adrenergic receptors.

A portion of angiotensin's stimulant effect on the guinea pig ileum, *in vitro*, has been shown to be the result of acetylcholine release from the ganglion cells in the muscular wall of the gut (18). Because of the above as well as the observations that acetylcholine is present normally in the human placenta (19) and elicits a vasoconstrictor effect on these vessels which is blocked by atropine (1), atropine was tested as an antagonist in an attempt to discern whether a portion of the pressor response to angiotensin in these nerve-free vessels (20) was the result of acetylcholine release. In this investigation atropine was only a weak angiotensin antagonist and produced a mean pressure decrease of 2.50 mm. Hg at maximum efficacy. From the results it is not possible, at this time, to attribute the antagonistic ability of atropine observed in these experiments to an antagonism of acetylcholine possibly released in response to angiotensin administration. Also, the observation that atropine can produce vasodilatation by a direct effect on vascular smooth muscle (21) cannot be ignored as a mechanism of angiotensin antagonism.

Since Distler *et al.* (22) have shown that angiotensin administration may result in the release of norepinephrine, a constrictor of placental vessels

(1, 11), from helical strips of the aorta and carotid artery of the pig, cocaine was chosen for testing as an antagonist because it has been shown to block the release of norepinephrine from storage sites in the terminals of sympathetic nerves (23). Cocaine appeared to be the least effective antagonist studied in the dose employed (mean pressure decrease of 1.73 mm. Hg) and the results obtained were not statistically significant ($P > 0.050$).

Lidoflazine, a specific angiotensin antagonist, has been shown to block the noncompetitive, indirect component of angiotensin's stimulant action on the guinea pig ileum *in vitro* (24); it was chosen for this study because it was the only specific angiotensin antagonist known. In this investigation lidoflazine was the most potent agent employed, as evidenced by a mean pressure decrease at maximal efficacy of 8.86 mm. Hg. Its onset of action (17.4 min.), however, was not greatly different from the other compounds employed. In four separate experiments an appropriate amount of 0.17 *M* acetic acid was tested for angiotensin antagonism because this was the solvent for lidoflazine. Only a negligible degree of antagonism (mean pressure decrease of 0.4 to 0.8 mm. Hg) was noted, indicating that the response to lidoflazine was not the result of an action of its solvent.

The results of this investigation indicate that the pressor response to angiotensin in the vasculature of the perfused human placenta is due principally to a direct stimulation of the vascular smooth muscle and, to a lesser degree, a stimulation of α-adrenergic receptors present in these vessels (11). No release of either acetylcholine or norepinephrine by angiotensin, as a portion of its pressor action in these vessels, can be postulated from the results of this study. It seems clear, therefore, that this preparation may be used to screen compounds that have potential therapeutic efficacy in the toxemias of pregnancy and as an aid in discerning the mechanisms of these and other vasoactive substances endogenous to the human body.

Mechanistic Toxicology of Triethyl Citrate in Cultured Mammalian Cells by Cinematography

By ALAN B. JONES, W. L. GUESS, and J. AUTIAN

The role of triethyl citrate in growth inhibition of mouse fibroblast cells (strain L-929) in culture has been studied by the use of phase-contrast microscopy and time-lapse microphotography. Concentrations of the ester studied ranged from 7.9 to 48 m*M* of growth medium. It was found that at concentrations below 12 m*M*, the primary site of action of the toxicant was mitochondria resulting in mitochondrial swelling, inhibiting the function of this organelle, and growth inhibition. At higher dose levels, a second mechanism masks the mitochondrial involvement. The cytological picture is characterized by cytoplasmic gelation, plasma membrane contraction, and eventual lysis of the cell. The mechanism proposed was protein denaturation, but further studies are necessary for its definition. The method is a valuable tool for observing the effects of toxicants on living cells. When coupled with biochemical procedures, it offers a workable technique for the interpretation of mechanisms of actions of toxicants.

TRIETHYL CITRATE and other esters of citric acid are commonly used as plasticizers in polyvinyl chloride and cellulosic formulations. The *in vitro* toxicity of triethyl citrate has received some attention in the past as evidenced by previous studies from this laboratory (1). In these studies, Rosenbluth demonstrated the inhibitory effect of a homologous series of citric acid esters on the growth of mammalian cells in culture, and characterized triethyl citrate as being a nonspecific physical toxicant. As a physical toxicant, its biological effects could be related to the physical properties of the compound by mathematical relationships derived by Ferguson (2). In the homologous series studied, triethyl citrate represented the lowest number of the series exhibiting this phenomenon of physical toxicity since trimethyl citrate toxicity was shown to be of a chemical nature.

Compounds exhibiting physical toxicity are generally thought to accumulate in the lipoprotein of the cell due to their specific physical properties. Previous work on the mechanism of action of depressants, which fall into the category of physical action, have yielded two proposed mechanisms of action. Albert (3) suggested that the accumulation of a depressant drug caused a swelling of the plasma membrane. This swelling results in the mechanical separation of the enzyme systems necessary for active transport. Also, this swelling could result in a physical blocking of the pores in the membrane, thus again blocking the passage of material into and out of the cell. On the other hand, in 1961, Pauling (4) suggested that depressants exert their activity by forming clathrates through localized complexation of crystalline water in the cell.

A different mechanism of action for depressants was proposed by Warburg in 1921 (5). He suggested that they act by an inhibition of respiration of the cell at the level of the mitochondria. Later biochemical evidence by Butler (6), demonstrated that amobarbital specifically interfered with the cytochrome reductase system resulting in a decreased cellular respiration.

In contrast to these above noted modes of action, compounds exhibiting chemical specificity are in numerous reports in the literature. In the cases of these chemical toxicants, the biological activity cannot be related to the physical characteristics of the compound in question by mathematical relationships as previously mentioned. They are able to evoke a biological response at a much lower concentration than is predicted in Ferguson's relationships.

As a continuation of the *in vitro* studies previously mentioned, the present study was undertaken to elucidate a mechanism or mechanisms by which triethyl citrate acts at the subcellular level to inhibit cell growth. The approach taken was primarily based on the fact that dynamic and morphological changes induced by a toxicant in cellular and subcellular structures are directly related to biochemical changes which have occurred previous to the time of the noted change. Through the establishment of a sequence of events which lead to growth inhibition and possibly cell death, it was felt that the deduction of general biochemical changes which occur preceding these events might be possible and a mechanism of action obtained.

In normal cellular functions and activities,

Received April 14, 1967, from the Drug-Plastic Research and Toxicology Laboratory, College of Pharmacy, University of Texas, Austin, TX 78712

Accepted for publication October 5, 1967.

Presented to the Pharmacology and Biochemistry Section, APhA Academy of Pharmaceutical Sciences, Las Vegas meeting, April 1967.

This research was supported in part by grant CA-06120 from the National Institutes of Health, U. S. Public Health Service, Bethesda, Md. and contract PH43-64-557 from the Division of Biologics Standards, National Institutes of Health, U. S. Public Health Service, Bethesda, Md.

the cell maintains a high degree of integrity. This maintenance is part of a dynamic system and requires a continuous source of energy. The subcellular organelle, the mitochondrion, supplies this energy in the form of adenosine triphosphate (ATP), which it manufactures through a series of metabolic reactions. Since the mitochondria are responsible for maintaining the energy system of the cell, any interference or inhibition of their functions would result in a significant effect upon cellular activity and should be manifested in altered cellular morphology (7).

The mitochondria have been shown to be quite sensitive to unfavorable conditions for cell life (8) yet at times quite resistant (9). However, other cellular organelles and cellular substructures such as the nucleus, plasma membrane, nuclear membrane, *etc.*, play a key role in maintaining the cellular integrity, and their responses to a toxicant should be evaluated in the interpretation of any of the biochemical reactions which occurred preceding the noted morphological change.

In order to obtain these data, the system of choice was the phase contrast microscope since it enabled observations to be made on the living cell. Their morphological alterations were noted under the influence of triethyl citrate administration and recorded with aid of time-lapse cinematography.

MATERIALS AND METHODS

Mouse fibroblast cells (Earle's NCTC929), a typical mixture of cell types maintained in static culture in this laboratory, were used exclusively. The cell line was last cloned in 1963 and has undergone an unknown number of passages since that time. The cells were cultured in Eagle's basal medium (10) plus 4.0 ml. of calf serum, 1.0 ml. of a 200 mM solution of L-glutamine, and 5.0 mg. of streptomycin/100 ml. of growth medium in a 5% CO_2–air atmosphere maintained at 35°. Routine subcultures were made every 4 days using a 0.05% trypsin solution.

Sykes-Moore tissue culture chambers (Belco Glass, Inc.), fitted with 2.5-mm. working distance rubber "O"-rings, were used for all microscopic work. Upon the preparation of the culture chambers at the time of subculturing, a cell suspension of approximately 10^4 cells per ml. was added to the chambers using the procedures of Sykes and Moore (11). After the chambers were filled with the cell suspension, they were placed right side up in an incubator at 35° and allowed to remain in that position for 12 hr. to allow the cells to settle to the bottom and attach to the lower coverslip.

Time-lapse experiments were begun 24 to 36 hr. after the chambers were filled. The purpose of this lapse in time after filling was to insure that the cells had recovered from any of the trauma induced by trypsinization during the subculturing procedures.

Prior to infusion of the test chemicals, study cells were observed by photography for a minimum of 30 min. for normal activity, thus serving as an internal control. Repeated media change induced no cellular alterations during control periods of study.

Concentrations of the triethyl citrate (Chas. Pfizer and Co., Inc.) used were determined by weighing the ester and dissolving it in the required amount of growth medium. The concentrations used in this study were 7.9 mM, 9 mM, 12 mM, 24 mM, and 48 mM and were prepared immediately before use. Approximately 6 mM and 12 mM represent the ID_{50} and the ID_{100} for the 72-hr. cultures previously reported (1). The introduction of the medium plus chemical was accomplished by perfusing the chamber with exactly 1.0 ml. of medium containing the drug. This resulted in a concentration in the chamber of 0.65 times the concentration of the perfusion medium (11, 12). Prior to infusion, all fluids were prewarmed to 35° and the pH of the medium was adjusted by aeration with an air mixture containing 5% carbon dioxide. In this communication, all concentrations indicated are those of the medium in the chamber and not the perfusion medium. It should also be noted that all procedures discussed to this point were conducted using aseptic techniques.

For observation, the chambers were placed on the stage of a Nikon model M inverted phase-contrast microscope housed in an electric incubator maintained at 35°. The illuminator was a low voltage lamp (6 v., 15 w.) equipped with both a green filter and a heat reflecting filter. A 100× oil immersion phase-contrast objective was chiefly used. The time-lapse equipment consisted of a Bolex SH 44 16 mm. movie camera with Nikon's connecting hardware and a time control panel with camera drive mechanism (R. J. Matthias and Associates). Other photomicrographic equipment consisted of a Nikormat FS 35 mm. camera with Nikon adaptor connections.

The individual cells for time-lapse observations were selected by scanning the culture for a cell undergoing mitosis, then waiting 8 hr. after anaphase before the administration of the triethyl citrate. At this time, all cells were well into interphase and had taken on their normal interphase characteristics and certain subcellular structures were readily visible. After the administration of the triethyl citrate, the cells were observed for 4 hr. with exposures taken every 3.6 sec.

Kodak 16 mm. Tri-X reversal movie film and Kodak 35 mm. Plus-X panatomic film were used exclusively. The processed movie film and prints from the 35 mm. film were analyzed for morphological alterations. The movie film was analyzed not only at normal projection speeds which accelerated movements in the cells by about 70× but also through the use of a single frame projection editor made in the laboratory. Replicate experiments were conducted at each dose level.

RESULTS AND DISCUSSION

The normal L-cell during interphase (Fig. 1) in a static culture is firmly attached to the glass surface of the container in which it is growing. It may be found in one of many configurations, ranging from almost circular to greatly elongated, such that its length may be 8 to 10 times its width.

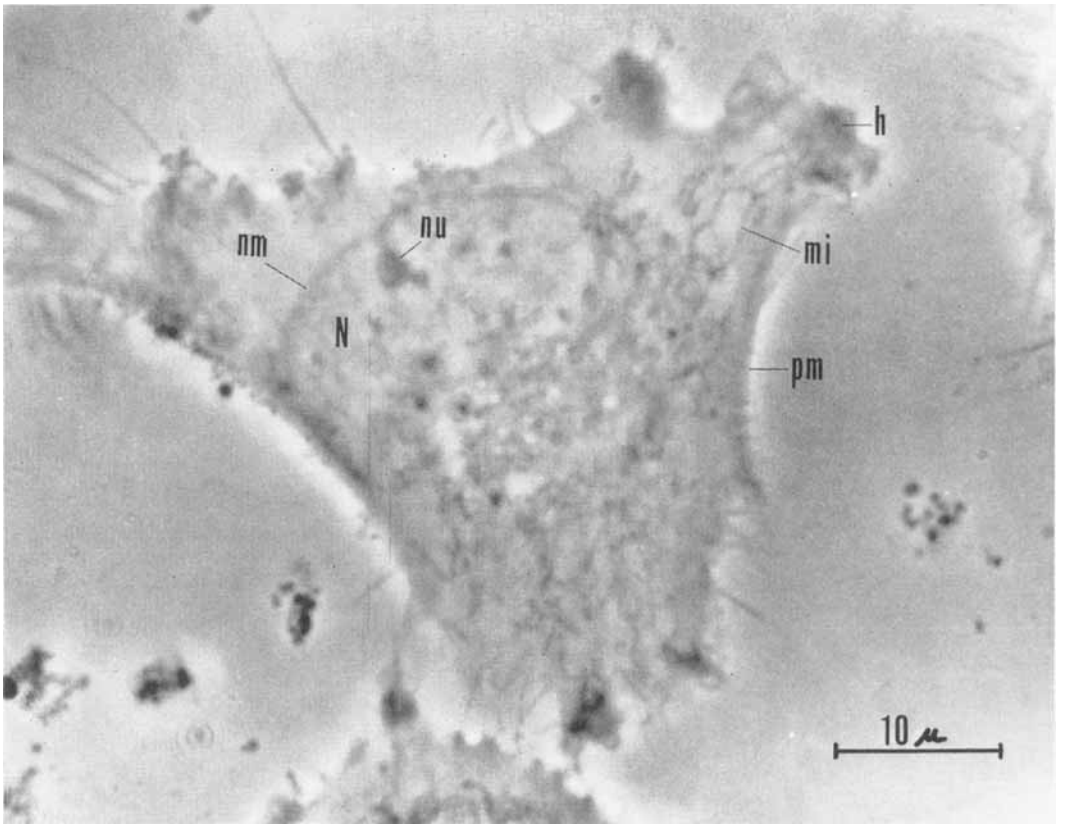

Fig. 1—Normal interphase cell illustrating the nucleus (N), *nuclear membrane* (nm), *nucleolus* (nu), *plasma membrane* (pm), *mitochondria* (mi), *and hyaloplasmic zone* (h).

Control experiments showed that in general, the cells appeared somewhat elongated (Fig. 1), such that the length was two to three times the width. The plasma membrane, which is responsible for the maintenance of concentration gradients between the cytoplasm and the exterior medium appears very irregular with many filament-like extensions. These are actual extensions of the membrane and are filled with cytoplasm. On time-lapse photography, these zones of the plasma membrane show very little movement.

Active areas of movement were seen in zones of the plasma membrane where the membrane had extended beyond the points of attachment to the glass. The entire zone, known as the hyaloplasmic zone, is noted to undergo wavelike motions when the cine records are observed. This hyaloplasmic zone is generally associated with pinocytosis and quite frequently, a small vesicle arising from pinocytosis is seen in the adjacent cytoplasm.

The normal cytoplasm is filled with small particulate material, most of which is distinguishable only as ground substance due to the limit of resolution of the light microscope. This ground substance is more concentrated in the perinuclear area with the peripheral cytoplasm being relatively free of visible particulate matter. However, among this ground substance, one major subcellular structure, the mitochondria, is readily discernible. The mitochondria generally take on long rod-shaped configurations which are especially identifiable in the peripheral cytoplasm. Other than vesicles, these mitochondria are generally the only subcellular structure which are readily identifiable in the hyaloplasmic zones.

Located near the middle of the cytoplasm, the nucleus of the normal 8-hr. cell was readily visible. It generally has a kidney-shaped cross section, the indentation being due to the presence of the rigidly fixed centrioles in the cytoplasm. The membrane boundary of the nucleus was sharply outlined with smoothly curving contours. The nucleoplasm appeared homogeneous at magnifications used in this study with one to five nucleoli spread throughout it. The nucleoli appeared as darker condensed masses with fairly well-defined peripheries.

Control experiments revealed the following additional facts about the normal cell from 8 to 12 hr. after anaphase. As has been previously indicated, in the 4-hr. observation period, there is little movement of the plasma membrane, except for the wavelike movements in the hyaloplasmic zones. The vesicles arising in these areas migrated toward the center of the cell and during the migration increased in absorbance while they decreased in size. As they joined the ground substance in the perinuclear zone, they became indistinguishable.

The mitochondria in the peripheral areas of the cytoplasma undergo active movements. These movements appeared to be associated with the localized movements of the cytoplasm. The ground substance in the perinuclear zone was observed to

migrate both in and out of the area as there is a constant transfer of material to the various locales within the cell.

The nucleus retained its general orientation with the rest of the cell. However, with time it often rotates about the centrioles. This rotation may or may not occur, since in some controls it rotated and in others it did not. When rotations did occur, the maximum angle of rotation was observed to be about 30°.

When a normal healthy cell was exposed to a medium change while under observation, there was no change in the morphological characteristics previously mentioned. However, when various concentrations of triethyl citrate were present in the infusion medium, the following responses of the individual subcellular units were noted.

Plasma Membrane—In early response to the toxicant, the plasma membrane retracted as indicated by the disappearance of the hyaloplasmic zones (Fig. 2, *A* and *B*). At all dose levels this response was observable. The onset times ranged from 2 to 3 min. at the lower concentrations to a matter of seconds at the higher doses. The initial contraction was followed by a general contraction of the plasma membrane with a decrease in cross-sectional area of the cell and an accompanying decrease in surface area of the plasma membrane. This general contraction was a gradual process as indicated by the changes in cross-sectional area of the cell as illustrated in Fig. 2, *C* and *D*. The general retraction of the plasma membrane was observable on the cine records within 15 min. at all dose levels except 7.9 m*M*. In this cine record, membrane activity appeared normal until 3 hr. after dosing. At this time, slight retraction was noticeable.

At doses of 24 m*M* and 48 m*M* the general retraction of the membrane appeared to be continuous with the retraction of the hyaloplasmic zones. Also at the 48-m*M* dose level, the retraction was followed by the appearance of superficial vacuoles (Fig. 3) at 2 hr. Lysis of the cell followed within a few minutes. Cultures at other dose levels were not observed continuously until death. However, the 12-m*M* and 24-m*M* cultures were dead within 24 hr. Their mode of death also appeared to be lysis with the superficial vacuoles still present.

Cytoplasm—As indicated above, the ground substance and the particulate matter in the cytoplasm moved about in definite patterns in the normally functioning cell. In general, triethyl citrate caused a slowing of movements of the particles through the cytoplasm. This phenomenon, called cytoplasmic gelation was seen in the cine records at higher dose levels, but appeared to be dose dependent. The onset of gelation occurs simultaneously with the general retraction of the plasma membrane. At dose levels of 9 m*M* and 12 m*M*, the gelation appeared to start from the peripheral portions of the cell and migrate toward the nucleus. At the higher concentration levels, the onset was so rapid that such a migration was not observable. Total cessation of movement was observed only at the 48-m*M* level. Immediately prior to lysis, all cellular movements ceased. Also only at this dose level did the movements of the ground substance ever appear to be inhibited in the region of the centrioles and Golgi complex.

Appearance of Dense Granules in the Cytoplasm—At all dose levels with the exception of 48 m*M*, within 20 to 30 min. after the infusion of the medium containing the drug, small dark spheres of 0.5 to 1 μ in diameter appeared in the cytoplasm (Fig. 2, *C* and *D*). At the higher dose level, lysis occurred so rapidly that this response was apparently not observed. Associated with the appearance of these spherical granules was the disappearance of the rod-shaped mitochondria. Examination of the cine records revealed that the spherical granules appeared to arise from the mitochondria. Thus these dense particles are apparently swollen mitochondria. Their appearance in different areas of the cytoplasm followed no set pattern, nor was it a totally dose-related phenomenon. However, it was uncommon to see them in the region of the centriole, the area least affected by gelation. They were generally confined to other portions of the cytoplasm.

Nucleus—The nucleus appeared to be unaffected during the period of observation at dose levels below 12 m*M*. However, at this dose and at 24 m*M*, the nuclear membrane did appear to increase in optical density as if some materials were being deposited on or in it. This nuclear involvement occurred at 3.5 hr. and 3 hr., respectively. The same response was noted at the 48-m*M* dose level at 1.5 hr. Associated with this response, the nuclear membrane lost its smooth contour and became very irregular with a scalloped configuration. However, at 48 m*M*, there followed a constriction of the nucleus with an increase in the optical density of the nuclear membrane and a decrease in the optical density of the nucleoplasm. The nucleoli also increased in their optical density (Fig. 3). Upon lysis of the cell, the nucleus remained in this fixed configuration. The same fixed nuclear morphology was noted in the lysed cells dosed at 12 m*M* and 24 m*M* which were discussed above.

DISCUSSION

In the light of the previously described results, it is concluded that there are at least two possible mechanisms of action by which triethyl citrate inhibits cell growth and results in cell death. At the lower dose levels, where growth inhibition has been noted (1), triethyl citrate acts specifically on the mitochondria, eventually resulting in a decrease in the production of ATP, and thus a decrease in the growth rate of the cultures. As the dose level was increased to 12 m*M*, another mechanism probably comes into play which at higher concentrations (48 m*M*) completely masks any mitochondrial involvement. In such situations, the triethyl citrate precipitated the soluble proteinaceous materials in the cytoplasm resulting in osmotic changes and cell lysis.

If the toxicant is to act intracellularly, it must cross the plasma membrane by one of several mechanisms. Different mechanisms by which a compound may enter the cell are pinocytosis, phagocytosis, active transport across the membrane, and simple diffusion across the membrane. Triethyl citrate does cross the cell membrane and acts intracellularly as evidenced by the various morphological alterations noted. The exact mechanism of the penetration was of course not determined in this study but it was concluded that the

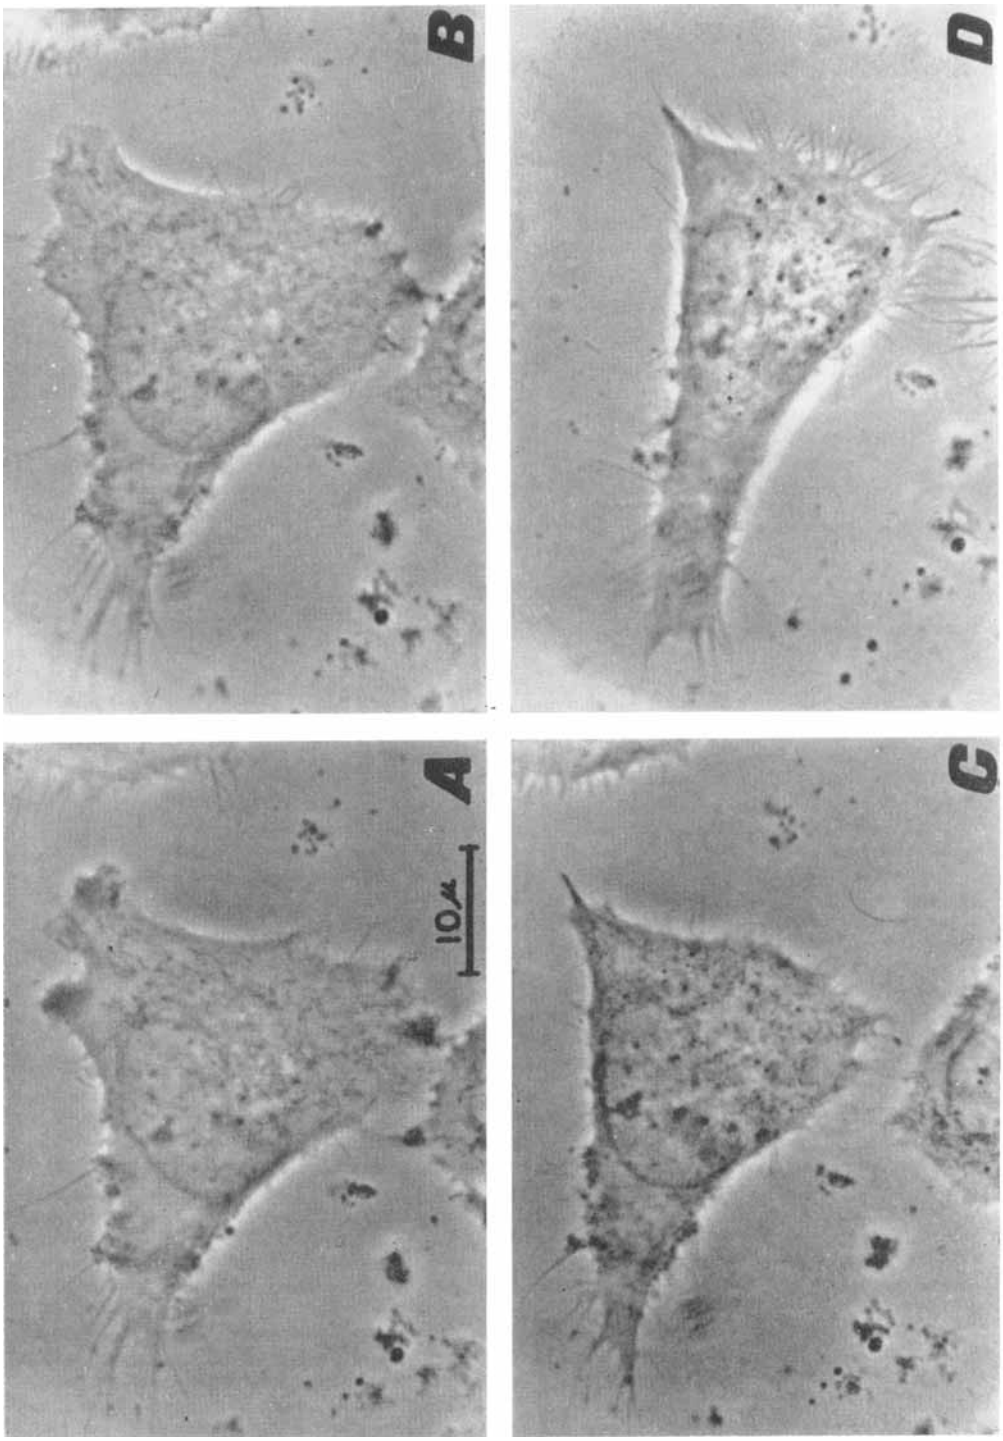

Fig. 2—Responses of a cell when dosed with a 16-mM solution of triethyl citrate. Key: A, prior to dose; B, 2 min. after dose; C, 1 hr. after dose; D, 5 hr. after dose. (See text for discussion.)

compound crossed by simple diffusion or active transport, since under the experimental conditions used with the mouse fibroblast cells, only an occasional pinocytotic vesicle appeared and no phagocytosis was observed.

The primary result of the intracellular activity of triethyl citrate at the lower concentrations (7.9 m*M* and 9 m*M*) was eventual mitochondrial swelling, since this reponse was observed well before any other responses. Similar morphological alterations in mitochondria have been noted by other workers. Biesele (8) observed this phenomenon in the treatment of embryonic mouse skin fibroblasts and mouse sarcoma 180 with 6-mercaptopurine, and Chevremont *et al.*, (13), noted it with trihydroxy-*N*-methylindole when treating primary embryonic chick

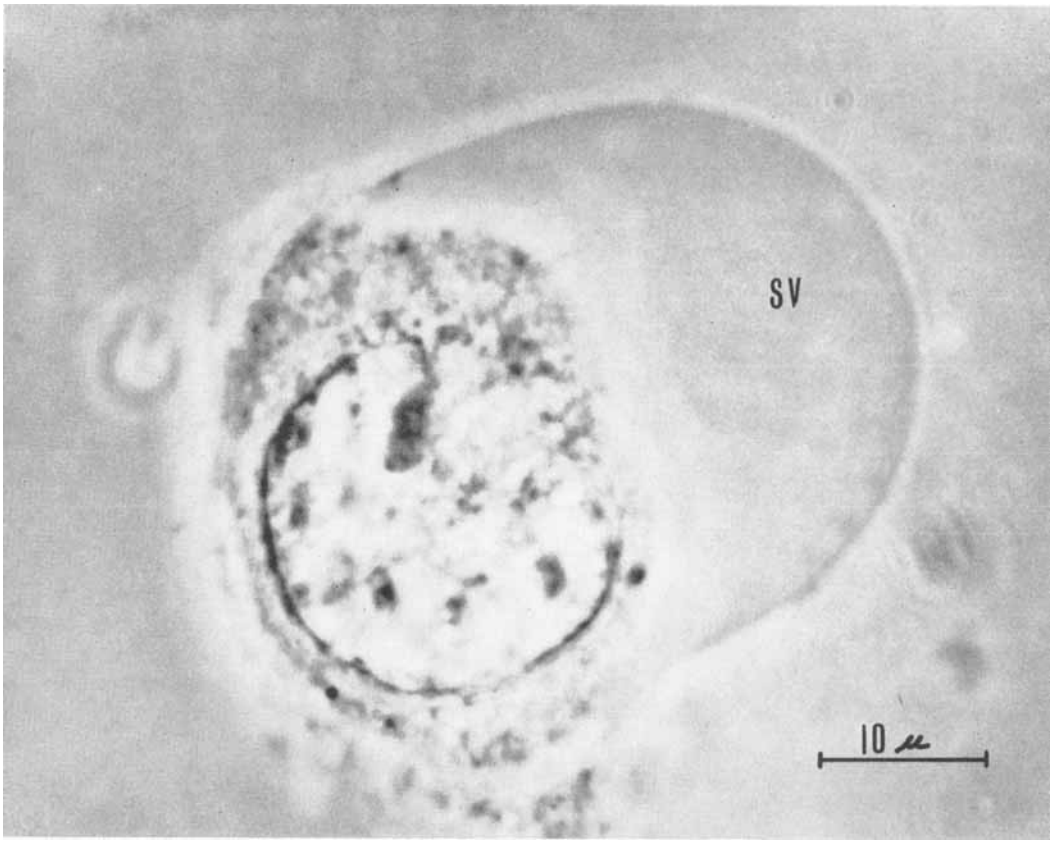

Fig. 3—Cell prior to lysis. Note superficial vacoule (sv), *rounded configuration, irregular nuclear membrane, and condensed nucleoli.*

muscle cultures. As Biesele indicated, mitochondria are notoriously sensitive to unfavorable conditions of cell life and the specificity of any morphological change in them is therefore open to question when this parameter is considered alone.

In studies with L-cells, Danes and Struthers (14), demonstrated that an iron–dextran complex interfered with the respiratory system (the mitochondria) of the cell and with only a slightly reduced respiratory activity, there was a greatly reduced growth. In similar studies with L-cells, Golaz (15) has demonstrated a decrease in the ATP production with 9m*M* and 12m*M* concentrations of triethyl citrate. These decreases were noted after 1.5 hr. of treatment.

Since ATP is produced in the mitochondria and observation of cytological changes showed mitochondrial swelling, it is concluded that this organelle is a specific point of attack for the triethyl citrate. As indicated above, only a slight depression in the respiratory system is necessary for growth inhibition. Thus, it is believed that triethyl citrate causes mitochondrial swelling and interferes with ATP production and respiration of the cell, whereby growth inhibition results.

On the other hand, at dose levels above 12 m*M*, additional response noted cannot be attributed to mitochondrial involvement. As has been indicated, plasma membrane contraction and cytoplasmic gelation are apparent at these dose levels prior to mitochondrial swelling. It is well known that many compounds of a chemical nature are capable of precipitating proteins. Pure triethyl citrate, when added to calf serum, causes an immediate precipitation of serum proteins. However, in concentrations used in the growth medium, no noticeable precipitation was noted. This points to a possible complexation of triethyl citrate with proteins in the cell, resulting in the observed progressive gelation. With high concentrations in the medium, the triethyl citrate rapidly penetrated the cell membrane. In doing so, some complexation with membrane lipoprotein could occur, but the data did not demonstrate this, since the membrane itself is well below the resolution of the phase-contrast microscope.

As the triethyl citrate entered the cytoplasm, and increased in concentration in this phase, there was an apparent interaction with the proteinaceous material there. Specifically, there appeared to be some interaction with the actin-myosin-like proteins in the cytoplasm which, among other things, are associated with the movements of the cytoplasm throughout the cell (16). Such an interaction would account for the rapid cessation of movements in the hyaloplasmic zones. Further interactions would account for the contraction of the membrane and the cessation of movements in other areas of the cytoplasm. In addition to the actin-myosin-like proteins, other cytoplasmic proteins may also be affected and thereby play a role in membrane contraction and the gelation phenomenon.

The decrease in the optical density of the nucleoplasm along with the condensation of the nucleoli and the contraction of the nuclear membrane probably follows this same nonspecific mechanism.

Occurring simultaneously with the nuclear contraction was the appearance of the superficial vacuoles followed by cell lysis. This response, however, was not related to the nuclear involvement but probably due to the complete gelation which was present. With such a gelation along with mitochondrial suppression the active transport system of the membrane was unable to obtain the required ATP necessary for maintaining concentration gradients necessary for normal cell function. The fact that gelation occurred rapidly at the higher dose levels also accounted for the lack of ATP for the membrane since the ATP could not be transported to the membrane through the gel matrix. Thus, the sodium ion diffused across the energyless membrane and obligatory water entered the cell resulting in the appearance of the superficial vacuoles with eventual lysis.

Bessis (17) observed similar sequential events which resulted in cell death and as he and other authors (18, 19) have pointed out, these sequential events can be a great aid in deciding where to look for supportive biochemical data.

SUMMARY

The role of triethyl citrate in growth inhibition of mammalian cells in culture has been studied by the use of phase-contrast microscopy with the following major findings.

(*a*) At dose levels below 12 m*M*, the mitochondria of the cell are initially inhibited in their functions resulting in the growth inhibition of the cell.

(*b*) At dose levels above 12 m*M*, a second mechanism masks the mitochondrial involvement. The cytological picture is characterized by cytoplasmic gelation, plasma membrane contraction, and eventual lysis of the cell. The mechanism proposed was protein denaturation, but further studies are necessary for its definition.

(*c*) Phase-contrast time-lapse cinematography is a valuable tool for determining sequential events occurring in the morphological patterns of living cells under the influence of toxic agents. When coupled with biochemical procedures, it offers a workable technique for the interpretation of mechanisms of action of toxicants, and should play a key role in bridging the gap between *in vitro* and *in vivo* systems.

Synthetic Porphyrins II

Preparation and Spectra of Some Metal Chelates of *para*-Substituted-*meso*-Tetraphenylporphines

By NIRMALENDU DATTA-GUPTA and THOMAS J. BARDOS*

Various new metalloporphyrins, including both Fe(II) and Fe(III), Co(II), and Co(III) complexes of *p*-substituted-tetraphenylporphines, were synthesized for use as possible model compounds in the study of the mechanisms of the oxidation-reduction of the heme-enzymes and cobalamines. Characteristic differences were observed in the near-ultraviolet, visible, and infrared spectra of the complexes of different metal ions. These compounds may also be of interest as specific radiation sensitizing or protecting agents.

THE IMPORTANT biological roles of metalloporphyrins (heme, chlorophyll) and of the structurally related metallocorrins (vitamin B_{12}) suggested that the appropriate metal chelates of certain synthetic *para*-substituted-*meso*-tetraphenylporphine derivatives (1) may serve as antimetabolites, or as model compounds in the study of the modes of action of these interesting natural substances. In addition, such compounds would be expected to be effective in absorbing radiation energy at certain wavelengths and may serve either as radiation sensitizing or as radiation protecting agents (2). It is of particular interest that some porphyrin derivatives apparently show selective distribution properties in the various tissues. Hematoporphyrin was reported to accumulate selectively in tumors and other rapidly growing tissues (3–5) and was used as a fluorescent indicator for the delineation of neoplastic tissue in cancer patients (6). It would seem, therefore, that certain metalloporphyrins may be used as tumor-selective radiation sensitizers or "carriers" of various cytotoxic groups and/or metals [*e.g.*, Hg (7) or ^{57}Co (8)] in the chemotherapy of neoplastic diseases.

Recently, Winkelman and co-workers reported (8, 9) that a sulfonated derivative of *meso*-tetraphenylporphine was even more selectively localized (attaining a 50–100 times higher concentration in the tumor tissues) than hematoporphyrin, but that the ^{57}Co chelate of this sulfonated compound lost its metal and only the free ligand was absorbed. This is in contrast with the reported stabilities of various injected Zn (3), Hg (7), and ^{64}Cu (10) porphyrins throughout their organ-uptake and/or excretion and is, of course, also in contradiction with the known stability of the Co-corrin derivative, vitamin B_{12}. Thus, the fate of the chelated metal during the absorption and localization of the metalloporphyrins in the tissues requires further investigation.

In the present paper, the synthesis and physicochemical properties of various metal chelates of the recently reported (1) *para*-substituted-*meso*-tetraphenylporphines are described. Due to the interest in obtaining model compounds for the study of the mechanisms of oxidation-reduction of the various heme-enzymes as well as of the cobalt in the various cobalamincoenzyme mediated reactions, particular efforts were centered on the synthesis of metalloporphyrins containing Fe and Co, respectively, at various oxidation states. The structures and chemical names of the new metalloporphyrins described in this paper are shown in Table I.

RESULTS AND DISCUSSION

The metalloporphyrins (I to VII) were synthesized by refluxing the ligand (1) and the metal salt in a suitable solvent (see under *Experimental*). Progress of the reactions was followed by observing the changes in the visible spectra of the reaction mixtures. The reactions were stopped when complete disappearance of the characteristic visible absorption maxima of the ligands occurred. The choice of solvent, due to solubility problems, was limited to pyridine, glacial acetic acid, and 88% formic acid. The suitable solvent for each preparation could be found only by carrying out small-scale reactions. The choice of metal salts was limited to the readily available chlorides or acetates. The ferrous complex (compound IV) was prepared and purified under nitrogen atmosphere, since the Fe(II) rapidly oxidized to Fe(III).

Compound VIII was prepared by two alternative methods, that is, either by direct chelation of the corresponding ligand, *meso*-tetra-(*p*-carboxyphenyl)-porphine, or by alkaline hydrolysis of *meso*-tetra-(*p*-carbomethoxyphenyl)porphinocobalt(II) (compound VII). The latter compound (VII) was solu-

TABLE I—STRUCTURES AND CHEMICAL NAMES OF NEW SYNTHETIC METALLOPORPHYRINS

	R	M	Name
I	CH_3	Co(II)	*meso*-Tetra-*p*-tolylporphinocobalt(II)
II	CH_3	Cu(II)	*meso*-Tetra-*p*-tolylporphinocopper(II)
III	CH_3	Zn(II)	*meso*-Tetra-*p*-tolylporphinozinc(II)
IV	CH_3	Fe(II)	*meso*-Tetra-*p*-tolylporphinoiron(II)
V	CH_3	Cl-Fe(III)	*meso*-Tetra-*p*-tolylporphinoiron(III) chloride
VI	CN	Cl-Fe(III)	*meso*-Tetra-(*p*-cyanophenyl)porphinoiron(III) chloride
VII	CO_2CH_3	Co(II)	*meso*-Tetra-(*p*-carbomethoxyphenyl)porphinocobalt(II)
VIII	COOH	Co(II)	*meso*-Tetra-(*p*-carboxyphenyl)porphinocobalt(II)
IX	CH_2OH	Co(II)	*meso*-Tetra-(*p*-hydroxymethylphenyl)porphinocobalt(II)
X	CH_3	Br-Co(III)	*meso*-Tetra-*p*-tolylporphinocobalt(III) bromide

ble in dry tetrahydrofuran and was also used as the starting material for the synthesis of *meso*-tetra-(*p*-hydroxymethylphenyl)porphinocobalt(II) (compound IX). Before attempting to reduce VII with lithium aluminum hydride, *meso*-tetra-*p*-tolylporphinocobalt(II) (compound I), as a model compound, was treated with lithium aluminum hydride in dry tetrahydrofuran solution in order to determine whether the solubility of the cobalt complex and the chelation or the oxidation state of cobalt(II) would be affected by a reaction with the reagent. Only the unchanged starting material (I) was isolated; thus lithium aluminum hydride did not seem to have any effect on the chelated Co(II) ion. However, it is quite possible that the divalent cobalt in I was reduced by lithium aluminum hydride to monovalent cobalt but the latter was rapidly reoxidized to divalent cobalt during work-up (11). Thus, reduction of VII with lithium aluminum hydride gave the Co(II) chelate of the hydroxymethyl derivative (IX) in 79.3% yield.

Meso-tetra-*p*-tolylporphinobromocobalt(III) (compound X) was prepared from I in a manner analogous to the synthesis of the corresponding derivative of aetioporphyrin (I) by Johnson and Kay (12). Attempts were also made according to the procedure of the same authors (12) to synthesize *meso*-tetra-*p*-tolylporphindicyanocobaltate. The product obtained contained theoretical amount of cyanide radicals, nitrogen and hydrogen, but the analytic results for C, Co, and K were unsatisfactory. The material was stable in alcohol but slowly decomposed in chlorinated solvents. Further work on the nature of the *meso*-tetra-*p*-tolylporphindicyanocobaltate is in progress.

The near-ultraviolet and visible spectra of the metal complexes of tetraphenylporphines are characterized by a strong "Soret band," in the 400–440 mμ region, and by another strong absorption band ("K-band") in the visible spectral region; the latter is usually accompanied by much weaker vibrational bands ("R-bands") (13). Thus, these metalloporphyrins differ from the corresponding "free base" *meso*-tetraphenylporphines by the absence of the characteristic five-banded patterns in the visible spectra of the latter (1), and also from other metalloporphyrins (*e.g.*, etio-type) which generally show a different, two-banded (α and β-bands) pattern in their visible spectral region (14).

The absorption maxima of the new metalloporphyrins are shown in Table II. Molar extinction coefficients of all, except III, VI, and VIII, have been calculated in two different solvents. Compounds III and VIII could be quantitatively dissolved only in pyridine and 5% aqueous sodium carbonate, respectively, whereas compound VI could not be quantitatively dissolved in any solvent. It is apparent from Table II that a change of the solvent from benzene (or chloroform) to pyridine, results in certain changes in the positions or intensities (or both) of the absorption bands; these changes vary in magnitude from one metal chelate to another. In either solvent, the spectra show characteristically different patterns dependent on the chelated metal ion; different *p*-phenyl substituents in the ligands have relatively small influence on the spectral patterns of the metal chelates. The Soret bands of all metal chelates, with the exception of Cu^{II} and Zn^{II}, are significantly less intense than those of the corresponding free base porphyrins

TABLE II—NEAR ULTRAVIOLET AND VISIBLE ABSORPTION SPECTRA OF NEW METALLOPORPHYRINS

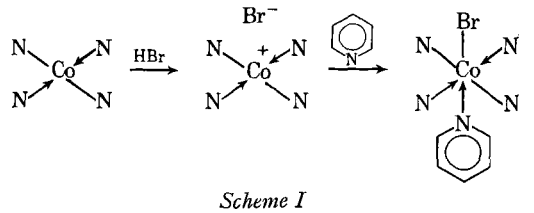
(1). The number of the visible absorption bands of the metal chelates vary between one (Co^{II}) and five (Fe^{III}).

The spectrum of the Co(III) complex (X) very markedly differs from those of the Co(II) chelates in pyridine solution, but the difference is less pronounced when the spectra are compared in benzene. The more significant difference in the spectrum of X in pyridine is probably due to the extra ligand action of a molecule of pyridine with the trivalent cobalt. The spectrum of X in pyridine may correspond to that of an octahedral pyrimidinobromocobalt(III) complex, as proposed by Johnson and Kay (12) (Scheme I).

The spectra of the Fe(II) complex (IV) in benzene and pyridine are similar to each other, except for the position of the Soret band. The intensity of this band is remarkably low in both solvents. No other Fe(II) complex of a *meso*-tetraphenylporphine has been reported previously. The spectra of the corresponding Fe(III) complex(V) in either benzene or pyridine, are quite different from those of the Fe(II) complex. Although the spectra of V in the two solvents considerably differ from each other, their



Scheme I

composite pattern shows remarkable similarity to the spectrum of the free base porphyrin (1) in the positions of the absorption bands. However, the intensity of the Soret band of V is extremely low (particularly, in the benzene spectrum), just as in the case of the Fe(II) complex (IV).

The infrared spectra of the new metalloporphyrins, obtained in potassium bromide phase, are shown in Table III. The weak N-H stretching vibrations above 3300 $cm.^{-1}$ observable in the spectra of all the ligands (1) having no hydroxyl group, are missing from the spectra of their chelates, due to the replacement of N-H protons by metal ions. Probably the most characteristic difference between the infrared spectra of a tetraphenylporphine ligand and its metal chelates is that the three bands appearing between 960–1000 $cm.^{-1}$ in the spectra of the former (1) collapse to one strong band near 1000 $cm.^{-1}$ in the spectra of the latter. This absorption band has been associated with a C-H vibration of the pyrrole rings. In a limited series of metalloporphyrins containing certain divalent cations, Thomas and Martell (15) were able to correlate the relative frequencies of this band with the relative stabilities of chelation. In the present series, the metal complexes of *meso*-tetra-*p*-tolylporphine, (I–V, and X) show the following relative order of frequencies for the "1000 $cm.^{-1}$ band": Co(II) > Fe(II), Fe(III) > Cu(II) > Zn(II) > Co(III). Except for the relative positions of the iron chelates, this series seems to agree with the stability order of metalloporphyrins as determined by various methods (16, 17).

[a] TPP = *meso*-tetraphenylporphine.

EXPERIMENTAL[1]

General Method of Synthesis by Insertion of Metal Ion—In general, the metalloporphyrins were prepared by refluxing the appropriate ligand (1) with 4–5 times excess of a metal salt and a solvent, for a certain length of time (until disappearance of the free base spectral bands) as given in Table IV. After evaporation of the solvent, the excess inorganic salt was removed by washing with water, and the reaction product, obtained in the residue in essentially quantitative yield, was recrystallized from a suitable solvent or solvent mixture (Table IV).

Alternative Method for the Preparation of VIII—The *meso*-tetra-(*p*-carboxyphenyl)porphinocobalt-

[1] Microanalyses were performed by Galbraith Laboratories, Inc., Knoxville, Tenn.

(II) was also synthesized by basic hydrolysis of *meso*-tetra-(*p*-carbomethoxyphenyl)porphinocobalt-(II) (VII). A mixture of VII, 3 Gm., 4% aqueous potassium hydroxide solution, 100 ml., and tetrahydrofuran, 500 ml., was refluxed for 24 hr. The solvents were removed *in vacuo*. The residue was dissolved in water and neutralized with 6 *N* sulfuric acid. The purple precipitate was centrifuged and repeatedly washed with water. The material was dried over anhydrous calcium chloride. Yield: 2.66 Gm. (94.5%). This product had identical spectra with that obtained by the insertion method.

Alternative Method for the Preparation of IX—A mixture of *meso*-tetra-(*p*-carbomethoxyphenyl)-porphinocobalt(II) (VII), 1.7 Gm., lithium aluminum hydride, 1.7 Gm., and tetrahydrofuran (freshly distilled over lithium aluminum hydride), 50 ml., was refluxed for 2 hr., then 1 additional Gm. of lithium aluminum hydride and 50 ml. of dry tetrahydrofuran were added to the reaction mixture. Refluxing was continued for 2 more hr., followed by decomposition of the unreacted lithium aluminum hydride by moist ether at 0°. The slurry thus obtained was filtered and washed with 150 ml. of tetrahydrofuran. On evaporation of the solvent, 1 Gm. of purple crystalline solid was obtained. An additional 0.16 Gm. of material was obtained by further washing of the aluminum hydroxide slurry with 100 ml. of tetrahydrofuran, followed by evaporation of the solvent. Total yield: 1.16 Gm. (79.3%).

Synthesis of Meso-tetra-p-tolylporphinocobalt (III)Bromide(X)—The *meso*-tetra-*p*-tolylporphinocobalt(II) (I), 300 mg., was dissolved in 50 ml. of chloroform, and to this was added 50 ml. of methanol and 1 ml. of 47.5% hydrobromic acid. The mixture was stirred at room temperature for 2 hr., and then 50 ml. of chloroform was added. The reaction mixture was washed with water, dried over anhydrous sodium sulfate, and evaporated to dryness. The residue was crystallized from a mixture of chloroform and petroleum ether (b.p. 40–60°). Yield: 300 mg. (90%). An analytical sample was obtained by recrystallization from the same solvent mixture and drying over phosphorus pentoxide at 100° for 8 hr.

Anal.—Calcd. for $C_{48}H_{36}BrCoN_4$: C, 71.38; H, 4.46; N, 6.94. Found: C, 71.29; H, 4.62; N, 6.73.

Spectral Measurements—The near ultraviolet and visible absorption spectra (Table II) were determined on Beckman DU (attached to a Gilford absorbance indicator, model 2000) and Beckman DB spectrophotometers. The infrared spectra (Table III) were determined on Perkin-Elmer model 137 and Beckman model IR-8 spectrophotometers.

Colorimetric Assay for Chloramphenicol Using 1-Naphthol

By DANIEL S. MASTERSON, JR.

Chloramphenicol heated in 6 *N* sodium hydroxide with 1-naphthol gives a blue color that is the basis for a quantitative assay method.

ASSAY METHODS for chloramphenicol are many and varied, but most of them have significant restrictions with respect to their applicability. Microbiological methods (1, 2) cannot be used for chloramphenicol palmitate, since the unhydrolyzed ester lacks antibacterial activity. Polarographic analysis is also not applicable to chloramphenicol palmitate because of unfavorable solubility characteristics (3). Reduction and diazotization methods (4, 5) give the same color response with numerous other compounds containing the aromatic nitro substituent and thus cannot specifically identify the reactant as chloramphenicol. In addition, the latter methods, dependent only on the nitrophenyl group of the molecule, will not reflect degradation involving other parts of the molecule. The ultraviolet spectrophotometric procedure (6) for the assay of chloramphenicol, its derivatives, and their many dosage forms, reflects the absorbance, irrespective of its origin, of the test solution at wavelengths from 271 to 278 mμ. Thus, the chloramphenicol ingredient must be separated from other components of its dosage forms, which can give erroneously high results. Also, the spectrophotometric procedure will not reflect degradative modifications not involving the nitrophenyl group.

In the course of his work on a colorimetric test for dihydrostreptomycin, Weiss (7) discovered that chloramphenicol, after acid and alkaline hydrolysis, produced a blue color with 1-naphthol in alkaline solution. This result proved to be unique among all the antibiotics then available. The present work was undertaken to establish the optimum conditions for the utilization of the reaction as an analytical procedure, and to check its specificity among various antibiotics and compounds structurally related to chloramphenicol.

The reduction, diazotization, and coupling method of Glazko (4) as modified by Levine and Fischbach (5), the ultraviolet spectrophotometric assay (6), and the microbiological assay (1, 2) were used as corroborative procedures. Further modification of the reduction-diazotization procedure was found to be of advantage, and the details of the method used are given below.

Received May 25, 1967, from the Division of Antibiotics and Insulin Certification, Bureau of Science, Food and Drug Administration, U. S. Department of Health, Education and Welfare, Washington, DC 20204

Accepted for publication September 11, 1967.

The author expresses his gratitude to Drs. Peter J. Weiss, William W. Wright, Daniel Banes, and Kenneth A. Freeman, and Mr. George Selzer, Food and Drug Administration, for their counsel during the course of this investigation.

The author acknowledges his debt to the Microbiological Branch, Division of Antibiotics and Insulin Certification, for the microbial assays, and to Parke, Davis and Co., Detroit, Mich., for providing compounds structurally related to chloramphenicol.

EXPERIMENTAL

Preparation of Chloramphenicol Samples

Chloramphenicol Powder—Accurately weigh approximately 50 mg. of the working standard or sample, transfer to a 250-ml. volumetric flask, dissolve in about 5 ml. of methanol, dilute to volume with water, and mix. For the analysis of chloramphenicol palmitate, dilute the standard to volume with chloroform instead of water.

Capsules—Place the contents of five 250-mg. capsules in a 250-ml. volumetric flask, swirl with approximately 25 ml. of methanol, bring to volume with water, and mix. Dilute this solution with water to an estimated concentration of 0.1 mg./ml.

Tablets—Grind five tablets to a fine powder. Accurately weigh approximately 60 mg. (equivalent to 50 mg. of chloramphenicol) and transfer to a 250-ml. volumetric flask. Add 10 ml. of methanol, swirl the mixture for several minutes, bring to volume with water, and mix.

Chloramphenicol Sodium Succinate Powder—Accurately weigh approximately 70 mg. (equivalent to 50 mg. of chloramphenicol), transfer to a 250-ml. volumetric flask, and dissolve in and bring to volume with water.

Chloramphenicol Palmitate Powder—Accurately weigh approximately 87 mg. (equivalent to 50 mg. of chloramphenicol), transfer to a 250-ml. volumetric flask, and dissolve in and bring to volume with chloroform.

Oral Suspension—Measure 1 ml. of suspension, using a syringe fitted with a 13-gauge needle, and place in a 125-ml. separator containing 25 ml. of chloroform. Shake the separator vigorously for

2–3 min., add 10 ml. of water, and shake vigorously for an additional 2–3-min. period. Allow the layers to separate and filter the chloroform layer through absorbent cotton one or more times until the filtrate is clear. Dilute an aliquot of filtrate with chloroform to a concentration of 0.2 mg. of chloramphenicol per ml.

1-Naphthol Method

Reagents—1-Naphthol, 2 mg./ml. in 6 *N* sodium hydroxide, prepared immediately before use by dissolving 1-naphthol in a small amount of methanol, adding 12 *N* sodium hydroxide and diluting 1:1 with water. Sodium hydroxide (12 *N*) prepared from a 50% solution.

Procedure—Into 100-ml. volumetric flasks place 4.0, 6.0, and 8.0 ml. of the standard solution and 6.0, 4.0, and 2.0 ml. of water to give a final volume of 10 ml. Use a flask containing 10 ml. of water as a blank.

Place 5.0 ml. of the 0.2 mg./ml. solutions of chloramphenicol or chloramphenicol sodium succinate into 100-ml. volumetric flasks and add 5.0 ml. of water.

In the case of capsules and aqueous injection, assay 10.0 ml. of solutions containing 0.1 mg./ml.

For chloramphenicol palmitate chloroform solutions, pipet 5.0 or 6.0 ml. into 100-ml. volumetric flasks and evaporate to dryness at room temperature, using a stream of air. Dissolve the residue in 1 ml. of methanol by careful swirling and then dilute with 10 ml. of water.

To each flask add 10 ml. of 12 *N* sodium hydroxide and 10 ml. of 1-naphthol solution. Swirl the flasks and place in a boiling water bath for 30 min.; then cool to room temperature within the next 5 min. in a tap water bath. Add methanol to volume and mix. After a color development period of 1 hr., measure the absorbance at 610 mμ against the reagent blank, using a suitable spectrophotometer.

Precision of the 1-Naphthol Method—A series of 75 absorbance *versus* concentration experiments, each involving from one to four concentrations, was performed and the 200 absorptivity (1 mg./ml., 1 cm.) values ranged from 24.1 to 40.4 (average 33.3), with 95% of them being between 30.0 and 37.3. The deviation of any absorptivity value from the average in those experiments with two or more samples was less than 3% for 158 of the 172 values determined. Because of the large variation in absorptivity values among different groups of two or more as opposed to the good precision obtained within groups, it was concluded that the absorptivity value of the standard should be determined each time samples are assayed. In addition, the absorptivity value obtained varied with different lots of 1-naphthol.

Effect of Changes in Conditions, Reagents, and Procedure—The blue color could not be extracted into chloroform from alkaline solution. However, when the solution was acidified and extracted with chloroform, and the chloroform extract shaken with fresh alkali, the color appeared in the alkaline phase.

When the blue solution was gradually neutralized, the blue color remained visible, though lessened, down to pH 9.6. From 9.6 to 9.1, it gradually disappeared, leaving a pink color. Addition of alkali restored the blue color.

It was found that 1-naphthol may be added to the reaction either before or after the heating step. Prior addition was found to be superior if aqueous solutions of chloramphenicol were employed, but subsequent addition was found to be advantageous when the chloramphenicol was dissolved in methanol, although the latter procedure was not sufficiently reproducible for quantitative applications.

The ability of 1-naphthol to produce the blue color decreased notably when this reagent was prepared in less concentrated (1 *N*) sodium hydroxide. When the heating was done in less concentrated alkali or the alkali was partially neutralized before dilution with methanol, the blue color was less stable, *i.e.*, the final color would be purple or bluish-pink. The same result occurred when in the final step the reaction mixture was diluted in water rather than methanol. When the solution was partially neutralized (pH 11 or 12) following hydrolysis, the blue color appeared more rapidly, but on standing it would not achieve the same final intensity and purity as when 6 *N* sodium hydroxide solution was used.

Low temperature (80–85°) reduced the reaction rate and was impractically slow, while high temperature (120–150°) experiments disclosed no apparent advantage.

In some experiments 10 ml. of water was added prior to dilution with methanol. This was done to eliminate carbonate precipitation which occurred occasionally after the addition of methanol.

Other alcohols, such as ethanol, 1-propanol, or isopropanol, either decreased the blue color (ethanol) or produced a green solution (propanol).

When dissolved in methanol, *p*-nitrobenzaldehyde reacted similarly to chloramphenicol, but when dissolved in water it produced a green color. Dichloroacetic acid, nitrobenzene, and benzaldehyde did not give a color.

2-Naphthol, 1,4-naphthoquinone, and 1-naphthol-3,6-disulfonic acid did not give a color response when substituted for 1-naphthol. When 1-naphthylamine and 1-hydroxy-2-naphthoic acid were substituted, the former gave a pink color of lower intensity and the latter gave an unstable blue color.

Mechanism of the 1-Naphthol Reaction—The determination of the chemical nature of the colored complex and of the products of the heating step was not deemed to be within the scope of this investigation. However, it is notable that *p*-nitrobenzaldehyde produces azoxy compounds (8) and chloramphenicol gives azo compounds (9) when heated in alkaline solution. A coupling reaction between 1-naphthol and azo compounds has been proposed (10). Further, the production of a blue color in concentrated sodium hydroxide by the reaction of 1-naphthol with *p*-nitrodiazobenzaldehyde has been used as a test for 1-naphthol in 2-naphthol (11).

A similar reaction, production of a blue color with thymol and chloramphenicol in alkali, is preceded by reduction of the chloramphenicol by means of aluminum wire (12).

Diazotization Method

Reagents—Five percent aqueous sodium nitrite, 5% aqueous sodium sulfamate, and 0.5% aqueous *N*-(1-naphthyl)ethylenediamine dihydrochloride solutions. Aqueous sodium hydrosulfite containing 25 mg./ml. prepared immediately before use.

Procedure—Into 100-ml. volumetric flasks pipet 1.0, 2.0, and 3.0 ml. of a 0.2 mg./ml. solution of

[a] Theoretical potency. [b] Not tested.

chloramphenicol standard, 2.0 ml. of 0.2 mg./ml. solutions of chloramphenicol powder, or the volume (1–3 ml.) equivalent to 0.4 mg. chloramphenicol of solutions prepared from other dosage forms as in the 1-naphthol method. Add 5.0 ml. of 0.1 *N* sodium hydroxide. (In the case of chloramphenicol palmitate, the chloroform solutions are evaporated to dryness, the residue is dissolved in 1 ml. of methanol, and 5.0 ml. of 0.1 *N* sodium hydroxide is added.) Place the flasks in a boiling water bath for 15 min., allow the flasks to cool to room temperature, and add 2 ml. of sodium hydrosulfite solution to each. Fifteen minutes later, add 1 ml. of sodium nitrite solution and 1 ml. of concentrated hydrochloric acid. After 3–5 min., add 2 ml. of sodium sulfamate. After another 3–5 min., during which the flasks are occasionally swirled vigorously, apply a stream of air to assure elimination of nitrous fumes. To each flask add 1 ml. of *N*-(1-naphthyl)ethylenediamine dihydrochloride solution, 25 ml. of methanol, and sufficient water to make 100 ml. After 2 hr. record the absorbance between 530 and 570 mμ. Peak absorption is observed at 553 ± 2 mμ.

RESULTS

Application of the 1-Naphthol Assay Method—Samples of chloramphenicol powder, capsules, tablets, and aqueous injection vials, chloramphenicol sodium succinate, and chloramphenicol palmitate powder and oral suspension were tested by the 1-naphthol colorimetric test and the ultraviolet spectrophotometric method, and in some cases by the reduction-diazotization procedure or the microbiological turbidimetric assay. As shown in Table I, results obtained by the 1-naphthol method compare favorably with the results of other procedures.

Tests on Degraded Material—Tests were run on a sample of chloramphenicol palmitate oral suspension which had been frozen in transit and thawed by heating. The suspension had a strong caramel odor and was dark brown (ordinarily suspensions have a pleasant flavory odor and are cream colored). As shown in Table II, there was good agreement between the 1-naphthol method and the reduction-diazotization procedure, while the ultraviolet spectrophotometric method gave considerably higher results. The former methods gave values for chloramphenicol content of a magnitude that would be reasonably expected and indicated the product was low in potency, while the latter method reflected excess nonspecific absorption due to the presence of degradation products.

TABLE II—ASSAY RESULTS ON DEGRADED CHLORAMPHENICOL PALMITATE ORAL SUSPENSION

Bottle	Extract	1-Naphthol[a]	Red.-Diaz.[a]	UV[a]
1	1	27.9	27.4	50.3
	2	27.9	27.1	56.0
2	1	24.0	26.9	41.6
	2	25.9	23.9	42.2
3	1	25.3	24.9	48.6
	2	25.0	23.7	48.4

[a] Milligrams chloramphenicol per ml. of suspension. Label claim 31.25 mg./ml.

Aqueous chloramphenicol standard solutions of various ages ranging up to 9 months were assayed by the various methods used above. The ultraviolet and reduction-diazotization methods indicated all solutions to be 100% potent. The microbiological and 1-naphthol assays reflected continuing loss of potency with age. However, the coincidence of the results produced by these two methods was only qualitative, not quantitative, in that the 1-naphthol assays did not show as much loss as the microbiological assays.

Specificity of the Methods—Several compounds structurally related to chloramphenicol were subjected to 1-naphthol, reduction-diazotization, ultraviolet, and microbiological assays. The results summarized in Table III reveal that all the chemical methods were insensitive to differences in structural configuration. The only other modifications to which the 1-naphthol method was insensitive were those involving the acyl group. The *m*-nitro analog of chloramphenicol did not give a blue color.

TABLE III—ASSAY OF CHLORAMPHENICOL AND STRUCTURALLY RELATED COMPOUNDS

D-Threo-1-*m*-nitrophenyl-2-dichloroacetamido-1,3-propanediol	Yellow	0	849	268	765	0	125

[a] Wavelength at which absorption maximum occurred. [b] In terms of mcg. of chloramphenicol equivalent potency per mg. [c] *S. lutea* (1). [d] *E. coli* (2).

1-*p*-Nitrophenyl-2-amino-1,3-propanediol gave 5.5 times the color response of *p*-nitro-α-acetamino-β-hydroxypropiophenone, while the reduction-diazotization and ultraviolet procedures yielded relatively little difference in response with these compounds. Otherwise, the only structural modification to which these methods responded was the loss of the nitrophenyl function. Some of the compounds structurally related to chloramphenicol possessed an antimicrobial activity ranging up to 12.5% of that of chloramphenicol.

SUMMARY

A new analytical method for chloramphenicol involves the reaction between 1-naphthol and the product of heating chloramphenicol in strong alkali. Certain advantages of specificity and applicability over present methods are obtained.

Modification of USP Vitamin D Assay to Remove Interference of Vitamin E

By MODEST OSADCA and ELMER DE RITTER

When tocopherol is incorporated in multivitamin products at the 10–30 mg. levels, corresponding to the daily adult requirement, serious interference is encountered in determining vitamin D by the USP method. A modification of the USP assay method is described in which the tocopherol is separated by column chromatography on secondary magnesium phosphate prior to the normal USP chromatographic purification steps. Proper conditioning and performance testing of the secondary magnesium phosphate are essential to assure good separation of tocopherol and quantitative recovery of vitamin D.

THE RECOGNITION of a daily adult requirement for tocopherol in the range of 10–30 mg. (1) has led to increased usage of vitamin E in multivitamin supplements. For example, the formulas for decavitamin capsules and tablets in the USP XVII (2) include a suitable form of α-tocopherol at a level equivalent to 15 mg. of *dl*-α-tocopheryl acetate per capsule or tablet. Vitamin D levels, on the other hand, have tended to be lowered in such products due to increased emphasis on the desirability of avoiding intakes of vitamin D in excess of the recommended daily allowance (1). As a result of these developments, the ratio of vitamin E to vitamin D in many products has increased markedly to the point where the vitamin E causes considerable overestimation of vitamin D by the USP assay method (2).

A modified vitamin D assay procedure has been developed in which tocopherol is removed from the solvent extract by column chromatography on secondary magnesium phosphate prior to the normal chromatographic purification steps in the USP method. The use of secondary magnesium phosphate for separations in the assay of vitamin E has been described by Bro-Rasmussen and Hjarde (3). Careful conditioning of the adsorbent and performance testing before use are of critical importance in the vitamin E assay and also in the vitamin D assay described below.

Mulder *et al.* (4) separated tocopherols from vitamin D by column chromatography on alkaline alumina prior to passage through the diatomaceous earth[1] and Fuller's earth[2] columns, but the oils tested contained slightly less than 1 mg. of α-tocopheryl acetate per 1,000 units of vitamin D. Multivitamin mixtures containing 10–30 mg. of vitamin E plus 400 units of vitamin D represent ratios of vitamin E to vitamin D about 25 to 75 times as great as those reported by Mulder *et al.* (4). In our experience with alkaline alumina, when quantitative recovery of vitamin D was obtained, the removal of these higher levels of vitamin E was not complete and significant interference was encountered in the vitamin D assay.

EXPERIMENTAL

Reagents and Apparatus—These are described in USP XVII (2) with the following additions.

Diethyl Ether—must be free of peroxides; Mallinckrodt's black label has been suitable.

Petroleum Ether—Merck reagent grade benzin, boiling range 30–65°; purify by passing through a silica gel column until no absorption is found at 300 mμ.

Secondary Magnesium Phosphate—The following products have been used successfully when conditioned as directed below.

(*a*) Magnesium phosphate, dibasic, pure, E. Merck A. G., Darmstadt, West Germany—distributed by Brinkmann Instruments, Inc., Westbury, L. I., N. Y. (*b*) Magnesium phosphate, C.P., dibasic—distributed by Amend Drug and Chemical Co., Inc., New York, N. Y.

Conditioning Procedure for Secondary Magnesium Phosphate—Dry about 250 Gm. for 4 hr. at 180° and cool over concentrated H_2SO_4. Boil the powder for 10 min. with 2 L. of a solution of 16 Gm. of secondary sodium phosphate (anhydrous, reagent grade) in H_2O. Cool slightly, filter through Whatman No. 1 paper on a Büchner funnel, and wash with about 1.5 L. of H_2O. Dry the secondary magnesium phosphate for 48 hr. at 180° and cool to room temperature over concentrated H_2SO_4. Grind in a mortar, screen through a 120-mesh sieve, and store in a tightly closed container. Prior to use, transfer a weighed amount of this material to a jar, add 7% H_2O, close jar, and shake thoroughly to break up all lumps and distribute the water. Store in a tightly closed jar. Let stand at least 2–3 hr. before use and do not keep for more than 2 days after adding the H_2O.

Preparation of Column—Plug the lower, constricted end of a 17–20 mm. i.d. chromatography tube about 25 cm. long with glass wool. With the stopcock closed, fill about two-thirds with petroleum ether. Add conditioned secondary magnesium phosphate portionwise, allowing it to flow slowly into the tube and settle without pressure or vacuum until a column height of 10–12 cm. is

Received April 25, 1967, from the Products Development Department, Hoffmann-La Roche, Inc., Nutley, NJ 07110
Accepted for publication September 28, 1967.

[1] Celite, Johns-Manville Corp., New York, N. Y.
[2] Florex, Floridin Co., Pittsburgh, Pa.

obtained. Drain off the petroleum ether until the solvent is about 3 mm. above the surface of the adsorbent.

Column Performance Check—Using a mixture of 75 mg. of α-tocopheryl acetate and 25,000 USP units of vitamin A as acetate or palmitate, obtain a sample preparation as described under *Procedure*. Transfer the 10 ml. of petroleum ether extract onto the prepared column and open the stopcock. Wash down with two 5-ml. aliquots of petroleum ether, being careful not to let the surface of the column run dry. Elute with a 6:94 (v/v) mixture of diethyl ether–petroleum ether until the vitamin A zone (seen as a green-yellow fluorescence with the aid of a long wavelength UV light) reaches the glass wool plug. This should require 35–60 ml. of eluant and all of the tocopherol which precedes vitamin A is then in the eluate receiver. Change the receiver and elute the vitamin A with a 3:7 (v/v) mixture of diethyl ether–petroleum ether. Vitamin A elution as observed with the UV light should be complete with about 50 ml. of eluant.

Check recovery of vitamin D from a second, similar column of secondary magnesium phosphate by adding 10 ml. of a petroleum ether solution containing 2,000 USP units of vitamin D and no vitamin A or vitamin E. Proceed with chromatography as described above, using the volume of 6:94 diethyl ether–petroleum ether mixture determined above to be necessary to bring the vitamin A down to the glass wool plug. Change the receiver and elute the vitamin D with 70 ml. of the 3:7 mixture of diethyl ether–petroleum ether. Evaporate this second eluate and measure the vitamin D colorimetrically as per USP XVII. Quantitative recovery of vitamin D should be obtained with this procedure.

When a new lot of secondary magnesium phosphate is received, a portion should be conditioned and checked for performance as described above. Drying times and moisture content of the adsorbent influence its activity. If the above conditions are not optimal for a particular lot of secondary magnesium phosphate, they may have to be modified until the above performance criteria are met. If vitamin A spreads all through the column and moves down too rapidly, the adsorbent is not sufficiently active. Longer drying or less water addition may then be needed. If the vitamin A does not move down or moves too slowly, addition of more water is indicated.

Procedure—Obtain a sample preparation as described on p. 892 of USP XVII except to add 50 mg. of hydroquinone instead of 2 ml. of cottonseed oil prior to saponification and to take up the residue after evaporation of the solvent hexane extract in 10 ml. of petroleum ether rather than solvent hexane. The vitamin D level in the original sample taken may be as low as 2,000 units. Transfer an aliquot of the petroleum ether extract containing 2,000–4,000 USP units of vitamin D onto the prepared secondary magnesium phosphate column. Open stopcock and allow solution to drain into column without pressure or suction. Do not let top of column run dry. Wash down with two 5-ml. portions of petroleum ether. Elute tocopherol with 6:94 mixture of diethyl ether–petroleum ether until the vitamin A zone reaches the glass wool plug. Change the receiver and elute vitamin D along with vitamin A with 70 ml. of a 3:7 mixture of diethyl ether–petroleum ether. Evaporate the eluate just to dryness under a stream of nitrogen with the flask immersed in a water bath at 40°. Dissolve the residue in 5 ml. of solvent hexane. Take a 2 or 4-ml. aliquot containing about 1,600 USP units of vitamin D for "first column chromatography" as described in USP XVII and continue to follow the USP procedure.

Table I—Comparison of USP and Modified USP Assays for Vitamin D in Presence of Vitamin E

(per 0.6 ml.[b])					
500	10	2,500			
		Initial	612	480	132
		2 mo. at 45°	654	450	204
		3 mo. at 45°	636	444	192

[a] Samples without vitamin D were treated as if they contained 400 USP units per specified quantity of vitamin E. [b] Vitamin D content represents the actual amount added in manufacturing; vitamin A and E values represent label claims.

Applications of Procedure—Both the USP XVII procedure for vitamin D assay and the present modified procedure have been applied to (*a*) samples of vitamin E only, (*b*) a laboratory mixture of vitamins A, D, and E, (*c*) multivitamin tablets and drops, the latter including samples aged at 45°. In all cases the equivalent of 2,000 USP units of vitamin D based on label claim was taken as the original sample and the entire 2,000 units taken for the first column chromatography in both procedures.

RESULTS

The results are summarized in Table I. When only vitamin E is carried through the USP vitamin D assay procedure, a significant amount of brown color is obtained and measured as vitamin D. The additional chromatography on secondary magnesium phosphate in the modified procedure reduces this nonspecific blank to a very low level. In the model mixture of vitamins A, D, and E, the USP method overestimated the 400 units of vitamin D by 45–74% in the presence of 15 mg. of α-tocopheryl acetate. Recoveries in the two trials of the modified procedure with this combination of vitamins were 100 and 101%. Similarly, with multivitamin products the USP method overestimates the vitamin D content to a considerable degree (130–210 USP units on a total of 500–600 units). The results by the modified procedure are close to the actual levels of addition of vitamin D.

The magnitude of the interference due to tocopherol in the USP assay for vitamin D is not sharply reproducible from one sample or product to the next. On the basis of the results in Table I, it does not appear that a generally applicable correction to the USP assay value could be calculated based on the relative proportions of tocopherol and vitamin D and the dilutions used. Preliminary removal of the tocopherol *via* column chromatography on secondary magnesium phosphate provides an effective and reliable method of removing this source of interference.

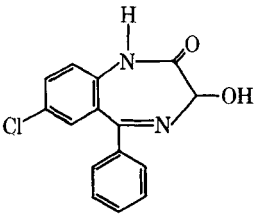
Qualitative and Quantitative Tests for Oxazepam

By EDWARD F. SALIM*, J. L. DEUBLE†, and G. PAPARIELLO†

Provisional, unofficial monographs are developed by the Drug Standards Laboratory, in cooperation with the manufacturers of the drug concerned, for publication in the *Journal of Pharmaceutical Sciences*. The ready availability of this information affords discriminating medical and pharmaceutical practitioners with an added basis for confidence in the quality of new drug products generally, and of those covered by the monographs particularly. Such monographs will appear on drugs representing new chemical entities for which suitable identity tests and assay procedures are not available in the published literature. The purity and assay limits reported for the drugs and their dosage forms are based on observations made on samples representative of commercial production and are considered to be reasonable within expected analytical and manufacturing variation.

7-CHLORO-1,3-DIHYDRO-3-HYDROXY-5-PHENYL-2H-1,4-BENZODIAZEPIN-2-ONE; $C_{15}H_{11}ClN_2O_2$; mol. wt. 286.72. The structural formula of oxazepam may be represented as I.



I

Physical Properties—Oxazepam occurs as a creamy white to pale yellow, practically odorless powder. It is practically insoluble in water, slightly

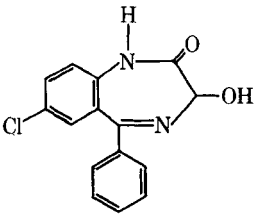
By EDWARD F. SALIM*, J. L. DEUBLE†, and G. PAPARIELLO†

Provisional, unofficial monographs are developed by the Drug Standards Laboratory, in cooperation with the manufacturers of the drug concerned, for publication in the *Journal of Pharmaceutical Sciences*. The ready availability of this information affords discriminating medical and pharmaceutical practitioners with an added basis for confidence in the quality of new drug products generally, and of those covered by the monographs particularly. Such monographs will appear on drugs representing new chemical entities for which suitable identity tests and assay procedures are not available in the published literature. The purity and assay limits reported for the drugs and their dosage forms are based on observations made on samples representative of commercial production and are considered to be reasonable within expected analytical and manufacturing variation.

7-CHLORO-1,3-DIHYDRO-3-HYDROXY-5-PHENYL-2H-1,4-BENZODIAZEPIN-2-ONE; $C_{15}H_{11}ClN_2O_2$; mol. wt. 286.72. The structural formula of oxazepam may be represented as I.



I

Physical Properties—Oxazepam occurs as a creamy white to pale yellow, practically odorless powder. It is practically insoluble in water, slightly

Accepted for publication September 20, 1967.
† Wyeth Laboratories, Philadelphia, PA 19101. Wyeth Laboratories has cooperated by furnishing samples and data to aid in the development and preparation of this monograph.
The Drug Standards Laboratory gratefully acknowledges the assistance of Miss Carolyn Damon and Miss Hannah Klein.

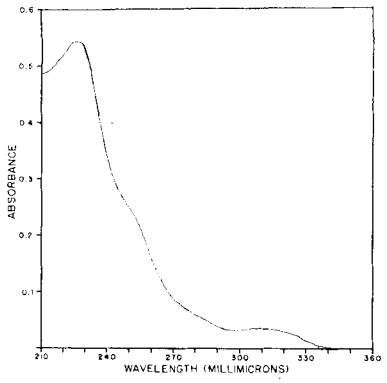

Fig. 1—Ultraviolet absorption spectrum of oxazepam in alcohol (4 mcg./ml.); Beckman model DK-2A spectrophotometer.

soluble in alcohol and in chloroform, and very slightly soluble in ether. The pH of a 2% suspension in carbon dioxide-free water is between 4.8 and 7.0.

Identity Tests—A 1 in 250,000 solution of oxazepam in alcohol exhibits an ultraviolet absorbance maximum at about 229 mμ [absorptivity (*a*) about 124]. The spectrum is shown in Fig. 1.

The infrared spectrum of a 0.5% dispersion of oxazepam in potassium bromide, in a disk of about 0.82 mm. thickness, is shown in Fig. 2.

Purity Tests—Dry about 1 Gm. of oxazepam, accurately weighed, at 105° in vacuum, maintaining the pressure below 5 mm. of mercury, for 3 hr.; it loses not more than 2% of its weight.

Char about 1 Gm. of oxazepam, accurately weighed, cool the residue, add 1 ml. of sulfuric acid, heat cautiously until evolution of sulfur trioxide ceases, ignite, cool, and weigh: the residue does not exceed 0.3%.

Assay—Transfer about 400 mg. of oxazepam, accurately weighed, to a tall-form beaker, and dissolve in 100 ml. of dimethylformamide. Using a magnetic stirrer and taking precautions against absorption of atmospheric carbon dioxide in the sample and titrant, titrate the solution with 0.1 *N* tetrabutylammonium hydroxide [prepared in benzene–methanol (9:1)] to a potentiometric end point using glass *versus* calomel electrodes. Perform a blank determination, and make any necessary correction. Each milliliter of 0.1 *N* tetrabutylammonium hydroxide is equivalent to 28.67 mg. of $C_{15}H_{11}ClN_2O_2$. The amount of oxazepam found is not less than 98% and not more than 102%, calculated on the dried basis.

DOSAGE FORMS OF OXAZEPAM

Oxazepam Capsules

Identity Test—The ultraviolet absorption spectrum of the final solution prepared from the capsule sample in the *Assay* is similar to the spectrum obtained from the oxazepam standard solution.

Assay—Remove, as completely as possible, the contents of not less than 20 oxazepam capsules, and weigh. Transfer a quantity of mixed powder, equivalent to about 50 mg. of oxazepam, to a medium-porosity, sintered-glass funnel that is fitted into a small suction flask. Extract the sample with five 25-ml. portions of alcohol, transfer the combined

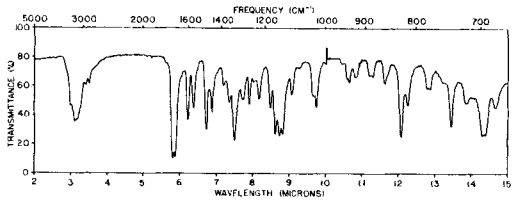

Fig. 2—Infrared spectrum of oxazepam in potassium bromide disk (0.5%); Perkin-Elmer model 21 spectrophotometer, sodium chloride prism.

extracts quantitatively to a 250-ml. volumetric flask, make to volume with alcohol, and mix. Transfer 2.0 ml. of the solution to a 100-ml. volumetric flask, dilute to volume with alcohol, and mix. Concomitantly determine the absorbance of this solution and of a standard solution of oxazepam, in the same medium, at a concentration of about 4 mcg./ml., in 1-cm. cells, at the maximum at about 229 mμ, with a suitable spectrophotometer, using alcohol as the blank. Calculate the quantity, in milligrams, of $C_{15}H_{11}ClN_2O_2$ in the portion of capsules taken by the formula $12.5 \times C(A_u/A_s)$, in which C is the exact concentration of the standard solution, in mcg./ml., A_u is the absorbance of the sample solution, and A_s is the absorbance of the oxazepam standard solution. The amount of oxazepam found is not less than 90% and not more than 110% of the labeled amount.

DISCUSSION

USP and NF terminology for solubility, melting range, reagents, *etc.*, has been used wherever feasible.

Oxazepam[1] is a psychotropic agent in the benzodiazepine class which is useful in the management and control of anxiety, tension, agitation, irritability and such related symptoms commonly seen in patients with a diagnosis of psychoneurotic or psychophysiological reaction. Oxazepam is structurally related to chlordiazepoxide and diazepam and the relative effectiveness of these compounds as tranquilizing agents has been reported (1, 2).

Identity Tests—The infrared spectrum of oxazepam constitutes an acceptable identification test for the compound. Ultraviolet absorption spectra in alcohol and 0.1 *N* alcoholic sulfuric acid can be used to differentiate the important benzodiazepine derivatives. The following tabulation indicates the wavelengths of maximum absorption for each compound in each solvent system.

	Wavelength, mμ	
	Alcohol	0.1 *N* Alcoholic Sulfuric Acid
Oxazepam	229	229
Diazepam	227	235, 280
Chlordiazepoxide hydrochloride	243, 262	247, 310

Quantitative Tests—Potentiometric nonaqueous titration of oxazepam with tetrabutylammonium hydroxide gave an average value of 98.9 ± 0.4%.[2] Preparation, standardization, and storage of the titrant have been detailed by Cundiff and Markunas (3). Determination of the end point potentiometrically is preferred to a visual titration with thymol

[1] Marketed as Serax by Wyeth Laboratories, Philadelphia, Pa.

blue T.S. since the indicator change which is somewhat gradual produces a greater variation in results. Similar titrations using azo violet or thymolphthalein were noted to give sharper end points but in each case a green color was observed at the stoichiometric point. The initial color of these indicators when added to a dimethylformamide solution of oxazepam is yellow and this leads to a green end point instead of the characteristic blue associated with the indicators.

Analysis of commercial 10-mg. oxazepam capsules by the spectrophotometric method gave a value of 97.8 ± 0.6%[2] of the labeled amount. A spectrophotometric approach can be used for analysis of bulk oxazepam provided suitable reference standard material is available for absorbance measurement.

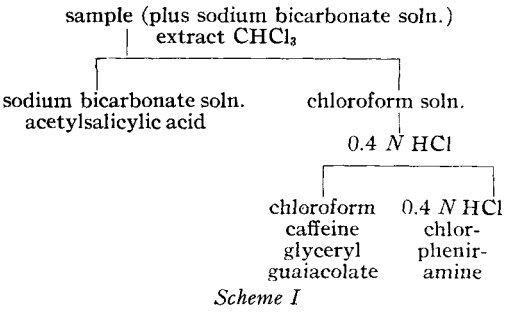
Paper Chromatographic Assay of Glyceryl Guaiacolate in a Pharmaceutical Formulation

By S. AHUJA*

A preliminary extraction scheme, which permits the separation of glyceryl guaiacolate [3-(*o*-methoxy-phenoxy)-1,2-propanediol] and caffeine from acetylsalicylic acid and chlorpheniramine maleate and other tablet excipients, has been developed. The separation of glyceryl guaiacolate and caffeine is achieved by paper chromatography. Glyceryl guaiacolate is then assayed on the basis of its absorbance in the UV region, after elution from paper chromatographic strips.

IN THIS LABORATORY, a simple and specific method was desired for assaying glyceryl guaiacolate in tablets containing glyceryl guaiacolate, acetylsalicylic acid, caffeine, and chlorpheniramine maleate in addition to the usual tablet excipients. Glyceryl guaiacolate can be determined titrimetrically (1, 2) or by gas chromatography of its acetate derivative (3). Giebelmann (4) described paper chromatographic methods (by the ascending technique) for qualitative detection of glyceryl guaiacolate. Since paper chromatography provides a good combination of a simple and specific method, this technique was investigated. This report describes a quantitative method for determination of glyceryl guaiacolate with paper chromatography (by the descending technique) with a newly developed solvent system. This solvent system provides good separations within 3 hr. Successful separation of the various constituents of the formulation is shown in Scheme I.

Glyceryl guaiacolate and caffeine are separated by paper chromatography and glyceryl guaiacolate is assayed spectrophotometrically after elution from paper chromatographic strips.



Scheme I

EXPERIMENTAL

Materials and Methods—An accurately weighed sample (equivalent to 195 mg. of glyceryl guaiacolate) is transferred to a separator. Sodium bicarbonate solution (25 ml. of 4% solution) is added and the separator is shaken well to ensure dissolution of the sample. This solution is extracted with chloroform (30 ml.) and the chloroform extract is transferred to another separator and shaken with 0.4 *N* hydrochloric acid (25 ml.). The chloroform extract is saved for paper chromatographic assay of glyceryl guaiacolate. This process is repeated

TABLE I—RECOVERIES WITH THE PAPER CHROMATOGRAPHIC METHOD

Batch	mg. Glyceryl Guaiacolate/Tablet—Actual	Found	% Recovery
A	195.0	195.2	100.1
		191.0	98.0
B	195.0	193.6	99.3
		194.0	99.5
C	195.0	195.0	100.0
		193.2	99.1

four more times using fresh portions of chloroform, but using the same 0.4 *N* hydrochloric acid solution. The combined chloroform extracts are diluted to yield a concentration of 1 mg./ml. of glyceryl guaiacolate. One hundred microliters of this extract is placed on paper chromatographic strips[1] (20 in. long) impregnated with the lower phase of the following solvent system: benzene–ethanol–water (2:1:1). Blank strips and strips with a standard solution of the same concentration (1 mg./ml.) are prepared similarly. The strips are allowed to equilibrate for 2 hr. in a tank saturated with the above-mentioned solvent system, and developed with the upper phase of the solvent system (developing time approximately 3 hr.). Glyceryl guaiacolate and caffeine spots are located with a UV lamp (R_f of glyceryl guaiacolate is 0.52, R_f of caffeine, 0.70).

Glyceryl guaiacolate spots from two strips are combined and eluted with 10 ml. ethanol. The absorbance of these solutions is read at 275 mμ with a spectrophotometer and corrected for the paper blank. (The absorbance readings of the sample without correction are generally over 13 times the magnitude of the paper blank reading. Paper blanks and placebos yield absorbance readings of approximately 0.020 units.) The concentration of glyceryl guaiacolate is calculated against the standard, similarly corrected for the paper blank.

[1] Whatman No. 1.

The results for three different batches of glyceryl guaiacolate tablets, with a known concentration of glyceryl guaiacolate, are given in Table I.

CONCLUSIONS

An average recovery of 99.3% (S.D. = ±1.05) may be achieved by the paper chromatographic method of assay described for glyceryl guaiacolate tablets. This method is simple, reliable, and specific. The specificity is achieved by the separation of the desired component by the paper chromatography followed by its determination at the appropriate wavelength in the ultraviolet region. The concentrations of glyceryl guaiacolate estimated were in the order of 195 mg. However, the design of this method permits estimations down to approximately 0.5 mg. of glyceryl guaiacolate or as high as might be desired. Furthermore, this method permits the quantitative determination of the other ingredients present in the formulation, such as acetylsalicylic acid, chlorpheniramine maleate, and caffeine, by the conventional methods.

Colorimetric Assay and Improved Method for Identification of Vancomycin Hydrochloride

By JAMES R. FOOKS, IAIN J. MCGILVERAY, and ROBERT D. STRICKLAND*

Procedures are described for the qualitative and quantitative determination of vancomycin hydrochloride by means of spectrophotometry and thin-layer chromatography. The Folin-Ciocalteau reaction which forms the basis of both procedures is also amenable to the estimation of vancomycin factor A, a commonly occurring impurity.

VANCOMYCIN, an antibiotic obtained from *Streptomyces orientalis* (1), is retained for use against Gram-positive cocci resistant to the more common antibiotics and for treatment of patients allergic to penicillins and cephalosporins (2). The structure of this drug has yet to be fully established, but chemical studies (3–5) have demonstrated the presence of carboxyl, amino, and phenolic groups. Glucose and amino acid fragments have also been identified after partial hydrolysis. Vancomycin as obtained from *S.*

orientalis may contain an unidentified fraction, factor A, which has similar chemical properties (5).

The USP XVII (6) refers to the Federal Register (7) for identity and assay procedures. Tests described in B.P. 1963 (8) and the Federal Register for identity and potency of vancomycin depend on microbiological assay using *Bacillus subtilis*. The official paper chromatographic methods (7, 8) for identifying vancomycin and estimating vancomycin factor A also employ this microorganism.

Betina included vancomycin in a systematic study of antibiotics by paper chromatography (9). Lightbown and de Rossi (10) described the separation of four biologically active compounds from vancomycin international reference standard by electrophoresis in agar gel. No reports could be found in the literature of a substitute for the time-consuming paper chromatographic and bioautographic procedures used in the characterization of vancomycin hydrochloride.

The object of this paper is to supplement and improve the present standards by providing chemical methods for the identification and assay of the antibiotic and a more rapid and sensitive means of separating it from closely related substances.

EXPERIMENTAL

Vancomycin hydrochloride injectable and vancomycin factor A used in this study were kindly supplied by the Eli Lilly & Co., Indianapolis, Ind. The "fresh" sample was dated 1966 and the "aged" had an expiration date in 1960. Vancomycin hydrochloride USP reference standard was obtained from USP Reference Standards, New York, N. Y.

Colorimetric Assay—In the Folin-Ciocalteau method the reagents were sodium carbonate 5% aqueous and Folin-Ciocalteau phenol reagent.[1]

A solution of vancomycin USP reference standard (1 ml.) representing 10 mcg./ml. was treated with sodium carbonate (1 ml.) reagent followed by diluted 1:3 Folin-Ciocalteau reagent (0.5 ml.). The solution was then made up to a volume of 5 ml. The development of color in this solution was followed by absorbance measurements at 725 mμ every 15 min. for 2 hr. A reagent blank was prepared by replacing the antibiotic with distilled water.

A calibration curve was obtained with standard amounts of vancomycin hydrochloride USP reference standard. The Folin-Ciocalteau and sodium carbonate reagents were added as described above and the absorbance of each solution at 725 mμ was measured after 1 hr.

Two commercial samples of vancomycin hydrochloride were assayed using this standard curve.

Microbiological Assays—The assay procedure for vancomycin hydrochloride described in the Federal Register was used (7).

Tests for Identity and Purity Using Thin-Layer Chromatography (TLC)—*Chromatographic Plates*—(*a*) Glass plates (20 × 20 cm.) were coated to a thickness of 250 μ with a slurry of Kieselguhr G (Merck) (40 Gm.) in distilled water (80 ml.) according to the method of Stahl (11) and left to dry overnight. They were used within 2 days without preactivation. (*b*) Glass plates were coated as above with Silica Gel G (Merck), but activated at 105° for 10 min. before use.

Solvent Systems—(*a*) Benzene–*n*-butanol–water (20:20:100) aqueous phase. (*b*) Methanol–water (1:99).

Detection Agent—(*a*) Sodium carbonate 20% aqueous and (*b*) Folin-Ciocalteau phenol reagent diluted 1:2 with distilled water.

Samples of an aqueous solution of vancomycin hydrochloride and factor A each representing 10 mcg. were applied to the same point on a Kieselguhr-coated plate by means of a Hamilton microsyringe. After drying in a stream of warm air, the plates were inserted in a previously equilibrated, filter paper-lined tank saturated with solvent system (*a*) and chromatographed to a height of 15 cm. (approximate time taken 50 min.). The residual solvent was removed immediately in a stream of warm air and the spots located by spraying with 20% sodium carbonate solution followed by Folin-Ciocalteau reagent. Gray-blue areas were observed for both vancomycin hydrochloride and factor A.

The sequence was repeated for 5 mcg. of vancomycin and factor A on Silica Gel G with solvent system (*b*). Approximate R_f values in each system were calculated from 10 plates. The limit of detection was determined by spotting dilutions of vancomycin hydrochloride USP reference standard and factor A separately in amounts ranging from 10 to 0.01 mcg. on five plates. Both compounds were visible at concentrations below 0.1 mcg.

The approximate R_f values of a number of drugs which also react with Folin-Ciocalteau reagent were compared by TLC in the above systems.

Quantitative TLC by Densitometry—The instrument used to scan the plates was a Photovolt densitometer (model 520M) equipped with a TLC stage, attached to a Varicord recorder (model 42B), a search unit C, and an Integraph integrator. A blue filter (max. 420 mμ) and a slit 0.1 mm. wide and 6 mm. long were used. The distance between plate and search unit was maintained at 1 mm. with a response setting of 10.

Thin-layer chromatograms of 2–10 mcg. quantities of vancomycin hydrochloride were developed with solvent system (*a*) on Kieselguhr. The plates were dried without delay in a stream of warm air and then sprayed immediately with 20% sodium carbonate solution. After drying thoroughly, they were sprayed with freshly prepared Folin-Ciocalteau reagent (1:3) and dried for 15 min. in a stream of warm air.

Densitometric scanning began as soon as the sprayed plate was dry and each spot was measured separately. The densitometer was vectored to the highest reading at the center of the spot, the plate clamped firmly in position, and the densitometer readjusted to the lowest background reading. Subsequently automatic scanning was effected in the direction of solvent flow. The operation was performed in a darkened room to prevent interference from stray light.

[1] Folin-Ciocalteau phenol reagent manufactured by Hartman-Ledden Co., Philadelphia, Pa.

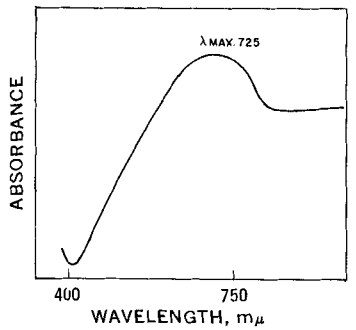

Fig. 1—Reaction of vancomycin with Folin-Ciocalteau reagent. Absorption curve of the product.

TABLE I—TIME OF COLOR DEVELOPMENT *vs.* ABSORBANCE FOR VANCOMYCIN WITH FOLIN-CIOCALTEAU REAGENT

Time, min.	Absorbance
0	0.075
15	0.116
30	0.148
45	0.162
60	0.166
75	0.173
90	0.178
105	0.180
120	0.186

The integrated areas were evaluated to give a standard curve. The process was repeated and some mixtures of vancomycin and factor A were estimated from the curve.

RESULTS AND DISCUSSION

The presence of phenolic groups in vancomycin has been demonstrated (1, 5). The phenolic moieties have been found to give the typical Folin-Ciocalteau reaction resulting in a blue-gray color (absorption maximum at 725 mμ) (Fig. 1). Color intensity was found to increase rapidly up to 1 hr. and, though a slight increase occurred after this time (Table I), the readings taken were sufficiently reproducible for assay purposes. The pH of the solutions produced by the reaction conditions averaged 9.6. When the pH was increased using more concentrated sodium carbonate solutions (*i.e.*, 20%), the color intensity of the product was lower and carbon dioxide was evolved which interfered in the measurement of color. Under the conditions used, Beer-Lambert's law was obeyed over the range 0.4–100 mcg./ml. Experimental results showing a comparison of the three vancomycin samples are shown in Table II which also lists the microbiological results. Both sets of results compare favorably.

Higgins *et al.* (3) observed that vancomycin, after hydrolysis in acid or alkaline solution, reacted with ninhydrin to give a positive test for amino groups. In our efforts to obtain a quantitative response with this reaction, various conditions were investigated for acid hydrolysis of vancomycin and for color development with the ninhydrin reagent. Results using the method of Yemm and Cocking (12) devised for amino acids were found to be inconsistent, and this reaction cannot be recommended as useful for the determination of vancomycin.

TABLE II—DETERMINATION OF SAMPLES OF VANCOMYCIN—COMPARISON OF COLORIMETRIC AND MICROBIOLOGICAL RESULTS

Sample	Absorbance	Concn. Found, mcg./ml.	Concn. Expected, mcg./ml.	%	% Microbiological

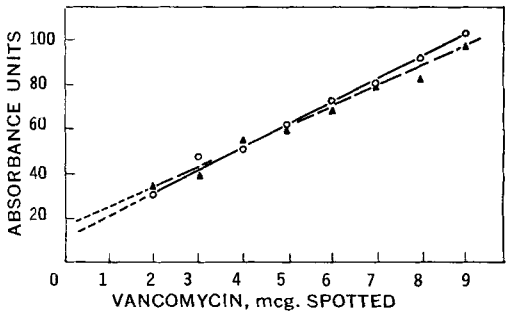

Fig. 2—Standard curves from TLC densitometry. Key: ○, USP vancomycin; ▲, USP vancomycin with 1 mcg. factor A.

The systems described for thin-layer chromatography were chosen after an empirical study of many solvent-adsorbent variations. Solvent system (*a*) was satisfactory for the separation of vancomycin from factor A up to the 20-mcg. level. Adverse tailing effects were observed with greater concentrations. With solvent system (*b*) on silica gel, effects of overloading were apparent with even less material and the system, though very rapid, is recommended only as an auxiliary for separation of vancomycin from other drugs as seen in Table III. From this table it is evident that system (*a*) does not differentiate methicillin and novobiocin from vancomycin. In solvent system (*b*), however, they

exhibit different R_f values. Table III shows the average R_f value of vancomycin and factor A in the two solvent systems.

Vancomycin and factor A could be determined semiquantitatively by densitometry over a range from 2 to 10 mcg. Reliable scanning was difficult with greater amounts because of streaking, especially where mixtures of the two components were involved. Figure 2 shows the linear curve of vancomycin (USP reference standard) concentration *versus* average spot density calculated from five plates and the effect of factor A on this curve. Factor A has little or no effect on the lower range (3 to 6 mcg.) but appears to inhibit color development at higher levels.

The vancomycin factor A used in this work was impure, as it contained approximately 20% vancomycin as estimated by TLC. The R_f values quoted as "factor A" are for the major, slower running spot. In making the densitometer readings for vancomycin in mixtures it was necessary to begin the scan from the lowest background reading between the spots for vancomycin and factor A.

The Folin-Ciocalteau assay is obviously not specific for vancomycin hydrochloride and should not be used in the absence of other criteria of identity. One such procedure is thin-layer chromatography which also detects the presence of interfering materials including factor A. Where nonphenolic impurities occur, the Folin-Ciocalteau method is recommended as the most convenient assay. Where impurities such as factor A are encountered, the semiquantitative assay of vancomycin by TLC with Folin-Ciocalteau spray followed by densitometry provides an alternative.

These data show that the chemical methods may supplement the current microbiological procedures for the qualitative and quantitative determination for this drug.

Design and Evaluation of a Miniature Air-Suspension Coating Apparatus

By HAL N. WOLKOFF, GEORGE PINCHUK, and PAUL H. SHAPIRO

Experiments were conducted, using a miniature air-suspension coating apparatus designed and built in these laboratories, to determine the feasibility of uniformly coating gram quantities of various sized and shaped particles. The coating chamber used has an inner diameter of 1.22 in. and an overall length of 4.875 in. A schematic drawing of the apparatus is presented and the function of each component as well as its critical dimensions are discussed. The coating capabilities of the apparatus were explored using nonpareil seeds, tablets of several sizes and shapes, and hard gelatin capsules. Data are presented to compare the relative coating efficiency of the miniature unit with the widely used 6-in. Wurster apparatus. The results indicate that minor differences do exist in terms of coating efficiency but that the two units are comparable with respect to the uniformity of coating which can be achieved.

AIR-SUSPENSION coating techniques have generated considerable interest since Wurster's disclosures in 1953 and 1957 (1, 2). The process has been widely used on an experimental basis and, to a lesser extent, in commercial production. It has as its major advantages simplicity of operation, versatility, rapidity, and uniformity of the final product. As opposed to conventional pan coating techniques, this process provides for rigorous control over the many factors responsible for batch-to-batch variability.

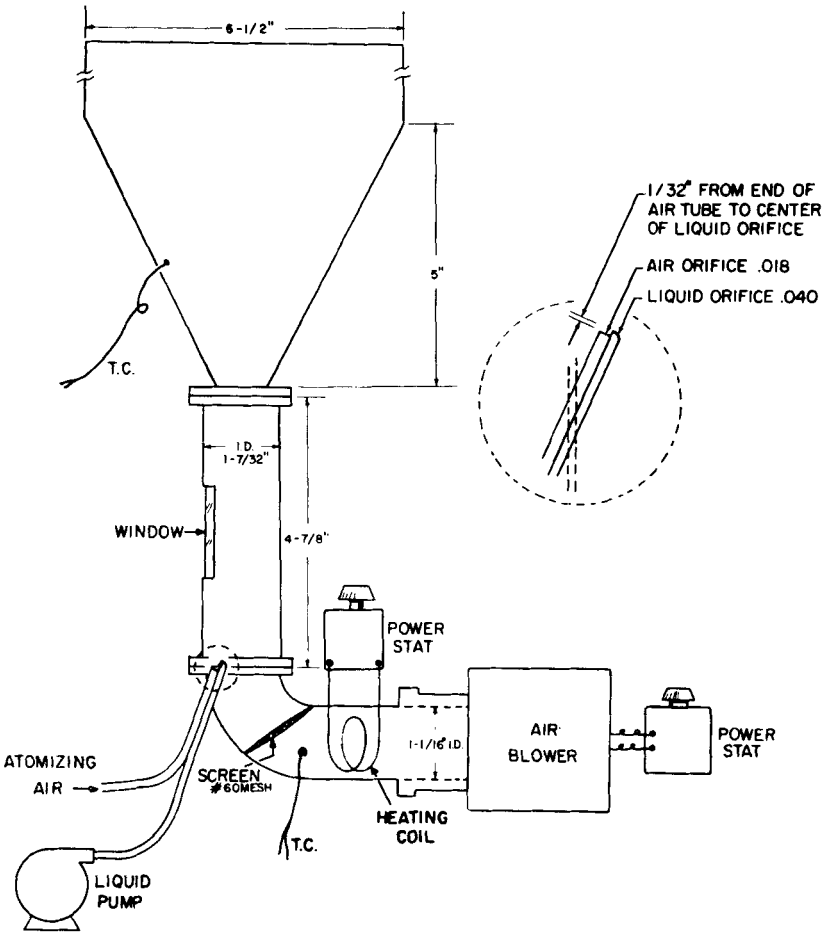

Fig. 1—Schematic diagram of the miniature air-suspension coating apparatus.

Several reports have appeared in the literature concerning the design and utility of laboratory air-suspension coating devices (3–6). The optimum load for each of these units is in the kilogram range. In the authors' experience, it has been frequently desirable to work with much smaller quantities of material. This may be the case when a drug is in short supply during early biopharmaceutical studies, or when new coating agents which are not yet available in sizeable quantities are being evaluated.

An air-suspension coating apparatus, capable of processing gram quantities of material, ideally satisfies these needs. This report deals with the design and evaluation of such a unit, referred to as a miniature air-suspension coating apparatus.

EXPERIMENTAL

Apparatus—A schematic diagram of the miniature air-suspension coating apparatus is shown in Fig. 1. The air supply is provided by a Master heat gun, model HG 301 (Master Appliance Corp., Racine, Wis.). The heating element and blower were rewired to allow for independent control of air volume and temperature. The unit has a maximum capacity of approximately 35 cu. ft. of air per min. Air output can be controlled by either varying the voltage delivered to the blower or by adjusting the air intake shield.

A Sigmamotor, model T8, equipped with a Westinghouse hi-torque speed control, type 902, was used to deliver the coating solutions through Tygon tubing ($^1/_{32}$ or $^1/_{16}$ in. i.d. × $^1/_{32}$ or $^1/_{16}$ in. wall thickness) to the atomizing nozzle. The coating solution was aerosolized at the point of entry into the coating chamber by the construction shown in the insert of Fig. 1. The air-liquid tubes of the atomizer head, coating chamber, and expansion chamber were constructed of No. 316 stainless steel. A clear, solvent-resistant plastic window[1] was inserted into the coating chamber to permit observation of the coating process.

The inlet and outlet air temperatures are determined by the use of electrical thermometers model 380 (Radio Frequency Labs, Inc., Boonton, N. J.).

A photograph of the apparatus and auxiliary equipment are shown in Fig. 2. The panel board is equipped with inlet and outlet air temperature gauges, atomization air pressure control knob and gauge, and a master on-off switch. The variable transformers shown on the right side of the photo-

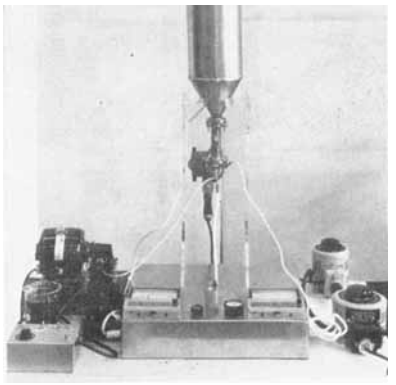

Fig. 2—Miniature air-suspension coating apparatus and ancillary equipment.

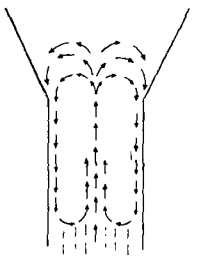

Fig. 3—Schematic representation of optimum particulate flow pattern.

graph are for air volume and temperature control. The control box to the left governs the race at which the Sigmamotor delivers coating solution to the atomizing head.

Materials—Eastman cellulose acetate phthalate, Distillation Products Industries; ethylcellulose, 50 cps., pharmaceutical grade, Dow Chemical Co.; isopropyl alcohol, acetone, and chloroform, reagent grade; castor oil USP; syrup USP; D&C Red No. 21, H. Kohnstamm and Co.; chlorpheniramine maleate tablets, 4 mg.;[2] and nonpareil seeds coated with chlorpheniramine maleate, 4.0 mg./1.64 Gm. (prepared by applying a sugar solution containing the drug to 20-mesh nonpareil seeds in a coating pan).

Coating Solutions—Ethylcellulose solution was prepared by dissolving 12.5 Gm. of polymer and 0.05 Gm. D&C Red No. 21 in 1 L. of a 50/50 acetone–isopropyl alcohol mixture.

Cellulose acetate phthalate solution was prepared by dissolving 25 Gm. of CAP and 7.5 Gm. of castor oil in 500 ml. acetone and then adding sufficient isopropyl alcohol to adjust the volume to 1 L.

RESULTS AND DISCUSSION

Equipment Characteristics—The feasibility of coating particles using the air-suspension technique depends, in addition to the surface characteristics and strength of the particle, on establishing an appropriate flow pattern. The desired flow pattern is schematically presented in Fig. 3. The extent to which a circulation pattern of this type can be established is determined by the particle size, shape, and density, the total weight of material in the coating chamber, and the air distribution in the operating parts of the unit.

The general utility of the miniature air-suspension apparatus was determined by evaluating the flow patterns established with a number of particles having different sizes and shapes. This information is presented in Table I. Obviously, variations in either the atomization air pressure or fluidizing air velocity would result in different optimum and maximum chamber loads. As the load is decreased from optimum, the circulation pattern becomes erratic.

TABLE I—CONDITIONS FOUND TO ESTABLISH CIRCULATORY FLOW PATTERNS WITH VARIOUS SIZED AND SHAPED PARTICLES[a]

Particle Description	Optimum Load, Gm.	Max. Load, Gm.
$^5/_{16}$ in. Std. concave tablet Av. gauge = 0.145 in. wt. = 200 mg.	4.00	8.00
$^7/_{16}$ in. Std. concave tablet Av. gauge = 0.220 in. wt. = 550 mg.	1.65	5.50
Oval concave tablet (0.200 × 0.300 in.) Av. gauge = 0.150 in. wt. = 170 mg.	4.00	8.00
Clover leaf tablet ($^5/_{16}$ in.) Av. gauge = 0.150 in. wt. = 170 mg.	3.91	7.82
Hexagonal tablets ($^7/_{16}$ in.) Av. gauge = 0.220 in. wt. = 570 mg.	2.85	5.70
No. 1 gelatin capsule wt. = 410 mg.	2.05	2.46
No. 0 gelatin capsule wt. = 530 mg.	1.59	2.12
Nonpareil seeds (20 mesh)	10.00	16.00

[a] The atomization air pressure was maintained constant at 20 p.s.i. and the transformer setting for the fluidizing air was 90 (intake shield at maximum opening).

Coating Studies—During the course of biopharmaceutical testing, it is often desirable to evaluate enteric-coated dosage forms. At this stage of new drug research materials are frequently in short supply, and therefore a technique for handling small amounts of material is highly desirable. The miniature air-suspension coating apparatus was evaluated as a tool for applying cellulose acetate phthalate (CAP) to a variety of solid dosage forms.

The typical coating procedure used was as follows. The fluidizing air is turned on and brought to the appropriate temperature range by the adjustment of the heating coil transformer. The coating solution is pumped through the feeding tube to the atomizer head. The atomization air is turned on and the particles introduced into the coating chamber by way of the exhaust air duct. The coating rate is controlled so that about a 20° differential exists between the inlet and outlet air temperatures. When all of the solution has been applied, the pump and atomization air is turned off. A few minutes of additional drying time are provided to minimize solvent retention. The heating coil and fluidizing air are then turned off, the unit disassembled, and the coated material recovered.

The enteric properties of the CAP-coated tablets and capsules were evaluated using the USP XVII procedure (7).

A modification of this procedure was used to evaluate the enteric-coated nonpareil seeds. The seeds were placed into a stainless steel cylinder

[2] Chlor-Trimeton Maleate, trademark of Schering Corp.

(25 × 64 mm.) covered at each end with an 80-mesh stainless steel screen. The cylinder was moved in a vertical plane beneath the surface of the test fluid by means of a Stoll-Gershberg apparatus (8). The nonpareil seeds were examined after 1 hr. in simulated gastric fluid at 37 ± 2°. Any visual evidence of nonpareil seed disintegration was interpreted as a failure of the enteric coating. The same procedure was repeated using simulated intestinal fluid and the time for total disintegration (more than 90% of material passing through the screen) was recorded.

The results presented in Table II demonstrate the versatility with which the apparatus can be used to enteric coat a spectrum of solid pharmaceutical dosage forms. It should be pointed out, however, that the uniform disintegration times of the various dosage forms in simulated intestinal fluid is probably best interpreted as due to the high solubility of cellulose acetate phthalate in this media rather than as an indication of uniform film thickness.

The data presented in Table III clearly demonstrate the effect of coating suboptimal chamber loads. Coating efficiency decreases markedly with decreasing chamber loads, probably due to an erratic flow pattern and decreased bed density. Coating efficiency for very small chamber loads can be increased by decreasing the diameter of the coating chamber. This was done by inserting a 0.75-in. i.d. tube mounted with rubber stoppers into the coating chamber. One gram of 5/16-in. standard concave tablets was coated with 2.5 ml. of 2.5% CAP solution. The coated tablets weighed 1.065 Gm., indicating a coating efficiency of approximately 80% as opposed to 12% when the same quantity of tablets was coated in the 1.22-in. chamber.

[a] Defined as wt. gain (mg.)/solids applied (mg.) × 100.

Correlation with 6-in. Wurster Apparatus—Experiments were carried out to determine whether information generated using the miniature unit could be extrapolated to larger air-suspension coating units. The quantity of ethylcellulose required to retard the release of chlorpheniramine maleate from tablets and seeds was determined in the miniature unit. Tablets and seeds were then coated in the 6-in. unit using an amount of coating solution proportional to the increased batch size.

Coating Procedure—Twenty milliliters of 1.25% ethylcellulose applied to 10 Gm. of seeds yielded a product which released chlorpheniramine maleate for over 16 hr. Four liters of the same solution was then applied to 2 Kg. of seeds in the 6-in. unit.

Twenty chlorpheniramine maleate tablets (5/16-in. standard concave, 200 mg.) were coated with 3 ml. of 1.25% ethylcellulose solution in the miniature coater. Similarly, 750 ml. was applied to 5,000 tablets in the large unit.

Release Rate Determination—The release rates were determined at 37 ± 0.1° in 150 ml. of 0.01 *N* HCl in a 3.5 × 16-cm. test tube. The sample (one tablet or 1.64 Gm. of seeds) was placed in a 24 × 64 mm. stainless steel cylinder covered at each end with an 80-mesh screen. The cylinder was oscillated in a vertical plane with a Stoll-Gershberg apparatus. The chlorpheniramine maleate was assayed spectrophotometrically at 264 mμ with a Beckman DU spectrophotometer modified with a Gilford model 220 absorbance converter. A continuous record was made of chlorpheniramine maleate from the seeds by pumping the solution through a 1-cm. flow cell with a Sigmamotor pump and recording the output of the absorbance converter on a Gilford-Honeywell recorder. In the case of the tablets, only a single point determination was made at 4 hr.

Discussion—The chlorpheniramine maleate release rates from the nonpareil seeds are shown in Fig. 4. The results of the tablets are given in Table IV. The variation in release rates is much smaller with the nonpareil seeds than with the tablets be-

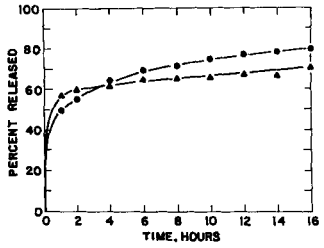

Fig. 4—Release of chlorpheniramine maleate from ethylcellulose-coated nonpareil seeds in 0.01 N HCl maintained at 37 ± 0.1°. Key: ●, miniature; ▲, 6-in. model.

TABLE IV—MINIATURE *Versus* 6-in. WURSTER CHLORPHENIRAMINE MALEATE TABLETS COATED WITH 1.25% ETHYLCELLULOSE SOLUTION

Expt. No.	1.22-in. Chamber	6-in. Chamber I	6-in. Chamber II
	% Release in 4 hr.		
1	54	18	17
2	33	18	14
3	50	17	33
4	46	36	31
5	60	51	50

cause the measurement of the release rates from 1.64 Gm. of seeds gives the average of a large number of individual assays, while the tablets were assayed individually. However, although the release rates are not precisely identical, the results do show that it should be possible to scale-up from the 1.22-in. coater to the 6-in. model with very little additional experimentation.

SUMMARY

An apparatus has been described which is capable of processing gram quantities of material in much the same manner as the larger 6-in. model Wurster unit. The miniature device has been evaluated and found to be highly versatile with respect to the types of discrete particles for which it can effect a continuous coating. Coating experiments indicate the miniature unit to be qualitatively comparable with the larger 6-in. model, although some quantitative differences were observed. The data suggest that minimal scale-up problems would probably accompany transition to the large unit.

Notes

Pharmacology and Toxicology of Potassium Perrhenate and Rhenium Trichloride

By THOMAS J. HALEY and FRANK D. CARTWRIGHT

A pharmacologic and toxicologic investigation of potassium perrhenate and rhenium trichloride showed that these compounds exhibited the same delayed acute toxicity previously reported for other rare elements. Rhenium trichloride was 10 times more toxic than potassium perrhenate but the latter compound was among the least toxic of all of the rare inorganic compounds studied. Potassium perrhenate was not irritating to the eyes and rhenium trichloride produced only a minimum of such irritation. Neither compound was irritating to the skin. Potassium perrhenate had no effect on isolated intestine while the liberation of acid from rhenium trichloride caused an intestinal spasm. Potassium perrhenate caused death by cardiovascular collapse coupled with respiratory failure. The compound also affected the superior cervical ganglion. Decomposition of aqueous solutions of rhenium trichloride and their extreme acidity prevented any pharmacodynamic studies.

IN 1933, HURD *et al.* (1) reported that they were unable to determine the LD_{50} for $KReO_4$ in mice or rats. They found wide distribution of the chemical in body tissues of the rabbit but no pharmacological effects in the dog. In 1940, Maresh *et al.* (2) reported that the i.p. lethal range for Re metal, given as $NaReO_4$, was 900–1,000 mg./Kg. for rats. Symptoms of toxicity included: cyanosis, increased respiration, and tonic convulsions. Rhenium trichloride was very toxic but the LD_{50} was not determined. Rhenates had no effect on the

TABLE IV—MINIATURE *Versus* 6-in. WURSTER CHLORPHENIRAMINE MALEATE TABLETS COATED WITH 1.25% ETHYLCELLULOSE SOLUTION

Expt. No.	1.22-in. Chamber	6-in. Chamber I	6-in. Chamber II
	% Release in 4 hr.		
1	54	18	17
2	33	18	14
3	50	17	33
4	46	36	31
5	60	51	50

cause the measurement of the release rates from 1.64 Gm. of seeds gives the average of a large number of individual assays, while the tablets were assayed individually. However, although the release rates are not precisely identical, the results do show that it should be possible to scale-up from the 1.22-in. coater to the 6-in. model with very little additional experimentation.

SUMMARY

An apparatus has been described which is capable of processing gram quantities of material in much the same manner as the larger 6-in. model Wurster unit. The miniature device has been evaluated and found to be highly versatile with respect to the types of discrete particles for which it can effect a continuous coating. Coating experiments indicate the miniature unit to be qualitatively comparable with the larger 6-in. model, although some quantitative differences were observed. The data suggest that minimal scale-up problems would probably accompany transition to the large unit.

Pharmacology and Toxicology of Potassium Perrhenate and Rhenium Trichloride

By THOMAS J. HALEY and FRANK D. CARTWRIGHT

A pharmacologic and toxicologic investigation of potassium perrhenate and rhenium trichloride showed that these compounds exhibited the same delayed acute toxicity previously reported for other rare elements. Rhenium trichloride was 10 times more toxic than potassium perrhenate but the latter compound was among the least toxic of all of the rare inorganic compounds studied. Potassium perrhenate was not irritating to the eyes and rhenium trichloride produced only a minimum of such irritation. Neither compound was irritating to the skin. Potassium perrhenate had no effect on isolated intestine while the liberation of acid from rhenium trichloride caused an intestinal spasm. Potassium perrhenate caused death by cardiovascular collapse coupled with respiratory failure. The compound also affected the superior cervical ganglion. Decomposition of aqueous solutions of rhenium trichloride and their extreme acidity prevented any pharmacodynamic studies.

IN 1933, HURD *et al.* (1) reported that they were unable to determine the LD_{50} for $KReO_4$ in mice or rats. They found wide distribution of the chemical in body tissues of the rabbit but no pharmacological effects in the dog. In 1940, Maresh *et al.* (2) reported that the i.p. lethal range for Re metal, given as $NaReO_4$, was 900–1,000 mg./Kg. for rats. Symptoms of toxicity included: cyanosis, increased respiration, and tonic convulsions. Rhenium trichloride was very toxic but the LD_{50} was not determined. Rhenates had no effect on the

Preliminary report: *The Pharmacologist*, **8**, 225(1966).

hemogram of rats. The chemicals did cause a transient tachycardia and a slight hypotension in dogs. Inasmuch as this is the total information on the biological effects of perrhenates and rhenium trichloride and because the element and its compounds are coming into greater usage (3), the authors have re-evaluated the pharmacological and toxicological properties of $KReO_4$ and Re_2Cl_6.

METHODS

The samples of potassium perrhenate ($KReO_4$) and rhenium trichloride (Re_2Cl_6) had a minimum purity of 99.9%. The intraperitoneal LD_{50}'s were obtained with male CFl mice weighing 21 to 34 Gm.

The method of Draize *et al.* (4) was used to study eye and skin irritation in rabbits. In the eye irritation studies, two rabbits were used, and each animal had one eye exposed to 3 mg. of crystalline compound while the other eye served as a control. The rabbit skin irritation studies used six animals per compound and 0.5-Gm. amounts of each salt were applied.

The effects of the compounds on guinea pig ileal strips bathed in Ringer-Locke solution were studied in a thermostatically regulated 25-ml. bath using the Trendelenburg (5) method. Studies were also made on the isolated rabbit ileum in the presence of either 2.5 mcg. of acetylcholine or 0.5 mcg. of nicotine.

For the study of the effects of intravenous administration of these compounds, 15 cats of both sexes, weighing 2.3 to 4.6 Kg. were anesthetized with 0.5 ml./Kg. of allobarbital[1] urethan solution intraperitoneally. A six-channel recorder with transducers was used to record carotid arterial pressure, respiration, nictitating membrane contraction, ECG lead II, femoral arterial pressure, and femoral arterial flow. The latter was obtained with a 25-ml. flowmeter (6). Preganglionic stimulation of the cervical sympathetic fibers and the contralateral vagus fibers was accomplished with a stimulator at 8 v./10 sec. One hour was allowed to elapse prior to beginning drug administration. Intravenous dosages of the drugs used were: potassium perrhenate, 10–90 mg./Kg.; potassium chloride 10–140 mg./Kg.; rhenium trichloride, 10–20 mg./Kg.; hydrochloric acid, 1 ml. of 7.5, 15, and 30%; epinephrine, 5 mcg./Kg.; acetylcholine, 5 mcg./Kg.; histamine, 2 mcg./Kg.; and atropine, 2 mg./Kg. All injections were made at a constant volume of 1 ml., except at the highest doses where solubility dictated the total volume injected. Where appropriate, the results were analyzed statistically by the method of Litchfield and Wilcoxon (7).

RESULTS

Acute Toxicity—The LD_{50}/7 days for $KReO_4$ was 2.8 Gm./Kg. with a range of 2.5 to 3.05 Gm./Kg.; slope value was 1.07 (1.06–1.08). Toxic symptoms were sedation and severe ataxia with death or recovery within 7 days. No convulsions were observed. The LD_{50}/7 days for Re_2Cl_6 was 280 mg./Kg. with a range of 264.4 to 296.5 mg./Kg.; slope value was 1.1 (1.08–1.13). Toxic symptoms were sedation and abdominal irritation with death or recovery within 7 days.

Eye Irritation—Potassium perrhenate caused no detectable damage to the cornea, iris, or conjunctiva throughout the 72-hr. observation period. Rhenium trichloride caused an immediate irritation of the cornea, congestion and swelling of the iris, redness of the conjunctiva, and a very slight lacrimal discharge. However, all these ocular effects cleared up within 24 hr. and no permanent damage resulted from the exposure.

Skin Irritation—Neither potassium perrhenate nor rhenium trichloride had any effect on abraded or unabraded rabbit skin but the latter compound interacted with the hair to produce a permanent black stain. Similar staining was also observed on human skin and was probably caused by deposition of the metal on skin proteins.

Effects on Isolated Ileum—Potassium perrhenate in the dosage range of 2.4 to 952.4 mcg./ml. had no effect on the tonus or contractility of the isolated rabbit ileum and did not block the responses to either acetylcholine or nicotine. Similar results were obtained on the Trendelenburg guinea pig enteric ganglia preparation. Within the dosage range of 0.24 to 2.14 mg./ml., rhenium trichloride had no effect on the isolated rabbit ileum but at a dose of 2.38 mg./ml. the compound decomposed and the ileum went into spasm from the acid liberated.

Pharmacological Effects—Doses of 10–50 mg./Kg. of $KReO_4$ produced a transient hypertension with tachycardia but had no effect on respiration. Hypotension and bradycardia as well as bradypnea occurred at doses of 60 and 70 mg./Kg. Atropinization did not affect the above responses but did increase the toxic dose by 10 mg./Kg. Femoral blood flow decreased at doses of $KReO_4$ of 40 to 70 mg./Kg. and atropinization shifted the responses to doses of 60 to 80 mg./Kg. Death from cardiovascular collapse coupled with respiratory failure occurred in 4 of 5 cats at 70 mg./Kg. and atropinization increased the dosage to 80 mg./Kg. for three cats and 90 mg./Kg. for the other two animals. Electrocardiographic changes caused by $KReO_4$ included: elevated P-waves, bradycardia, dropped beats, absent P-waves, absent T-waves, increased S-T interval ventricular tachycardia, transient auricular fibrillation, transient ventricular fibrillation, and 2 to 1 heart block. Atropinization had no influence on the cardiac changes produced by the chemical. $KReO_4$ did not block the pharmacological responses to acetylcholine, epinephrine, or histamine. Control studies with KCl indicated that the K^+ ion contributed little or nothing to the responses obtained with $KReO_4$ because KCl required 110 to 120 mg./Kg. to affect the cats, whereas $KReO_4$ produced its effects at much lower doses.

$KReO_4$ caused contraction of the nictitating membrane of the nonatropinized preparations but not of the atropinized ones, indicating a direct effect on the superior cervical ganglion because the responses resembled those obtained with acetylcholine and electrical stimulation rather than an epinephrine response and because atropine blocks at the ganglionic synapse.

Rhenium trichloride produced a slight hypertension at a dose of 10 mg./Kg. and was lethal to the cat when 20 mg./Kg. was given. However, these effects were related to the acid liberated by decomposition of the Re_2Cl_6 and were duplicated by the administration of the same concentration of hydrochloric acid to a control animal.

[1] Trademarked as Dial by Ciba Pharmaceutical Co., Inc., Summit, N. J.

DISCUSSION

The low order of toxicity of potassium perrhenate (1) and the high order of toxicity of rhenium trichloride (2) have been confirmed and extended to determination of their intraperitoneal LD_{50}'s. The rhenium compounds tested showed no real irritating properties on the eyes or skin of animals and no effects on isolated intestine. This is a striking contrast to observations on other rare elements (8–10). The chemical composition of the rhenium compounds, their solubility, and their rate of decomposition determines their lethality to animals. Rhenium trichloride, which decomposes readily with the liberation of hydrochloric acid, was 10 times more toxic than potassium perrhenate.

Photodisintegration Studies of ^{14}C-Carboxyl 2,3,5-Triiodobenzoic Acid

By R. H. JARBOE, JR., J. B. DATA, and J. E. CHRISTIAN

^{14}C-Carboxyl labeled 2,3,5-triiodobenzoic acid was examined at various intervals of time during exposure to ultraviolet irradiation. Photodisintegration occurred and the amount of degradation increased in quantity with increased duration of exposure. 2,5- and 3,5-diiodobenzoic acid were identified as two products resulting from the irradiation. Other unidentified products are also present.

IN CERTAIN PLANTS 2,3,5-triiodobenzoic acid (TIBA) has pronounced hormonal effects on the flowers, fruits, yields, metabolism, and translocation of natural plant constituents (1–8). Because these plants serve as a source of food to man or indirectly by first serving as food for animals which ultimately constitute man's diet, the question naturally arises as to the safety of this material to man. Furthermore, when TIBA is used on plants, it could be questioned whether the photodisintegration products from TIBA might be a health hazard. If sunlight causes photochemical deterioration either before or after absorption in the plant, the products of degradation could be translocated throughout the plant and eventually, directly or indirectly, become incorporated in foods.

EXPERIMENTAL

Materials—Glass chromatographic plates, 20 × 20 cm., utilizing silica[1] of 250 μ thickness, were used. A plastic preservative for thin-layer chromatograms, Brinkmann Instruments Co., Westbury, L. I., N. Y. was used.[2] The ultraviolet source (Ultra-Violet Products, Inc., South Pasadena, Calif., long-wave UV model S1 3660) was equipped with a long wavelength filter to approximate normal sunlight. The samples were counted in a Packard model 3003 Tri-Carb liquid scintillation spectrometer. The solvent system used was composed of a ratio of 10 parts of petroleum ether (b.p. 30–60°) and 1 part of propionic acid. Solvents and chemicals used in this study were of reagent grade or their equivalent.

Purification of TIBA-^{14}C—TIBA labeled in the carboxyl position with ^{14}C (9) was purified utilizing thick-layer chromatographic techniques prior to the photodisintegration studies. The purification procedure consisted of pipeting an alcoholic solution of approximately 93% TIBA-^{14}C onto previously prepared 1-mm. silica plates and air dried. The plates were developed in a solvent system of petroleum ether–propionic acid in the ratio of 10 parts of petroleum ether (b.p. 30–60°) and 1 part of propionic acid and subsequently exposed to photographic film (Eastman Kodak No Screen medical X-ray film). The resultant autoradiogram was used to identify TIBA-^{14}C. The TIBA-containing silica was scraped from the plate and placed in a Soxhlet extractor and extracted with anhydrous ether for a period of 72 hr. The Soxhlet extractor was wrapped with black paper to protect the contents from exposure to light. After the extraction period the ethereal solution was then concentrated to dryness under reduced pressure without heat in the dark.

Photochemical Degradation of TIBA-^{14}C—The TIBA-^{14}C used for the preparation of 30 ml. of a 2.1 × 10^{-2} % aqueous suspension was the same as that used in a study conducted on field grown soybeans by Spitznagle (9). About 5 ml. of the suspension was

[2] Neaton

placed in a quartz cell used in spectrophotometric analyses work, and the solution exposed continuously to the ultraviolet source at a distance of 20 cm. for 8 weeks. The cell was equipped with a plastic lid which was sealed by vacuum grease to prevent atmospheric effects.

Twenty-five microliter samples were removed at 0, 1, 2, 4, 8, 12, 24, 48, and 72 hr. and at 1, 2, 3, 4, 5, 6, 7, and 8 weeks. These samples were spotted on thin-layer silica plates. After development in the petroleum ether–propionic acid solvent, the plates were air dried and sprayed with undiluted plastic preservative to prevent sloughing of the silica during the photographic exposure period. To prepare the autoradiogram the thin-layer plates were exposed for about 5 days to Eastman Kodak No Screen medical X-ray film and then developed and fixed in Eastman Kodak liquid developer and liquid fixer, respectively.

The radioactivity of each labeled compound, separated on the thin-layer plates, was quantitatively determined in the Packard Tri-Carb liquid scintillation spectrometer. The radioactive areas were scraped from the plates and placed into a counting vial which contained a scintillator fluid composed of 0.4% PPO (2,5-diphenyloxazole) and 0.01% dimethyl POPOP [1,4-bis(4-methyl-5-phenyl-2-oxazoyl)benzene] in an equal volume each of toluene and 2-ethoxyethanol. Because TIBA was proved to be soluble in the scintillator fluid, suspension gel was not needed. A preliminary determination of possible quenching indicated no appreciable change in the counting rate with the amounts of silica contained in the samples.

Figure 1 is a drawing of the autoradiogram of the thin-layer chromatogram showing the separated degradation products of TIBA-^{14}C. Identification of the compounds was accomplished using unlabeled standards of TIBA, 2,5-, and 3,5-diiodobenzoic acid and location with bromocresol green reagent (10).

Figures 2 and 3 show the quantitative relationships between labeled TIBA and the products resulting from the deterioration as the irradiation time is increased.

Results—The TIBA-^{14}C at zero time contained 2.15% impurity after the thick-layer chromatographic purification process. This situation results from either the impurity not being completely removed in the purification process or that some type of degradation occurs during the isolation

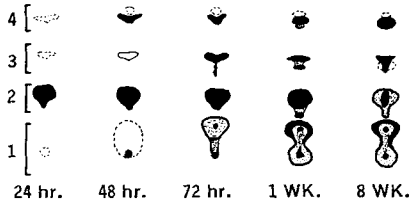

Fig. 1—Autoradiogram of the thin-layer chromatogram of TIBA-^{14}C and its products of photodisintegration at different time intervals. Key: spot 1, unidentified material at the origin; spot 2, TIBA-^{14}C; spot 3, 2,5-diiodobenzoic acid; spot 4, 3,5-diiodobenzoic acid. Unidentified impurities associated with these spots were not separated further nor identified. The spot with its associated impurities (represented by bracketed area) was removed, assayed, and calculated as one component.

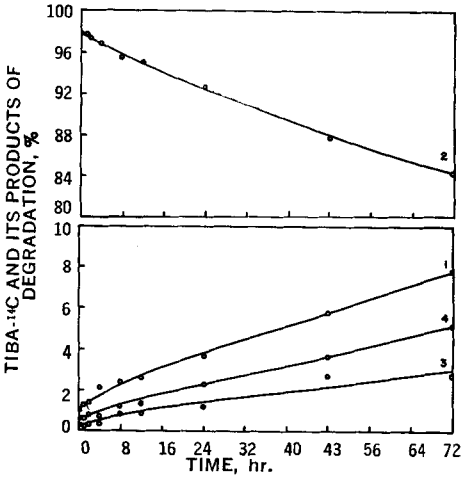

Fig. 2—Graphic relationship between the percentage of TIBA-^{14}C (curve 2) and the percentage of its products of degradation (curves 1, 3, and 4) at different hourly intervals. The curve number corresponds to the spot number in Fig. 1 where the nature of the products of degradation is explained.

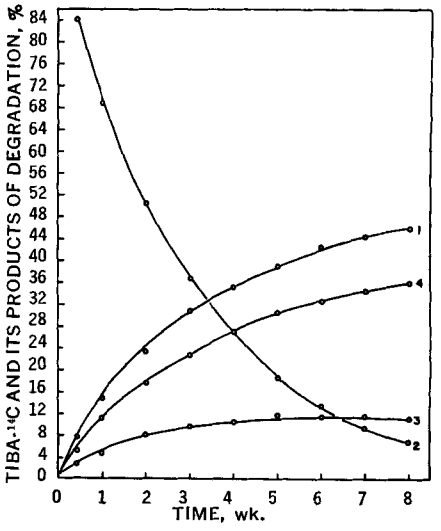

Fig. 3—Graphic relationship between the percentage of TIBA-^{14}C (curve 2) and the percentage of its products of degradation (curves 1, 3, and 4) at different weekly intervals. The curve number corresponds to the spot number in Fig. 1 where the nature of the products of degradation is explained.

which makes it difficult to obtain the desired product in absolutely pure form. Control samples of the TIBA-^{14}C kept in a light-resistant container showed no significant change at the end of 5 and 8 weeks.

It was observed that with increased time of exposure to the ultraviolet light the products resulting from the degradation increased in quantity and number since the solvent system used in the separation no longer sharply or completely separated the components of the mixture (compare the degree of resolution in Fig. 1 for the same spot at different time intervals of exposure). Impurities associated with the identified components were not separated but were counted as the entire spot (identified compound

plus its associated impurity). This was done for the purpose of evaluating the relationship between the concentration of TIBA-^{14}C and the products resulting from the photodisintegration. The unidentified compound(s) remaining at the origin were treated in an analogous manner.

The trace of unidentified impurities (spot 1) remaining at the origin increased in quantity to almost 8% of the total radioactivity at the end of 72 hr. of exposure and to 46% after 8 weeks. The quantity of TIBA-^{14}C (spot 2) decreased to 84% at the end of 72 hr. of exposure and to 7% at the end of 8 weeks. Spot 3 of the control (0 time) was identified as 2,5-diiodobenzoic acid. Spot 3 increased to 3% at the end of 72 hr. and 11% at the end of 8 weeks. *o*-Iodobenzoic acid, using the petroleum ether–propionic acid system for separation, has an R_f value very close to that of 2,5-diiodobenzoic acid and may be one of the impurities associated with it. Spot 4 in the control (0 time) was identified as 3,5-diiodobenzoic acid. This compound along with other products of photodisintegration associated with it increased to 5% at the end of 72 hr. and 36% at the end of 8 weeks. *m*-Iodobenzoic acid and also benzoic acid have R_f values using the above solvent system close to that of 3,5-diiodobenzoic acid and are probably impurities associated with the latter. At subsequent time intervals additional unidentified products from the degradation of TIBA-^{14}C became apparent.

CONCLUSIONS

2,3,5-Triiodobenzoic acid in a 2.1×10^{-2}% aqueous suspension is photochemically degraded by ultraviolet light. Ninety-three, 88, 84, 69, and 7% of TIBA are recovered from solution after 24, 48, 72 hr., 1 and 8 weeks of exposure, respectively. Two products of degradation were identified as 2,5- and 3,5-diiodobenzoic acid. From this study, it can be concluded that TIBA might be degraded in a like manner by sunlight after its application to plants.

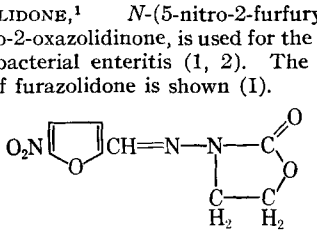
Method Specific for Determination of Furazolidone in Urine: Evidence for Drug-Related Metabolites

By R. D. HOLLIFIELD and JOHN D. CONKLIN

Furazolidone, *N*-(5-nitro-2-furfurylidene)-3-amino-2-oxazolidinone, is a chemotherapeutic drug used orally for the treatment of bacterial enteritis. A new, more specific analytical method for the determination of furazolidone in urine is described. Utilizing this procedure, furazolidone was not detected in urine samples collected from dogs and humans following oral administration of the drug. Evidence is provided for the presence of drug-related metabolites.

FURAZOLIDONE,[1] *N*-(5-nitro-2-furfurylidene)-3-amino-2-oxazolidinone, is used for the oral treatment of bacterial enteritis (1, 2). The structural formula of furazolidone is shown (I).



I

Previously, urinary concentrations of furazolidone were measured either by bioassay (1) or by the method of Nakamura and Inoue (3), which is based on the conversion of the drug to 5-nitrofurfural phenylhydrazone. A new analytical procedure, more specific for the determination of furazolidone in urine, is described in this report. Results obtained by this procedure and by the Nakamura and Inoue method are presented regarding furazolidone concentrations in dog and human urine following oral drug administration.

EXPERIMENTAL

Drug Administration—Micronized furazolidone (about 5 μ or less) in gelatin capsules was administered orally to unfasted, adult, male beagle dogs at 1.25 mg./Kg. q.i.d. at 4-hr. intervals (5 mg./Kg./day). Urine samples were then collected by catheterization at selected intervals. Furazolidone as a

[1] Eaton Laboratories' trademark for furazolidone is Furoxone.

plus its associated impurity). This was done for the purpose of evaluating the relationship between the concentration of TIBA-^{14}C and the products resulting from the photodisintegration. The unidentified compound(s) remaining at the origin were treated in an analogous manner.

The trace of unidentified impurities (spot 1) remaining at the origin increased in quantity to almost 8% of the total radioactivity at the end of 72 hr. of exposure and to 46% after 8 weeks. The quantity of TIBA-^{14}C (spot 2) decreased to 84% at the end of 72 hr. of exposure and to 7% at the end of 8 weeks. Spot 3 of the control (0 time) was identified as 2,5-diiodobenzoic acid. Spot 3 increased to 3% at the end of 72 hr. and 11% at the end of 8 weeks. *o*-Iodobenzoic acid, using the petroleum ether–propionic acid system for separation, has an R_f value very close to that of 2,5-diiodobenzoic acid and may be one of the impurities associated with it. Spot 4 in the control (0 time) was identified as 3,5-diiodobenzoic acid. This compound along with other products of photodisintegration associated with it increased to 5% at the end of 72 hr. and 36% at the end of 8 weeks. *m*-Iodobenzoic acid and also benzoic acid have R_f values using the above solvent system close to that of 3,5-diiodobenzoic acid and are probably impurities associated with the latter. At subsequent time intervals additional unidentified products from the degradation of TIBA-^{14}C became apparent.

CONCLUSIONS

2,3,5-Triiodobenzoic acid in a 2.1×10^{-2}% aqueous suspension is photochemically degraded by ultraviolet light. Ninety-three, 88, 84, 69, and 7% of TIBA are recovered from solution after 24, 48, 72 hr., 1 and 8 weeks of exposure, respectively. Two products of degradation were identified as 2,5- and 3,5-diiodobenzoic acid. From this study, it can be concluded that TIBA might be degraded in a like manner by sunlight after its application to plants.

		12–24	None detected	1.6 (2.4)[b]

[a] Micronized furazolidone (about 5 μ or less) in gelatin capsules was administered orally at 1.25 mg./Kg. q.i.d. every 4 hr. [b] Represents the percentage of dosed material convertible to 5-nitrofurfural phenylhydrazone recovered in the urine within 24 hr.

100-mg. tablet[2] or as 100 mg. of macrocrystalline drug (about 75 μ) in a gelatin capsule was administered orally to healthy adult, human males q.i.d. at 4-hr. intervals (5 mg./Kg./day for an 80-Kg. adult). Voided urine specimens were then obtained at selected intervals.

Drug Analysis—The reagents include: crystalline furazolidone (Eaton Laboratories); saturated ammonium sulfate solution, pH 6.0, special enzyme grade (Mann Research Lab., Inc.); spectro-quality nitromethane and *N*,*N*-dimethylformamide (DMF), reagent grade (Matheson, Coleman, and Bell); and p-diisobutylcresoxyethyoxyethyl dimethylbenzyl ammonium hydroxide[3] (DDAH) 1 *M* in methanol (443 Gm./L. methanol, Packard Instrument Co., catalog No. 6003005). One milliliter of this DDAH solution is diluted to 25 ml. with DMF to produce a 0.04 *M* solution. A Beckman DU spectrophotometer was used to measure absorbance.

Reference drug solutions are prepared by dissolving 50 mg. of furazolidone in 50 ml. of DMF and diluting this with water to obtain the necessary drug concentrations. One milliliter of urine and 2 ml. of water are mixed together, 3 ml. of saturated ammonium sulfate solution added, and the contents mixed. Ten milliliters of nitromethane is then added, the contents mixed vigorously for 1 min. and centrifuged for 10 min. at 2,000 r.p.m. Eight milliliters of the nitromethane extract (top layer) is transferred to a test tube containing 1 Gm. of sodium sulfate, and the contents are mixed vigorously for 1 min. to dry the solvent. Six milliliters of the nitromethane extract is removed and placed in a 50-ml. flask, and the solvent is evaporated under vacuum at 50° using a flash evaporator. Following evaporation, the residue is dissolved in 3 ml. of DMF. Exactly 2.9 ml. of this solution is transferred to a test tube, 0.5 ml. of 0.04 *M* DDAH in DMF (freshly prepared) added, and the absorbance determined at 600 mμ. Since the presence of water inhibits the color formation, water contamination of the DMF should be avoided. It is recommended that the absorbance of each sample be measured within 10 min. following addition of the DDAH solution since the color formed deteriorates slowly with time.

Some of the urine samples were examined chromatographically. The sample was extracted with nitromethane, the extract spotted on Whatman No. 1 paper, and subjected to ascending paper chromatography for 15 hr. at room temperature. After drying, the papers were examined under UV light and the R_f of each spot determined. The solvent systems used were: 95% ethanol, *n*-butanol, and either 0.5 *N* acetic acid or ammonium hydroxide (1:4:1).

RESULTS AND DISCUSSION

DMF-DDAH Procedure—The furazolidone–DDAH complex in DMF exhibits an absorbance maximum at 600 mμ. The standard curve for this color complex in DMF follows Beer's law to 50 mg./L. The drug recoveries from dog and human urine (Table I) indicate that the reference standards and internally corrected standards are identical, and that the sensitivity of the method is at least 2 mg./L.

Urinary Drug Concentrations—The method described was applied to the determination of furazolidone in urine samples collected after drug administration. Micronized furazolidone (about 5 μ or less) in gelatin capsules was administered orally to dogs. Furazolidone as a 100-mg. tablet or as macrocrystalline drug (about 75 μ) in gelatin capsules was administered orally to human subjects. Urine samples were collected at designated intervals. As shown by the results (Tables II and III), furazolidone was not detected in any of the urine samples analyzed by the DMF–DDAH method.

For comparison, the urine samples were also analyzed for drug by the Nakamura and Inoue procedure (3), which revealed the presence of material(s) convertible to 5-nitrofurfural phenylhydrazone. It has been reported that 5-nitrofurfural phenylhydrazone in toluene exhibits a red band when eluted on a column of aluminum oxide (4). Some of the urine samples (Tables II and III) were subjected to the colorimetric procedure of Buzard *et al.* (5), in which furazolidone is converted to 5-nitrofurfural phenylhydrazone and extracted with toluene. The characteristic red band was observed when these toluene extracts were examined on aluminum oxide columns, providing additional evidence for the presence of material(s) convertible to 5-nitrofurfural phenylhydrazone in dog and human urine following furazolidone dosage.

Recently, interest has been directed toward drug particle size and its related effects *in vivo* with regard to the absorption of nitrofuran derivatives (6). Relative to this, it was observed that greater amounts of material(s) convertible to 5-nitrofurfural phenylhy-

drazone were recovered in the urine of humans administered the furazolidone tablet than were found in the urine of subjects administered the macrocrystalline drug (Table III).

Chromatography—A chromatographic comparison of urine collected from dogs and humans administered furazolidone and of urine to which furazolidone had been added was conducted. Although furazolidone was detected when added to the urine (Table IV), the drug was not detected in either dog or human urine following oral furazolidone administration. However, the presence of two drug-related metabolites, one yellow and the other orange in appearance under UV light, in both dog and human urine, was established.

Following chromatography the drug-related spots were eluted and their absorbance spectra determined. These eluates were also analyzed chemically. When the spot representing drug added to urine (R_f 0.65–0.68, Table IV) was eluted, it exhibited an absorbance spectrum with a maximum at 367 mμ in water, which is characteristic of that reported for furazolidone (1). This eluate yielded the expected blue color when subjected to either the DMF–DDAH or Nakamura and Inoue procedures. As shown in Table V, each of the metabolites exhibited an absorbance spectrum with a maximum near 415 mμ in water. Apparently, the spot which appears orange under UV light (Table V) represents one of the material(s) in dog and human urine which is convertible to 5-nitrofurfural phenylhydrazone. The presence of drug-related metabolites which absorb near 415 mμ in the urine of animals administered certain nitrofuran derivatives has been reported previously (7–9).

On the basis of spectral analysis, the yellow material appears to be present in a greater amount than the orange material in dog urine, while the orange material is present in greater amounts than the yellow material in human urine. This indicates that although the two drug-related metabolites are each present in dog and human urine, they apparently are present in different relative amounts. This may explain the twofold difference observed between dog and man (Tables II and III) in the percent excretion of dosed micronized material convertible to 5-nitrofurfural phenylhydrazone.

Under *in vitro* conditions, furazolidone exhibits significant inhibitory activity against *Escherichia coli* (1). Urine samples collected from dogs and humans following furazolidone administration demon-

TABLE V—CHARACTERISTICS OF THE DRUG-RELATED URINARY METABOLITES

Sample	R_f Value[a]: Acidic	Basic	Appearance: White Light	UV Light	Absorbance Max. in Water, mμ	Chemical Assay: DMF–DDAH Method	Nakamura and Inoue Method
Dog urine	0.05	0.07	Yellow	Yellow	415	No color	No color
	0.51	0.43	Yellow	Orange	415	No color	Blue color
Human urine	0.05	0.07	Yellow	Yellow	415	No color	No color
	0.55	0.44	Yellow	Orange	415	No color	Blue color

[a] See Table IV.

strate little activity against *E. coli* (1), suggesting that only small amounts of furazolidone are excreted in dog and human urine. This also indicates that the urinary drug-related metabolites observed in the present study are not significantly active against *E. coli*.

In summation, when urines collected from dogs and humans administered furazolidone orally were analyzed by a new analytical procedure, furazolidone was not detected. Chromatographic examination of these urine samples verified this conclusion and also revealed the presence of two drug-related metabolites in both dog and human urine.

Fractionation of Fatty Acids of *Cucurbita maxima* Seed Oil With Urea

By J. P. TEWARI and M. C. SRIVASTAVA

The mixed fatty acids of *Cucurbita maxima* seed oil have been fractionated by liquid–solid countercurrent distribution with urea. The percentage fatty acid composition of oil is: palmitic, 21.5; stearic, 8.4; oleic, 27.0; and linoleic, 43.10.

UNDER the Indian Council of Medical Research inquiry on anthelmintic activity of *Cucurbita maxima* seeds (family, *Cucurbitaceae*), the anthelmintic activity and the chemotherapeutic actions of aqueous, alcoholic, and ethereal extracts of the decorticated seeds of *C. maxima* have been reported (1, 2).

A large amount of the oil was obtained as a by-product during the defatting of the seeds prior to the isolation of cucurbitin. In view of the importance of this oil in the Indian system of medicine (3, 4) the mixed fatty acids of *C. maxima* oil were fractionated by the liquid–solid countercurrent distribution of fatty acids with urea employing the method of Sumerwell (5).

The results of fractionation have been recorded in Table I and agree closely with those obtained by Chowdhury *et al.* spectrophotometrically (6).

EXPERIMENTAL

The oil from the seeds of *C. maxima* was saponified and fatty acids were obtained from the soap after removing the unsaponifiable matter. The mixed fatty acids (30.5 Gm. I.V., 103.2; N.V., 198.2) were fractionated by liquid–solid countercurrent distribution of fatty acid with urea employing the method

Isolation of Candicine Chloride, Laurifoline Chloride, and Xanthoxyletin from the Bark of *Zanthoxylum elephantiasis*

By JOZEF TOMKO*, ALBERT T. AWAD†, JACK L. BEAL, and RAYMOND W. DOSKOTCH

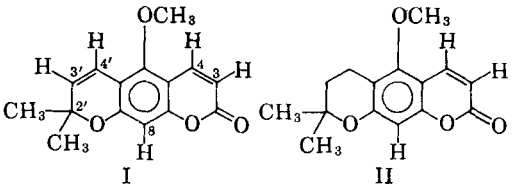
A study of the quaternary alkaloids of the bark of *Zanthoxylum elephantiasis* was made. Utilizing a silicic acid and diatomaceous earth (4:1) chromatographic column, the quaternary alkaloids laurifoline chloride and candicine chloride were separated and identified. In addition, xanthoxyletin was isolated from a petroleum ether extract of the bark. Its identification was made by physical and chemical data.

In a previous publication (1) the presence of quaternary bases in the bark of *Zanthoxylum elephantiasis* Macf. was reported. From the mixture of quaternary bases, only laurifoline chloride was isolated in small quantity by a rather unsatisfactory procedure. An improved procedure for the separation of laurifoline chloride from the mixture and, in addition, the isolation and identification of candicine chloride from the same mixture are reported here.

The petroleum ether extract of the powdered bark when chromatographed on acid alumina with benzene as eluting agent yielded xanthoxyletin (I) previously reported in a species of *Zanthoxylum* (2). Its identity was established by comparision of its physical properties with those reported in the literature and the preparation of the dihydroxanthoxyletin (II).

The NMR spectra of xanthoxyletin is consistent with its structure showing a singlet at δ = 1.47 (6H) for the two methyl groups at C-2′, a singlet at 3.88 (3H) for the methoxy group, and one at 6.52 (1H) for the aromatic proton at C-8. The protons at C-3 and C-4 appeared as a pair of doublets at δ = 6.20 and 7.87 (J = 9.5 c.p.s.), respectively, and those at C-3′ and C-4′ also as a pair of doublets were found at δ = 5.73 and 6.61 (J = 10 c.p.s.), respectively.

In dihydroxanthoxyletin the singlet for the two methyl groups at C-2′ was shifted upfield to δ = 1.38 and the pair of doublets for C-3′ and C-4′ were lost and now appeared as a pair of triplets centered at δ = 1.82 (2H) and 2.79 (2H), respectively. The other peaks of the spectrum remained essentially unchanged.



EXPERIMENTAL[1]

Separation of Candicine Chloride and Laurifoline Chloride—A quantity of 550 mg. of the mixture of quaternary alkaloid chloride salts obtained by chromatography on alumina as described in the previous publication (1) was dissolved in methanol and adsorbed on 5 Gm. of silicic acid and diatoma-

TABLE I—SILICIC ACID AND DIATOMACEOUS EARTH CHROMATOGRAPHY OF QUATERNARY ALKALOIDS

Fraction No.	Eluant	Quantity, ml.	Alkaloid, mg.
1	Chloroform	500	...
2	Chloroform–methanol (10%)	1000	...
3	Chloroform–methanol (20%)	500	...
4	Chloroform–methanol (30%)	400	...
5	Chloroform–methanol (30%)	100	Trace, laurifoline chloride
6	Chloroform–methanol (40%)	100	86, laurifoline chloride
7	Chloroform–methanol (40%)	100	62, laurifoline chloride
8	Chloroform–methanol (40%)	100	84, mixture of laurifoline chloride and candicine chloride
9	Chloroform–methanol (40%)	100	77, mixture of laurifoline chloride and candicine chloride
10	Chloroform–methanol (50%)	300	220, candicine chloride
11	Chloroform–methanol (70%)	100	Trace, candicine chloride

ceous earth[2] (4:1). This was placed on top of a column (2.6 cm. diameter) of 100 Gm. of the same adsorbent which was prepared in the manner described in a previous publication (3). The results are given in Table I.

Fractions 6 and 7 were dissolved in methanol, filtered, and acetone added to point of cloudiness to obtain 90 mg. of laurifoline chloride, m.p. 249–251° dec., $[\alpha]_D^{29}$ + 40° (c 0.985 in methanol). The compound was identical in IR, UV, and R_f (0.16 for solvent system *1* and 0.68 for *2*) with that of an authentic sample.

The material in fraction 10 was crystallized from methanol–ether to give 180 mg. of candicine chloride, m.p. 278–279° dec. The IR, UV, and R_f (0.23 for solvent system *1* and 0.75 for *2*) were the same with those values of an authentic sample.

Isolation of Xanthoxyletin—The residue from the petroleum ether extract was placed on a column of acid alumina (Woelm, activity grade I, 100 Gm.) and elution started with benzene. Elution with benzene yielded xanthoxyletin (2 Gm.) which crystallized from a mixture of chloroform and diethyl ether, m.p. 133–134° [lit. (2) m.p. 133°].

Anal.—Calcd. for $C_{15}H_{14}O_4$: C, 69.75; H, 5.46. Found: C, 70.28; H, 5.58.

UV spectrum: $\lambda_{max.}^{MeOH}$ 221 mμ (log ε = 4.37); 269 (4.42), 346 (4.10), unaffected by dilute acid or alkali.

[2] Celite 545. Johns-Manville Corp., New York, N. Y.

Hydrogenation of 165 mg. of xanthoxyletin with 50 mg. of PtO_2 in 12 ml. of ethanol showed an uptake of 1 *M* equivalent of hydrogen and the crystalline dihydroxanthoxyletin (120 mg.) was obtained from ethanol–diethyl ether, m.p. 145–146°; [lit. (2) m.p. 144.5–145.5°]; UV spectrum showed $\lambda_{max.}^{MeOH}$ 332 mμ (log ε = 4.15).

Muscarine in *Clitocybe* Species

By K. GENEST, D. W. HUGHES, and W. B. RICE

Results of chemical and bioassays for muscarine in a sample of *Clitocybe dealbata* indicate the absence of other muscarine-like substances or muscarine potentiators. Evidence was found for the presence of muscarine in herbarium samples of *C. illudens*, *C. cerussata*, *C. dealbata*, and *C. rivulosa*. The age of samples ranged from 12 to 26 years.

A PREVIOUS COMMUNICATION (1) reported the isolation and determination of muscarine in *Clitocybe dealbata* and qualitative results on the physiological action of mushroom preparations injected into rats. It was of interest to know whether comparable results for muscarine content could be determined by chemical and biological assay, since muscarine-like potentiating factors have been reported in some species of *Inocybe* (2, 3). Other *Clitocybe* species have frequently been described as being toxic or of doubtful edibility (4–8). A collection of herbarium samples of such species was also examined for muscarine content.

EXPERIMENTAL

Material and Methods

Clitocybe dealbata—1965 crop: 57 Gm.; 1966 crop: 1.5 Gm.[1] of dry powder, passing 100-mesh sieve. Both samples from same location in Ottawa, Ontario.

Herbarium Samples—Samples were obtained from the Herbarium, Taxonomy and Mycology Section, Plant Research Institute, Department of Agriculture, Ottawa, Ontario. Relevant authenticative data are listed in Table I.

Chemical Determination—Muscarine was determined in accordance with the method described previously (1). For herbarium samples 0.25–0.5 Gm. of dried mushroom powder was used.

Biological Examination—The bioassay method of Malone *et al.* (9) was applied to the 1965 sample of *C. dealbata*. The standard for the bioassay was *dl*-muscarine iodide (Geigy). Healthy, nonfasted, adult male albino rats of the Wistar strain were used.[2] Muscarine was injected intraperitoneally into three groups of 10 rats each at 0.0125, 0.025, and 0.05 mg./Kg. (calculated as *l*-muscarine, free base). Mushroom preparations containing 27.3, 54.7, and 109.4 mg. of mushroom powder (100 mesh) per 15 ml. were injected into three groups of 10 rats each (1 ml./200 Gm.). Agar (0.25%) in water was used as dosage vehicle. Scores of the salivation metameter, as defined by Malone *et al.* (9), were measured. Preparations from herbarium samples were injected in amounts shown in Table II.

TABLE I—HERBARIUM SAMPLES OF *Clitocybe* SPECIES

Herbarium No.	Botanical Name	Common Name	Place and Time of Collection
DAOM 11834	*Cantharellus aurantiacus* (Wulf.) Fr. = *Clitocybe aurantiaca* (Fr.) Studer	Orange-yellow Chanterelle	Sept. 24, 1944, Chalk River, Ontario
DAOM 55728	*Clitocybe cerussata* var. *difformis* (Fr.) sensu Bres.	...	July 24, 1949, Yukon Territory
DAOM 33896	*Clitocybe dealbata* (Sow. ex Fr.) Kummer	Ivory clitocybe	Oct. 18, 1951, Vancouver, British Columbia
DAOM 10018	*Clitocybe illudens* Schw.	Jack-o'-lantern	Sept. 2, 1940, Oakville, Ontario
DAOM 24168	*Clitocybe illudens* Schw.	Jack-o'-lantern	Aug. 17, 1950, Ottawa, Ontario
DAOM 113652	*Clitocybe illudens* Schw.	Jack-o'-lantern	Aug. 10, 1954, Kentville, Nova Scotia
DAOM 64791	*Clitocybe rivulosa* (Pers. ex Fr.) Kummer	...	Sept. 16, 1946, Uppsala, Sweden

RESULTS AND DISCUSSION

Comparison of Chemical and Bioassays for C. dealbata—The muscarine content of the 1965 sample of *C. dealbata* was found to be 0.18% (0.16–0.21)[3] ($N = 16$) as determined by the chemical method (1) and calculated as *l*-muscarine (free base). The statistical analysis of the bioassay results is given in Table III. By this method, the sample was found to contain 0.26% (0.23–0.30)[3] (30 rats) of muscarine, also calculated in terms of the naturally occurring isomer. The λ value for this assay was found to be 0.2308 which agrees well with that reported by Malone *et al.* (9). The chemical and bioassays are in general agreement and the difference between the two is probably not due to the presence of other muscarine-like agents and/or potentiators, reported to occur in *Inocybe* species (2, 3), for which values obtained by bioassays were 3 to 13 times higher than those obtained by chemical assays. This interpretation is strengthened by the fact that the authors used *dl*-muscarine as standard and

Total	59	308.413			

calculated results for the bioassay on the basis that the racemic mixture has half the activity of naturally occurring *l*-(+)-muscarine (10). Some pharmacological studies, however, indicate that this is only an approximation (11).

Herbarium Samples—Various *Clitocybe* species have been classified as poisonous or of doubtful edibility. The older mycological literature can be confusing, mainly due to nonuniformity of nomenclature (12). *C. dealbata*, for instance, was classified without qualification as edible (4). Recent sources, however, list *C. dealbata*, *C. illudens*, *C. rivulosa* (6, 7), and *C. cerussata* var. *difformis* (7) as poisonous, and *C. aurantiaca* (6) as a mushroom of possible toxicity. Herbarium samples of these species were investigated for the presence of muscarine by the chemical method. Results of these tests and of the investigation of two recently collected samples of *C. dealbata* are given in Table II. Muscarine could be detected in all species which are considered poisonous. Two samples of *C. illudens* were muscarine positive, but the alkaloid was not detected in a third specimen. *C. aurantiaca* was negative also. The classification of this mushroom appears to be controversial, and while it is considered poisonous by some mycologists, others consider its edibility established (6, 13). Farnsworth (14) pointed out that the age of herbarium samples limits the usefulness of chemical tests, but the same author cites cases where 1300-year-old plants were still found to give positive alkaloid tests. A decline of muscarine content with time in herbarium samples is suggested by the results on samples 3 months, 15 months, and 15 years old (Table II). Yet compositional differences have also been observed between crops of the same year. Among the herbarium samples investigated *C. rivulosa* is the *Clitocybe* species exhibiting the highest potency, a finding which confirms recent work on surface-grown cultures of that species (15, 16). Results of chemical tests carried out on the herbarium samples were confirmed by biological tests (Table II). Since very little herbarium material was available, bioassays could not be performed. Qualitative muscarine symptoms in rats were afforded by all samples containing 0.0075% or more of muscarine.

Fluorometric Determinations Comparable to Eye Response

By JOSEPH E. SINSHEIMER, JAMES T. STEWART*, and JOSEPH H. BURCKHALTER

A filter-photomultiplier tube system approaching the spectral response of the human eye has been selected, its spectral response recorded, and the system evaluated with a series of model fluorescent compounds.

FLUORESCENT tagging agents are being synthesized in these laboratories for potential use in fluorescent antibody-antigen techniques (1). To determine more rationally structures to be synthesized, it was desirable to direct these studies by an objective and sensitive comparison of fluorescence. Cognizant that the antibody-antigen technique ultimately depended upon visual observation of fluorescence, a filter-photomultiplier tube detection system that approached the spectral response of the human eye (2, 3) was developed for use with commercially available fluorometers. As this system has general application for the comparison of materials to be employed for their visible fluorescence, the selection and evaluation of this system is reported.

EXPERIMENTAL

Apparatus—The Aminco-Bowman spectrophotofluorometer No. 4-8106, equipped with an Electro Instruments X-Y recorder No. 1620-809, and a detection system consisting of a Kodak Wratten filter No. 106 and a RCA 1P28 phototube were employed in this procedure.

Spectral Response of the Detection System—In order to describe the spectral response of a 106 filter–1P28 photomultiplier detection system, the following comparison of experimental to reference corrected spectra was employed. Relative quantum intensity data were obtained from a corrected fluorescent spectrum of quinine sulfate[1] by dividing the intensity at 10-mμ increments by the maximum intensity. The relative quantum intensity for the aluminum chelate of an azonaphthalene sulfonic acid dye (aluminum-PBBR chelate) has been described by White (4) and served as the second reference corrected spectrum.

Solutions of quinine sulfate (10×10^{-6} Gm./ml. in 0.1 N H_2SO_4) and the aluminum-PBBR chelate were placed in the fluorometer equipped with the 106 filter and their fluorescence emission spectra were taken in the usual manner at the appropriate excitation wavelengths (365 and 540 mμ, respectively).

Based upon these experimental spectra, values at 450 mμ for quinine sulfate and 630 mμ for aluminum-PBBR chelate were each set equal to 100% quantum intensity and values at the other wavelengths for each compound were made relative to it. Dividing these percentages by the relative quantum intensity from the corrected spectra gave quantum values which were then divided by their respective wavelengths to give energy per wavelength data. The energy data were plotted so that the values for both compounds were made equal at 580 mμ (a common wavelength nearest to that of 560 mμ, the peak for the average human eye). Values at the other wavelengths for both compounds were made relative to 100% for the maximum at 575 mμ of the combined curves. (See Fig. 1.)

Fluorometric Determinations Comparable to Eye Response

By JOSEPH E. SINSHEIMER, JAMES T. STEWART*, and JOSEPH H. BURCKHALTER

A filter-photomultiplier tube system approaching the spectral response of the human eye has been selected, its spectral response recorded, and the system evaluated with a series of model fluorescent compounds.

FLUORESCENT tagging agents are being synthesized in these laboratories for potential use in fluorescent antibody-antigen techniques (1). To determine more rationally structures to be synthesized, it was desirable to direct these studies by an objective and sensitive comparison of fluorescence. Cognizant that the antibody-antigen technique ultimately depended upon visual observation of fluorescence, a filter-photomultiplier tube detection system that approached the spectral response of the human eye (2, 3) was developed for use with commercially available fluorometers. As this system has general application for the comparison of materials to be employed for their visible fluorescence, the selection and evaluation of this system is reported.

EXPERIMENTAL

Apparatus—The Aminco-Bowman spectrophotofluorometer No. 4-8106, equipped with an Electro Instruments X-Y recorder No. 1620-809, and a detection system consisting of a Kodak Wratten filter No. 106 and a RCA 1P28 phototube were employed in this procedure.

Spectral Response of the Detection System—In order to describe the spectral response of a 106 filter–1P28 photomultiplier detection system, the following comparison of experimental to reference corrected spectra was employed. Relative quantum intensity data were obtained from a corrected fluorescent spectrum of quinine sulfate[1] by dividing the intensity at 10-mμ increments by the maximum intensity. The relative quantum intensity for the aluminum chelate of an azonaphthalene sulfonic acid dye (aluminum-PBBR chelate) has been described by White (4) and served as the second reference corrected spectrum.

Solutions of quinine sulfate (10×10^{-6} Gm./ml. in 0.1 N H_2SO_4) and the aluminum-PBBR chelate were placed in the fluorometer equipped with the 106 filter and their fluorescence emission spectra were taken in the usual manner at the appropriate excitation wavelengths (365 and 540 mμ, respectively).

Based upon these experimental spectra, values at 450 mμ for quinine sulfate and 630 mμ for aluminum-PBBR chelate were each set equal to 100% quantum intensity and values at the other wavelengths for each compound were made relative to it. Dividing these percentages by the relative quantum intensity from the corrected spectra gave quantum values which were then divided by their respective wavelengths to give energy per wavelength data. The energy data were plotted so that the values for both compounds were made equal at 580 mμ (a common wavelength nearest to that of 560 mμ, the peak for the average human eye). Values at the other wavelengths for both compounds were made relative to 100% for the maximum at 575 mμ of the combined curves. (See Fig. 1.)

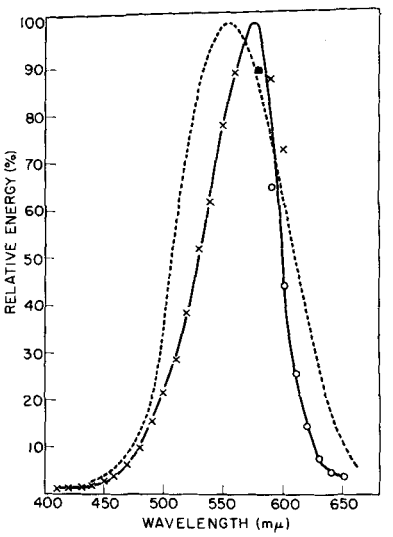

Fig. 1—Relative energy response of the 106 filter-1P28 photomultiplier system as compared to the average human eye. Key: ------, human eye responses; ——, 106-1P28 response; X, quinine sulfate data; O, Al-PBBR data.

Visual Detection Measurements—A fluorescent compound was dissolved in an appropriate solvent and its emission spectrum determined in the Aminco-Bowman spectrophotofluorometer equipped with the 106 filter. Concentrations were chosen to be in a range linear with fluorescence and the proper excitation wavelengths were employed for each compound. The approximate area under an emission peak for a particular substance (peak height by width at half height in cm.) was divided by the concentration of that compound in moles per milliliter to provide intensity in terms of cm.^{2} mole^{-1} ml. data for each compound.

DISCUSSION AND RESULTS

A comparison of the blue fluorescence of a series of compounds synthesized in these laboratories to that of quinine sulfate by the quinine reference unit procedure (5) proved successful for estimating relative fluorescence of these compounds. However, this same comparison was not satisfactory for predicting success in the fluorescent antibody technique. That is, compounds found by this procedure to possess fluorescence of medium intensity compared to fluorescein isothiocyanate, a widely used antibody tagging reagent (6), did not provide observable fluorescent conjugates in the fluorescent antibody technique. Thus, a need for a detection system approaching that of the human eye was indicated.

The nine-stage photomultiplier tubes (RCA 1P21, 1P28, and 931A) commonly employed with commercially available fluorometers were investigated. As the relative spectral response of these tubes approach that of the eye at wavelengths above 500 mμ, there was only the need to modify the response at the lower wavelengths. Both a Kodak Wratten filter No. 106 and a Corning filter No. CS 3-124 were evaluated for this purpose with RCA 1P21, 1P28, and 931A tubes. A comparison of these systems for the spectral response of fluorescence obtained from quinine sulfate to the corrected relative response of quinine sulfate as reported by Lippert (7) was made. For the individual tubes used in the present study, the 106 filter was the most satisfactory and gave approximately the same relative response curves for each of the three types of tubes. However, as the 106–1P28 combination was two times more sensitive than the other system, it was used for more extensive study.

In a further description of the 106–1P28 detection system, quinine sulfate and the aluminum–PBBR chelate, suggested by White (4), were used as reference sources. These compounds covered the range of fluorescence emission that was of interest in approximating the eye response, and their corrected emission spectra have been established (4, 7). Emission spectra of these compounds were determined in the Aminco-Bowman spectrophotofluorometer with the 106 filter in front of a 1P28 photomultiplier tube. In this manner, the standard materials serve as a defined source so that the ratio of the experimental curves to their corresponding standard corrected curves serve to describe the effect of filter, photomultiplier tube, and emission monochromator. This procedure is analogous to the use of such standard compounds for the calibration of the emission portion of a fluorometer (4).

The relative quantum intensity data obtained in this manner were expressed in energy units by dividing by wavelength to give a direct comparison to the relative energy data available for the human eye. Finally, in order to form a continuous curve, the intensity values obtained for each reference compound were made relative to their values at 580 mμ as an equal value. This wavelength was chosen as being common to both reference spectra and the wavelength nearest to the 560 mμ maximum for the average human eye.

TABLE I—FLUORESCENCE RELATIONSHIPS TO RHODAMINE B

Compd.	Excitation λ (mμ)	Normal Emission λ (mμ)	Relative Fluorescence Without Filter	Relative Fluorescence With Filter[g]
Rhodamine B[a]	540	580	1.000	1.000
Rhodamine B isothiocyanate[b]	540	580	0.300	0.260
Disodium fluorescein[c]	490	520	12.500	5.000
Fluorescein isothiocyanate[b]	490	520	10.000	3.330
4-Naphtho-(1,3;4,5)-triazolylstilbene-2-sulfonic acid, sodium salt[d]	365	460	6.330	0.510
4,4′-Bis(4-anilino-6-di-ethanolamine-*s*-triazin-2-ylamino)-2,2′-stilbene-disulfonic acid disodium salt[e]	365	435	1.800	0.024
Quinine sulfate[f]	365	455	4.900	0.051

[a] Allied Chemical Co. [b] Baltimore Biological Laboratories. [c] Eastman Kodak. [d] Geigy Chemicals. [e] American Cyanamid Co. [f] Mallinckrodt Chemical Works. [g] All values in this column could be multiplied by a factor of 0.35 to compare fluorescence relative to rhodamine B determined without filter.

The relative energy responses of the 106–1P28 detection system used in these studies and derived as just described is given in Fig. 1. For purpose of comparison, the relative energy response of the human eye is also given in this figure.

An application of the 106–1P28 system for the evaluation of compounds whose fluorescence is of interest in the visible range is given in Table I. All compounds were compared at concentrations in the linear portion of their concentration-fluorescence curves. Two series of fluorescent intensities were compared to those of rhodamine B with and without the presence of the 106 filter. Of the compounds evaluated, rhodamine B with an emission maximum at 580 mμ nearest to the 575 mμ maximum of the system showed the least effect (35% reduction) with the presence of a 106 filter. While fluorescein shows a significant change in relative fluorescence in the two systems, this change is even more pronounced with compounds of blue fluorescence at the lower wavelengths.

Compounds exhibiting fluorescence at these lower wavelengths are of particular interest in our studies, so that the 106 filter–1P28 photomultiplier system has proven of value in our evaluation of the fluorescence of potential antibody tagging agents. This same system should have general application where a fluorescence detection system approaching that of the human eye is required.

Quantitative Analysis and Alkaline Stability Studies of Allopurinol

By PHILIP D. GRESSEL and JOSEPH F. GALLELLI

Methods for quantitative chromatographic separation and spectrophotometric analysis are reported for allopurinol [4-hydroxypyrazolo(3,4-*d*) pyrimidine] in the presence of its alkaline decomposition products. Stability data are presented using rate constants obtained from Arrhenius-type plots; $t_{90\%}$ for an unbuffered sodium allopurinol solution is approximately 150 days at 25°. The formate salt of 3-amino-4-pyrazolecarboxamide accounts for essentially all the degradation under pharmaceutically usable conditions.

ALLOPURINOL, 4-hydroxypyrazolo(3,4-*d*)pyrimidine, is a new, potent inhibitor of xanthine oxidase used in the treatment of hyperuricemia associated with gout. Extensive studies with the parenteral form of this drug have been performed by the National Cancer Institute to evaluate its effectiveness in the prevention of hyperuricemia and uric acid nephropathy in patients treated with X-ray and/or chemotherapy. The chemical stability studies in the present work were oriented toward conditions likely to be encountered in the clinical studies.

Some preliminary work (1) had been done previously on the assay of allopurinol solutions, using the ratio of optical absorbance at 262 mμ:255 mμ. It is found, however, that the UV spectrum of the major decomposition product does not differ enough from that of allopurinol, at any pH, to enable one to perform accurate determinations (see Fig. 1). The preliminary work (1) utilizing simple spectrophotometric analysis had not resulted in the detection of any decomposition of a refluxing solution of sodium allopurinol. However, thin-layer chromatography conducted in this laboratory on similar samples clearly showed the presence of two compounds in significant amounts. This led to the search for a larger scale quantitative method of separation of the components in aqueous solutions.

A specific method of assay was developed for allopurinol in the presence of its decomposition products, utilizing ion-exchange chromatographic separation and spectrophotometric analysis. Kinetic studies employing the assay method were done for some alkaline conditions.

Partially degraded allopurinol soln.	Acetone, A.R.	0.33, 0.57
Allopurinol	Acetone, A.R.	0.57

Ion-Exchange Chromatographic Separation Procedure—Columns were packed with slurries of the anion-exchange resin in pH 10 phosphate buffer. Methods of packing and eluting the column and detecting the solutes in the effluent are essentially the same as those used in previous work conducted in this laboratory (3). The pH 10 buffer was used to elute the pure allopurinol fraction; then pH 4 buffer was substituted to elute the decomposition product from the columns. Effluent fractions corresponding to individual peaks were pooled and quantitatively diluted in pH 4 phosphate buffer to obtain ultraviolet spectra for quantitative analysis.

Columns were regenerated for reuse by pumping 300 ml. of the pH 4 phosphate buffer, then 300 ml. of the pH 10 phosphate buffer, through the apparatus.

Kinetic Studies—Chemical assays using the separation techniques above were performed on aliquots of solutions kept under various conditions (see Table II) at time intervals varying with observed reaction rates. Studies at the listed conditions were conducted at 37° in a constant-temperature water bath, and at 52° in a constant-temperature oven. One study was done at those temperatures as well as at 76° in a constant-temperature oven.

used in the thin-layer chromatographic procedures.

All other chemicals were reagent grade, except as specified.

Apparatus—Thin-layer chromatography plates were prepared with a Desaga thin-layer chromatography kit.[4] Chromatographic column elution under positive pressure was performed with a Sigmamotor pump.[5] The eluent was monitored with a GME ultraviolet absorption meter, model UV 265 IF;[6] percent transmittance was recorded on a Texas Rectilinear recording milliameter.[7] Borosilicate glass columns, 1 cm. inner diameter, 25 cm. in length, and fitted with ground-glass connections for a reservoir for packing or eluting under air pressure, were used to hold the ion-exchange resin. Ultraviolet analyses were carried out on either a Beckman model DU spectrophotometer or a Cary 11 recording spectrophotometer. Infrared spectra were obtained on a Beckman IR5A spectrophotometer. Melting points were obtained on a Thomas-Hoover melting point apparatus.[8] Constant-temperature ovens (±1°) and a constant-temperature water bath (±.02°) were used in stability studies.

Thin-Layer Chromatographic Separation Procedure—Activated layers 250 μ thick, of Silica Gel GF_{254}, were used for qualitative studies. Spots were detected by their quenching of fluorescence under ultraviolet light. (See Table 1).

Determination and Identification of the End Product of Degradation—Recovery of the major end product was accomplished by two methods. In one procedure, solutions in the phosphate eluents were vacuum distilled to dryness; the residue was extracted with *n*-butanol to isolate the free base. In the second procedure, solutions were made acidic (pH 1–2) with sulfuric acid, concentrated to about one-half their original volume by vacuum distillation, then refrigerated for several days to obtain crystals of the sulfate salts. Ultraviolet, infrared, NMR, and mass spectral analyses were performed, as well as elemental analyses. Retention of the unknown on a cation-exchange resin[9] was observed. Duclaux values (4) were obtained on a dilute solution of distillate from a sample of allopurinol solution which had been refluxed for 15 hr. in sufficient excess NaOH to make the solution pH 11.7 at 25°. Melting point data were obtained on the sulfate salt of the unknown, known 3-amino-4-pyrazolecarboxamide hemisulfate hydrate, and on an intimate mixture of the known and unknown.

Results and Discussion

End Products of Reaction—All the evidence points to 3-amino-4-pyrazolecarboxamide as the

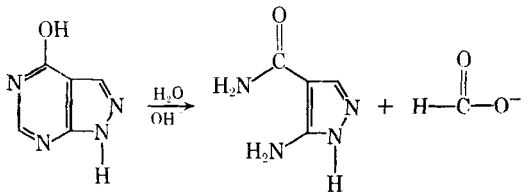

Scheme I

only significant end product. The overall reaction is shown in Scheme I.

Spectral evidence further confirms 3-amino-4-pyrazolecarboxamide; the IR spectra of known and unknown 3-amino-4-pyrazolecarboxamide are identical in either the free basic form or the salt form, although the spectra of the free form of either differ significantly from those of the salt form. UV spectra are identical throughout the normal pH scale. High resolution mass spectra of the degradation product show a parent peak with mass 126.0526. Calculated formula weight for 3-amino-4-pyrazolecarboxamide is 126.0541. The melting point of an admixture of its known and unknown hemisulfate hydrate is not depressed: known, 220–221°; unknown, 219–220°; equal mixture, 221–222°, all uncorrected.

The reaction scheme was confirmed indirectly by the confirmation of formate in a rapidly degraded solution. Duclaux values (3) obtained on the distillate were 2.7%, 2.9%, and 3.1%, respectively. The values for a correspondingly low concentration (0.2%) of authentic formic acid were 2.8%, 3.3%, and 3.6%.

Ion-Exchange Recovery of Allopurinol—The acidic nature of allopurinol, as well as the basic nature of its degradation product, coupled with their solubility in very polar solvents, made allopurinol a suitable candidate for ion-exchange chromatographic separation. In this work allopurinol was quantitatively retained on the column as the anion while 3-amino-4-pyrazolecarboxamide was being eluted off along with nonionic constituents. (See Fig. 2.) Then the pure allopurinol fraction was quantitatively removed in the pH 4 elution.

The pKa of allopurinol is approximately 9.4. Thus a pH of at least 10 was required to have the molecule substantially in its anionic form. The choice of anion-exchange resins, therefore, was limited to those which have strongly basic groups whose ionization was not materially affected at the required pH's.

Calculation for Intact Allopurinol—Allopurinol follows Beer's law in absorbance range 0–2 under controlled conditions. At pH 4, using the phosphate eluent, $\lambda_{max.} = 250$ mμ. Molar absorptivity (ϵ) = $7.74 \times 10^3/M$; absorptivity (a) = 56.5. No interference is encountered from nonionic compounds, which have been eluted in the first fraction.

Stability of Allopurinol Solutions—Results of the kinetic studies are found in Table II. In each case there was reasonably good adherence to first-order kinetics with respect to allopurinol. (See Fig. 3.) The trials at different pH's under otherwise similar conditions indicate a first-order dependency on hydroxyl ion concentration. Arrhenius-type plots were used to extrapolate higher temperature data to 25°. (See Fig. 4.) Activation energy of the reactions was about 25,500 cal./M.

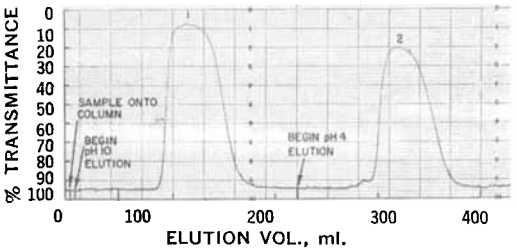

Fig. 2—Typical ion-exchange column chromatogram of a partially degraded sample of allopurinol.

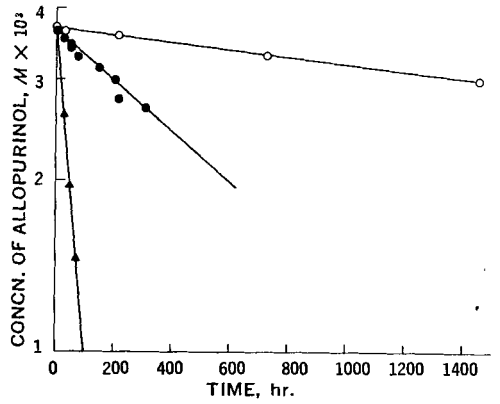

Fig. 3—Typical first-order plots showing the disappearance of allopurinol as a function of time at 37°(○), 52° (●), and 76° (▲), under otherwise similar conditions (solution C, Table II).

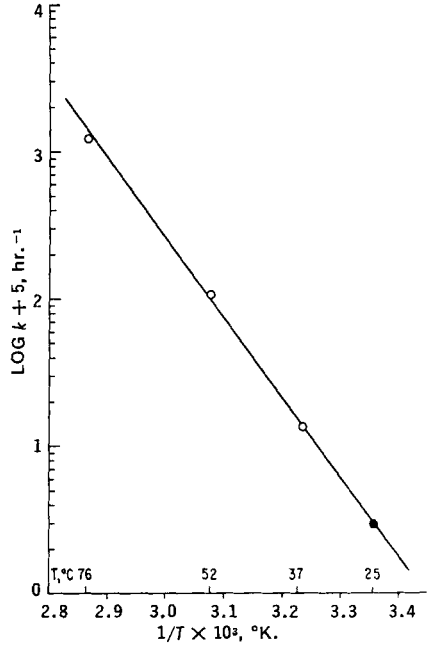

Fig. 4—Arrhenius-type plot of a typical stability study (solution C, Table II).

CONCLUSIONS

A quantitative method of assay has been found for allopurinol in the presence of inorganic salts, carbohydrate fillers, and its only significant alkaline degradation product. The method utilizes anion-exchange chromatography followed by spectrophotometric analysis.

The major product of alkaline degradation of allopurinol under pharmaceutically usable conditions is 3-amino-4-pyrazolecarboxamide, as the formate salt.

The lowest pH commensurate with the desired solubility should be used in formulating injections. At pH 10.8, an unbuffered solution of allopurinol has a $t_{90\%}$ of about 150 days.

Investigation of the Use of Derivative Neutron Activation Analysis for Drug Assay

By W. A. SKINNER, M. A. LEAFFER, and R. M. PARKHURST

The use of neutron activation analysis for assay of chlorine- or bromine-containing drugs or derivatives of drugs was investigated. The ubiquitous nature of chloride greatly limited the use of this analytical method for chlorine-containing derivatives because of the background problem. Bromine-containing derivatives of aspirin and salicylic acid were prepared for neutron activation analysis, but again background bromide and interfering substances limited detection to 1×10^{-2} mcg. of bromide. Sensitivity of this analytical method is not comparable to that attainable with gas chromatography or spectrofluorometry.

In 1964, Steim and Benson (1) studied the use of derivative activation chromatography as a method for analysis of bromine-containing derivatives of amino acids, carboxylic acids, keto acids, sugars, and unsaturated fatty acids. The lower limits for detection of most amino acids separated as *N*-brosyl derivatives on paper were 0.01 mcg., as were the limits for citric or lactic acid as their bromophenacyl esters. The major limitation in sensitivity was the background arising from activation of contaminants in the paper. Conventional G-M counting was used.

There has been interest in sensitive methods for the assay of drugs in plasma or urine and it was decided to investigate the use of derivative neutron activation analysis for this purpose.

EXPERIMENTAL

Activation Source and Counting Methods—The Triga Mark I nuclear reactor at General Atomics, San Diego, Calif., with a thermal neutron flux of 1.8×10^{12} n/cm.^{2}-sec. was used for these studies. In the case of chloride determinations, the 1.64 Mev. gamma ray of 37.3 min. ^{38}Cl was used for identification and quantitative measurements while with bromide, the 0.78 Mev. gamma ray of 35.7 hr. ^{82}Br was used. Measurements were by the use of multichannel gamma ray spectrometry. Counting for bromide samples was on the fourth day after irradiation to allow short-lived isotopes to decay. Activation time in the reactor was 30 min.

Assay of Chlorine-Containing Drugs—In order to investigate the problems of background related to chloride analyses, chlorpromazine was used as a model drug. The paper selected for paper chromatographic and neutron activation studies was Schleicher and Schuell No. 589 which reportedly (1) has a lower background than others. The solvent system used was *n*-butanol–acetic acid–water (60:15:25). Chlorpromazine hydrochloride was found to move near the solvent front (R_f, 0.93) in this system. The high R_f has the advantage that any oxidation products of the drug are more polar and will trail the drug on the paper. Detection of 1 mcg. of chlorpromazine hydrochloride on Silica Gel G thin-layer plates could be made with ultraviolet light, ceric sulfate spray, or 50% sulfuric acid spray.

The chloride background of SS No. 589 white C paper was investigated prior to initiating studies with the drug. Neutron activation was for 30 min. at a flux of 1.8×10^{12} n/cm.^{2}-sec. Wide variation in chloride content of various sections of the paper

TABLE I—ANALYSIS OF BROMIDE IN THE *p*-BROMOPHENACYL DERIVATIVE OF ASPIRIN BY NEUTRON ACTIVATION ANALYSIS AFTER CHROMATOGRAPHY

Section (cm. from Bottom)	Wt. of Silica Gel G, mg.	mcg. Br (Found)
4–6	33.7	ND[a] < 0.071
6–8	32.8	ND < 0.067
8–10	43.4	8.88 ± 0.15
10–12	35.0	0.238 ± 0.032
12–14	49.2	ND < 0.085

[a] Not detected.

TABLE II—ANALYSIS OF BROMIDE IN THE *p*-BROMOPHENACYL DERIVATIVE OF ASPIRIN BY NEUTRON ACTIVATION ANALYSIS

Wt. of Silica Gel G, mg.	mcg. Br (Found)	mcg. Br. (Theoret.)
26.0	0.947 ± 0.034	1.00
34.3	ND ± 0.072	0.10
41.7	ND ± 0.071	Blank

was noted. Two-by-two inch strips from bottom to top had chloride contents of 20.4 ± 0.5 mcg., 21.0 ± 0.7 mcg., 37.0 ± 0.7 mcg., and 41.7 ± 0.7 mcg. Washing the paper with deionized, distilled water for 8 hr. reduced the background of the 2 × 2-in. strips to 5 mcg. Other papers besides SS No. 589 white C paper were investigated for their chloride content and best results were obtained with SS 589 orange paper. Washing the paper for 3 days with 10% acetic acid followed by 7 additional days of washing with deionized, distilled water resulted in chloride values of 0.5 to 2.7 mcg. for 0.5 × 1.0-in. sections of paper.

Various silica gels for TLC were analyzed for chloride content by neutron activation. Values ranged from 0.3 to 3.5 mcg. of chloride per 5 mg. of Silica Gel GF (typical quantity per spot). The presence of manganese in Silica Gel H greatly decreased the sensitivity of the chloride assay.

Assay of Bromine-Containing Derivatives of Drugs—In contrast to the case of chloride, the bromide background of the paper was lower and more uniformly distributed. The average bromide background on SS No. 589 white C paper was 0.10 ± 0.02 mcg. per 2 × 2-in. section. Washing the paper for 8 hr. with deionized, distilled water reduced the background of the 2 × 2-in. sections to nondetectable levels, *i.e.*, <0.03 mcg.

Silica gels for TLC were analyzed by neutron activation analysis for bromide background. A 5-mg. sample of Silica Gel GF had nondetectable levels of bromide present.

In order to ascertain the problem of chromatographic separation and spreading on the plates, bromine-containing derivatives of aspirin and its metabolite were prepared. Reaction of acetylsalicylic acid with *p*-bromophenacylbromide yielded the *p*-bromophenacyl derivative of the drug. Similarly, reaction of *p*-bromophenacylbromide with salicylic acid yielded the corresponding derivative of a metabolite of the drug. The *p*-bromophenacyl derivative of aspirin has not been previously reported in the literature and was thus analyzed, m.p. 133–135°, uncorrected (capillary tube).

Anal.—Calcd. for $C_{17}H_{13}BrO_5$: C, 54.13; H, 3.45. Found: C, 54.25; H, 3.59.

The aspirin derivative was spotted on a plate in an amount so that 10 mcg. of bromide was at the origin. The chromatogram was developed in chloroform, the plate sectioned, and sent for neutron activation analysis of bromide. The results are shown in Table I.

Samples of the bromine-containing derivative of aspirin were spotted on a Silica Gel G plate which was not developed, but the silica gel was scraped off and analyzed for bromide. Table II shows these results.

Manganese in the silica gel interfered with the detection and reduced the sensitivity. It was found that bromine-containing derivatives could be removed from the silica gel plates with analytical grade acetone and the acetone evaporated in the polyethylene vials used for the neutron activation thus eliminating the interfering manganese. However, the polyethylene vial blank analyzed for 0.0435 ± 0.0087 mcg. of bromide due to interfering substances present in the polyethylene. A tube in which analytical grade acetone was evaporated analyzed for 0.0303 ± 0.0101 mcg. of bromide indicating that the solvent does not contribute to the background. The experience of General Atomics has been that polyethylene is the best available substance for these studies.

An empty polyethylene vial used for sample activation by General Atomics was activated and after removal from the reactor, the vial was washed with analytical grade acetone, and the washings transferred to a nonirradiated vial, evaporated to dryness, and counted for gamma rays. Less than 1.3×10^{-2} mcg. equivalent of bromide was detected. Maximum upper limits were established on the basis of 3 σ of the count rate in the area of the 0.777 Mev. photopeak of 35.8 hr. ^{82}Br. To determine whether any extractable bromide was present in Silica Gel HF, two samples were extracted with acetone and treated as above. The results were $<8.8 \times 10^{-3}$ mcg. bromide and $<1.22 \times 10^{-2}$ mcg. of bromide indicating that extraction of bromide from the silica gel did not contribute to the background.

SUMMARY

Background problems of paper or silica gel used for chromatography greatly limit the use of neutron activation analysis for chlorine-containing drugs. Washing of the paper lowered the background to a level of 0.5 to 2.7 mcg. for 0.5 × 1.0-in. sections of paper while Silica Gel GF values ranged from 0.3 to 3.5 mcg. per 5 mg. of gel.

Although background problems encountered in the neutron activation analysis of bromide in bromine-containing derivatives of drugs were much less than in the case of chloride, they were quite limiting. Silica gel was preferred to the use of paper for separation of the drug derivatives studied. Due to interference of substances present in the polyethylene vials used for sample holding during activation, it was necessary to extract the sample after activation and count in another vial after

solvent removal. With these precautions, limits of detection of bromide were approximately 1×10^{-2} mcg. which is far less sensitive than spectrofluorometric and gas chromatographic methods for certain drugs. With longer activation times perhaps the sensitivity could be increased but costs of analyses would also increase and, perhaps, background problems.

Effects of Some Adrenergic Agents on Low Frequency Electroshock Seizures

By PENG NAM YEOH and HAROLD H. WOLF

The effect of several adrenergic agents on low frequency electroshock seizures was studied in normal, reserpine and α-mmT pretreated mice. Seizure threshold was elevated by pronethalol and propranolol and reduced by phenoxybenzamine and isoproterenol. Both reserpine and α-mmT antagonized the threshold altering activity of pronethalol and phenoxybenzamine. Reserpine plus pronethalol or propranolol completely abolished the central stimulation induced by isoproterenol. A central adrenergic system involving antagonistic types of receptors appears to be involved.

It has been shown that β-adrenergic blocking agents possess anticonvulsant activity when evaluated by maximal electroshock and chemoshock techniques (1, 2). Preliminary studies in these laboratories (unpublished) indicate that the β-adrenergic blocking agents pronethalol and propranolol also reduce seizure susceptibility in audiogenic seizure susceptible mice, whereas phenoxybenzamine, an α-adrenergic blocking agent, enhances this phenomenon.

It was the objective of this study to determine whether such drug effects reflect general changes in the level of brain excitability which could be readily quantitated by measuring alterations in low frequency electroshock seizure threshold (l.f. EST). Increasing evidence indicates that endogenous brain amines may play an important role in the expression of seizure states (3–6). The experiments were designed to facilitate an evaluation of the relationship between the adrenergic drug activity described and the existing level of endogenous brain amines.

EXPERIMENTAL

Adult, male, albino mice of a random bred Swiss strain (Maxfield Animal Supply, Cincinnati, Ohio) ranging from 16 to 28 Gm. were used as experimental animals. They were housed in groups of 9 to 11 animals in plastic cages (26 × 15 × 12 cm.) with wire mesh or perforated metal tops. Except during periods of experimentation, they were maintained on Purina laboratory chow and given free access to tap water.

Pronethalol [(2-isopropylamino)-1-(2-naphthyl) ethanol hydrochloride] and propranolol [(1-isopropylamino)-3-(1-naphthyloxy)-2-propanol hydrochloride] were employed as β-adrenergic blocking agents and phenoxybenzamine hydrochloride as an α-adrenergic blocking agent. The catecholamine depleting agents used were reserpine (2 mg./Kg., 24-hr. pretreatment) and α-methyl-metatyrosine (α-mmT; 400 mg./Kg., 24-hr. pretreatment).

All drugs were given intraperitoneally as solutions in distilled water except pronethalol which was administered in 0.2% methylcellulose.[1] They were prepared so that 10 ml./Kg. contained the required dose. Requisite volumes of saline or methylcellulose (0.2%) were administered to control animals. In studies where two or more drugs were employed in sequence, the control animals received only the drug (or drugs) used for pretreatment. Except for fluorometric assays, all experiments were conducted between 4 and 11 p.m. at 23–25°.

Neurotoxicity Studies—The method of Weaver and Miya (7) with slight modifications was employed to obtain the time of peak effect and the dose of each of the adrenergic agents which produced overt evidence of neurological toxicity in 50% of mice (TD_{50}). Mice were placed on a rolling bar, 2.5 cm. in diameter, rotating at 6 r.p.m. An animal was considered to be unaffected if it could stay on the bar continuously for 1 min. in any one of three consecutive trials. Data obtained in this test were statistically analyzed by the method of Litchfield and Wilcoxon (8). In all further experiments (unless otherwise stated) the dose of all adrenergic agents used was $^1/_2$ TD_{50}.

Low Frequency Electroshock Seizure Threshold (l.f. EST) Test—A Grass stimulator (model S4G, Grass Instrument Co., Quincy, Mass.) was used to apply a unidirectional current (6 pulses per second, 0.2 msec. duration, 3 sec. stimulus duration) through corneal electrodes (9). Mice were shocked at various intensities according to the staircase method of Finney (10). The presence of a "stunning" response (at least 3 sec. of immobility) or minimal clonus was con-

TABLE I—NEUROTOXICITY OF SOME ADRENERGIC BLOCKING AGENTS

Drug	Time of Peak Effect, min.	Toxic Dose$_{50}$, mg./Kg.
Pronethalol	5	52.0 (35.9–75.4)[a]
Propranolol	15	59.5 (53.1–66.6)
Phenoxybenzamine	60	74.0 (64.9–84.4)

[a] The figures within parentheses represent 95% fiducial limits.

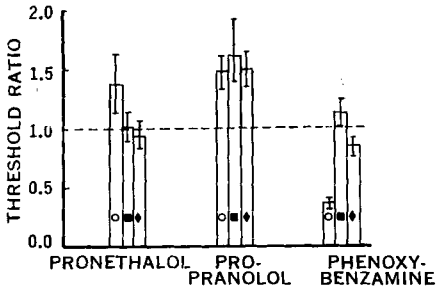

Fig. 1—Effect of some adrenergic blocking agents on l.f. EST. Key: ○, *drug* per se; ■, *reserpine + drug;* ◆, *α-mmT + drug.*

sidered indicative of a seizure. Groups of at least 24 mice each were administered $^1/_2$ TD_{50} of the various adrenergic agents and subjected to the l.f. EST test at the time of peak neurotoxicity. Control groups were always tested concurrently with drug-treated animals. The l.f. EST was determined as previously described (11). The threshold ratio (threshold of drug group/threshold of control group) was calculated and the 95% confidence limits for this ratio determined by the method of Litchfield and Wilcoxon (8).

Catecholamine Assays—The amount of depletion of brain catecholamines (norepinephrine and epinephrine) produced by reserpine and α-mmT (under experimental conditions where the depleting agents, *per se*, do not alter seizure threshold) was determined. Fluorometric assays of whole brains (3 brains per sample) were conducted according to a modified method of Anton and Sayre (12). Fluorescence was read using an Aminco-Bowman spectrophotofluorometer with photomultiplier tube IP21. The excitation–emission wavelengths for norepinephrine at pH 7.0 and for epinephrine at pH 2.0 were (395–505) and (410–520), respectively. The level of brain catecholamines (mcg./Gm. wet tissue) in reserpine and α-mmT pretreated mice was compared statistically to that of control animals by means of a *t* test.

RESULTS

A summary of the results obtained in the neurotoxicity studies is presented in Table I.

The effects of $^1/_2$ TD_{50} of the various adrenergic blocking agents employed on l.f. EST can be seen in Fig. 1. In this and Fig. 2, the vertical bracketed lines represent 95% confidence intervals for the calculated ratios and any line which does not cross 1.0 indicates that the treatment employed had a significant ($p < 0.05$) effect on convulsive threshold.

Thus it can be calculated that pronethalol and

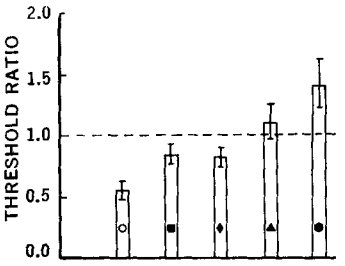

Fig. 2—Effect of isoproterenol on l.f. EST. Key: ○, *isoproterenol* per se; ■, *reserpine + isoproterenol;* ◆, *α-mmT + isoproterenol;* ▲, *reserpine + pronethalol + isoproterenol;* ●, *reserpine + propranolol + isoproterenol.*

propranolol elevate seizure threshold by 37% and 47%, respectively, whereas phenoxybenzamine lowers it by 65% when compared to saline-treated controls. Pretreatment with either reserpine or α-mmT antagonizes most of the central effects of pronethalol and phenoxybenzamine, but not that of propranolol.

No significant change in l.f. EST was demonstrated in control mice treated with either reserpine (2 mg./Kg., 24-hr. pretreatment) or α-mmT (400 mg./Kg., 24-hr. pretreatment). However, under these same experimental conditions, significant depletion of brain catecholamines was demonstrated. An examination of the results of the fluorometric assay of brain catecholamines indicated that the dose of reserpine employed produces 85.8% and 63.2% depletion of norepinephrine and epinephrine, respectively, whereas that of α-mmT induces 70.0% depletion of norepinephrine and 31.3% depletion of epinephrine.

DISCUSSION

The results of this investigation indicate that the anticonvulsant effects of pronethalol and propranolol do extend to low frequency electroshock seizures. Furthermore, phenoxybenzamine appears to lower markedly the threshold for such seizures. While the central activity seen with propranolol does not seem to be related to the existing brain level of endogenous catecholamines, that observed following treatment with either pronethalol or phenoxybenzamine is significantly altered in animals whose catecholamines have been partially depleted by reserpine or α-mmT.

Since essentially opposite effects on l.f. EST were produced by the α- *versus* β-adrenergic blocking agents examined, it was decided to investigate the central effects of an agent known to stimulate selective adrenergic receptors in the periphery. For this purpose the β-receptor stimulant isoproterenol was chosen and the same experimental procedure outlined above was followed. The TD_{50} for isoproterenol was found to be 470 (401.7–549.9) mg./Kg. with a time of peak effect of 10 min. The effect of isoproterenol on l.f. EST may be seen in Fig. 2.

Isoproterenol *per se* markedly lowers seizure threshold at a dose of $^1/_2$ TD_{50}. Pretreatment with either reserpine or α-mmT significantly reduces (but does not abolish) this effect. Finally, this same dose of isoproterenol does not induce any evident central stimulation in animals pretreated

with reserpine and a β-adrenergic blocking agent (pronethalol or propranolol). In fact, it can be seen that the propranolol plus reserpine pretreated mice have elevated seizure thresholds following the administration of isoproterenol.

The results of this preliminary study suggest the presence of central adrenergic receptors which may be involved in the expression of l.f. EST. This concept is supported by the previous work of Swinyard *et al.* (3, 4), who demonstrated that the threshold for both chemically and electrically induced seizures in mice can be altered by prior administration of epinephrine and norepinephrine. Moreover, Baldessarini and Kopin (13) have recently reported that a marked release of ^{3}H-norepinephrine from rat brain occurs in response to electrical stimulation and Scudder *et al.* (14) have demonstrated the existence of a positive correlation between the level of endogenous brain amines and maximal electroshock seizure latency in mice.

The failure to observe consistently significant alterations in l.f. EST when reserpine or α-mmT were given *per se* may reflect incomplete amine depletion, lack of inhibition of amine biosynthesis (in the case of reserpine), or production of active metabolites from α-mmT, *e.g.*, *m*-hydroxyamphetamine, metaraminol, or *m*-methoxyamphetamine (15). Nevertheless, the results observed with the adrenergic agents employed seem to imply that threshold for low frequency electroshock seizures may be markedly influenced by the degree of drug-induced differential stimulation applied to opposing central adrenergic receptors. In order to substantiate this hypothesis, additional data of a similar nature must be collected for a variety of adrenergic drugs which are known to interact specifically with α and β receptors. Furthermore, the work must be conducted in animals that have been subjected to a more selective inhibition of brain amine biosynthesis than that reported above. Such studies are currently in progress.

Ion-Exchange Resins and Cinchona Alkaloids I. Exchange Equilibria

By S. S. KANHERE, R. S. SHAH, and S. L. BAFNA

The exchange equilibria of four cinchona alkaloid sulfates with sulfonic acid cation-exchange resins of different degrees of cross-linking and particle size have been studied and the results are discussed.

THE AVAILABLE ion-exchange studies with cinchona alkaloids (1–21) do not seem to cover detailed physicochemical studies and hence it should be of interest to undertake such work. This paper summarizes the study of exchange equilibria of four cinchona alkaloid sulfates with styrene divinylbenzene copolymer-based sulfonic acid cation-exchange resins (in hydrogen form) of different degrees of cross-linking (percent nominal divinylbenzene content) and particle size.

Received February 27, 1967, from the Chemistry Department, Faculty of Science, M. S., University of Baroda, Baroda, India.
Accepted for publication September 15, 1967.

EXPERIMENTAL

Resins (22) and chemicals (23) were from the samples used in earlier work. The stock solution of the alkaloid sulfate (as $Q_2H_2SO_4 \cdot nH_2O$, where Q denotes the alkaloid base) was prepared in distilled water and its concentration in gram equivalents (half the molecular weight of the alkaloid sulfate) per liter was evaluated by sulfate estimation (as barium sulfate).

To study the exchange equilibria of the alkaloid sulfates with the resins, weighed amounts of air-dried resins were placed in contact with suitable volumes of the aqueous sulfate solution of known concentration, in well-stoppered flasks, with frequent shaking at room temperature (~30°). Preliminary work was carried out to find the approximate time within which equilibrium was attained. After sufficiently more time than this (about 4 to 35 days, depending

with reserpine and a β-adrenergic blocking agent (pronethalol or propranolol). In fact, it can be seen that the propranolol plus reserpine pretreated mice have elevated seizure thresholds following the administration of isoproterenol.

The results of this preliminary study suggest the presence of central adrenergic receptors which may be involved in the expression of l.f. EST. This concept is supported by the previous work of Swinyard *et al.* (3, 4), who demonstrated that the threshold for both chemically and electrically induced seizures in mice can be altered by prior administration of epinephrine and norepinephrine. Moreover, Baldessarini and Kopin (13) have recently reported that a marked release of ^{3}H-norepinephrine from rat brain occurs in response to electrical stimulation and Scudder *et al.* (14) have demonstrated the existence of a positive correlation between the level of endogenous brain amines and maximal electroshock seizure latency in mice.

The failure to observe consistently significant alterations in l.f. EST when reserpine or α-mmT were given *per se* may reflect incomplete amine depletion, lack of inhibition of amine biosynthesis (in the case of reserpine), or production of active metabolites from α-mmT, *e.g.*, *m*-hydroxyamphetamine, metaraminol, or *m*-methoxyamphetamine (15). Nevertheless, the results observed with the adrenergic agents employed seem to imply that threshold for low frequency electroshock seizures may be markedly influenced by the degree of drug-induced differential stimulation applied to opposing central adrenergic receptors. Ion-Exchange Resins and Cinchona Alkaloids I. Exchange Equilibria

By S. S. KANHERE, R. S. SHAH, and S. L. BAFNA

The exchange equilibria of four cinchona alkaloid sulfates with sulfonic acid cation-exchange resins of different degrees of cross-linking and particle size have been studied and the results are discussed.

THE AVAILABLE ion-exchange studies with cinchona alkaloids (1–21) do not seem to cover detailed physicochemical studies and hence it should be of interest to undertake such work. This paper summarizes the study of exchange equilibria of four cinchona alkaloid sulfates with styrene divinylbenzene copolymer-based sulfonic acid cation-exchange resins (in hydrogen form) of different degrees of cross-linking (percent nominal divinylbenzene content) and particle size.

Received February 27, 1967, from the Chemistry Department, Faculty of Science, M. S., University of Baroda, Baroda, India.
Accepted for publication September 15, 1967.

EXPERIMENTAL

Resins (22) and chemicals (23) were from the samples used in earlier work. The stock solution of the alkaloid sulfate (as $Q_2H_2SO_4 \cdot nH_2O$, where Q denotes the alkaloid base) was prepared in distilled water and its concentration in gram equivalents (half the molecular weight of the alkaloid sulfate) per liter was evaluated by sulfate estimation (as barium sulfate).

To study the exchange equilibria of the alkaloid sulfates with the resins, weighed amounts of air-dried resins were placed in contact with suitable volumes of the aqueous sulfate solution of known concentration, in well-stoppered flasks, with frequent shaking at room temperature (~30°). Preliminary work was carried out to find the approximate time within which equilibrium was attained. After sufficiently more time than this (about 4 to 35 days, depending

on X, the relative cross-linking of the resins), the solutions were analyzed for alkaloid sulfate concentration by taking out a known volume from each flask, diluting suitably with distilled water, and measuring the absorbance at the invariant wavelengths (23). The total sulfate in the equilibrium mixture was estimated gravimetrically for each resin and it showed no measurable difference in the initial and equilibrium values. Preliminary work also indicated that the values of P_R at room temperature, 35°, and 45° did not differ significantly; also the lowering of the pH to about 2.5 (by addition of sulfuric acid) did not significantly affect the value of P_R.

RESULTS AND DISCUSSION

The selectivity coefficients for alkali metal ions with resins in hydrogen form in sulfate solution had been studied earlier (22). When calculations were carried out for exchange in solutions of the cinchona alkaloid sulfates studied, with resins in the hydrogen form, the calculated values of P_R (Tables I and II; P_R = 100 times the mole fraction of counter ions in the resin phase at equilibrium) were practically constant for resins of higher degree of cross-linking and varied only to a relatively small extent for resins of lower degrees of cross-linking when P_A was varied.

The results were not measurably different when either the amount of alkaloid sulfate solution was held constant and the amount of added resin varied or when the amount of added resin was held constant and the amount of alkaloid sulfate solution was varied, provided the ratio of the initial concentration (in meq./L.) of the resin to the initial concentration of the alkaloid sulfate was the same. This suggests that the value of the equilibrium constant for the exchange (24–32) of the cation QH^+ is large and the equilibrium $HR + QH^+ \rightleftharpoons RQH + H^+$ is shifted very much to the right. However, all the replaceable hydrogen ions in the resin phase are not accessible for exchange, or the available capacity is only a fraction of the total capacity, probably due to the size of the organic counter ions. It is likely that the marked shift of the equilibrium to the right is aided by the operation of nonexchange interactions (31–33) and that the interactions tend to increase the extent of exchange with increase in $(A)_e$. This may be feasible, to some extent, by further expansion of and/or further separation between some segments in the swollen (34,35) or expanded resin network and should depend on the degree of cross-linking and the extent to which exchange has already occurred. If the further expansion and/or segment separation is sufficient to accommodate some more organic cations by exchange, P_R should increase with increase in $(A)_e$ or decrease in P_A; this is so for lower cross-linked resins in hydrogen form. On the other hand,

if the further expansion and/or segment separation is too small to accommodate more organic cations by exchange, P_R should remain practically constant with increase in $(A)_e$ or decrease in P_A; this is so for higher cross-linked resins in hydrogen form.

For the resins X1 and X2 (Tables I and II), the value of P_R increases to a small extent with increase in $(A)_e$ or decrease in P_A. For the resin X4, the variation in the values of P_R is to a lesser extent than that for resin X2, for cinchonine sulfate and cinchonidine sulfate; for quinine sulfate and quinidine sulfate, the value of P_R is practically independent of P_A. For the resin X8 the values of P_R for all the four cinchona alkaloid sulfates are practically independent of P_A and for higher values of P_A are less than those for the resin X4. The decrease is more for quinine sulfate and quinidine sulfate than that for cinchonine sulfate and cinchonidine sulfate. This decrease may be attributed to the reduced pore size because of higher X; the higher value of P_R for cinchonine sulfate and cinchonidine sulfate than that for quinine sulfate and quinidine sulfate should be due to the smaller size of cinchonine and cinchonidine than that of quinine and quinidine. For resins of higher degree of cross-linking, X12, X16, and X20, the behavior is similar and the value of P_R decreases with increase in X.

Similar studies were carried out with resins IR-120, IR-200, and Am-15 of different particle size (IR-120: a = 0.58, 0.37; IR-200: a = 0.84, 0.58, 0.37, 0.23; Am-15: a = 1.13, 0.84, 0.58, 0.37). It was observed that the values of P_R were practically independent of a. Tables I and II give some representative data. The macromolecular resins IR-200 and Am-15 presumably have the value of X as approximately 20 but have expanded structure and hence are more porous than the gel-type resin X20; the values of P_R for IR-200 and Am-15 are therefore higher than those for the resin X20.

Nomenclature—

$(A)_i$ = the initial concentration of alkaloid sulfate solution in meq./L.,

$(A)_e$ = the equilibrium concentration of alkaloid sulfate in external solution in meq./L.,

$(\bar{A})_e$ = the meq. of alkaloid in the resin phase per liter of solution, at equilibrium,

$(\bar{H})_i$ = the meq. of resin per liter of the solution in the hydrogen form, initially,

$P_A = 100 \cdot (\bar{A})_e/(A)_i$ = the percent exchange of alkaloid sulfate at equilibrium,

$P_R = 100 \cdot (\bar{A})_e/(\bar{H})_i$ = the percent resin capacity exchanged at equilibrium.

Antiradiation Compounds IX. Dithiocarbamates of Strongly Basic Pyridines and Pyrimidines

By WILLIAM O. FOYE and DOUGLAS H. KAY

Dithiocarbamates of exceptionally strong bases in the pyridine and pyrimidine series, *e.g.*, the 1-alkyl-2- and 4-imino derivatives, have been obtained. Significant protection in mice against ionizing radiation was provided by a dithiocarbamate of one of the strong bases, whereas the dithiocarbamates of weaker bases have generally shown a lower level of protection.

BROWN (1) reported that the introduction of an alkyl group on one of the ring nitrogens of aminopyrimidines greatly increases the basicity of the molecule, the amino group being converted to the imino form. For example, 2-aminopyrimidine has a pKa of 3.54 and 1,2-dihydro-2-imino-1-methylpyrimidine has a pKa of 10.75. Likewise, in the aminopyridine series Albert (2) reported that 2-aminopyridine and 4-aminopyridine have pKa values of 6.9 and 9.2, respectively, whereas the alkylated derivatives, 1,2-dihydro-2-imino-1-methylpyridine and 1,4-dihydro-4-imino-1-methylpyridine have pKa values of 12.2 and 12.5, respectively.

Dithiocarbamates of these exceptionally strong bases were desired as potential antiradiation agents. Such compounds could be considered cyclic dithio acid analogs of mercaptoethylguanidine, which is also strongly basic. Of the compounds mentioned above, only 1,2-dihydro-2-imino-1-methylpyridine has previously been treated with carbon disulfide (3), giving a compound described as 1,2-dihydro-1-methyl-2-pyridinylimmonium 1,2-dihydro-1-methyl-2-pyridinyldithiocarbamate (I). The reactions of amino and imino pyrimidines and pyridines with carbon disulfide described here also gave dithiocarbamate salts rather than zwitterions. The latter might be expected since dithiocarbamate formation takes place preferentially on the weaker of two competing bases and cation formation on the stronger (4). Infrared absorption spectra of the dithiocarbamates of the strongly basic imines showed stretching frequencies for both C=S (~1000 cm.$^{-1}$) and C=N (1650–1675 cm.$^{-1}$), which supports the structures proposed (I). Dithiocarbamates of the corresponding weak (nonalkylated) bases were also prepared for comparison of radiation-protective activity.

Antiradiation testing results show that the dithiocarbamate of one of the imines protects mice at a higher level of radiation (1,000 r) than has generally

Antiradiation Compounds IX. Dithiocarbamates of Strongly Basic Pyridines and Pyrimidines

By WILLIAM O. FOYE and DOUGLAS H. KAY

Dithiocarbamates of exceptionally strong bases in the pyridine and pyrimidine series, *e.g.*, the 1-alkyl-2- and 4-imino derivatives, have been obtained. Significant protection in mice against ionizing radiation was provided by a dithiocarbamate of one of the strong bases, whereas the dithiocarbamates of weaker bases have generally shown a lower level of protection.

BROWN (1) reported that the introduction of an alkyl group on one of the ring nitrogens of aminopyrimidines greatly increases the basicity of the molecule, the amino group being converted to the imino form. For example, 2-aminopyrimidine has a pKa of 3.54 and 1,2-dihydro-2-imino-1-methylpyrimidine has a pKa of 10.75. Likewise, in the aminopyridine series Albert (2) reported that 2-aminopyridine and 4-aminopyridine have pKa values of 6.9 and 9.2, respectively, whereas the alkylated derivatives, 1,2-dihydro-2-imino-1-methylpyridine and 1,4-dihydro-4-imino-1-methylpyridine have pKa values of 12.2 and 12.5, respectively.

Dithiocarbamates of these exceptionally strong bases were desired as potential antiradiation agents. Such compounds could be considered cyclic dithio acid analogs of mercaptoethylguanidine, which is also strongly basic. Of the compounds mentioned above, only 1,2-dihydro-2-imino-1-methylpyridine has previously been treated with carbon disulfide (3), giving a compound described as 1,2-dihydro-1-methyl-2-pyridinylimmonium 1,2-dihydro-1-methyl-2-pyridinyldithiocarbamate (I). The reactions of amino and imino pyrimidines and pyridines with carbon disulfide described here also gave dithiocarbamate salts rather than zwitterions. The latter might be expected since dithiocarbamate formation takes place preferentially on the weaker of two competing bases and cation formation on the stronger (4). Infrared absorption spectra of the dithiocarbamates of the strongly basic imines showed stretching frequencies for both C=S (~1000 cm.$^{-1}$) and C=N (1650–1675 cm.$^{-1}$), which supports the structures proposed (I). Dithiocarbamates of the corresponding weak (nonalkylated) bases were also prepared for comparison of radiation-protective activity.

Antiradiation testing results show that the dithiocarbamate of one of the imines protects mice at a higher level of radiation (1,000 r) than has generally

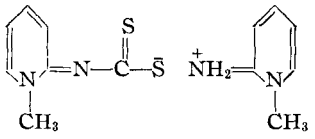
been shown by the dithiocarbamates of weaker bases.



I

DISCUSSION

The method of Brown (1) was used to prepare 1,2-dihydro-2-imino-1-methylpyrimidine hydriodide, and the free base was obtained in benzene by a modified extraction procedure. A minimum amount of water was found necessary in the neutralization step to prevent rearrangement to 2-methylaminopyrimidine which occurs readily in warm alkaline solution (1). The free base in benzene was treated with carbon disulfide, without heating, to yield the desired dithiocarbamate, obtained as the imine salt. The next higher homolog, 1,2-dihydro-2-imino-1-ethylpyrimidine was converted similarly to the dithiocarbamate salt, obtained by very slow precipitation from toluene. It should be noted that these dithiocarbamates were not recrystallized, thus avoiding the possibility of such further condensations as were recently reported by Takeshima *et al.* (5) for the immonium salt of a dithio acid.

The preparation of 1,2-dihydro-2-imino-1-ethylpyrimidine hydriodide (m.p. 191–193°) has not previously been described. However, Kogon (6) has described an isomer, 2-ethylaminopyrimidine (m.p. 50–51°), its hydriodide (m.p. 154–155°), and the picrate (m.p. 160–161°). The latter hydriodide was obtained by refluxing a solution of 2-aminopyrimidine and ethyl iodide in absolute ethanol. By using a less polar solvent, dioxane, the desired 1,2-dihydro-2-imino-1-ethylpyrimidine hydriodide was obtained. However, this hydriodide was found to rearrange readily in 10% aqueous alkali to 2-ethylaminopyrimidine. A minimum amount of water in the neutralization step was found necessary to prevent this rearrangement. Proof that it did not occur is shown by the formation of the picrate (m.p. 178–179°) of the free base in toluene just prior to treatment with carbon disulfide.

N-2-Pyridyldithiocarbamate was obtainable as the triethylammonium salt by the procedure of either Fairfull and Peak (7) or Knott (8). This product was found to be light-sensitive. The preparation of 2-pyridylammonium *N*-2-pyridyldithiocarbamate was previously reported, using the sodium salt of 2-aminopyridine in nonaqueous media with carbon disulfide (9).

4-Pyridylammonium *N*-4-pyridyldithiocarbamate was more conveniently prepared than the triethylammonium salt (8). In regard to the former compound, Camps (10) reported that reaction of 4-aminopyridine, ethanol, and carbon disulfide yielded a product melting at 152°, which he suspected to be the pyridylammonium salt of the dithiocarbamate. No elemental analyses were reported, and it is probable that Camps' product was a thiourea derivative rather than the pyridylammonium salt of the dithiocarbamate, which was found to melt at 134–135°.

The methods of Chichibabin were used to prepare 1,2-dihydro-2-imino-1-methylpyridine hydriodide (11) and 1,4-dihydro-4-imino-1-methylpyridine hydriodide (12). The free base of the 2-imino isomer was obtained by extracting an aqueous alkaline solution of the hydriodide with benzene. The other isomer was obtained by triturating the hydriodide with powdered potassium hydroxide in benzene and extracting with warm benzene. The dithiocarbamate salt of 1,2-dihydro-2-imino-1-methylpyridine (I) was prepared by the procedure of Topchiev (3). The corresponding 4-imino isomer was prepared by treating a benzene solution of the free base with carbon disulfide.

Although the tendency for a shift of the methyl group from the ring nitrogen of an aminopyridine to form a methylamino derivative appears to be much less than in the pyrimidine series, proof that this shift did not occur was obtained by preparing the picrates of the free bases in benzene prior to treatment with carbon disulfide. These picrates differed substantially from those of the rearranged bases. Additional evidence that rearrangement did not occur to give the dithiocarbamates of the *N*-methylaminopyrimidines was shown by the failure of the rearranged 2-methylaminopyrimidine to give a dithiocarbamate under the reaction conditions employed. 2-Aminopyrimidine also failed to undergo dithiocarbamate formation using any of the methods described.

Isomeric with these imines are 3-aminomethylpyridine and 4-aminomethylpyridine. Treatment of these amines in absolute ethanol with carbon disulfide gave the respective dithiocarbamate salts.

Antiradiation Properties—Antiradiation screening for several of the compounds has been carried out at the Walter Reed Army Institute of Research under the direction of Dr. D. P. Jacobus. Tests were done as previously indicated (13) in mice *versus* 1,000 r (γ-rays), and results received so far show that 1,2-dihydro-1-methyl-2-pyridinylimmonium 1,2-dihydro-1-methyl-2-pyridinyldithiocarbamate (I) provided up to 24% protection with doses up to 350 mg./Kg. The dithiocarbamates of the corresponding 4-iminopyridine and of the 2-imino-1-methylpyrimidine showed no protection at this radiation level with doses of less than 50 mg./Kg. A previous report (14) of radiation-protective activities of dithiocarbamates of weaker bases showed activity only at a lower level of radiation dosage (600 r, X-rays).

EXPERIMENTAL

Analyses for carbon, hydrogen, and nitrogen were done by Weiler and Strauss, Oxford, England, or by Carol K. Fitz, Needham, Mass. Sulfur analyses done by Parr bomb peroxide fusion. Melting points were taken on a Mel-Temp apparatus and are corrected. Infrared absorption spectra were obtained with a Perkin-Elmer model 137B spectrometer.

1,2 - Dihydro - 1 - methyl - 2 - pyrimidinylimmonium 1,2 - Dihydro - 1 - methyl - 2 - pyrimidinyldithiocarbamate—Fifteen grams (0.063 mole) of 1,2-dihydro-2-imino-1-methylpyrimidine hydriodide (1) was placed in a glass mortar immersed in an ice bath. The solid was covered with 50 ml. of dry benzene, and powdered potassium hydroxide (15 Gm.) was added slowly during 30 min. to the cooled mixture (below 10°) with trituration. The yellow benzene extract was decanted, and the residue was triturated with an additional 150 ml. of anhydrous benzene in three portions during 1 hr. The benzene

extracts were combined and dried, and the residue was stored in a stoppered container with 40 ml. of anhydrous benzene at 0° for 2 days.

The combined benzene extracts were dried and filtered into a flask equipped with a drying tube. The benzene solution of 1,2-dihydro-2-imino-1-methylpyrimidine was ice-cooled, and 2 ml. (0.03 mole) of carbon disulfide in 10 ml. of anhydrous benzene was added slowly with stirring during 15 min. Stirring with ice-cooling was continued for 4 hr., and the mixture was allowed to stand overnight at room temperature.

An additional milliliter of carbon disulfide was added and the mixture was stirred for 3 hr. at room temperature. The orange-colored solid was collected quickly, was washed three times with 40-ml. portions of anhydrous benzene, and dried *in vacuo*, giving 1.7 Gm. of product that melted at 111–113°. Further washing with benzene gave 1.5 Gm. melting at 115–117° with slight decomposition beginning about 110°; $\nu_{min.}^{Nujol}$ 970, 1000, 1140, 1180, 1325, 1540, 1600, 1650, 1670.

Anal.—Calcd. for $C_{11}H_{14}N_6S_2$: C, 44.89; H, 4.76; N, 28.57. Found: C, 45.09; H, 4.69; N, 28.40.

1,2 - Dihydro - 2 - imino - 1 - ethylpyrimidine Hydriodide—Ten grams (0.105 mole) of 2-aminopyrimidine and 130 ml. of dioxane were heated to boiling, filtered, and refluxed with 20 ml. (0.25 mole) of ethyl iodide for 1 hr. The mixture was kept at room temperature for 24 hr., and this procedure was repeated twice. The precipitated solid was removed prior to each reflux period. After recrystallization from 95% ethanol 8.0 Gm. (30.3%) of product was obtained, m.p. 191–193°.

Anal.—Calcd. for $C_6H_{10}IN_3$: C, 28.70; H, 4.01; I, 50.56; N, 16.73. Found: C, 29.15; H, 4.07; I, 49.90; N, 16.28.

The picrate was crystallized from 95% ethanol, m.p. 178–179°.

Anal.—Calcd. for $C_{12}H_{12}N_6O_7$: C, 40.92; H, 3.43. Found: C, 41.35; H, 3.26.

1,2 - Dihydro - 1 - ethyl - 2 - pyrimidinylimmonium 1,2 - Dihydro - 1 - ethyl - 2 - pyrimidinyldithiocarbamate—Ten grams (0.04 mole) of 1,2-dihydro-2-imino-1-ethylpyrimidine hydriodide was placed in a glass mortar containing 10 Gm. of powdered potassium hydroxide. The mixture was triturated with 200 ml. of toluene, in four portions, during 1 hr. The combined toluene extracts were filtered and then dried.

The toluene extract (5 ml.) was treated with 5 ml. of a saturated solution of picric acid in toluene, giving a picrate melting at 178–179°, the value for the picrate of 1,2-dihydro-2-imino-1-ethylpyrimidine.

The toluene solution of 1,2-dihydro-2-imino-1-ethylpyrimidine was treated with 5 ml. (0.07 mole) of carbon disulfide, and mechanically stirred during a 3-week period. A yellow solid slowly precipitated which became orange in color by the end of the first week. The orange solid was collected, washed with two 25-ml. portions of anhydrous ether, and dried. About 1.2 Gm. of orange solid was obtained that melted at 101–105°.

Anal.—Calcd. for $C_{13}H_{18}N_6S_2$: C, 48.42; H, 5.62; N, 26.06. Found: C, 48.73; H, 5.80; N, 25.55.

Triethylammonium N-2-Pyridyldithiocarbamate—The procedure of Fairfull and Peak (7) was used. From 6.27 Gm. (0.07 mole) of 2-aminopyridine, 7.0 Gm. (39%) of product was obtained that melted at 88–89°, which agrees with the reported value (7); $\nu_{min.}^{KBr}$ 980, 1030, 1090, 1150, 1235, 1300, 1500, 1575, 2450, 2600.

4-Pyridylammonium N-4-Pyridyldithiocarbamate—A mixture of absolute ethanol (30 ml.) and 9.4 Gm. (0.1 mole) of 4-aminopyridine was refluxed on a water bath until the 4-aminopyridine dissolved. Then 14 ml. (0.2 mole) of carbon disulfide was added slowly during 10 min. Refluxing was stopped after 15 min. when hydrogen sulfide was evolved.

The reaction solution was stirred with ice-cooling for 2 hr., and then refrigerated overnight. A yellow solid was collected and washed with absolute ethanol. After refluxing the filtrate for 30 min. and cooling, a total of 5.0 Gm. (38%) of product was obtained, m.p. 134–135°. $\nu_{min.}^{KBr}$ 1000, 1060, 1200, 1250, 1300, 1500, 1600, 1650, 2050, 2500.

Anal.—Calcd. for $C_{11}H_{12}N_4S_2$: C, 49.97; H, 4.57; N, 21.19; S, 24.27. Found: C, 50.16; H, 4.55; N, 21.40; S, 24.53.

1,2 - Dihydro - 2 - imino - 1 - methylpyridine—Eighteen grams (0.076 mole) of 1,2-dihydro-2-imino-1-methylpyridine hydriodide (11) dissolved in 50 ml. of 2 *N* sodium hydroxide solution was extracted with 150 ml. of warm benzene for 9 hr. in a liquid-liquid extraction apparatus. The extraction was repeated twice. The combined benzene extracts were evaporated *in vacuo* at 45°/20–25 mm., giving 7.5 Gm. (88%) of a red oil that boiled at 110°/20 mm., which agrees with the reported value (11) for the free base. The picrate of the free base was prepared, and it melted at 205–207° after recrystallization from 95% ethanol. [Lit. m.p. 201° (11).]

1,2 - Dihydro - 1 - methyl - 2 - pyridinylimmonium 1,2 - Dihydro - 1 - methyl - 2 - pyridinyldithiocarbamate—The procedure of Topchiev (3) was used. From 7.5 Gm. (0.07 mole) of 1,2-dihydro-2-imino-1-methylpyridine, 7.2 Gm. (67%) of product was obtained that melted at 153–154° with decomposition beginning about 145°, which agrees with the reported value (3); $\nu_{min.}^{Nujol}$ 950, 1030, 1050, 1070, 1160, 1235, 1560, 1600, 1650, 1670.

1,4-Dihydro-4-imino-1-methylpyridine Hydriodide—The method of Chichibabin (12) was used. From 20 Gm. (0.21 mole) of 4-aminopyridine, 40 Gm. (80%) of product was obtained that melted at 190–192°. [Lit. m.p. 187–188° (12).]

1,4 - Dihydro - 1 - methyl - 4 - pyridinylimmonium 1,4 - Dihydro - 1 - methyl - 4 - pyridinyldithiocarbamate—Thirty grams (0.13 mole) of 1,4-dihydro-4-imino-1-methylpyridine hydriodide was placed in a glass mortar. Anhydrous benzene (50 ml.) was added, and 25 Gm. of powdered potassium hydroxide was added slowly during 30 min. with trituration. The cloudy benzene extract was removed by decantation and filtered under nitrogen. The residue was triturated thoroughly with 350 ml. of warm benzene in seven portions during 1 hr.

About 20 ml. of the combined benzene extract was evaporated with a stream of nitrogen to yield a white hygroscopic solid that melted at 150–151°, which agrees with the reported value (12) for the free base. The picrate of the free base was prepared, m.p. 192–194°, after recrystallization from 95% ethanol. [Lit. m.p. 188–189° (12).]

The cloudy benzene extract was treated with 2 ml. (0.03 mole) of carbon disulfide, which was added

dropwise during 5 min. with constant stirring. The mixture was stirred for 30 min., and the orange solid was collected, washed with two 50-ml. portions of benzene, and dried *in vacuo*. About 5.5 Gm. of product was obtained, m.p. 170–172°. $\nu_{min.}^{Nujol}$ 960, 980, 1040, 1135, 1200, 1540, 1650.

Anal.—Calcd. for $C_{13}H_{16}N_3S_2$: C, 53.39; H, 5.52; N, 19.16; S, 21.93. Found: C, 53.08; H, 5.59; N, 19.32; S, 21.10.

4-Pyridylmethylammonium N-4-Pyridylmethyldithiocarbamate—4-Aminomethylpyridine (11 Gm., 0.1 mole) (Reilly Tar and Chemical Corp.) in 30 ml. of absolute ethanol was ice-cooled and stirred while 3.5 ml. (0.05 mole) of carbon disulfide was added dropwise. The mixture was stirred for 15 min. and the solid was collected and washed with two 25-ml. portions of absolute ethanol. About 12 Gm. (80.5%) of a white, light-sensitive solid was obtained, m.p. 131–132°. $\nu_{KBr}^{min.}$ 940, 1000, 1070, 1115, 1225, 1300, 1600.

Anal.—Calcd. for $C_{13}H_{16}N_4S_2$: C, 53.39; H, 5.52; N, 19.16; S, 21.93. Found: C, 53.19; H, 5.58; N, 18.70; S, 21.87.

3-Pyridylmethylammonium N-3-Pyridylmethyldithiocarbamate—The same procedure was used as above. From 3-aminomethylpyridine (11 Gm., 0.1 mole) was obtained 13.8 Gm. (92.6%) of a white solid that melted at 130–132°. $\nu_{KBr}^{min.}$ 920, 975, 1050, 1185, 1250, 1300, 1575.

Anal.—Calcd. for $C_{13}H_{16}N_4S_2$: C, 53.39; H, 5.52; N, 19.16; S, 21.93. Found: C, 53.19; H, 5.27; N, 18.55; S, 21.89.

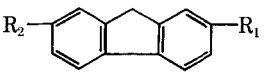
New Compounds: Fluorene Derivatives as Potential Carcinogens

By NELLIE W. PITZER and FRANCIS E. RAY*

A series of eight new *N*-substituted fluorenamides have been synthesized for evaluation of carcinogenic activity.

IT HAS BEEN reported that diethylnitrosamine produces hepatic carcinomas in rats (1, 2). Since *N*-2-fluorenylamine is also a carcinogen (3), it was thought that *N*-2-fluorenylethylnitrosamine (I) might have a similar or stronger activity.

Because *N*-2-fluorenylsuccinamic acid is a potent carcinogen (4), additional derivatives (II, III, IV, V and VI) were synthesized. Since nicotinic acid is known to be involved in the biological oxidation systems (5), carcinogenic activity might be found in *N*-2-fluorenylnicotinamide (VII). In the generally less carcinogenic fluorenone series, *N,N',N''*-2,4,7-fluorenylene(9-acetoxy)trisacetamide (VIII) was obtained.[1]



I, R_1 = N·(NO)CH_2CH_3, R_2 = H
II, R_1 = $NHCOCH_2CH_2COOH$, R_2 = $NHCOCH_2CH_2COOH$
III, R_1 = $NHCOCH_2C$:$(CH_2)COOH$, R_2 = H
or R_1 = NHCOC:$(CH_2)CH_2COOH$ (Structural studies on this compound will be presented in a future communication.)
IV, R_1 = $NHCO(CH_2)_6CH_3$, R_2 = H
V, R_1 = $NHCO(CH_2)_6CH_3$, R_2 = $NHCO(CH_2)_6CH_3$
VI, R_1 = $NHCO(CH_2)_{14}CH_3$, R_2 = H

[1] Compounds I, II, III, and VIII were proved to be carcinogenic in the preliminary investigation by Dr. Harold P. Morris, National Cancer Institute, Bethesda, Md. All compounds are subject of further studies in this institute.

N-2-Fluorenylethylnitrosamine (I)—*N*-2-Fluorenylethylamine (6) (6 Gm., 0.03 mole) was heated in 300 ml. of water until the solid melted; 20 ml. of hydrochloric acid was added, and the mixture was cooled to 0–4°. Sodium nitrite (3.5 Gm. in water), 200 ml. of water, and 100 ml. of ether were added. With stirring, more ether was added. The aqueous and ether layers were separated, and the aqueous layer was extracted with ether. The combined ether extracts were washed with water, 10% sodium bicarbonate, and water; dried over sodium carbonate and evaporated *in vacuo*. The yellow product (I) was washed with pentane and dried. Yield, 1.7 Gm. (25%); m.p., 129–134°. Recrystallization from 250 ml. hexane gave 1.3 Gm., m.p. 132–134°. $\lambda_{max.}$, mμ 266–268 (ε 13,000), 304–307 (ε 18,000).

Anal.—Calcd. for $C_{15}H_{14}N_2O$: C, 75.60; H, 5.92; N, 11.76. Found: C, 75.70; H, 5.86; N, 11.66.

N,N'-2,7-Fluorenylenebis-succinamic Acid (II)—To a solution of 20 Gm. (0.1 mole) of *N,N'*-2,7-fluorenylenediamine in 50 ml. of pyridine was added 22 Gm. (0.22 mole) of succinic anhydride, and the mixture was heated with stirring. The precipitate was filtered, washed successively with pyridine and ethanol, and dried. The solid was heated in 0.2 *N* NaOH with charcoal, the solution was filtered hot, and acidified with HCl. The white precipitate (II) was filtered, washed with water, stirred 15 min. in glacial acetic acid, filtered, washed, and dried. Yield, 20 Gm. (55%); m.p. 251–260°. A sample for analysis was dissolved in pyridine, precipitated with hexane, collected, and extracted with toluene, m.p. 256–257°; $\lambda_{max.}$, mμ 303–304, 312–315 sh, 320–322 sh.

Anal.—Calcd. for $C_{21}H_{20}N_2O_6$: C, 63.63; H, 5.09; N, 7.07. Found: C, 63.71; H, 5.02; N, 7.02.

N-2-Fluorenylitaconamic Acid (III)[2]—To a solution of 4.6 Gm. (0.025 mole) of *N*-2-fluorenylamine in 50 ml. of chloroform at 50–55° was added rapidly a solution of 2.8 Gm. (0.025 mole) of itaconic anhydride also at 50–55°, to obtain a white precipitate, 6.8 Gm. (93%), m.p. 207–208°. Recrystallization from ethanol gave a m.p. 219°. $\lambda_{max.}$, mμ 289–292 (ε 28,600), 300–302 sh (ε 20,700), 314.5 (15,800).

Anal.—Calcd. for $C_{18}H_{15}NO_3$: C, 73.70; H, 5.15; N, 4.78. Found: C, 73.63; H, 5.12; N, 4.88.

N-2-Fluorenyloctanoylamide (IV)—To a solution of 4.5 Gm. (0.035 mole) of *N*-2-fluorenylamine in 350 ml. of dry benzene was added 5.5 ml. of octanoyl chloride, and the mixture was refluxed 5–6 hr. The white precipitate was filtered and washed with hexane. Yield, 5.4 Gm. (91%), m.p. 157–160°. Recrystallization from ethanol gave a m.p. 160–161°. $\lambda_{max.}$, mμ 289 (45,600), 303 (34,300), 314 (28,900).

Anal.—Calcd. for $C_{21}H_{25}NO$: C, 82.04; H, 8.20; N, 4.56. Found: C, 82.15; H, 8.20; N, 4.68.

N,N'-2,7-Fluorenylenebis-octanoylamide (V)—To a suspension of 10 Gm. (0.05 mole) of *N,N'*-2,7-fluorenylenediamine in 200 ml. of dry benzene was added 18 ml. of octanoyl chloride, and the mixture was refluxed 2 hr. Yield, 18 Gm. (74%); m.p. 238–246°. Recrystallization from dimethylformamide gave a m.p. of 254°. $\lambda_{max.}$, mμ 304 (ε 53,000), 320–322 sh (ε 44,400).

[2] Prepared by Miss Sandra Rose in this laboratory.

Anal.—Calcd. for $C_{29}H_{40}N_2O_2$: C, 77.63; H, 8.99; N, 6.24. Found: C, 77.62· H, 9.20; N, 6.06.

N-2-Fluorenylpalmitoylamide (VI)—To a solution of 9 Gm. (0.05 mole) of *N*-2-fluorenylamine in 500 ml. of dry benzene was added 15.5 ml. of palmitoyl chloride and the mixture was refluxed 2 hr. to give a white precipitate. Yield, 16 Gm. (76%); m.p. 148–151°. Recrystallization from ethanol gave a m.p. of 150–151°. $\lambda_{max.}$, mμ 289 (ε 36,100), 314 (ε 19,600).

Anal.—Calcd. for $C_{29}H_{41}NO$: C, 82.99; H, 9.85; N, 3.34. Found: C, 82.78; H, 9.69; N, 3.50.

N-2-Fluorenylnicotinamide (VII)[3]—To 12 Gm. (0.08 mole) of nicotinoyl chloride was added a solution of 18 Gm. (0.14 mole) of *N*-2-fluorenylamine in 125 ml. of dry benzene alternately with 21 Gm. of Na_2CO_3. The thick mixture was refluxed 1 hr., filtered, and washed with benzene. The dried cake was broken up and, in 30-Gm. portions, was stirred and heated in water for 20 min. Yield, 20 Gm. (70%). Recrystallized from ethanol, the m.p. was 203–205°; $\lambda_{max.}$, mμ 268–278 sh (ε 16,800), 314–316 (ε 25,700).

Anal.—Calcd. for $C_{19}H_{14}N_2O$: C, 79.70; H, 4.93; N, 9.78. Found: C, 79.66; H, 4.89; N, 9.80.

N,N',N'' - 2,4,7 - Fluorenylene - (9 - acetoxy)-tris-acetamide (VIII)—2,4,7-Trinitrofluorenone (5.25 Gm. 0.017 mole) in 125 ml. of glacial acetic acid was heated in a pressure bottle, 0.06 Gm. PtO_2 was added, and the hot mixture was placed quickly on the Parr pressure reaction apparatus. Hydrogen was added at 40 p.s.i. The pressure dropped to 25.5 p.s.i. in 20 min. The reaction mixture was filtered into 20 ml. of acetic anhydride and left for 1 hr. It was heated 2 hr., the volume was reduced, and the mixture was allowed to stand overnight. The dark red precipitate was filtered, washed with acetic acid and then benzene, and extracted with hot ethanol. Yield, 3.5 Gm. (52%); m.p. over 400°. It was recrystallized from dimethylformamide: $\lambda_{max.}$, mμ 286 (ε 31,100).

Anal.—Calcd. for $C_{21}H_{21}N_3O_5$: C, 63.79; H, 5.35; N, 10.63. Found: C, 64.33; H, 5.12; N, 10.39.

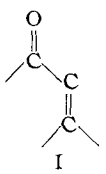
Structural Studies on Complexes I. Postulation of Polarization Bonding in Xanthine Complexes

Sir:

A number of workers have been engaged in research attempting to elucidate the exact nature of the complex formation observed between xanthine derivatives and various drugs containing unsaturated ring systems. Foremost among these studies are those of Higuchi *et al.* (1–3), whose phase solubility diagrams on caffeine and theophylline complexes led to his postulation that hydrophobic bonding was playing an important role in these association complexes. In attempts to further characterize the nature of the hydrophobic bonding in xanthine complexes, workers postulated different types of mechanisms.

Guttman and Athalye (4) studied the solubilization of riboflavin by using various xanthines and felt their results were in agreement with the ideas of Foley and Harbury (5) whose spectral studies on complexes of various isoalloxazine derivatives indicated a charge transfer mechanism might be operative. The idea of an electron donor-acceptor mechanism has also been presented by Eckert (6) whose spectroscopic measurements on a series of procaine–xanthine complexes indicated this possibility. In the latter study a charge transfer band was observed only when the concentrations of the complex ingredients were quite large, which possibly indicates that the interaction was a weak one. Eckert concluded that in order to form a complex with procaine, the electron acceptor should have the structural feature shown in I.



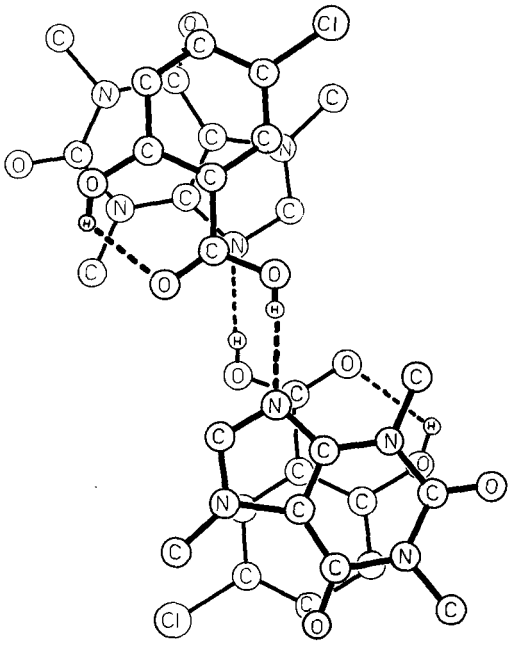
I

In another vein, the Pullmans (7) using quantum mechanical calculations, found that caffeine and other xanthines should act as good electron "donors." In a recent review article by Schnaare and Martin (9), a model for the interaction between caffeine and benzocaine was presented using an approach similar to the Pullmans. This model is quite different to the one presented by Eckert. To the best of the author's knowledge, there has been no experimental evidence reported in the literature to substantiate such a mechanism. It is interesting to note that the recent solubility studies of Jan and Donbrow (8) on caffeine–benzoic acid complexes seem to favor caffeine as an electron acceptor.

In the remaining portion of this communication, I shall present evidence that "polarization bonding," as described by Wallwork (10), appears to be a fundamental force behind some of these xanthine complexes. These interactions are described as pi–pi ones that range in gamut from the charge transfer bonding of Mulliken (11) on the stronger side, to the weaker interactions between polar groups on one component and a polarizable second component [Briegleb (12)]. An example of this type of bonding is found in the crystal structure of 2-phenol-1-quinone (13), where the carbonyl groups of the quinone are found to lie over the centers of the phenyl rings of the phenols. Interestingly enough, other crystal structures of complexes involving planar moieties, one containing a carbonyl group and the other an unsaturated ring system, show similar molecular packing (14, 15).

Recently, the structure of the 1:1 complex of tetramethyl uric acid and pyrene was reported (16). The authors suggested that polarization bonding is possibly the dominating force as they found that there is a "smaller degree of overlap, which seems to indicate the charge transfer forces, if any must be weak." Though no charge transfer band was positively identified for this compound, it is interesting to compare the structure to the conclusions of Eckert. The packing of the molecules in the crystal lattice is such that the C(6) carbonyl of the tetramethyl uric acid occupies a position directly above the center of the pyrene pi system.

The crystal structure of a 1:1 complex of caffeine and 5-chlorosalicylic acid has recently been completed in this laboratory. Crystal structures do not pretend to represent the exact molecular arrangement in solution, but they are of value in determining the types of forces that can be present in solution. Structure II shows two important features. One is a relatively strong hydrogen bond between the carboxyl hydrogen and N9 of caffeine, shown by the dashed line. The other feature is the relative position of the phenyl ring



II

in relation to the caffeine molecule. This arrangement is consistent with the ideas presented above for polarization bonding. A more detailed account of this material will be published at a later date.

In conclusion, it is felt that in order to propose molecular models for xanthine complexes of pharmaceutical interest, one should take into account polarization interactions. Studies on other pyrimidine and purine complexes are being carried out in this laboratory to shed more light on this problem.

Effect of Certain Tetracycline Analogs on Phenylalanine-^{14}C Incorporation by *Escherichia coli* B Cell-free Extracts

Sir:

This communication reports the effects of several tetracycline analogs on messenger RNA (mRNA) and polyuridylic acid (poly U)-directed phenylalanine-^{14}C incorporation by *E. coli* B cell-free extracts. This study was undertaken to determine (*a*) if mRNA and poly U-directed amino acid incorporation are differentially sensitive to inhibition by the tetracyclines, and (*b*) to examine structure-activity relationships in this series of drugs.

The tetracyclines have been observed (1) to inhibit protein synthesis *in vivo* (*Staphylococcus aureus*). Franklin (2) has studied the incorporation of leucine-^{14}C into polypeptides by rat liver or *E. coli* cell-free extracts and has observed that the tetracyclines inhibit the transfer of amino acids from the aminoacyl-tRNA complex to the growing polypeptide. Suarez and Nathans (3) showed that tetracycline inhibits protein synthesis in *E. coli* cell-free extracts and impedes the binding of aminoacyl-tRNA to mRNA-ribosome complex. Hierowski (4) and Maxwell (5) have made similar observations.

The relative inhibitory activity of the tetracycline analogs was examined at a drug concentration of 1.79×10^{-4} *M*. *E. coli* cell-free extracts and reaction mixtures were prepared according to Nirenberg (6). Incubations were terminated after 70 min. by the addition of 5%

Effect of Certain Tetracycline Analogs on Phenylalanine-^{14}C Incorporation by *Escherichia coli* B Cell-free Extracts

Sir:

This communication reports the effects of several tetracycline analogs on messenger RNA (mRNA) and polyuridylic acid (poly U)-directed phenylalanine-^{14}C incorporation by *E. coli* B cell-free extracts. This study was undertaken to determine (*a*) if mRNA and poly U-directed amino acid incorporation are differentially sensitive to inhibition by the tetracyclines, and (*b*) to examine structure-activity relationships in this series of drugs.

The tetracyclines have been observed (1) to inhibit protein synthesis *in vivo* (*Staphylococcus aureus*). Franklin (2) has studied the incorporation of leucine-^{14}C into polypeptides by rat liver or *E. coli* cell-free extracts and has observed that the tetracyclines inhibit the transfer of amino acids from the aminoacyl-tRNA complex to the growing polypeptide. Suarez and Nathans (3) showed that tetracycline inhibits protein synthesis in *E. coli* cell-free extracts and impedes the binding of aminoacyl-tRNA to mRNA-ribosome complex. Hierowski (4) and Maxwell (5) have made similar observations.

The relative inhibitory activity of the tetracycline analogs was examined at a drug concentration of 1.79×10^{-4} *M*. *E. coli* cell-free extracts and reaction mixtures were prepared according to Nirenberg (6). Incubations were terminated after 70 min. by the addition of 5%

TABLE I—EFFECT OF TETRACYCLINE ANALOGS ON mRNA-DIRECTED PHENYLALANINE-^{14}C INCORPORATION BY *E. Coli* B CELL-FREE EXTRACTS[a]

Inhibitor	Phenylalanine-^{14}C Incorporation (dpm./mg. protein ± S.E.)	Percent Inhibition
Experiment 1		
Control	476 ± 47	..
Isotetracycline	367 ± 39[b]	23
Tetracycline	316 ± 20[b]	34
4-Epitetracycline ammonium salt	478 ● 7[c]	..
Pyrrolidinomethyl-tetracycline	402 ± 6[c]	16
4-Dedimethylamino-tetracycline	424 ± 47[c]	11
Experiment 2		
Control	968 ± 45	..
Tetracycline	603 ± 64[b]	38
7-Chlorotetracycline	697 ± 52[b]	30

[a] Each incubation flask contained in 0.70-ml. total volume: *E. Coli* B cell-free extract (1.40–2.0 mg. protein), phosphoenolpyruvate (5.4 × 10^3 μM), 2-mercaptoethanol (4.2 μM), magnesium acetate (5.2 × 10^3 μM), phosphoenolpyruvate kinase (1.2 EU), aminoacid-^{12}C mixture (143 μM in each of 19 aminoacids, phenylalanine excepted), D, L-3′-phenylalanine-^{14}C (143 μM, 0.57 μc.), adenosine-5′-triphosphate (761 μM), guanosine-5′-triphosphate (23 μM), potassium chloride (3.6 × 10^4 μM), and Tris (7.1 × 10^4 μM). pH = 7.8. Four or five samples per group. [b] $p < 0.05$. [c] Not significantly different from control, $p > 0.05$.

trichloroacetic acid. Protein content was determined by the Lowry method and radioactivity determination made using a liquid scintillation spectrometer. Data were corrected for quenching by use of the internal standard technique.

In the mRNA-directed system (Table I), with tetracycline assigned an activity of 100, the relative activities of the analogs were: (*a*) 7-chlorotetracycline (80), (*b*) isotetracycline (67), (*c*) pyrrolidinomethyltetracycline (47), (*d*) 4-dedimethylaminotetracycline (32), and (*e*) 4-epitetracycline ammonium salt (0). These findings suggest that the nature of the substituents on C_2, C_3, and C_4 are relatively more important than those on C_{11} and C_{12} of the drug molecule.

In the case of poly U-directed phenylalanine-^{14}C incorporation (Table II) the relative activities of each analog *versus* tetracycline (100) were: (*a*) pyrrolidinomethyltetracycline (102), (*b*) 7-chlorotetracycline (98), (*c*) 4-epitetracycline ammonium salt (93), (*d*) 4-dedimethylaminotetracycline (43), and (*e*) isotetracycline (0). The relatively low inhibition by 4-dedimethylaminotetracycline and isotetracycline suggested that the C_4-dimethylamino group and/or C_{11}-keto and C_{12}-hydroxyl groups are important in the presence of artificial messenger.

TABLE II—EFFECT OF TETRACYCLINE ANALOGS ON POLY U-DIRECTED PHENYLALANINE-^{14}C INCORPORATION BY *E. Coli* B CELL-FREE EXTRACTS[a]

Inhibitor	Phenylalanine-^{14}C Incorporation (dpm. mg. protein ± S.E.)	Percent Inhibition
Control	2174 ± 108	...
Isotetracycline	2178 ± 144[c]	...
Tetracycline	1009 ± 53[b]	54
4-Epitetracycline ammonium salt	1082 ± 67[b]	50
Pyrrolidinomethyl-tetracycline	980 ± 36[b]	55
4-Dedimethylamino-tetracycline	1660 ± 131[b]	23
7-Chlorotetracycline	1018 ± 104[b]	53

[a] Incubation mixtures prepared as in Table I, except that 1.04 × 10^4 μM magnesium acetate and polyuridylic acid (20 mcg./ml.) were used. Five samples per group. [b] $p < 0.01$. [c] Not significantly different from control, $p > 0.05$.

These data suggest that there may be different modes of action of the tetracycline antibiotics in the inhibition of mRNA and poly U-directed phenylalanine-^{14}C incorporation by *E. Coli*. Further studies on the nature of the differential inhibition are in progress.

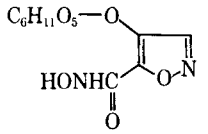
Structure of Hiptagin as 1,2,4,6-Tetra-*O*-(3-nitropropanoyl)-β-D-glucopyranoside, Its Identity with Endecaphyllin X, and the Synthesis of Its Methyl Ether

Sir:

Although *Hiptage madablota* Geartn. (family *Malpighiaceae*) does not grow widely in Java, the plant was apparently well known to the natives, who ascribed aphrodisiacal properties to an extract of the roots and provided detailed instructions for dispensation to bulls (1). Ritsema (1) reported the isolation in rather high yield of a white, crystalline, nitrogenous compound from this extract but was unable to duplicate the purported physiological effects when the substance was administered subcutaneously.[1] Ritsema's compound was named hiptagin by Gorter (2), who repeated and improved the original isolation procedure, assigned the (incorrect) formula $C_{10}H_{14}N_2O_9 \cdot {}^1/_2H_2O$, and carried out a number of hydrolysis experiments with this substance, m.p. 110°. Hiptagin could be hydrolyzed under a variety of acidic and basic conditions and Gorter was able to identify a formidable array of products, among them glucose. Aside from glucose, however, the product most directly relevant to the structure of hiptagin was hiptagenic acid, a compound subsequently shown by Carrie (3) to be identical with the aglycone derived from karakin and finally identified by Carter and McChesney (4) as the long known (5) 3-nitropropanoic acid. The plethora of hydrolytic transformations observed by Gorter were somewhat ingeniously rationalized by his proposal (2) of structure I for hiptagin although, in retrospect, they are readily traced to the presence of the 3-nitropropanoyl moiety. In view of the challenge to structure I inherent in Carter's formula-

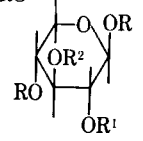


I

tion (6) of karakin, a closely related glucoside, as 1,4,6-tri-*O*-(3-nitropropanoyl)-β-D-glucopyranoside (II), the structure of hiptagin was clearly in need of revision.

We were led naturally to a consideration of this problem in connection with work with the endecaphyllins (7), a group of glucose polyesters of 3-nitropropanoic acid isolated from a toxic extract of *Indigofera endecaphylla* Jacq. (family (*Leguminosae*, subfamily *Papilionatae*). Following the directions of Gorter (2), we have easily isolated from an acetone extract[2] of defatted root-bark of *H. madablota* a white, crystalline glucoside, m.p. 102–104°, which we believe to be hiptagin and for which the structure 1,2,4,6-tetra-*O*-(3-nitropropanoyl)-β-D-glucopyranoside (III) is required by the evidence presented below.

At the outset, this substance proved to be identical with endecaphyllin X (7) by mixed melting point, optical rotation, and infrared spectral comparisons and thus could be formulated as a glucose tetraester of 3-nitropropanoic acid ($C_{18}H_{24}N_4O_{18}$).[3] In addition, acid-catalyzed diazomethylation (7,8) provided a monomethyl ether, m.p. 139–141° (IV), which was shown to be indistinguishable from the derivative similarly prepared from endecaphyllin X. The NMR spectra of III and IV (hexadeuteroacetone solution) revealed the anomeric proton as a doublet centered at τ4.10 with $J_{1,2}$ = 8.3 c.p.s. These values indicate that the C-1 hydroxyl group is acylated and is in the β-configuration. Detailed analysis of these spectra allowed assignment of a triplet centered at τ5.90 (separation, 8.5 c.p.s.) to the C-3 proton in III which corresponds to a triplet at τ6.1 (separation, 9 c.p.s.) in the spectrum of IV. This upfield shift of the C-3 proton on methylation requires that the free hydroxyl group in III be located at the 3-position.



II, karakin; R = $O_2NCH_2CH_2CO$-
$R^1 = R^2 = H$

III, hiptagin; R = $R^1 = O_2NCH_2CH_2CO$-
$R^2 = H$

IV, hiptagin methyl ether;
R = $R^1 = O_2NCH_2CH_2CO$-
$R^2 = CH_3$

[1] As pointed out by Gorter (2), this result must be considered inconclusive since the pure compound is insoluble in water and, insofar as we are aware, no additional biological data have been reported.

[2] This extract was kindly supplied by Dr. G. Ganguli, Department of Chemistry, University College of Science, Calcutta, India. A solid which precipitated during this acetone extraction has been identified as mangiferin. Finnegan, R. A., Stephani, R. A., Ganguli, G., Ganguly, S. N., and Bhattacharya, A. K., to be published.

[3] Interestingly, we have also repeated the isolation of karakin from the kernels of *Corynocarpus laevigata* Forst. (family *Anacardiaceae*) and find it to be identical with endecaphyllin B (7). Although the data upon which Carter based the assignment of structure II to karakin (6) are equivocal, we have adduced spectroscopic evidence in support of II.

This conclusion was verified by a synthesis of IV which made use of the known (9) 3-*O*-methyl-α-D-glucose, m.p. 164–166°. Acylation with 3-nitropropanoyl chloride in *N*-methylpyrrolidone solution provided an oily tetra-ester whose NMR spectrum showed it to be an anomeric mixture (C-1 proton of α-anomer at τ3.63, $J_{1,2}$ = 4 c.p.s.; C-1 proton of β-anomer at τ4.10 $J_{1,2}$ = 8.3 c.p.s.). However, crystallization from methylene chloride solution afforded an authentic sample of the β-anomer, m.p. 136–140°, whose infrared and NMR spectra were indistinguishable from those of naturally derived IV and whose mixed melting point was undepressed.

Advances in Chromatography. Vol. 4. Edited by J. CALVIN GIDDINGS and ROY A. KELLER. Marcel Dekker, Inc., 95 Madison Ave., New York, NY 10016, 1967. 15.5 × 23 cm. xiv + 380 pp. Price $16.50.

Most of the topics included in vols. 1–3 of this series, by and large, provided the balance of breadth and depth of coverage which is needed to present the reader with an overall view of the progress in the entire field of chromatography. It was noted in the reviews of these volumes [*J. Pharm. Sci.*, **55**, 863(1966); **56**, 1047(1967)], however, that not all of the chapters achieved this goal set by the editors.

The latter case is true to a greater extent in vol. 4 than in its predecessors. The one chapter relating directly to pharmaceutical chemistry (Steroid Separation and Analysis: The Techniques Appropriate to the Goal, by R. Neher) is disappointingly superficial; the other chapters, for the most part, emphasize depth of coverage at the expense of breadth. The chapter which achieves the desired balance is "Mass-Spectrometric Analysis of Gas-Chromatographic Eluents," by W. H. McFadden.

In addition, vol. 4 contains the following chapters: "R_f values in Thin-Layer Chromatography on Alumina and Silica," by Lloyd R. Snyder; "Some Fundamentals of Ion-Exchange-Cellulose Design and Usage in Biochemistry," by C. S. Knight; "Adsorbents in Gas Chromatography," by A. V. Kiselev; "Packed Capillary Columns in Gas Chromatography," by István Halász and Erwin Heine; "The Polarity of Stationary Liquid Phases in Gas Chromatography," by Lutz Rohrschneider.

Ganglion-Blocking and Ganglion-Stimulating Agents. By. D. A. KHARKEVICH. First English Edition, translated from the Russian by R. Crawford. Pergamon Press, Inc., 44-01 21st St., Long Island City, NY 11101, 1967. xi + 367 pp. 14 × 22 cm. Price $14.00.

Most medicinal chemistry researchers have probably had occasion to encounter both the interesting reports in such journals as *Farmakol. Toksikol.* and *Zhur. Obsh. Khim.* and the reluctance of the scientists to communicate *via* letters or reprints. Dr. Kharkevich's contribution is welcome, not only for the wealth of information and the quality of his book, but perhaps as evidence that more rapport between workers in this field may be imminent. While the reviewer is hardly competent in Russian, Dr. Crawford's translation is very obviously good English and appears to be faithful to the facts.

A study of agents affecting the ganglia is pullulate with experimental problems. The difficulties of obtaining and interpreting accurate data are well known. This book begins with a brief summary of

This conclusion was verified by a synthesis of IV which made use of the known (9) 3-*O*-methyl-α-D-glucose, m.p. 164–166°. Acylation with 3-nitropropanoyl chloride in *N*-methylpyrrolidone solution provided an oily tetra-ester whose NMR spectrum showed it to be an anomeric mixture (C-1 proton of α-anomer at τ3.63, $J_{1,2}$ = 4 c.p.s.; C-1 proton of β-anomer at τ4.10 $J_{1,2}$ = 8.3 c.p.s.). However, crystallization from methylene chloride solution afforded an authentic sample of the β-anomer, m.p. 136–140°, whose infrared and NMR spectra were indistinguishable from those of naturally derived IV and whose mixed melting point was undepressed.

Ganglion-Blocking and Ganglion-Stimulating Agents. By. D. A. KHARKEVICH. First English Edition, translated from the Russian by R. Crawford. Pergamon Press, Inc., 44-01 21st St., Long Island City, NY 11101, 1967. xi + 367 pp. 14 × 22 cm. Price $14.00.

Most medicinal chemistry researchers have probably had occasion to encounter both the interesting reports in such journals as *Farmakol. Toksikol.* and *Zhur. Obsh. Khim.* and the reluctance of the scientists to communicate *via* letters or reprints. Dr. Kharkevich's contribution is welcome, not only for the wealth of information and the quality of his book, but perhaps as evidence that more rapport between workers in this field may be imminent. While the reviewer is hardly competent in Russian, Dr. Crawford's translation is very obviously good English and appears to be faithful to the facts.

A study of agents affecting the ganglia is pullulate with experimental problems. The difficulties of obtaining and interpreting accurate data are well known. This book begins with a brief summary of

what chemical structures will be encountered. This is followed by an admittedly superficial but interesting survey of the anatomy and techniques of various pharmacological preparations useful in this work. A long chapter follows (143 pages) in which the various compounds known to have ganglion-blocking activity are discussed. Of course, the material is brought from many sources and comparisons are often difficult. The format reminds the reviewer of the *Medicinal Chemistry* series; the chapter is arranged according to chemical homology and the discussion remains relatively discrete to each chemical group. Most readers will feel quite at home in this chapter. Chapter 4, rather enigmatically titled "The Influence of Ganglion-blocking Agents on the Interneuronal Transmission in Autonomic Ganglia" really amplified a bit on the earlier chapter surveying experimental techniques and provides more interpretive comparison of chemical agents quite diverse in structure. Throughout conflicting opinions are presented clearly and objectively. Chapters 5 and 6 then treat ganglion-stimulating agents in the same format as chapters 3 and 4 treated the blockers, although understandably less space is devoted to the subject. The book is capped off by a summary of the ganglionic activity of a variety of compounds known for some activity other than that on ganglia—for example, narcotics and muscle relaxants.

A few errors in structures are so obvious that they cannot cause trouble. The appendix leaves a little to be desired because of its brevity. A list of references is presented in a usable manner. The book will be valuable to a varied audience. It is sufficiently broad to serve as supplementary reading in graduate courses, and it appears to be commendable to either a pharmacologist or medicinal chemist contemplating research in the area of ganglion-active compounds. For the active researcher in the area, it is a valuable review through 1962 (although the book was ostensibly "brought up to date" for the 1967 edition); for these persons, the book's most valuable asset is the collection of data from Russian sources.

Mass Spectrometry of Organic Compounds. By H. Budzikiewicz, C. Djerassi, and D. H. Williams. Holden-Day, Inc., 500 Sansome Street, San Francisco, Calif., 1967. xv + 690 pp. 19 × 26 cm. Price $17.95

This book is aimed at two groups of readers. The first includes students who may wish to become proficient in the interpretation and use of mass spectral data. The second group includes organic chemists who are familiar with mass spectrometry and employ it from time to time in their research. The authors use the "mechanistic" approach to the interpretation of mass spectra and this should be particularly appealing to the modern organic chemist.

A general introduction is devoted to the mass spectrometry aspects of ionization, localization of charge, bond fissions, and metastable peaks. In addition, mention is also made of some specific techniques employed, such as element mapping, the kinetic approach to mass spectra, and the combined vapor phase chromatography–mass spectrometry. Each of the 27 chapters that follow deals with a particular functional group (or related functional groups) in organic compounds. In each chapter, the aliphatic members are first discussed, followed by a discussion of the aromatic members. This organization is a distinct improvement over that of the first volume.

Although this volume appears at first glance to be only a revision of the authors' earlier book, "Interpretation of Mass Spectra of Organic Compounds," the reader soon becomes aware that the extensive revisions and new material discussed, indeed, make this a new book warranting the new title. New material includes lactones (chapter 4), acids and anhydrides (chapter 5), *N*-oxides, nitrosamines, and quaternary ammonium salts (chapter 8), nitrogen-containing carbonyl derivatives (chapter 10), epoxides (chapter 13), alcohol derivatives (chapter 14), carbonates and ureas (chapter 15), sulfoxides, sulfones, and related compounds (chapter 19), organic phosphorus compounds (chapter 26), and organo-metallic compounds (chapter 27). The extent of this new material demonstrates the need for this new volume and is reinforced by the need to update the other topics.

The book is well written and the coverage is thorough and up-to-date. The references listed for each chapter include early 1967 papers as well as several private communications of work not yet published. Such a reference list is extremely valuable to the mass spectrometrist and renders this book a must in his personal library. The book has a few typographical errors which do not detract from its overall value in any way. Another special value of the book is the listing of summaries and conclusions wherever possible. For example, the reader is given general rules for mass spectral behavior for alkyl eliminations (p. 264), hydrogen losses (p. 282), acetylnaphthoquinones (pp. 533–534), and metal complexes of β-diketones (pp. 664–665). These rules should prove to be particularly useful in the general interpretation of mass spectra.

Finally, the authors frequently point out areas requiring additional study either by high-resolution mass spectrometry, deuterium labeling, or the need to study more compounds (or derivatives) containing a particular functional group. The suggestions offered should stimulate further research in these areas.

In summary, this excellent work extends and amplifies the application of mass spectrometry in organic and biological chemistry. The nonexpert in the field will receive an introduction into this dynamic area and those knowledgeable in the field will find this to be a useful reference.

Specifications for the Quality Control of Pharmaceutical Preparations. Second Edition of the International Pharmacopoeia. World Health Organization, Geneva, Switzerland, 1967. xxxv + 906 pp. 16 × 24.5 cm. Price $18.00.

This second edition of the International Pharmacopoeia (IP) is the result of collaboration between members of the WHO Expert Advisory Panel on the IP and Pharmaceutical Preparations and many specialists from various countries. The Pharmacopoeia has no legal status, but is presented as a reference and to provide a similar basis on which any country may base its own specifications. Material included in this edition is based largely on specifications available for publication in national compendia or similar volumes. The first edition of the International Pharmacopoeia was completed with a Supplement in 1959. Thus, extensive revision was needed to utilize developments in the field which have occurred in the 8-year period since publication of the first edition.

Monographs for 162 items have been added, while 114 monographs have been deleted. Among the new additions are many of the semisynthetic penicillins and their dosage forms, thiazide diuretics, antimitotics, and steroids. For the first time, several radioactive preparations are covered by monographs, and an appendix has been added on the techniques for handling radioactive pharmaceuticals. Other chapters added on new analytical methods include determination of IR spectra, polarography, chromatography, nonaqueous titration, and oxygen flask combustion. The organization of this Pharmacopoeia is similar to that of the two U. S. compendia. The monographs are arranged alphabetically by name of the basic drug. The appendices of the IP include information comparable to that contained in the general tests, general information, and reagents sections of the NF and USP.

It is the hope of those presenting this second edition that " . . . this new volume will go even further than its predecessor towards ensuring the better control of pharmaceutical preparations everywhere and thus protecting the health of the public throughout the world."

Staff review

Handbook of Chemistry. Rev. 10th ed. Compiled and edited by NORBERT A. LANGE. McGraw-Hill Book Co., Inc., 330 W. 42nd St., New York, NY 10036, 1967. xiv + 2001 pp. 13.5 × 20.5 cm. Price $12.00.

This standard reference has been revised to keep current with recent changes in chemical concepts and technology, especially the change in atomic weight calculations necessitated by the change to carbon-12. Formula weights, equivalent weights of ceramic materials, the factors for gravimetric and volumetric analysis, and other numerical values have been recomputed to conform to the latest International Atomic Weights now based on carbon-12 equal to exactly 12. With this edition, some new material has also been added: (*a*) fundamental physical constants, as recommended by the Committee of Fundamental Constants of the NAS-NRC, (*b*) International System of Units and Conversion Factors, accepted in 1960 as the preferred system of units and adopted also by the NBS, (*c*) dissociation constants of water, and (*d*) prefixes for naming multiples and submultiples of units. Sections which have been up-dated include those on modern concepts of matter, effective radii of atoms and ions, ionization potentials of elements, names and formulas of organic radicals, recommended dietary allowances, and fluorescent indicators.

The handbook size is retained by the use of small but very readable type and the use of light-weight paper. This edition once again has been ably edited by Dr. Lange.

Handbook of Chemistry. Rev. 10th ed. Compiled and edited by NORBERT A. LANGE. McGraw-Hill Book Co., Inc., 330 W. 42nd St., New York, NY 10036, 1967. xiv + 2001 pp. 13.5 × 20.5 cm. Price $12.00.

This standard reference has been revised to keep current with recent changes in chemical concepts and technology, especially the change in atomic weight calculations necessitated by the change to carbon-12. Formula weights, equivalent weights of ceramic materials, the factors for gravimetric and volumetric analysis, and other numerical values have been recomputed to conform to the latest International Atomic Weights now based on carbon-12 equal to exactly 12. With this edition, some new material has also been added: (*a*) fundamental physical constants, as recommended by the Committee of Fundamental Constants of the NAS-NRC, (*b*) International System of Units and Conversion Factors, accepted in 1960 as the preferred system of units and adopted also by the NBS, (*c*) dissociation constants of water, and (*d*) prefixes for naming multiples and submultiples of units. Sections which have been up-dated include those on modern concepts of matter, effective radii of atoms and ions, ionization potentials of elements, names and formulas of organic radicals, recommended dietary allowances, and fluorescent indicators.

The handbook size is retained by the use of small but very readable type and the use of light-weight paper. This edition once again has been ably edited by Dr. Lange.

Specifications for the Quality Control of Pharmaceutical Preparations. Second Edition of the International Pharmacopoeia. World Health Organization, Geneva, Switzerland, 1967. xxxv + 906 pp. 16 × 24.5 cm. Price $18.00.

This second edition of the International Pharmacopoeia (IP) is the result of collaboration between members of the WHO Expert Advisory Panel on the IP and Pharmaceutical Preparations and many specialists from various countries. The Pharmacopoeia has no legal status, but is presented as a reference and to provide a similar basis on which any country may base its own specifications. Material included in this edition is based largely on specifications available for publication in national compendia or similar volumes. The first edition of the International Pharmacopoeia was completed with a Supplement in 1959. Thus, extensive revision was needed to utilize developments in the field which have occurred in the 8-year period since publication of the first edition.

Monographs for 162 items have been added, while 114 monographs have been deleted. Among the new additions are many of the semisynthetic penicillins and their dosage forms, thiazide diuretics, antimitotics, and steroids. For the first time, several radioactive preparations are covered by monographs, and an appendix has been added on the techniques for handling radioactive pharmaceuticals. Other chapters added on new analytical methods include determination of IR spectra, polarography, chromatography, nonaqueous titration, and oxygen flask combustion. The organization of this Pharmacopoeia is similar to that of the two U. S. compendia. The monographs are arranged alphabetically by name of the basic drug. The appendices of the IP include information comparable to that contained in the general tests, general information, and reagents sections of the NF and USP.

It is the hope of those presenting this second edition that " . . . this new volume will go even further than its predecessor towards ensuring the better control of pharmaceutical preparations everywhere and thus protecting the health of the public throughout the world."

Review Article

Biopharmaceutical Considerations in Subcutaneous and Intramuscular Drug Administration

By BERTON E. BALLARD

THE PURPOSES of this review are to consider some of the factors affecting the absorption rates of drugs administered subcutaneously and intramuscularly, and to consider some of the literature pertaining to their formulation and administration. This review will largely supplement rather than duplicate references contained in earlier reviews on these subjects (1–4). As a result, certain important but previously covered topics may be omitted entirely, or be discussed from different points of view. The parenteral route of drug administration is an important one for the preclinical screening and evaluation of drugs as well as their clinical use in human and veterinary medicine. The rational design of products intended for parenteral use depends upon many factors including the physical, chemical, pharmaceutical, pharmacological, and toxicological properties of the drug and the adjuvants used in its formulation. Certain anatomical or physiological factors, such as injection site and body movement, may influence the absorption rates of some parenteral products.

ENDOTHELIAL TISSUE

Although this review will not go into extensive detail on the anatomy and histology of the microcirculation at the many possible injection sites, a few key points are worth mentioning. At present there are many investigations of the several mechanisms involved in the passage of drugs and other substances through capillary and lymphatic vessels and the ground substance surrounding them. The subcutaneous region is well supplied by capillary and lymphatic vessels (5). Muscle tissue also has a rich supply of capillary vessels. However, it is generally agreed that there are few, if any, lymph vessels in muscle tissue proper (5, 6). There is an abundant supply of lymphatic vessels in connective tissue sheaths and tendons. Lymph vessels usually exist where fascial planes enter muscles, and the fluid moves through spaces along fascial planes between muscle fibers. One important difference among lymphatics in several regions of the body concerns the state of their intercellular junctions. In active regions of the body one junction in two to five may be open, but in motionless regions there may be only one open junction in 50 to 100. Normal lymphatics in motionless regions and normal blood vessels allow very few particles to pass through their junctions. In contrast, lymphatics in regions where there is much movement, injured lymphatics, and injured blood vessels all allow much more material to pass through their frequently opened junctions. Mild trauma near a lymphatic vessel in a motionless region can result in a marked increase in the vessel's permeability, probably due to the opening of many of the normally closed junctions (7).

This paper was supported by general research support grant FR 05453 from the Division of Research Facilities and Resources, National Institutes of Health, U. S. Public Health Service, Bethesda, Md.

The author wishes to dedicate this paper to Dean T. C. Daniels, whose leadership at the University of California has done so much to raise the standards of education and research in the pharmaceutical sciences.

The passage of various particles and fluid from one to the other side of blood and lymphatic endothelial tissue has been shown to occur in part by means of vesicles. Particles and fluid contacting one endothelial surface enter cells in small vesicles, and then leave the opposite surface from the same organelles. This process has been called cytopemphis (6, 7). There is evidence that these vesicles are not directed in their intracellular passage, but may move and discharge their contents randomly on either side. Cytopemphis permits the net transport of material to be proportional to the concentration difference of the substance on either side of the endothelial tissue. The various paths by which particles of different sizes are thought to traverse the lymphatic endothelium have been summarized by Casley-Smith (7). A classification of the types and sizes of apertures found in normal and injured capillary and venous walls has been compiled by Landis (8). As to particles, there are theoretically only four possible paths that can be taken through endothelial tissue and these include: intercellular, intracellular in organelles, cytoplasmic matrix, or fenestrae paths. It appears that all four of these paths are used to some extent in various endothelial tissues (7). For lipid-soluble molecules there is abundant evidence that they diffuse through capillary walls and can pass through regions of the wall that are relatively impermeable to lipid-insoluble molecules (9).

DIFFUSION

From a macroscopic point of view, many drugs in solution injected into subcutaneous or intramuscular sites behave as if their absorption were taking place passively by diffusion. For most drugs it has not been determined whether the microscopic absorption route is *via* capillaries, lymphatics, or both. Insofar as drug molecules penetrate endothelial tissues rapidly by passive diffusion, the penetration rate of the drug from the injection site can be described by Fick's Law in one direction.

$$dN/dt = \bar{D}A(dC/dx) \qquad \text{(Eq. 1)}$$

where dN/dt is the penetration rate, N is the amount of drug penetrating the tissue, and t is time. In a well-stirred system, the rate is proportional to the mean diffusion coefficient (10) of the drug in the membrane, $\bar{D}$, the area, A, of the absorbing membrane exposed to the solution, and the concentration gradient (dC/dx) of drug across the membrane. Equation 1 may be approximated (11) by:

$$dN/dt = \frac{\bar{D}AK}{\delta}(C_s - C_b) \qquad \text{(Eq. 2)}$$

where the dx term of Eq. 1 has been replaced by δ, the thickness of the thin subcutaneous or intramuscular membrane that is assumed to be constant for each animal and site, and the dC term of Eq. 1 has been replaced by the terms K and $(C_s - C_b)$. The term K is the equilibrium distribution ratio or partition coefficient of the lipid-soluble drug between the membrane lipids and the aqueous phases found at the injection site or body fluids. The term $(C_s - C_b)$ is the difference between the drug concentration at the injection site, C_s, and the drug concentration, C_b, in the body fluids, *e.g.*, blood and lymph, flowing past the absorption site at any time.

The term C_b can usually be ignored, since it can be reasonably assumed that the drug's concentration in the fluids of distribution is negligible compared to its concentration at the absorption site at any time. Thus, Eq. 2 can be written as:

$$dN/dt = \left(\frac{\bar{D}AK}{\delta}\right) C_s \qquad \text{(Eq. 3)}$$

When the volume of the drug solution at the absorption site, V_s, remains nearly constant throughout the experiment, the rate of penetration will be equal to:

$$dN/dt = \left(\frac{\bar{D}AK}{\delta V_s}\right) A_s \qquad \text{(Eq. 4)}$$

where A_s is the amount of drug at the site at any time. Equation 4 can be further reduced to:

$$dN/dt = PA_s \qquad \text{(Eq. 5)}$$

where P is the penetration coefficient which includes all the terms in parentheses in Eq. 4, and has the units of time^{-1}. The penetration coefficient or absorption rate constant has the same magnitude as the clearance constant, but the opposite sign. Thus, it can be seen from Eq. 4 that the absorption rate is directly proportional to $\bar{D}$, A, and K, but is inversely proportional to δ and V_s. The half-life of the drug at the absorption site, $t_{0.5}$, can be calculated from a plot of the logarithm of the fraction of drug remaining at the site at any time *versus* time. The half-life and penetration coefficient are related by:

$$P = \ln 2/t_{0.5} \qquad \text{(Eq. 6)}$$

Area—The local distribution of solutions injected subcutaneously or intramuscularly is of interest, because the penetration rate of the drug depends in part upon the geometry and the resulting area of the depot exposed to the tissue. When the water-immiscible silicone, dimethylpolysiloxane,[1] was injected subcutaneously into animals, most of it was limited to the tissue planes of the subcutaneous region.

[1] Dow Corning 360 medical fluid.

Pathologic findings in the rat, mouse, and guinea pig following the administration of massive doses of the silicone were essentially similar. In most instances the silicone was contained in innumerable thin-walled spherical or ellipsoidal sacs and several larger pools within the adipose tissue (12, 13). Brown *et al.* (14) studied the disposition of subcutaneous injections of a radiopaque water-in-oil emulsion in guinea pigs at the injection site. The horizontal and vertical aspects of the injection site were X-rayed over a period of days. A cross-section of the tissue showed on the film a lateral spread of the radiopaque material in the subcutaneous tissue that progressed over a period of days.

What is the immediate distribution of substances injected intramuscularly? Shaffer (15) injected radiopaque substances into the gluteus muscle of humans. He found that iodized oil and bismuth salicylate in oil were confined to the planes of fascia or connective tissue surrounding muscles and groups of muscles. Injections of metallic bismuth suspended in isotonic dextrose solution were similarly distributed in the fascial planes of the muscle. Fluoroscopic studies showed that viscous oily solutions, such as iodized oil, tended to form a sphere-shaped deposit about the needle point and then spread out more slowly. It did not spread as extensively along the fascial septums as did the aqueous systems studied. The oily solutions continued to spread from 1 to 5 min. before they became fixed in position. The aqueous suspension of bismuth spread to its final location almost as soon as the injection procedure was completed. Some authors (16) have suggested that the term "intramuscular" is a misnomer and should be called "intermuscular" when it refers to injections in this region, because of the spread of solutions along the fibrous tissue *between* muscle fibers. Gruhzit (17) also noted that water-soluble bismuth tartrate injected intramuscularly was precipitated in the tissues and distributed along the connective tissue fasciculi between the muscle fibers. Zelman (18) has stated that deep, firm massage of the muscle tissue following an intramuscular injection favors the spread of the medication through a wider area of tissue, thus increasing the area for absorption to take place.

From the foregoing examples it can be seen that with the usual needle-injection technique, it is difficult, if not impossible, to control the area of an injected solution, suspension, or emulsion in contact with the tissues. If other factors are equal (*e.g.*, metabolic and excretion rates), one would expect that higher initial serum levels of drug would result when the solution has a larger area exposed to the tissue, since drug penetration rate is directly proportional to this area.

Recently, an experimental technique in animals has been devised (19) to study the *in vivo* subcutaneous absorption rate of about 1% (w/v) benzyl alcohol in normal saline where the area of tissue exposed to the solution is held constant. A medical silicone adhesive is used, which is capable of affixing a cylindrical, hollow glass absorption cell to moist subcutaneous tissue. This adhesive prevents the spread of the solution from the site, and is reported to be completely inert to living tissue and will not cause irritation or sensitization. With this procedure it is possible to keep the solution in the cell constantly stirred, which cannot be conveniently done when needle-injection techniques are used. Furthermore, it is convenient when removing drug samples periodically for analysis.

Volume—The subcutaneous absorption cell just described has another advantage. The volume of solution in the cell, as well as the area exposed, can be held constant. Thus, the penetration coefficient, P, defined in Eqs. 4 and 5 will be constant for fixed values of $\bar{D}$, K, and δ. One would predict that if the volume of the solution in the cell were increased over control values, a decrease in the magnitude of P would occur. If so, the result would be that the penetration rate of the drug would also decrease. Similarly, a decrease in volume over controls should result in an increase in both P and the penetration rate. These predictions have not been verified experimentally using the subcutaneous absorption cell just described, but Sund and Schou (20) have shown that the intramuscular clearance rates of radioactive mannitol and sucrose solutions were inversely proportional to the volume of solution injected.

When radioactive drugs or ions are used in absorption studies, it has been observed that plots of the logarithm of the fraction of drug (*e.g.*, radioactive counts) remaining at the site *versus* time may not be linear (20). The absorption half-life at the beginning of the experiment is often shorter than that calculated at some later time. This may indicate that a bi- or polyexponential equation would fit the data better. A few of the reasons for this phenomenon are: (*a*) blood or lymph flow from the site may be impaired at the later time, (*b*) the solution at the site is not uniformly mixed and there is a longer diffusion path for molecules at the center of the injected solution, or (*c*) the magnitude of the penetration coefficient may not remain constant with time. For example, if the area of tissue exposed to the liquid progressively decreases, or if the volume of solu-

tion progressively increases at the site, the value for the penetration coefficient will decrease with time to give rise to a longer absorption half-life toward the end of the experiment. Either hydrostatic (*e.g.*, injection pressure), osmotic pressure effects, or both may also be factors in determining the net solvent flow between the fluids at the site and in the vessels.

Concentration—Sund and Schou (20) studied the effects of different drug concentrations on clearance rate. On the one hand, with a pharmacologically inert, neutral, water-soluble substance like sucrose, the clearance rate from rat muscle was independent of drug concentration over the range of 0.19–9.6 mg./ml. This is the predicted result on the basis of Eqs. 4 and 5 when the injection volume is constant as it was in their experiment. On the other hand, the absorption rate of a substance like atropine depends markedly upon its concentration at the injection site. The relative clearance rate for atropine decreases with increasing concentrations of the drug over a threshold value of about 0.5 mg./ml. Atropine and several other anticholinergic drugs when mixed with sucrose solutions decreased the clearance rate of sucrose. The self-depression of atropine absorption and the inhibited absorption of sucrose are probably both due to the local pharmacological action of atropine. Sund and Schou (21) conclude that although the exact mechanism is not known, atropine probably interferes with local blood flow at the injection site. Atropine also has interesting local effects on the inflammatory process. Houck (22) administered intradermal injections of 50% croton oil in peanut oil to rats. Croton oil, a water-immiscible vesicant, produces wounds that are reproducible. He found that the microcirculatory insufficiency characteristic of injuries produced by the diluted croton oil was eliminated by the subcutaneous administration of atropine. He proposed that one of the primary effects of atropine was to accelerate wound healing by restoring the biological continuity of the wound with the circulation and surrounding tissue.

Molecular Size—As a first approximation, the diffusion coefficient of a spherical or nearly spherical drug molecule that is larger than the solvent molecules is inversely proportional to its molecular radius (or weight). Thus, in a diffusion-controlled process, large molecules would be expected to have slower penetration rates than smaller ones.

However, none of the equations so far presented in this paper give the investigator any indication as to whether an injected molecule would be absorbed primarily *via* capillary vessels, lymphatic vessels, or both. Table I summarizes some of the literature relating molecular or formula weights of injected substances and their probable primary absorption routes. From the subcutaneous site it appears that molecules or ions having low molecular weights are absorbed primarily *via* the capillaries, while molecules having high molecular weights appear to be absorbed primarily *via* lymph vessels. Sund and Schou (20) followed the clearance rate of labeled carbohydrates from rat muscle. Table II lists the substances used, their molecular weights, aqueous diffusion coefficients, and the fraction of drug cleared 5 min. after the injection. As expected, it can be seen from this table that with an increase in molecular weight, there is a decrease in clearance rate. The fact that the fraction cleared at the end of 5 min. correlates with the diffusion coefficient, they state, is evidence that diffusion is the main driving force for the absorption. These investigators did not determine experimentally which of the molecular species was cleared primar-

TABLE I—RELATIONSHIP BETWEEN MOLECULAR OR FORMULA WEIGHT OF CHEMICAL SPECIES AND PROBABLE ROUTE OF ABSORPTION FOLLOWING AN INTRAMUSCULAR OR SUBCUTANEOUS INJECTION

Mol. Species	Mol. or Formula Wt.	Route of Administration	Probable Primary Absorption Route	Ref.
$^{24}NaCl$	58	i.m.	Capillary	(145)
Strychnine (salt?)	>334	s.c.	Capillary	(38)
$^{59}FeCl_3$	270	s.c.	Capillary	(146)
^{59}Fe-labeled plasma	?	s.c.	Lymphatic	(146)
Black tiger snake venom	>20,000	s.c.	Lymphatic	(38)
India cobra venom	2500–4000	s.c.	Capillary	(38)
Russell viper venom	~30,000	s.c.	Lymphatic	(38)
Diphtheria toxin	~70,000	s.c.	Lymphatic	(38)
Tetanus toxin	?	s.c.	Lymphatic	(38)
Iron polysaccharide complexes	10,000–20,000	i.m.	Lymphatic	(37)

Iron–sorbitol–citrate complexes	<5000	i.m.	~16% lymphatic ~50–60% capillary	(147)

[a] The neolymphins are neomycinpolymetacrillate, neomycindextransulfate, and neomycincarboxymethyl starch.

TABLE II—CARBOHYDRATE ABSORPTION FROM RAT MUSCLE (20)

Substance	Mol. Wt.	Aqueous Diffusion Coefficient × 10^6	Fraction of Drug Cleared 5 min. After i.m. Injection × 10
D-Mannitol-1-^{14}C	182	8.7	~7
Sucrose-^{14}C	342	7.5	~6
Inulin-methoxy-^{3}H	3000–4000	2.1	~2
Inulin-carboxyl-^{14}C	3000–4000	2.1	~2
Dextran-carboxyl-^{14}C	60,000–90,000	~0.5	~0.7

ily by the capillary or by lymphatic routes, although they pointed out that the drainage through lymph channels could be of relatively greater importance for the absorption of large molecules compared to smaller ones.

Lewis (23) attempted to explain why sudden anaphylactic deaths occasionally occurred in humans after subcutaneous injections of macromolecules like diphtheria antitoxin when absorption of this substance from the subcutaneous site was known to be slow. The test substance he used was horse serum. Table III shows that the serum was absorbed slowly from the subcutaneous region of dogs, probably because the absorption took place largely *via* the lymphatics. Massage of the wheal produced by the injection and the use of high injection pressures resulted in a more rapid appearance of the serum in the thoracic duct lymph. Lewis concluded that the serum's absorption rate was too slow to account for cases of anaphylactic death in humans, and that the probable reason for this phenomenon was an accidental intravenous injection of the serum.

The effect that molecular size or weight can have on the route of drug clearance from an injection site has been demonstrated by Málek and co-workers (24). They prepared salts of an antibiotic base like streptomycin or neomycin with high molecular weight anionic substances like polyacrylic acids, sulfonic or phosphorylated polysaccharides, and natural polycarboxyl acids. After an intramuscular injection of neomycin sulfate into a dog, a peak blood level of about 20 mcg./ml. was obtained at 2 hr., which fell to zero at 12 hr. After an intramuscular injection of neomycindextransulfate (neolymphin II), a peak neomycin blood level of about 3 mcg./ml. was obtained at 2 hr., and its concentration in the blood remained nearly constant at 1 mcg./ml. from 8 to 24 hr. They termed these macromolecular salts "antibiolymphins." According to the authors, the antibiolymphins were absorbed from the injection site primarily *via* the lymphatic system in contrast to the corresponding sulfate salt, which presumably was absorbed *via* the capillaries, although the authors did not state this.

TABLE III—APPEARANCE OF SUBCUTANEOUSLY ADMINISTERED HORSE SERUM IN LYMPH AND BLOOD OF DOGS UNDER VARIOUS CONDITIONS (23)

Conditions	Time to Detect —Presence of Horse Serum in— Thoracic Duct Lymph	Blood
No massage at site	40 min.	3.5 hr.
	...[a]	1.5 hr.[a]
Massage at site	15–20 min.	2 hr.
High-pressure injection	<5 min.	40 min.

[a] Thoracic duct not cannulated.

pH—Madison and Christian (25) studied the influence of pH on the absorption rate of $^{22}NaCl$ and $^{23}NaCl$ administered subcutaneously in rats. The magnitude of the absorption rate was evaluated on the basis of the amount of radioactivity present in a sample of heart blood removed 45 min. after the injection. From pH 2.5 to 10 inclusive there was little effect on the normal absorption rate of sodium ion. At pH values of 1.0 and 2.0, a decrease in sodium ion absorption rate was observed, while at pH values of 11.0 and 12.0 an increase in rate occurred.

In the case of organic bases, the pH of the injected solution can often have a profound effect on absorption rate. Cutts and Walker (26) repeated the work of White and Claflin (27). They confirmed that in mice intraperitoneal injections of the nitrogen mustard HN_2, methyl-bis(β-chloroethyl)-amine hydrochloride, at two different pH values resulted in different LD_{50} values. At pH 2 the LD_{50} was about 5 mg./Kg., while at pH 8 it was about 2 mg./Kg. White and Claflin (27) showed under their injection conditions that little HN_2 would have undergone cyclization. Since HN_2 has a pK′ of 6.45 at 15° (28), the molecule exists almost entirely as the water-soluble protonated form at pH 2. But at pH 8 a significant fraction of the amine exists in the undissociated form. On the basis of pH-partition considerations (29), the drug's absorption and distribution at the higher pH value should be facilitated resulting in the lower value found for the LD_{50}.

PHAGOCYTOSIS

Although passive diffusion is an important mechanism for drug absorption, the process of phagocytosis may also be involved in drug absorption from subcutaneous and intramuscular sites. Rees and co-workers (30) studied the systemic distribution of dimethylpolysiloxane,[2] following its subcutaneous administration, in mice. They stated that while the mechanism of absorption and systemic distribution of the silicone fluid in mice is at present unknown, it may be distributed to the viscera by gaining entrance to the general circulation (*via* capillaries?) or lymphatic channels. However, the authors suggest that the most likely mechanism is by the process of phagocytosis by histocytes.

When sodium urate crystals are injected subcutaneously into animals and man, an acute inflammatory response occurs accompanied by phagocytosis of the crystals by mononuclear and

[2] Dow Corning MDX 4-4011.

polymorphonuclear leucocytes (31). A similar acute inflammatory response occurs after subcutaneous injections of microcrystalline ammonium and potassium urates, uric acid, xanthine, hypoxanthine, calcium carbonate, and creatinine. Seegmiller and co-workers (32) have shown that when microcrystalline sodium urate and sodium orotate suspended in a 50% glycerol–water vehicle were injected subcutaneously in man, 24 hr. later the site in most subjects showed warmth, swelling, erythema, induration, and tenderness. There was essentially no reaction to control subcutaneous injections of the vehicle after the immediate pain and wheal had subsided 6 to 8 hr. after the injection. Malawista and Seegmiller (33) have shown, when humans were pretreated with colchicine, the inflammatory response to subcutaneously administered monosodium urate monohydrate and sodium orotate microcrystals was substantially reduced over controls not so pretreated. Malawista (34) has shown that colchicine interferes with the amoeboid motility of individual human polymorphonuclear leucocytes. Other substances like actinomycin D, 6-mercaptopurine, and puromycin have been found to block lymphocyte emigration into a region of inflammation (35). An interesting but as yet unexplained finding is that the inflammatory response to subcutaneous injections of amorphous sodium urate particles was much less than that found with microcrystalline preparations of the same salt (32).

Gómez-Luz (36) showed that when microcrystals of insoluble oxytetracycline were administered subcutaneously into man, crystals could be found in the peripheral blood either intracellularly or free and in human bone marrow 6 to 14 days following the injection. Patients suffering from nonspecific urethritis received the insoluble oxytetracycline subcutaneously, and microcrystals were found in their urethral discharges. Gómez-Luz explained these observations by suggesting that polymorphonuclear leucocytes and monocytes engulfed the microcrystals by the process of phagocytosis, and these crystals then were transported to the general circulation and finally to the site of infection.

Beresford and co-workers (37) showed that most of the absorption of iron polysaccharide complexes injected into rabbit muscle tissue occurred during the initial 72 hr. The absorption during this time was mediated in part by the inflammatory reaction evoked, and in part by lymphatic transport of the iron complexes. The iron complexes remaining after 72 hr. were fixed by tissue macrophages that seemed to impede further absorption.

BIOLOGICAL FACTORS

There are several biological factors, in addition to those mentioned, which can influence the rates of drug absorption. Some of these factors include body movement, pre-existing disease conditions, the age of the animal, the anatomical region into which the injection is made, and the condition of the tissue at the site.

Body Movement—If a molecule is absorbed primarily *via* the lymphatic route, body movement or exercise can often have a profound effect on how rapidly it reaches the general circulation. Muscular movement has long been known to increase the flow of lymph fluid along the lymphatic vessels. When an animal is at rest, little or no lymph flows (5). The effect that body movement has on the absorption rate of a substance in solution can be seen from the work by Barnes and Trueta (38). They injected black tiger snake venom subcutaneously into rabbits. Since this venom has a relatively large molecular weight (>20,000), it is transported from the injection site almost exclusively by the lymphatic drainage. Control animals lived no longer than 150 min. following the injection, while animals whose injected limb was immobilized by a plaster cast lived more than 8 hr.

Controlled physical activity has also been shown to have an effect on the rate at which subcutaneously implanted procaine penicillin G implants were absorbed in rats. Ballard (39) found that the mean absorption rate per mean pellet area[3] in animals rotated in a rodent activity cage at 3.83 r.p.m. was 2.57×10^{-3} Gm. hr.$^{-1}$ cm.$^{-2}$, while that of nonrotated control animals was 1.93×10^{-3} Gm. hr.$^{-1}$ cm.$^{-2}$. These differences were shown to be statistically significant.

Disease Conditions—Bauer and co-workers (40) noted that patients with cardiac failure and patients with myxedema had prolonged absorption half-lives following a jet injection of ^{131}I solutions into their thighs. When the myxedemic condition was reversed by appropriate thyroid medication, the absorption half-life of the drug returned to the normal range. De Groot and co-workers (41) noted delayed intramuscular absorption of a triiodothyronine formulation in one hypothyroid subject studied. Using the same jet injection technique, Bauer *et al.* (42) studied the absorption half-life of ^{131}I from the thighs of patients suffering from myocardial infarctions. None of the patients had congestive heart failure. In one patient the half-lives were

[3] An error in the caption at the top of column five of Table I (39) indicated that all the rates per unit area were tenfold slower than they should be.

60, 29, 14, and 8 min., respectively, on the first, eighth, fourteenth, and thirty-first days after the infarction. In healthy controls the mean absorption half-life for ^{131}I was 9 (range: 6–14) min. Irons (43) followed the blood levels of penicillin in patients suffering from a variety of bacterial infections after injections of an aqueous suspension of procaine penicillin G. He commented that a depression of penicillin blood levels tended to occur in a patient with severe cardiac failure because there was poor absorption of the drug from the injection site.

Animal Age—Lee (44) studied the effect of age on the acute toxicity of subcutaneously administered chlorpheniramine maleate and diphenhydramine hydrochloride in rats. He found that the LD_{50} of chlorpheniramine during the first 16 days of life varied between 175 and 230 mg./Kg., but after 25 days of life the LD_{50} was 360–365 mg./Kg. A similar trend was found for diphenhydramine. There was no apparent difference in the activity of enzymes concerned with the metabolism of both drugs in the livers of 15- and 40-day-old rats. Lee concluded that the development of greater resistance to both drugs with increasing age could be explained by a decrease in the amount of drug absorption from the subcutaneous region. The reason why age should influence drug absorption from the subcutaneous region is not known at present. However, if one may speculate, there are at least two possible reasons for this phenomenon.

Ballard and Menczel (19) studied the subcutaneous absorption half-life of aqueous benzyl alcohol solutions in rats. The mean absorption half-life for four animals was 1.6 hr., but the range was from 0.96 to 2.58 hr. under conditions where the tissue area exposed to the drug solution was constant. They suggested that one probable reason for the large interanimal variation in $t_{0.5}$ could be attributed to differences in the membrane thickness exposed to the drug solution in the abdominal region for the several animals. It is well known that the thickness of the subcutaneous tissue among humans is not constant (45). In Eqs. 4 and 6 it can be seen that the penetration coefficient is inversely proportional to δ, while $t_{0.5}$ is directly proportional to δ. It is reasonable to suppose that as young animals age the thickness of their subcutaneous tissue may increase as well, resulting in increases in $t_{0.5}$ and increases in LD_{50} values for drugs whose acute toxicity can be correlated with drug blood-level.

Another hypothesis among several others deals with the question: what influence does animal age have on the chemical composition of subcutaneous fat tissue? The penetration rate of a lipid-soluble drug should be directly proportional to the lipid/water partition coefficient of the drug. (See Eq. 4.) If the chemical composition of this tissue changes with age, and the apparent partition coefficient of the drug differs in younger and older tissue, then variations in absorption rate would be expected. Using gas chromatographic analysis Bondrup *et al.* (46) studied the triglyceride composition of subcutaneous fat obtained from premature stillborn and full-term stillborn children, and normal, lean, and obese adult patients. Between the children and adult groups they found that there was a pronounced difference in the relative percentages of C_{12} to C_{18} triglycerides in the two groups. The testing of these two hypotheses must await more data on the relative thicknesses of the subcutaneous tissue surrounding injected solutions in young and older animals, and apparent partition coefficient data for drugs in these triglyceride systems.

Anatomical Region and Tissue Condition—The absorption rate of subcutaneously or intramuscularly administered drug can often be profoundly affected by the anatomical region into which the drug is injected and the condition of the tissue found at the site. Nora and co-workers (47) studied the effect of the route of insulin administration in the management of diabetes mellitus in children. They found no significant difference in absorption rate of ^{131}I-labeled lente insulin from subcutaneous and intramuscular tissues at a given anatomical region, but they did find significant differences at different sites. For example, the mean absorption half-life for the drug following intramuscular arm injections was 224 min., and that for the subcutaneous arm injections was 232 min. By comparison, the mean absorption half-life of the drug for intramuscular thigh injections was 314 min., and that for the subcutaneous thigh injections was 310 min. They concluded that variability in diabetic control potentially could be encountered when alternating the anatomical region of the injection between arm and thigh, but such a problem would not be anticipated between the subcutaneous and intramuscular sites at a given anatomical region.

Burchell and Swasdio (48) compared the absorption rates of atropine injected by various routes. The absorption rate of drug administered by various routes could be compared by recording the time interval between drug injection and the advent of tachycardia. Maximum pulse-rate elevation was noted at about 7 min. after intravenous administration of atropine, 28 min. after broad ligament administration, and

40 min. for both subcutaneous and intramuscular drug administration. They did not discuss the reasons for the unexpected rapid absorption of drug from the broad ligament.

Braid and Scott (49) studied the systemic absorption of the local anesthetic drugs, lidocaine and prilocaine, in humans after using two types of regional nerve block, namely, lumbar epidural block and intercostal regional block. Their work showed that much higher serum levels of both drugs follow intercostal block compared to epidural block. The authors ascribed the higher serum levels found with the intercostal block to differences in the relative vascularity of the tissues at the two injection sites. Although the epidural space contains numerous blood vessels, there are comparatively few capillaries available for drug absorption.

The condition of the tissue at the injection site can also affect drug absorption rate. Root and co-workers (50) studied the subcutaneous absorption of insulin labeled with radioactive iodine in diabetics and volunteers. In the controls and patients with uncomplicated diabetes, the absorption rates of tagged insulin were nearly identical. Drug absorption rate was retarded in diabetics when insulin was injected into regions where induration or an insulin pad had formed. The pads disappeared when injections in these regions were discontinued. After a recovery period, the tissue regained its ability to absorb insulin rapidly once again. Their results agreed with the clinical observation that insulin tends to lose its effectiveness when injected in insulin pads.

Chavarría *et al.* (51) administered cycloguanil pamoate intramuscularly to patients with dermal leishmaniasis. One of the treatment failures occurred in a child with a suppurating abscess at the injection site. When the abscess was drained of pus, particles of the yellow drug were found indicating that it had not been completely absorbed. The authors suggested that this complication might explain the treatment failure in this patient.

ENZYME EFFECTS

It has been known for years that when the enzyme hyaluronidase is added to a drug solution intended for intramuscular use, the onset of drug action is more rapid than when the drug alone is used (52–54). Hyaluronidase hydrolyzes hyaluronic acid, a component of tissue ground substance, which limits the spread of fluids at the injection site. Thus, after hydrolysis, the area of drug distribution in the tissue is increased with the result that absorption rate is also increased (55). The enzyme chymotrypsin, on the other hand, influences drug absorption by a mechanism not yet understood. Seneca and Peer (56) administered orally enteric-coated tablets of this enzyme to volunteers. Four hours later the subjects again received chymotrypsin orally, and 100 mg. of tetracycline hydrochloride intramuscularly. A control group was treated in the same manner except that its members received placebo tablets instead of the enzyme. At the end of 6 hr. the placebo groups had excreted about 13% of the injected dose of tetracycline in the urine, while the enzyme groups excreted about 37% of the dose over the same time. Serum levels of drug at various times following its injection were not reported for these subjects. However, when tetracycline hydrochloride and chymotrypsin were given orally, the mean level of antibiotic in the serum and the cumulative amount of drug excreted up to 12 hr. were significantly higher than when tetracycline hydrochloride was given orally alone. The authors state that chymotrypsin either interferes with the excretion of tetracycline or it increases drug absorption rate. On the basis of the evidence provided in the above experiment and the literature (57, 58), the authors concluded that interference with drug excretion was probably not the mechanism for the enhanced blood levels.

FORMULATION—PHYSICAL ASPECTS

The preceding section discussed some of the mechanisms and factors affecting drug absorption In this section some aspects of parenteral drug formulation will be considered. Nash (59) pointed out that most reviews written about pharmaceutical suspensions devote little space to a discussion of the formulation of parenteral suspensions. There are formulation problems associated with these dispersed systems which other suspension systems do not share. Some of these factors are product sterility, syringeability, ease of resuspension, and drainage.

The manufacture of sterile parenteral suspensions requires careful control at the following stages: (*a*) final drug recrystallization, (*b*) drug micronization, (*c*) drug sterilization, (*d*) vehicle sterilization, (*e*) aseptic wetting of the sterile powder with a portion of the sterile vehicle, (*f*) aseptic dispersion and milling of the bulk suspension, and (*g*) aseptic filling of the sterile containers with the finished suspension. The use of sound parenteral formulation techniques and sterility controls in the first place results in reductions in the foreign matter content of such powders and the chances of contaminating the formulation with pyrogenic materials.

One of the most important physical properties of a good parenteral suspension is its syringeability, or the ability of a solution or suspension to pass easily through a hypodermic needle. Properties that tend to reduce the formulation's syringeability can be traced to increases in the vehicle's viscosity and density, increases in the particle size of solids in the suspension, and increases in the percentage of drug suspended in the formulation. Nash states that probably the most important of the above factors contributing to a decrease in syringeability is the viscosity of the formulation. He believes one practical standard for syringeability is that the entire contents of a syringe should pass easily through a 25-gauge hypodermic needle.

The resuspendability of a suspension may be defined in terms of the minimum amount of shaking that is required to suspend particles that have settled in the container. A practical consideration is how much effort will a busy nurse or physician exert to resuspend settled particles? Ideally, the best answer to this problem is to formulate initially a "permanent suspension," or a physically stable, flocculated suspension.

A parenteral suspension should exhibit good drainage. Good drainage can be seen when the suspension separates cleanly from the inner walls of the container. The current practice of coating containers and plugs with silicone preparations makes good suspensions drain better and helps minimize the tendency toward bad drainage of over-flocculated systems.

Rheology—The pharmaceutical industry in recent years has come to rely heavily on sophisticated rheological measurements in order to help solve some of the difficult stability problems encountered in pharmaceutical systems. However, Boylan (60) points out that pharmaceutical literature is nearly devoid of rheological studies involving parenteral products. In his review, he gives examples of the effect that the formula and vehicle can have on the rheological properties of some commercially available procaine penicillin G suspensions.

Polymorphism—In recent years drug product formulators, government agencies, and others have become increasingly aware of the importance of identifying and characterizing the physical and biological properties of drug polymorphs. For example, both chloramphenicol palmitate and stearate have two polymorphic forms, one form of the ester in each case is therapeutically active and the other is not (61). In 1965 the Food and Drug Administration (FDA) amended its regulations to include a limit of not more than 10% of polymorph A, the therapeutically inactive form, in chloramphenicol palmitate suspension (62).

Hayden and co-workers (63) studied the absorption spectra of 175 reference standard compounds under controlled conditions. Except in resolution and slight relative intensity reversals, they observed no significant infrared spectral changes when potassium halide disks containing 150 of the standards were remeasured after periods of 2 weeks to 6 months. However, 25 compounds[4] displayed significant spectral variations after standing. They attributed the changes exhibited by these compounds primarily to crystalline form transitions. The conditions of crystallization, force of grinding, or the disk storage period influenced the crystalline forms and their infrared spectra. Lees (64) cites other examples where drugs were converted from one polymorphic form to another by apparently innocuous grinding procedures.

Mesley and Johnson (65) studied the infrared spectra of pharmaceutically important steroids with particular reference to the occurrence of polymorphism. Of 35 steroids examined 19 had two or more polymorphic forms.[5]

The articles by Macek (3) and Collard (66) consider some of the physical problems associated with the formulation of drugs intended for parenteral use. Polymorphic changes and particle size control in suspensions are among the topics discussed. Identification of the various polymorphic or solvate forms of drugs is also important because it has been shown that the subcutaneous absorption rate of one form may differ from that of another (2, 67).

Scheindlin (68) has briefly reviewed the use of stabilizers in parenteral drug formulations. He discusses the following classes of stabilizers: buffers, antioxidants, chelating agents, protective colloids, and miscellaneous stabilizers such as nonaqueous solvents. Anschel (69) reviewed the literature dealing with some of the methods of solubilizing some steroid hormones and antibiotics.

FORMULATION—BIOLOGICAL ASPECTS

Apart from the physical aspects of parenteral

[4] Betazole hydrochloride, calcium panthothenate, carbinoxamine maleate, dihydrostreptomycin sulfate, epinephrine bitartrate, ergonovine maleate, estradiol, estradiol benzoate, hydroxystilbamidine isethionate, menadione, mercaptopurine, nifuroxime, nitrofurantoin, oxytetracycline, phenindamine tartrate, phentolamine methanesulfonate, probenecid, pyrilamine maleate, sodium diatrizoate, sulfamethazine, sulfamethoxypyridazine, tetracaine hydrochloride, thiamine hydrochloride, trimethaphan camphorsulfonate, and zoxazolamine.

[5] Compound (number of solid forms identified): betamethasone (2), cortisone acetate (7), dexamethasone acetate (4), dimethisterone (2), ethinyl estradiol (3), fludrocortisone acetate (4), fluocinolone acetonide (2), hydrocortisone (2), methylprednisolone (2), norethandrolone (2), norethynodrel (2), prednisolone (2), prednisolone trimethylacetate (3), prednisone (2), prednisone acetate (2), progesterone (2), spironolactone (3), testosterone (3), and triamcinolone (2).

formulation, the test of whether a given formulation will be acceptable also depends upon performance *in vivo*. It has been known for some time that formulation variables can affect the animal's response to the product under study, sometimes to a large degree.

Particle Size—The effect of particle size on the availability of a suspension has been demonstrated by Foglia and co-workers (70). They administered the estrogenic substance *p*-hydroxypropiophenone (PHP) in saline subcutaneously to spayed female rats. When the size of the suspended particles was about 10,000 μ^3, and a high dose was maintained for a long time, they observed no estrus. When samples of the same powder were recrystallized to yield a particle size of about 2,000 μ^3 or less, they observed estrogenic activity. After samples of these active microcrystals were recrystallized to yield particles having the original size of about 10,000 μ^3, they became inactive again. The authors concluded that PHP appears to be a weak estrogenic substance, and its activity depends upon the crystal size injected.

Solubilizers—Kopáčová and Vrba (71) studied the local anesthetic activity of 1.5, 3, and 6% concentrated solutions of benzocaine in highly concentrated aqueous solutions of the solubilizing agents antipyrine, dimethylformamide, diacetone alcohol, and butane-1,2,4-triol. They assumed that the depot activity of the benzocaine was due to prolonged absorption following the drug's precipitation at the injection site. All benzocaine solutions caused undesirable local reactions. Reactions were greatest with the solubilizers butane-1,2,4-triol and antipyrine, and least with dimethylformamide. As to the degree of anesthesia, benzocaine in dimethylformamide was somewhat less effective than benzocaine in the solubilizers antipyrine and diacetone alcohol.

Viscosity—Coles *et al.* (72) studied the effect of aluminum monostearate–paraffin gels on the antigen response to *Clostridium welchii* type D toxoid. When these formulations were injected subcutaneously into rabbits and guinea pigs, the level and duration of the antitoxin titer in the blood was directly related to the viscosity of the vaccine formulations studied. In attempting to explain why an iron–polysaccharide complex (IPH) marketed for human use was poorly absorbed from muscle tissue of rats, Beresford and co-workers (37) surmised that it had a higher viscosity than the other iron–polysaccharide complexes tested. Also, its molecular weight might lie beyond the range capable of penetrating the lymphatics.

Base and Salt Forms—Monash and Gibbs (73) studied the acute toxicities of a number of local anesthetics administered intraperitoneally and subcutaneously to mice. They dissolved the salts in normal saline, and prepared a suspension of the base using polysorbate 80 and normal saline. The LD_{50} data are shown in Table IV. Intraperitoneal injections of both bases and salts resulted in approximately equal toxicity. This suggests that these forms of the drugs were absorbed from the peritoneal region into the circulation at nearly similar rates. In general, absorption from the subcutaneous tissue was not as rapid as it was from the intraperitoneal region. The result was that the acute toxicity of the salt and base were both reduced in most cases. After subcutaneous injections of the two forms of the drug, the acute toxicity of the base was always less than that for the salt form of the drug. The authors stated that this occurred because the base was less water soluble and hence was absorbed more slowly. However, their results raise some unanswered questions. Why should the salt and base forms of the drug have substantially the same degree of toxicity when administered by the intraperitoneal route, yet have different degrees of toxicity when administered subcutaneously? Should not the argument concerning the lesser solubility of the base compared to its salt and the differences in their absorption rates apply equally well to both injection sites? Also, what possible influence does the polysorbate 80 and the particle size distribution of the suspension have on drug absorption rate from either absorption site?

Solvent Effects—Foldes and co-workers (53) studied the influence of solvent on the myoneural effects of succinylcholine administered intramuscularly to humans. The chloride salt of the drug was made into a 10% solution by dissolving it in water and in 0.9% saline. When succinylcholine was dissolved in water, the onset of action was more rapid and its intensity greater than when the solvent was normal saline. In the water group apnea developed in 155 (S.E. ± 15.6) sec. and lasted

TABLE IV—ACUTE TOXICITY OF SALTS AND BASES OF SOME LOCAL ANESTHETICS IN MICE (73)

	Median Lethal Dose, mg./Kg.			
	i.p. Injection		s.c. Injection	
Anesthetic	Base	Salt	Base	Salt
Tetracaine	60	60	85	50
Benoxinate	37	30	75	37
Dibucaine	50	35	60	35
Lidocaine	200	160	275	225
Procaine	225	225	1000	500
Pramoxine	300	300	900	750

881 (S.E. ± 93.4) sec. in 9 out of 10 subjects. In the saline group apnea developed in 253 sec. and lasted 993 sec. in only 3 out of 10 subjects. The authors suggested that the delayed onset and lesser intensity of action of the intramuscularly injected succinylcholine dissolved in normal saline were due to the retardation of its rate of absorption that prevented the development of a sufficiently high plasma concentration. There are at least two possible reasons for this phenomenon. First, both succinylcholine chloride solutions are hypertonic with respect to the body fluids. However, of the two, the saline solvent is more hypertonic. Thus, there should be a greater net flow of water toward the injection site in the case of the saline vehicle with the result that drug absorption rate is decreased due to the greater solvent drag effect. Second, in water the diffusing electrolyte is moving under the influence of the chemical potential gradient for that ionic species, and the electrical field produced by the motion of the oppositely charged ion or ions. The more mobile Cl^- will tend to diffuse more rapidly than the succinylcholine^{2+} species. In so doing, a microscopic charge separation will tend to occur. Since it is an experimental fact (10) that macroscopic charge separation does not occur, the diffusion velocity of the slower ion will increase, while that of the Cl^- will decrease. When succinylcholine chloride is diffusing in an aqueous medium having an appreciable sodium chloride concentration, the microscopic conditions prevailing in the solution are different from what they were before. Now there is no symmetry of the "ionic atmosphere" which was found where the drug was diffusing in water. The succinylcholine^{2+} (or tracer ion) is moving relative to a background of nondiffusing Cl^-, while in the former case all ions are diffusing with the same velocity (10). Regardless of the mechanisms involved, on the basis of the biological data provided by Foldes *et al.* (53) it would appear that the diffusion rate of the succinylcholine ion is retarded in the saline vehicle resulting in a decreased absorption rate.

Potency Testing—There exists a danger that a parenteral product will be evaluated in terms of the "active" ingredient contained in the formulation without due consideration to other pharmaceutically important substances present in the preparation, such as solubilizers, preservatives, buffering agents, and the like. Bueno-Montano *et al.* (74) studied what effect chlorobutanol, ethanol, phenol, sodium acetate, and propylene glycol might have on the *in vitro* spontaneous contractile patterns of isolated human uterus tissues. They found all of these agents to be depressant to isotonically contracting uterine smooth muscle. The authors point out that the presence of agents commonly used in commercial preparations may complicate the *in vitro* appraisal of a given product.

Foreign Particulate Matter—The parenteral product formulator must determine the origin and nature of foreign particulate matter which might be found in a product and eliminate the sources of this contamination. This problem is so important that the FDA sponsored a symposium in July 1966 entitled "The Safety of Large Volume Parenteral Solutions." Abstracts of the papers presented at this meeting and other pertinent work are included in *References 75–80.*

Scherr (81) and Zolov (82) have suggested that a possible cause of abscess formation found in some patients receiving subcutaneous emulsion therapy is due to metal particles introduced into the formulation during emulsification. In addition, Caplin (83) proposed that other foreign bodies such as cotton gauze and rubber stopper particles might give rise to untoward local reactions during emulsion therapy, although he does not cite experimental evidence for his statement.

Another source of foreign matter may arise as a result of coring when the needle is passed through the rubber closure of a vial or the skin. Magath and McClellan (84) noted when needles were inserted through stoppered vials, that rubber fragments might be cut out. They injected these particles into the gluteal muscle of guinea pigs and found that they migrated quickly from the injection site into the popliteal space. Magath and McClellan concluded that it was unlikely that the fragments would produce much damage unless they were accidently injected into a blood vessel or if they gave rise to an infection. Gibson and Norris (85) directed their research toward finding the answers to these questions: How often does a hollow needle piercing the skin core out a fragment of tissue? What is likely to cause this to occur? And what is the possible fate of the fragments? Using needles having bores in the range commonly used for intravenous solutions, they recovered skin fragments 69% of the time. They noted no real difference between new and resharpened needles. This needle coring is probably due to a very sharp or ragged back bevel. However, attempts to blunt the back bevel did not greatly reduce the number of skin fragments. Some of the fragments may remain in the needle bore, partially or completely blocking it. Some may become sus-

pended in the injection fluid or lodged in the barrel causing the piston to stick. The remainder will be ejected along with the fluid. Gibson and Norris (85) state that it is difficult to assess the clinical significance of their findings, since many thousands of injections are given daily and no harmful effects have been attributed to skin emboli. This fact suggests that little is to be feared from the injected skin fragments *per se*. However, the authors suggest that unless the skin is carefully prepared prior to the injection, there is a risk that an infection may occur at the subcutaneous, intramuscular, or pulmonary sites. Parenthetically, Dann (86) recently has provided evidence that the routine procedures for skin preparation before injections are unnecessary, unless the skin is obviously dirty. Also, pretreatment of the skin with an antiseptic was judged to be unnecessary when measle vaccine was injected intradermally and subcutaneously by means of a dermojet instrument (87). Some investigators have attempted to avoid this potential problem. Thompson *et al.* (88) used 18- to 20-gauge Huber point hypodermic needles to facilitate the injection of suspensions and to minimize the likelihood of introducing skin fragments into animals. Charlebois (89) says the problem of coring skin or closures by needles is of particular importance now with the growing popularity of epidural injections. To eliminate the possibility of injecting a core of skin into the epidural space, the physician should make the actual injection with a needle other, and smaller, than the one used to pierce the skin. To eliminate the possibility of injecting a core of the closure into the epidural space, the local anesthetic drug should *not* be obtained by piercing a pliable membrane. The container closure should be removed before withdrawing the solution. The author further concludes that no drug that has been obtained by piercing a pliable membrane should be injected into a patient, and multiple-dose vials should not be used by the medical profession.

Carcinogenesis—The product formulator should always be alert to the potential problem of carcinogenesis. Roe (90) has reviewed the evidence for carcinogenic activity of various pharmaceutical agents and preparations. Table V shows his categorization of these substances into high, medium, and low carcinogenic risk groups. Several substances listed are of interest to the parenteral product formulator. Roe comments on the significance of tumor induction in subcutaneous tissues of rats and mice. The induction of cancers in these rodents at a subcutaneous site may well be a result of physical rather than chemical carcinogenesis similar to the induction of neoplasms following the implantation of chemically inert materials. Also, rats and mice are especially susceptible to the induction of local tumors following the subcutaneous or intramuscular injection of various substances. For these reasons Roe states that it is generally agreed that not much weight can be given to positive results obtained from injections in rats and mice unless they are supported by positive results from other experiments employing other methods of exposure.

Nevertheless, the subcutaneous route is frequently used to screen substances for their possible carcinogenic activity. For example, the colors, blue VRS, green S, and brilliant blue FCF

TABLE V—ATTEMPT TO CATEGORIZE SPECIFIC PHARMACEUTICAL AGENTS AND PREPARATIONS INTO HIGH, MEDIUM, AND LOW CARCINOGENIC RISK GROUPS (90)

HIGH RISK
All biological alkylating agents, especially β-naphthyl-di-2-chloroethylamine
Urethan
Isonicotinic acid hydrazide
Arsenic
Phenylbutazone
Creosote and coal tar preparations
Estrogens
Materials such as plastic sponges used in surgery
Combination of ^{131}I and goitrogens
3-Phenyl-5β-diethylaminoethyl-1,2,4-oxadiazole
MEDIUM RISK
Penicillins given by s.c. or i.m. injection
Actinomycins given by s.c. or i.m. injection
Iron dextran, saccharated iron oxide, ferric sodium gluconate complex, and ferrous glutamate given by s.c. or i.m. injection
Tannic acid and tannins
Medicinal paraffin
Goitrogens
Cortisone
Pronetalol[a]
8-*o*-Hydroxyquinoline
Vaccine preparations from which the presence of oncogenic viruses has not been excluded
Griseofulvin
LOW RISK
Methotrexate
Sulfonamide
Chloramphenicol
Chlorpromazine
Reserpine
Thalidomide
Carbon tetrachloride and chloroform (in doses which do not cause obvious liver damage)
Injections of colloidal gold or silver
Spermicidal contraceptive preparations, except possibly those containing 8-*o*-hydroxyquinoline
Carrageenin
Carboxymethylcellulose
Progesterone and oral contraceptives
Cocarcinogenic agents including phenols, essential oils, and surface active agents

[a] Alderlin.

were tested subcutaneously in rats to determine whether they might be safe for use as food colors (91). Poirier and co-workers (92) studied the carcinogenic activities of *N*-hydroxy-2-acetylaminofluorene (*N*-hydroxy-AAF) and some of its metal chelates after subcutaneous administration into rats. They noted an approximate correlation between the retention times of the potassium salt of *N*-hydroxy-AAF and its various metal chelates and the incidence of sarcomas found at the injection site. Certain chelates (*e.g.*, Ni^{2+}, Co^{2+}, Fe^{3+}, and Cu^{2+}) had moderate to high incidences of sarcomas following one to four injections. For these chelates the half retention time, or the time when only one-half of the administered *N*-hydroxy-AAF species remained at the site, ran from 4 to 50 days. The potassium salt and the Mn^{2+} and Zn^{2+} chelates showed less activity at the injection site. Their half retention times ranged from 2.5 hr. to 2.5 days.

Hueper (93) investigated the carcinogenic potential of hypertonic (25%) solutions of the sugars: *l*-arabinose, anhydrous *d*-dextrose, *d*-galactose, lactose, *d*-levulose, *d*-maltose, *l*-sorbose, and *d*-sucrose. These solutions were administered subcutaneously to rats and mice twice a week for periods up to 2 years. Only 2 rats out of 60 animals given the sorbose solution developed sarcomas at the injection site. No tumors were found at this site in rats and mice injected with the other sugar solutions, injected with water, or traumatized by needle puncture. One conclusion of interest was that nonspecific chronic irritation (*e.g.*, repeated water injections and needle trauma) did not represent a mechanism for carcinogenesis in this case.

It is of interest that Roe (90) catagorized mineral oil as being in the medium carcinogenic risk group as shown in Table V, since it is used in the food-processing industry of this country (94). Boitnott and Margolis (95) studied lymph nodes taken from the porta hepatis at autopsy. They found in 38 cases (78%) that the nodes contained large oil droplets that were deposits of liquid saturated hydrocarbons. They state that in all likelihood these hydrocarbons were derived in large part from absorbed mineral oil from the intestinal tract. The high incidence of oil droplets found in these lymph nodes seemed out of proportion to laxative and other medicinal uses of mineral oil, although quantitative data on this point are not available. They cite evidence that the use of mineral oil in the food-processing industry is currently estimated to result in the ingestion of an average of 47.5 Gm. of mineral oil per capita per year in this country. Although there are no data on the absorption of mineral oil at dosage levels comparable to those present in foods, they felt that this yearly intake seemed adequate to explain the amounts and incidence of the oil found in their autopsy specimens.

The FDA recently terminated many of the investigational new drug (IND) applications for clinical investigations of a mineral oil-emulsifier product. Allergists had been adding antigens to the product in order to treat specific allergies of patients. The mineral oil and emulsifier, generally mannide monooleate, tended to act as a sustained-release medium for the antigens, permitting less frequent injection of the patient. Tests used for measuring the biological safety of mannide monooleate have been detailed by Berlin (96). Fiero (97) has reviewed the industrial procedures used to purify the grade of mineral oil used in medicine and pharmacy. The position of the FDA and the Committee on Mineral Oil Adjuvant Preparations concerning the hazards of mineral oil adjuvants has been detailed in a letter sent to an allergist (98). Allergists (99–102) have responded to the action taken by the FDA in letters and editorials. It appears that considerably more testing will be required before a safe, generally accepted repository material will be available for routine clinical use.

Injection Pain—The intensity of pain resulting from some intramuscular or subcutaneous injections may range from a mild or transient unpleasant sensation to a severe reaction which might necessitate the termination of the therapy. Since pain may arise from parenteral injections to these regions, the product formulator should be aware of some of the causes of such pain. Travell (103) has classified the different causes of the immediate pain following injections. Immediate pain may arise from: (*a*) local irritation due either to the antiseptic used on the skin or the properties of the parenteral formulation (*e.g.*, pH, tonicity, or chemical action on the tissues), (*b*) mechanical trauma due to the introduction of the needle to the injection site, or to the sudden distension of the tissues resulting from a too rapid discharge of the syringe contents, and (*c*) abnormal sensitivity of the tissue at the injection site. She states that some of the chief causes of delayed pain of injection include infection, aseptic irritation and necrosis, antigenic reactions, reactions to pyrogens, and painful muscle spasm.

The pain may be classified according to its origin as cutaneous, subcutaneous, or intramuscular pain. Cutaneous pain originates from the

stimulation of sensory nerve receptors found in the skin. To eliminate skin pain, Travell recommends that a sharp needle, free of barbs, having the smallest diameter compatible with the viscosity of the solution be used. A cooling spray (*e.g.*, ethyl chloride) should be applied to the site for 2 or 3 sec. before the injection, and the instant the liquid disappears, the needle should be quickly inserted through the skin. Weeks and Travell (104) found that at a skin temperature of 15° one-third of the subjects had anesthesia to a needle prick, while at 10° or below all had anesthesia to the same stimulus. Travell (103) states that the subcutaneous tissues are relatively insensitive to the movement of the needle unless the fascia of the underlying muscle tissue is entered and pulled. Subcutaneous pain can be induced by the injection of an irritant material or a hypotonic solution such as distilled water. The addition of a local anesthetic to the vehicle injected may reduce, but not entirely eliminate, the immediate pain response from the subcutaneous tissues. In contrast to skin, normal voluntary muscle tissue is practically insensitive to the insertion of a needle. However, hypersensitive or "trigger" areas may exist in the muscle tissue of some patients. When these areas are stimulated by pressure, palpation, or the insertion of a needle, pain may result which can be referred to adjacent regions. It can be seen from this brief account that pain derived from subcutaneous or intramuscular injections may arise not only from the formulation injected, but from the techniques used in making the injection, as well as certain predisposing conditions found in the target tissue.

A classic method used by the parenteral product formulator to minimize injection pain has been to add a local anesthetic such as benzyl alcohol, procaine, lidocaine, and the like to the preparation (103, 105). Miller (106) has been critical of the use of such local anesthetics in parenteral products on the grounds that the pain reflects tissue damage, and this is not corrected merely by blocking of the sensory nerves in the region. Perhaps it would be better if the offending substance could be identified and the product modified in its formulation so that the amount of irritation caused could be reduced.

Untoward Reactions—Fortunately, over the years there have been remarkably few serious untoward reactions reported in the literature directly resulting from the techniques used in injecting parenteral formulations. Such injuries may provide the basis for malpractice suits. In a recent case over a quarter of a million dollars was awarded to a patient for damages incurred after an intragluteal injection of penicillin (107). Table VI lists some of the drugs associated with severe complications following intra-arterial or intramuscular injections. The injuries include nerve damage (*e.g.*, sciatic), gangrene of extremities, progressive fibrosis of muscle (*e.g.*, quadriceps), and others. Lachman (45) states there is complete agreement among all authors that damage to the sciatic nerve after intragluteal injection is essentially independent of the drug used. While the damage has in large measure been attributed to the techniques used for making the injection, physical and possibly chemical properties of the injected substances must also have contributed to the injuries reported. A number of authors have discussed injection procedures that should be followed to minimize complications (18, 45, 108–116).

Tables VII and VIII list some of the reported milder local reactions after the administration of selected drug solutions and suspensions. The preparation of Tables VI–VIII was facilitated by recent advances in the abstracting of adverse drug reaction reports (117–119).

At present the causes of many of the local tissue reactions following drug administration are not well understood. Part of the difficulty stems from the fact that the mechanisms by which body

TABLE VII—LOCAL REACTIONS REPORTED FOR SELECTED DRUG SOLUTIONS[a]

Active Ingredient	Vehicle	Route of Administration and Untoward Local Reactions in One or More Humans or Animals	Species	Ref.
Ampicillin (as sodium salt)	.....	i.m.: severe pain at injection site	Human	(173)
Bis-(4-hydroxyiminomethyl-pyridine-1-methyl) ether dichloride[b]	.....	i.m.: dull, burning pain following injection using plastic self-injection ampul, which is manually emptied, but painless when automatic type is used. Pain assumed to be caused by needle movement	Human	(135)
Butyl-*p*-aminobenzoate 5%, procaine 1%, procaine HCl 0.25%[c]	Propylene glycol 78%, polyethylene glycol 300 2%, in distilled water	Intercostal nerve block: neuritis, inflammatory reactions, and lasting absence of nerve function resulted	Human	(174, 175)
Capreomycin	.....	i.m.?: bleeding at injection site	Human	(176)
Capreomycin	.....	i.m.: s.c. "lumps" at injection site from first week on	Human	(177)
Capreomycin	.....	i.m.: mild pain or stinging initially, palpable nodules, diffuse induration at injection site	Human	(178)
Capreomycin	.....	i.m.: sterile abscess of hip (due to injection technique?)	Human	(179)
Cephaloridine	Sterile water or isotonic saline	i.m.: moderately severe pain at site	Human	(180)
Chloramphenicol sodium succinate	Aqueous or saline	i.m.: local pain at injection site, sometimes severe	Human	(181)
Dihydrotriazine hydrochloride[d]	40% benzyl benzoate in castor oil	s.c.: local induration and frequently open lesions at injection site	Mice	(88)
Diphtheria–tetanus vaccine	No lidocaine	s.c.: initial pain occurring immediately after the injection and reaching a peak within a few minutes. Pain partly due to mechanical distension caused by the fluid, but mainly due to some unknown factor in the vaccine	Human	(105)
	Lidocaine added	s.c.: 12 of 13 volunteers felt less pain with the added lidocaine; one noted no difference		
Emulsion therapy with various pollens or molds	Adjuvant: 35% mannide monooleate, 65% mineral oil	s.c.: abscess at injection site	Human	(82)
Iron–dextran complex[e]	Aqueous	i.m.: injection abscess (may be due to faults in aseptic technique). Injections very painful and produced staining of skin	Human	(183)
Iron–sorbitol–citrate complexes[f]	Aqueous	i.m.: pain and skin discoloration at injection site	Human	(184, 185)
Nafcillin[g]	.....	i.m.: local pain and induration when given frequently in the same area	Human	(186)
Oxytetracycline ethanol–ammonium magnesium salt	80% propylene glycol in water, 2% lidocaine	i.m.: single injections almost invariably well tolerated, with only occasional complaints of mild pain lasting 15–30 min. Multiple injections usually well tolerated when given at 24-hr. intervals. More frequent injections occasionally associated with discomfort and more lasting pain	Human	(187)
N-(Pyrrolidino-methyl) tetracycline	Water, lidocaine	i.m.: local pain or discomfort at injection site	Human	(189)
N-(Pyrrolidino-methyl) tetracycline[h]	Water, lidocaine, ascorbic acid	i.m.: little discomfort at time of injection, but 15–20 min. later subjects complained of moderately severe pain at injection site lasting 1.5–2.5 hr. Without lidocaine same formulation caused moderate to severe pain from 1 min. to 2–3 hr. after	Human	(190)
Sodium fusidate[i]	Aqueous	s.c., i.p.: local tissue injury with necrosis at injection site, probably this irritating effect connected with the surface-active properties of the drug	Mice	(182)

(*Continued on next page*)

TABLE VII (*Continued.*)

Active Ingredient	Vehicle	Route of Administration and Untoward Local Reactions in One or More Humans or Animals	Species	Ref.
Sodium pentobarbital	2% benzyl alcohol in 60% propylene glycol in water, pH = 10.5	s.c.: pain usually present, firm nodule at injection site; i.m.: usually no pain	Human	(188)
Thiamine hydrochloride	Aqueous	i.m.: intense pain lasting on av. 122 sec. Addition of 0.5% procaine HCl reduced duration of pain to av. of 20 sec.	Human	(103)
7-(Thiophene-2-acetamido) cephalosporanate sodium[j]	Normal saline	i.m.: slight to moderately severe pain at injection site	Human	(191)
Trypsin	Gelatin in double-blind (DB) study Saline in alternating (A) study	i.m.: in "DB" study *ca.* 30% of subjects developed local tenderness at injection site with nodule formation. In "A" study local reaction was 10%, no nodule formation occurred	Human	(201)
Vitamin D_3 hydrosol	Water, ethanol polyoxyethylene ricinoleic acid	i.m.: hemorrhagic focal area 1 week after initial injection. After 3 weeks calcification occurred on muscle surface and dermis of skin in contact with musculature	Rat	(192)

TABLE VIII—LOCAL REACTIONS REPORTED FOR SELECTED DRUG SUSPENSIONS[a]

Active Ingredient	Vehicle	Route of Administration and Untoward Local Reactions in One or More Humans or Animals	Species	Ref.
Betamethasone sodium phosphate + betamethasone acetate[b]	Aqueous	i.m.: stinging, burning, or acute pain at injection site	Human	(193)
Cycloguanil pamoate	Lipid: 40% benzyl benzoate in castor oil	s.c.: transient palpable masses, and open lesions	Mice	(88)
	Aqueous: 1.5% pectin + 0.1% polysorbate 60	s.c., i.m.: palpable masses occurred only with very large injections	Monkey	(88)
Cycloguanil pamoate	40% benzyl benzoate in castor oil	i.m.: suppurating abscess developed at injection site	Human	(51)
Hydrocortisone acetate	0.9% NaCl, 0.5% Na carboxymethylcellulose, 0.1% methylcellulose, 0.19% polysorbate 80, 0.24% methylparaben, 0.026% propylparaben, water *q.s.*	i.t.[c]: pain at injection site or referred pain to face or behind eye	Human	(194)
Insulin	Aqueous	s.c.: local reactions may occur in the form of red painful indurated areas at injection site and may persist for 2–3 weeks, then gradually disappear. Insulin atrophy i.c.[d]: induration, necrosis, ulceration and scarring	Human	(195)
Monosodium urate	5% dextrose in water	s.c., i.d.[e]: erythema, induration, local temperature elevation	Human	(196)
Monosodium urate monohydrate	50% glycerin in water	s.c.: erythema, induration, warmth, tenderness	Human	(33)
Sodium orotate	50% glycerin in water	s.c.: erythema, induration, warmth, tenderness	Human	(33)
Tetracycline phosphate	Lidocaine, monoacetin	i.m.: local discomfort or pain	Human	(189)
Triamcinolone acetonide	Aqueous	i.m.: subcutaneous fat atrophy	Human	(197)
Triamcinolone acetonide	0.9% benzyl alcohol, 0.75% Na carboxymethylcellulose, 0.04% polysorbate 80 in water, NaCl *q.s.* for tonicity	i.m.: atrophy in area of injection, s.c. fat necrosis at injection site	Human	(198)
Triamcinolone acetonide	Aqueous	i.m.: atrophy of s.c. fat, local abscess	Human	(199)
Triamcinolone acetonide	Aqueous	s.c.: atrophy of keloids	Human	(200)

cells recognize injected foreign materials are complex. An explanation of these local tissue reactions is not generally possible at the molecular level. Some of the research concerned with foreign body reactions and the mechanisms of phagocytic discrimination has been reviewed by Boyden (120). On a macroscopic level some of the causes for these local tissue reactions include the following. After injections of sodium thiopental, Davies (121) believed that necrosis of tissue at the site was caused in part by direct toxic action of the solution, and in part by infection. Subcutaneous nodule formation following "intramuscular" injections has been attributed to erroneous deposition of the formulation into the subcutaneous region (45). After an intramuscular injection, painful subcutaneous nodules (15) sometimes form because leakage of the solution occurs back along the needle tract. In other cases the subcutaneous nodule formation is caused by the deposition of material into the subcutaneous region because needles of insufficient length were used (18). McLean *et al.* (122) discusses some of the causes of local untoward reactions to repository therapy; they conclude that a sterile abscess forms because a foreign body type of irritative process occurs. Goldman (123) discusses the local reactions following intra- and sublesional injections of corticosteroid suspensions. While local reactions are uncommon, they include (*a*) pain and discomfort, (*b*) hemorrhage, (*c*) atrophy, (*d*) secondary infection (local and diffuse), (*e*) pigmentation changes, (*f*) hypersensitivity reactions, and (*g*) panniculitis. If a relatively large amount of corticosteroid crystals is injected superficially, a slough may develop which appears to be due to a blockage of local circulation as well as changes in the local ground substance. If sloughing does not occur, the depot may remain visible in the skin for long periods of time.

Hanson (124) investigated some of the local toxic effects of the antibiotics: chloramphenicol, chloramphenicol sodium succinate, oxytetracycline, tetracycline, and their vehicles after subcutaneous and intramuscular injections into rabbits. Cioc and von Schilling (125) describe histological changes in rabbit and pig muscle tissue produced by injections of a number of drugs.[6]

Newer Techniques—Up to this point, the traditional syringe-and-needle method of introducing drugs subcutaneously and intramuscularly has been discussed almost exclusively. The history of the development of injection therapy has been thoroughly discussed by several authors (1, 126–128) and will not be reviewed again at this time. However, newer devices are appearing on the market. Under certain circumstances they may have advantages over the more conventional devices. Some of these instruments involve the principle of jet injection whereby the drug solution is forced through the epidermis and dermis as a fine dispersion under high pressure (40, 42, 87, 129–133). Some reports in the literature indicate that dosing errors might result from the use of some jet-injection instruments due to calibration problems (130, 132). (See Table IX.)

TABLE IX—SUMMARY OF RECORDINGS COMPARING THE DOSAGE-DELIVERANCE RELIABILITY OF TWO JET-INJECTION INSTRUMENTS AND A PIPET TECHNIQUE (132)

Anticipated Vol. Delivered, ml.	Mean % of Anticipated Vol. Actually Delivered		
	Jet No. 1	Jet No. 2	Pipet
1.0	82	113	100
0.7	94	119	101
0.5	97	128	102
0.2	39	170	98

Another instrument using the syringe-and-needle principle is the Hypule, which is designed for unit dosage systems. It is a prefilled, disposable device which delivers an exact volume of solution subcutaneously (134). Erdmann *et al.* (135) studied the absorption and excretion of an alkyl-phosphate antidote,[7] following its injection muscularly into humans, using two types of sterile, self-injection ampules: a plastic type,[8] which the user empties manually after puncture, and an automatic type,[9] which is self-emptying.

Prolonged-Action Formulations—One of the problems of evaluating the absorption rates of solids administered as suspensions *via* the subcutaneous or intramuscular routes is that no convenient method exists today for estimating the surface area of the solid exposed to the absorbing membranes while *in situ*. The effective area of the suspension exposed to the absorbing tissues varies according to the injection techniques used and the physical properties of the suspension. Since the effective area of solid exposed to tissues is not known, precise estimates of the drug absorption rate

[6] Dipyrone (50%), thiamine, ferro dextran complex, liver extract, vitamin B_6, dihydroergocornine-cryptine-cristine methanesulfonate (ergot fluid extract), trimethyl 3-oxyphenyl ammonium bromide, liver extract with vitamins B_1 and B_{12}, α-(*N*-β-diethylaminoethyl)aminophenylacetic acid, calcium bromide, and eucalyptol, guaiacol, and sage compound.

cannot be made, since the absorption rate is directly proportional to this area at any time. Where applicable one quantitative method of evaluating the absorption rate of solids is the use of the pellet implantation technique of drug administration. For example, suppose the parenteral product formulator intends to formulate a suspension and has several salt, polymorphic, or solvate forms of a given drug. He should be able to establish in a given species and a given absorption site the rank order for the mean absorption rates per mean pellet areas. From this and other information at his disposal, the investigator could make a preliminary estimate as to which of the drug forms should be studied in detail for possible use in the suspension formulation.

For a single implanted sphere of a drug the weight of solid at any time can be calculated (136) from:

$$W = \frac{\pi\rho}{6}(D^0 - kt)^3 \qquad \text{(Eq. 7)}$$

and for an implanted disk:

$$W = \frac{\pi\rho}{4}(D^0 - kt)^2(h^0 - kt) \qquad \text{(Eq. 8)}$$

where W is the weight of the solid at any time, ρ is the apparent density of the solid, D^0 is the initial diameter of the disk or sphere, h^0 is the initial height of the disk, k is the mean absorption constant having dimensions of length $\times$ time^{-1}, and t is the duration of pellet implantation. It is assumed that D^0 or $h^0 \geqslant kt$, and that the shape of the solid is not distorted during the implantation period. Once the value of k has been determined for one geometric shape of a particular drug in a given animal species at a given absorption site, it can be used to estimate the probable absorption rate characteristics for other geometric shapes of the same drug.

Recently, Ballard and Goyan (137) made use of an analog computer to study the kinetics of drug absorption, distribution, metabolism, and elimination of a model drug, sulfadiazine, in all forms following its administration as subcutaneous disk-shaped implants in rats. Since the partially absorbed solid was recovered from the implantation site, the mean absorption constant, k, could be determined by Eq. 8. The cumulative amount of free and acetylated drug was followed as a function of time. The kinetic model used is shown in Fig. 1. The term Si is the amount of drug in the disk at the implantation site, S is the amount of free drug in the fluids of distribution in the animal, Se is the cumulative amount of free drug excreted unchanged in the urine, Sa is the amount of acetylated drug in the fluids of distribution in the animal, and Sae is the cumulative amount of acetylated drug excreted into the urine up to any time. For purposes of achieving material balance between the amount of drug absorbed and that actually recovered in the urine as free and acetylated drug, it was necessary to postulate an amount of drug or metabolite, Su, in some unknown compartment. If Su represents free drug, then it is the cumulative amount excreted to any time by a route other than *via* the urine. In this case k_5 would be ignored. If Su is the amount of undetected metabolite to any time, then Sue is the cumulative amount of that metabolite excreted by some route to any time. While the absorption constant, k, has units of length $\times$ time^{-1}, the constants k_1, k_2, k_3, k_4, and k_5 are assumed to be first-order rate constants for the respective processes in units of time^{-1}. In Fig. 2, curve 1 (Se) shows the cumulative amount of free drug, and curve 2 (Sae) shows the cumulative amount of acetylated drug excreted *via* the urine as a function of time. Curve 3 (Su or Sue) is defined by material balance considerations and is the cumulative amount of free drug (Su), or the cumulative amount of an unspecified metabolite (Sue) excreted *via* an unknown route to any time. In the model the constant k_2 is assumed to be very large compared to k_1, and k_5 is very large compared to k_4. Curve 4 (S) represents the amount of free drug in the fluids

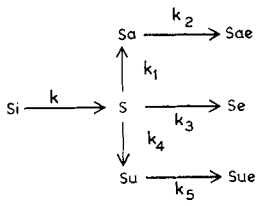

Fig. 1—Kinetic model showing disposition of sulfadiazine in all forms following its administration as a subcutaneously implanted disk-shaped pellet in a rat (137). Consult text for details. [Reprinted with permission from Med. Biol. Eng., *4, 483 (1966).]*

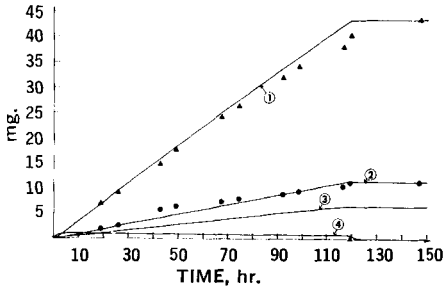

Fig. 2—Analog computer plots for rat B. Consult text for details concerning curves 1–4. Unpublished data (137). Key: ▲, free sulfadiazine; ●, acetylated sulfadiazine.

of distribution in the animal at any time. With curve 4 (S) one notes that after the peak amount of free drug is reached in the fluids of distribution about 10 hr. after implantation, there is a very gradual decline in amount until the pellet is removed (vertical arrow at 118.3 hr.), whereupon an exponential drop occurs. This gradual decline in amount would be expected because the pellet in losing mass with time, is also changing area very slowly.

There are several advantages in using the analog computer in *in vivo* drug kinetic studies such as the one illustrated here. First, it is generally simple to write out the differential equations for the proposed steps in the kinetic model shown in Fig. 1, and it is often possible to integrate these equations (137). However, their direct solution becomes extremely difficult by ordinary digital methods, particularly when one or more rate constants are not known exactly. Second, it is possible with an analog program to plot the probable amount-time course of drug or metabolites in compartments *not* analyzed directly in the investigation (*e.g.*, curves 3 and 4, Fig. 2). Third, once the pharmacokinetic constants have been determined for a particular shape of a drug implant in a given species and site of implantation, it should be possible to simulate with the computer the distribution and elimination time courses of the drug and its metabolites with other implant shapes and implantation times, even though the experiment was not actually undertaken *in vivo*.

A striking example of how the usefulness of a drug can be enhanced by preparing a repository formulation can be seen with the antimalarial drug cycloguanil pamoate. Shortly after chlorguanide was introduced, *in vitro* evidence indicated that the intact drug was essentially inactive, and that an active metabolite, 4,6-diamino-1-(*p*-chlorophenyl) - 1,2 - dihydro - 2,2 - dimethyl - *s* - triazine (DHT), was responsible for the activity of the drug. The hydrochloride salt of DHT is less active than chlorguanide against *P. cynomolgi* in monkeys when given orally or parenterally. The decreased activity of DHT compared to chlorguanide in monkeys is believed to be due to the rapid excretion of the soluble metabolite (88).

The pamoate salt of DHT, cycloguanil pamoate, has a solubility of 0.03 mg./ml. in pH 7, 0.1 *M* phosphate buffer. The drug has been formulated as parenteral suspensions in a lipid vehicle consisting of 40% benzyl benzoate and 60% castor oil, and in an aqueous vehicle consisting of 1.5% pectin and 0.1% polysorbate 60[10] in water. The drug was injected intramuscularly or subcutaneously as a 10 to 25% suspension in the vehicles described above. As a result of their experiments, the authors (88) made the following tentative generalizations regarding the repository effects of cycloguanil pamoate against *P. cynomolgi* in monkeys: the type of vehicle had little influence, the period of protection was related to the amount of drug per injection site, injection of a given amount at a single site was as effective as similar injections at multiple sites, and either intramuscular or subcutaneous routes were used without markedly different results.

From a pharmacokinetic standpoint, the rate-limiting step in the disposition of cycloguanil pamoate in the body is the dissolution rate of the salt in the fluids present at the injection site. As a consequence of the slow release of the drug from this site and the rapid excretion of the active metabolite *via* the urine, low plasma levels have been found. The plasma level of DHT following the injection of cycloguanil pamoate would mimic in many ways an extremely slow intravenous infusion of a soluble salt of DHT. If cycloguanil pamoate were administered as an implanted disk instead of as a suspension having an ill-defined area in contact with the tissues, the amount of free DHT in the fluids of distribution in the animal at any time would be represented qualitatively by the shape of curve 4 in Fig. 2. Since certain strains of malaria parasites have become increasingly resistant to some of the antimalarial drugs, attempts have been made to prepare parenteral repository preparations containing mixtures of drugs. This work has been reviewed by Powell (138).

The use of computers in pharmacokinetic studies has been discussed by Wagner (139). Analog, digital, and hybrid computers have been used principally for the rapid numerical analysis of data and for pharmacokinetic simulation. Wagner (139) points out that the equations and models used are always oversimplifications of the real system and their appropriateness in a given experiment can be judged only by their ability to describe the observed data and the accuracy with which they make predictions of future observed data. Some of the examples described in Wagner's paper include a pharmacokinetic analysis of the serum concentrations of linocomycin following an intramuscular injection of the drug hydrochloride, an analog computer prediction of the multiple-dose serum levels of lincmycin observed after a series of constant-rate intravenous infusions, and the digital computer simulation of serum levels produced by depot intramuscular preparations of lincomycin.

[10] Tween 60, Atlas Chemical Industries, Inc., Wilmington, Del.

In the past few years a number of other prolonged-action formulations have been reported on in the literature. Rizkallah and Taymor (140) gave, to normal females, intramuscular injections of various combinations of dihydroxyprogesterone aceophenide and estradiol enanthate in an attempt to discover which formulation would give the most satisfactory cyclic uterine bleeding response, yet produce minimum side effects. Kowarski and Bar-Natan (141) reported details of the biological responses to a number of prolonged-action diethylstilbestrol formulations intended for subcutaneous administration. Laffan and co-workers (142) studied the prolonged-action effects of fluphenazine enanthate dissolved in sesame oil after subcutaneous administration to animals. One preliminary report (143) casts doubt on the effectiveness of this formulation given intramuscularly in treating some schizophrenic patients. Linna *et al.* (144) managed to produce experimental hypertension in rats by prolonged subcutaneous administration of norepinephrine bitartrate in an oily vehicle.

In summary, this review has attempted to consider some of the biopharmaceutical aspects of drug absorption from subcutaneous and intramuscular routes of administration. A portion of the literature dealing with the formulation and administration of such parenteral formulations also has been discussed. From the foregoing it is clear that there are many areas where more basic research is needed. If this review stimulates others to conduct such research, one of the several goals of this paper will have been achieved.

Procaine Interaction with the Corneal Surface and its Relation to Anesthesia

By VICTOR F. SMOLEN and FREDERICK P. SIEGEL*

The effects of pH and procaine on the apparent density of charged groups fixed to the corneal surface of guinea pigs were studied. The net density of fixed charge was found to be negative over the pH range of 5 to 9 and decreased in the presence of procaine. These results are interpreted in terms of procaine interaction with the surface and its implications with regard to the factors that may influence the characteristics of the anesthetic response. The electrometric method employed allowed the study to be performed under physiological conditions using live animals. The method is general and can be equally applied to study other drug–tissue interactions.

THE CORNEA possesses a moist surface primarily composed of amphoteric colloids; pH and the interaction of solutes determine the extent to which attached groups are ionized and the resulting net density of fixed charge on the surface. The present study is an effort to elucidate the role of these factors in the mechanism by which the effectiveness of procaine in the eye is increased in alkaline solution (1–4).

An electrometric method modified from Joseph *et al.* (5, 6) was used to determine the apparent fixed charge density of the corneal surface of the guinea pig in response to variations in the pH of applied buffer solutions in the presence and absence of procaine. The cornea is particularly suited to this approach due to its relative simplicity and accessibility. It has also been the subject of many investigations with local anesthetics. Reliable pharmacological data particularly with procaine were found to be readily available (1). The method is generally applicable to the study of other tissue surfaces and other drugs as well. It allows the results to be obtained under nearly physiological conditions without damage to the tissues involved. Thus, in the present study, the apparent density of fixed charge of the corneal surface was determined under the same conditions that are known to influence its anesthetic response to procaine.

THEORETICAL

The dissociation of counterions from ionogenic groups covalently bonded to a tissue surface or the absorption of ions onto neutral surface sites gives

Procaine Interaction with the Corneal Surface and its Relation to Anesthesia

By VICTOR F. SMOLEN and FREDERICK P. SIEGEL*

The effects of pH and procaine on the apparent density of charged groups fixed to the corneal surface of guinea pigs were studied. The net density of fixed charge was found to be negative over the pH range of 5 to 9 and decreased in the presence of procaine. These results are interpreted in terms of procaine interaction with the surface and its implications with regard to the factors that may influence the characteristics of the anesthetic response. The electrometric method employed allowed the study to be performed under physiological conditions using live animals. The method is general and can be equally applied to study other drug–tissue interactions.

THE CORNEA possesses a moist surface primarily composed of amphoteric colloids; pH and the interaction of solutes determine the extent to which attached groups are ionized and the resulting net density of fixed charge on the surface. The present study is an effort to elucidate the role of these factors in the mechanism by which the effectiveness of procaine in the eye is increased in alkaline solution (1–4).

An electrometric method modified from Joseph *et al.* (5, 6) was used to determine the apparent fixed charge density of the corneal surface of the guinea pig in response to variations in the pH of applied buffer solutions in the presence and absence of procaine. The cornea is particularly suited to this approach due to its relative simplicity and accessibility. It has also been the subject of many investigations with local anesthetics. Reliable pharmacological data particularly with procaine were found to be readily available (1). The method is generally applicable to the study of other tissue surfaces and other drugs as well. It allows the results to be obtained under nearly physiological conditions without damage to the tissues involved. Thus, in the present study, the apparent density of fixed charge of the corneal surface was determined under the same conditions that are known to influence its anesthetic response to procaine.

THEORETICAL

The dissociation of counterions from ionogenic groups covalently bonded to a tissue surface or the absorption of ions onto neutral surface sites gives

rise to an unequal distribution of free ions present at the surface as compared to the bulk of a solution with which it is in contact. An electrical potential difference also develops across the colloid-aqueous boundary. The magnitude of the distribution ratios (r) for the mobile ions, present at the colloid surface as compared to the bulk of the applied solution, as well as the sign and magnitude of the electrical potential, depend upon the net density of the charge fixed to the tissue surface. The measurement of a potential, E_1, includes this equilibrium phase boundary potential as well as all other potentials developed in the circuit (see Figs. 1 and 2 for a circuit diagram and the experimental arrangement, respectively). These extraneous potentials have been found to remain constant for the short period of time required to replace the initial solution in contact with the tissue surface with a dilution of this same solution followed by the immediate recording of a second potential, E_2. The difference of these two measured potentials ($E_2 - E_1$), termed the dilution potential E_d, is thus devoid of the extraneous potentials and includes only those potential differences developed between the aqueous medium at the tissue surface and the bulk of the applied solutions. This consideration allows the interpretation of E_d in terms of the familiar Donnan equilibrium (10, 11) and its treatment as a diffusion potential (5). Under the conditions of its measurement, E_d is characteristic only of the tissue surface rather than reflecting the properties of the bulk or interior of the tissue phase. If this were not the case, some question might be raised regarding the physical significance of the measurements (11).

Following an approach similar to that of Joseph *et al.* (5) the principal author has derived equations (Eqs. 1 and 2 below) for E_d and the fixed charge density (f) (12). These equations are presented in their general form.

Equation 1 expresses E_d in terms of a ratio (r) defined as the ratio of the concentration (m_{i+c} or m_{i-c}) of an i'th cation or anion at the charged colloid surface to its concentration in the bulk of the applied solution (m_{i+a} or m_{i-a}), raised to a power equal to the reciprocal of its valence (z_{i+}) for cations, and the negative of the reciprocal of its valence (z_{i-}) for anions. The value of r, obtained from the solution of Eq. 1, is substituted into Eq. 2 from which the fixed charge density (f) is obtained. In Eq. 1 the symbols λ^0_{i+} and λ^0_{i-} denote the limiting ionic conductances of the i'th cation and anion, respectively, while D is the factor by which the experimental solution is diluted for the measurement of E_2. In the present study its value is 10. The symbol F refers to the Faraday constant; R is the gas constant and T is the absolute temperature.

Equation 1 is derived on the basis of considering the Gibbs free energy changes accompanying the transfer of charged species between the colloid surface and the bulk of the solution and expressing the transport numbers for the ions in terms of Kohlrausch's law of independent ion migration (13). Equation 1 resembles equations describing liquid junction potentials (13) which in effect it does when applied to the measurements described in this study. Values of E_d calculated from Eq. 1 agree closely with values calculated from Henderson's equation (13), which describes a liquid junction potential developed across a continuous mixture boundary. Equation 2 is merely an expression of macroscopic electroneutrality at the tissue surface.

The described electrometric method is of general applicability. It has been verified quantitatively with wool (6); the results obtained were comparable

$$E_d = \left[\frac{\sum\left(r^{z}_{i+}\cdot m_{i+a}\cdot\lambda^0_{i+}\right) - \sum\left(\frac{m_{i-a}}{r^{z}_{i-}}\lambda^0_{i-}\right)}{\sum\left(z_{i+}\cdot r^{z}_{i+}\cdot m_{i-a}\cdot\lambda^0_{i+}\right) + \sum\left(\frac{z_{i-}\cdot m_{i-a}}{r^{z}_{i-}}\lambda^0_{i-}\right)}\right]\frac{2.303RT}{F}\log D \qquad \text{(Eq. 1)}$$

$$f = \sum\frac{z_{i-}m_{i-a}}{r^{z}_{i-}} - \sum z_{i+}\cdot r^{z}_{i+}\cdot m_{i-a} \qquad \text{(Eq. 2)}$$

to titration curves of wool obtained directly (22). When the method is used *in vivo*, it conveniently and rapidly yields results not readily attainable by other means.

MATERIALS AND METHODS

Materials—All reagents were of analytical grade, except procaine hydrochloride USP.[1] Male guinea pigs of approximately 3 months of age were used.

All electrical potentials were read from a Sargent model SR recorder. Saturated calomel electrodes[2] were inserted together with KCl-agar salt bridges into 100-ml. beakers containing saturated KCl. The salt bridges consisted of 3–4 ft. lengths of transparent tygon tubing filled with saturated KCl solution. The ends were blocked with 6-in. lengths of glass tubing drawn at one end into a capillary filled with hardened KCl-agar gel and constricted in the middle to prevent loosening of the gel and subsequent leakage. The transparency of the tubing allowed ready detection of air bubbles which can profoundly interfere with conductance through the bridges.

Solutions—The composition of the solutions and the pH range selected for this study were chosen so that the results could be compared with those of Hiter (7) on the duration of corneal anesthesia. However, the pH 9.0 borate buffered solutions used by Hiter were found to give anomalous results in that observed and calculated diffusion potentials differed widely. As a consequence, 0.1 *M* phosphate buffers prepared from KH_2PO_4 and NaOH were used throughout the pH range of 5–9. The procaine solutions were always freshly prepared at the time of the experiment. Each buffered procaine solution below pH 9 contained 1% (36.7 m*M*) procaine hydrochloride. The pH 9.0 solution was saturated and the total concentration of procaine was calculated to be 4.35 m*M*. The calculation was based on the solubility of the free base given by Eisenbrand and Picher (8) as 0.13%, and from the degree of association, 44.2%, based on an acidic pK of 8.85 (9). An aliquot of each of the solutions was diluted 10-fold for use in the measurement of the potentials E_2 as described below.

The pH of the solutions was determined with a Beckman model 76 pH meter. The concentrations of the ionic species in each solution were calculated from the measured pH and the pK's of the dissociable substances (9).

Procedure—The position of the guinea pig in the experimental set-up is illustrated in Fig. 2. Figure 1 is a corresponding circuit diagram. A saturated KCl salt bridge was placed in a 0.15 *N* NaCl solution along with an immobilized shaved hind leg of the guinea pig which served as the reference surface. The animals were maintained immobile by the i.p. administration of 30–40 mg./Kg. pentobarbital.

The right eye of the guinea pig was used in the control study. The buffer solutions containing procaine were applied to the left eye. This order was reversed and alternated in subsequent experiments with the same animals which were allowed a minimum recovery time of 7 days. Animals observed to develop any abnormalities during this time were discontinued from further use.

The experimental procedure adopted for routine use involved a preliminary rinsing of the eye with isotonic NaCl solution to remove any secreted film on the cornea. This was followed by rinsing with the experimental solution to remove any solution remaining from a previous determination or treatment. Excess solution was removed by absorption into small strips of filter paper wick and gentle swabbing with dry cotton. A cotton dental pellet with a diameter less than the cornea was placed on the capillary end of a KCl-agar salt bridge and moistened with the experimental solution. The pellet was then carefully placed in contact with the cornea and the potential, E_1, was recorded for approximately 30 sec. The pellet was removed and the cornea swabbed lightly with dry cotton. A similar but smaller pellet was wetted with a 10-fold dilution of the previous solution and placed in the center of the area previously covered. A second potential, E_2, was recorded *immediately* upon contact. This procedure was repeated for all other pH values studied in a series. In developing this procedure to yield reproducible results, it was found necessary to carefully control the amount of solution applied to the cotton pellets and to prevent it from overflowing onto surrounding tissues by removing any excess onto filter paper wicks or cotton swabs. In more recent work the principal author has found that replacing the cotton pellets with solution wetted filter paper strips applied to the cornea with a micromanipulator, gave improved control and reproducibility.

The moist hydrated surface of the cornea allows diffusion and mixing of the solutions to readily occur at the surface causing initial changes in recorded potentials. The application of a procaine solution to a previously untreated cornea produces potentials (E_1) which approached relative constancy within approximately 15 sec. and remained at nearly the same value until the boundary was disturbed indicating the establishment of equilibrium at the surface. The application of diluted solutions may cause variations in recorded potential lasting up to several minutes, however in this case the initial value (E_2) is of interest. The effects of procaine were diminished or obliterated by rinsing the eye with isotonic NaCl or one of the control solutions indicating its effects are reversible.

RESULTS

Verification of Eq. 1—Equations for E_d and f specifically applicable to the solutions used in the present study were obtained by substituting appropriate values into Eqs. 1 and 2. The limiting ionic conductances of the various ions present were obtained from the literature (9, 13). The ionic conductance of procaine cation was experimentally determined by the measurement of liquid junction potentials (13). The accuracy of the resulting equations in describing the dilution potentials corresponding to each solution and its 10-fold dilution was experimentally checked by the measurement of diffusion potentials. Free diffusion-type boundaries were formed either within a capillary or by means of a filter paper bridge. The liquid junction potentials were found to be nearly inde-

pendent of the method which was employed to form the boundary. The electrical potentials measured in this manner are of the same magnitude as the corresponding dilution potentials at zero density of fixed charge, *i.e.*, when the ratio r equals one. The averages of 10 separate determinations performed with each experimental solution are listed in columns 3 and 6 of Table I along with maximum deviations. The agreement of these results with calculated values, listed in columns 2 and 5 of Table 1, was found in most cases to be within a mv.

Results of Applying Eqs. 1 and 2 to Measurements on the Cornea—Values of r corresponding to experimental values of E_d were obtained by graphical solution of Eq. 1. Eleven calibration curves, corresponding to the 11 buffer solutions used, were constructed by plotting calculated values of E_d as a function of r over a chosen range. Values of r corresponding to experimentally observed values of E_d were obtained from these curves and checked by calculation. An average value of E_d, observed from a minimum of six different determinations using six different animals, was used in each case. These values of E_d and corresponding values of r are listed in Table II for both the control buffer solutions and the buffered procaine solutions. The corresponding values of f are listed in columns 4 and 8 in Table II. They were calculated by substituting the values of r into Eq. 2. Figure 3 contains plots of f as a function of pH. Although the control and

[a] E_d is the difference of two measured potentials, $E_2 - E_1$, see text. The deviations are the maximum observed differences from the mean of a minimum of 6 determinations of E_d using different animals. [b] The values of r are obtained from E_d by graphical solution of Eq. 1. [c] The values of f in columns 4 and 8 are calculated by substituting the corresponding values of r into Eq. 2.

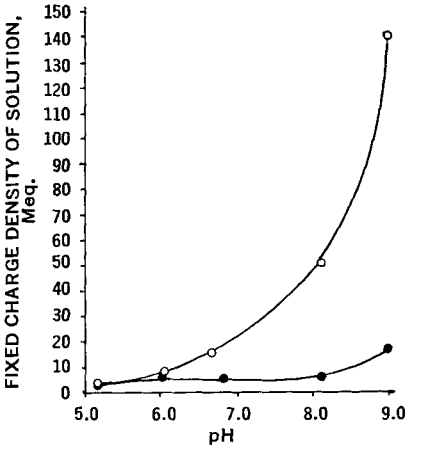

Fig. 3—Upper curve is the control titration curve of the guinea pig cornea; lower curve is the procaine displaced titration curve.

procaine displaced curves differ in shape, a negative net fixed charge density is common to each throughout the pH range studied. The isoelectric point (the pH below which the surface has a net positive charge) was found to be approximately 2.5. At normal physiological pH the anionic fixed charge density obtained from the control curve is 28 meq./L. of solution.

The procaine displaced curve lies entirely below the control curve indicating the anionic fixed charge density was decreased at every pH. The number of titratable groups is noted to be decreased by 90% in the presence of procaine. The changes at the corneal surface were generally found to be reversible as indicated by the fact that the shapes of the curves in Fig. 3 are independent of the order in which the corresponding E_d values are experimentally observed.

DISCUSSION

Interpretation of Titration Curves—The curves in Fig. 3 are analogous to titration curves observed for wool (14–15) and other insoluble proteinaceous structures (5, 6, 16, and 17). The net negative charge of the corneal surface that is apparent even at relatively low pH may in part be attributed to the strongly acidic sulfate groups of mucopolysaccharides (16). The titratable groups in the pH range of 5–9 may be assumed to be phosphatic, imidazolyl, imino, and α-amino groups. Carboxyl and sulfate groups are likely dissociated below pH 5 while ϵ-amino and phenolic groups are generally titratable above pH 9. Generally the tendency of

any group to dissociate is influenced by the composition of its medium and the state of the colloids as a whole (18, 19).

Mechanism of Procaine Effect—There are several mechanisms that could operate alone or in combination to bring about the lowering of anionic fixed charge density observed in the presence of procaine. Among them are a possible increase in the acidic pK's of the dissociable groups, an increase in the specific affinities of fixed anionic sites for binding the metal ions (Na^+ and K^+), the rupture of salt linkages between fixed groups of opposite charge followed by binding of mobile cations to the freed anionic groups, the absorption of procaine or other cations to uncharged sites on the colloids, and direct salt binding of procaine to fixed anionic sites. The complex nature of the possible interactions and the probable heterogeneity of the binding sites allows only speculation as to the relative contribution of each mechanism. However, lacking evidence to the contrary and considering that the two curves were obtained with solutions differing only in that one series contained procaine, it may be reasonably assumed that the lowering of the anionic charge density results primarily from the binding of procaine cations. Presumably the neutral species of procaine which is in equilibrium with the cationic form could also interact with the corneal surface. Its binding would not alter the net charge of the surface except perhaps indirectly by an inductive effect (18). The binding of the cationic species would be reinforced by long-range electrostatic forces which render its approach to binding sites increasingly favorable with an increasing density of negative fixed charge. Procaine cations taken up by the surface in a particular pH range need not necessarily bind to the anionic groups dissociating in that range. In fact, binding to uncharged sites on the surface would also lead to a stoichiometric decrease in anionic fixed charge density. That amine binding can occur is demonstrated by the fact that basic amino dyes such as toluidine blue are good tissue stains. Sawinski and Rapp (20) have shown that two binding sites are available for procaine on human serum albumin. Glassman (21) has concluded that long chain organic cations form a stoichiometric complex with plasma albumin. Steinhart and Zaiser (22) have also demonstrated binding of organic cations to wool and egg albumin.

In their studies of colloidal surfaces, Catchpole *et al.* (16, 17) have attributed the effect of cations on the fixed charge density of colloidal surfaces to a direct neutralization of fixed anionic groups due to salt binding. They also assumed a stoichiometric relation between the equivalents of bound cation and the observed decrease in negative fixed charge density. Adopting a similar approach to the treatment of the present results, the outermost surface of the cornea can be described to behave essentially as a cation exchanger having a variable affinity for procaine cations which is dependent upon the pH of the environment. Variations in the apparent affinities for association of procaine cations with the surface may be expected since the binding sites are probably dissimilar and thier intrinsic association affinities may be affected by the state of the colloids as a whole.

The overall equilibria pertinent to this model are shown below, where fHP, PH^+, and P refer to bound procaine, free procaine cations, and base, respectively, while f^- refers to the sites and fH to sites occupied by protons, H^+.

$$fHP \rightleftharpoons f^- + PH^+ \rightleftharpoons P + H^+ \quad \text{(Eq. 3)}$$

$$fH \rightleftharpoons f^- + H^+ \quad \text{(Eq. 4)}$$

In accordance with this scheme the extent to which procaine is bound and the accompanying decrease in fixed negative charge density depends upon the availability of anionic binding sites and procaine cations. Both factors depend upon pH. The increasing rate of lowering of fixed anionic charged density—evidenced by the widening vertical gap between the two curves in Fig. 3—with increasing pH, may in part be ascribed to the greater rate of availability of binding sites relative to the decrease in procaine cations occurring with pH.

The concentration of procaine bound to the corneal surface at each pH can be estimated from the assumed stoichiometric decrease in the negative charge density, Δf, which corresponds to the vertical difference between the two curves presented in Fig. 3. These values are listed in column 2 of Table III. The concentration of free procaine cations present at the corneal surface, $[P^+]_c$, can be calculated using the appropriate value of r and the concentration present in the applied solutions, $[P^+]_s$, *i.e.*, $[P^+]_c = r[P^+]_s$. Using these values apparent association constants, K_B, have been calculated from Eq. 5 where f' denotes the negative charge density taken from the lower, procaine, curve in Fig. 3. The values of K_B are listed in column 3 of Table III. As expected these values are not constant but increase with pH.

$$K_B = \frac{\Delta f}{f'[P^+]_s \cdot r} \quad \text{(Eq. 5)}$$

The volumes of the applied procaine solutions placed in contact with the cornea can be assumed to be relatively large in comparison to the volume of the corneal surface with which they equilibrate; the concentrations of the various components of the solutions can also be assumed to remain constant throughout the equilibration process. The total concentration of procaine occurring at the corneal surface, $[P]_t$, at each pH studied (taken as the sum of the concentrations of free procaine cation, free base, and bound procaine), can be estimated using Eq. 6.

$$[P]_r = r[P^+]_s + [P]_s \quad \text{(Eq. 6)}$$

TABLE III—CALCULATED RESULTS RELATING TO THE PROCAINE–CORNEAL SURFACE INTERACTION

pH of Solutions	Bound Procaine[a] (Δf), mmole/L.	Association Constant (K_b), L./mmole	Total Procaine Concentration at Corneal Surface, mmole/L.
5.18	0.4	3.0	37.6
6.06	0.6	3.0	38.1
6.84	9.5	30	46.9
7.58	27	140	64.0
8.15	44	231	81.0
9.00	123	461	133.

[a] Values of Δf corresponding to each pH listed were obtained from the vertical differences in the curves presented in Fig. 3.

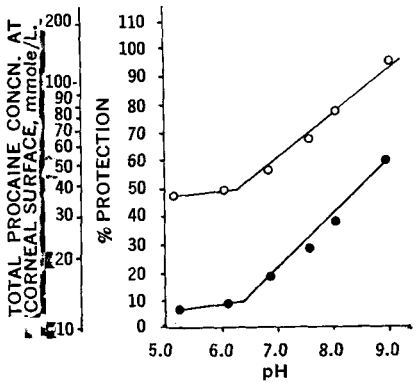

Fig. 4—Curve A represents the relationship of the logarithm of the total procaine concentration at the corneal surface to the pH of the applied solutions. Curve B represents the relationship of the duration of procaine-induced corneal anesthesia (plotted as percent protection) to the pH of the applied solutions.

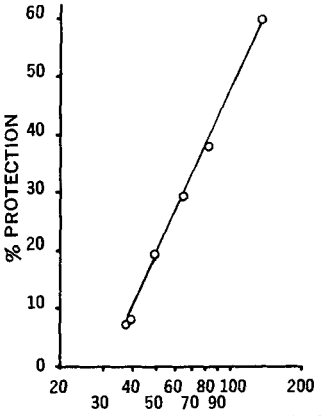

Fig. 5—Relationship of the logarithm of total procaine concentration at the corneal surface to duration of procaine-induced corneal anesthesia plotted as percent protection.

Since we are concerned with only the outermost surface of the cornea which resides in the same aqueous medium, the concentration of procaine free base at the surface can be assumed as equal to that in the bulk of the applied solutions $[P]_s$.

Values of $[P]_t$, listed in column 4 of Table III, show nearly a fourfold increase in the pH range of 5.18–9.0 arising primarily from increasing concentrations of bound procaine.

Relation of Procaine Binding to Duration of Anesthetic Effect—The procaine solutions used in the present study are similar to those used by Hiter in his study of the duration of procaine anesthesia induced upon the guinea pig cornea as a function of pH. His experimental approach was based upon a modified Chance and Lobestein technique (23). The procaine solutions were instilled into the eye and allowed to remain in contact with the cornea for 15 sec., a time found to be sufficient for the establishment of equilibrium between the procaine solution and the corneal surface. Excess solution was then removed from the cornea by the initiation of a blink reflex. The anesthetic effect was noted with a loss of the blink reflex when the cornea was stimulated at 1-min. intervals. The duration of the anesthetic effect was recorded as percent protection.[3]

The durations of anesthetic responses Hiter observed with 1% procaine solutions in the pH range of 5–9 are plotted in the lower curve in Fig. 4. The upper curve in Fig. 4 is a semilogarithmic plot of $[P]_t$ *versus* pH. The marked similarity in the two curves may be explained if the fact is considered that under conditions of constant pH, the duration of surface anesthesia in the eye is approximately a linear logarithmic function of the concentration of the local anesthestic in solution (1, 2). It may be expected that the duration of the anesthestic effect is also an approximately linear function of the logarithm of the concentration of the local anesthetic at the corneal surface itself. That this prediction is realized is evidenced by the curve shown in Fig. 5 where this relationship is demonstrated.

[3] The actual duration of the anesthetic effect was recorded in minutes, divided by 60 and multiplied by 100.

The treatment of the data which have been presented has in effect converted the pH dependency of the duration of anesthesia into a concentration dependency. The significance of this result lies in that it indicates that the duration of surface anesthesia can be related to and is dependent upon the total concentration of procaine estimated to be present at the corneal surface. Since the reversibly bound procaine is primarily responsible for the increasing total concentrations and is in equilibrium with free procaine, it may be assumed to act as a reservoir for the drug allowing it to be slowly released from its binding sites. By this means the bound procaine could serve in a manner analogous to continuous release dosage forms in prolonging the anesthetic response by maintaining threshold or suprathreshold levels of procaine at the biological sites of action for extended periods of time.

The role of lachrymal fluid in the onset and duration of the anesthetic response in relation to the effects of pH and buffer capacity (2) will be discussed in a future paper.

CONCLUSIONS

Although much of this treatment has been qualitative, it provides an example of the role that tissue structures may have in modulating their response to drugs. It also points out factors, in addition to the liberation of free base, which may be operating to increase the effectiveness of procaine in alkaline solution.

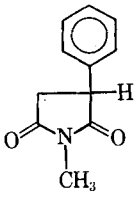
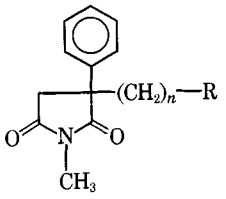
protective index (median toxic dose/median effective dose) than mephobarbital against electroshock seizures in mice. Mainly as a result of this apparent beneficial effect of an amino group on the anticonvulsant properties of these compounds, the authors were prompted to investigate the effect of more basic amino moieties on the anticonvulsant properties of phensuximide (III),



III

a known antiepileptic agent. Specifically, the interest was in introducing aminoalkyl groups into the 2-position of III. The resulting compounds would have the general structure IV, in which R may be either dialkylamino or heterocyclic amino groups and $n = 1$ or 2.



IV

Prior to the beginning of this project, substituted succinimides were prepared by the cyclization of appropriately substituted succinic acid intermediates with ammonia or a primary amine (3–13). The intent was to substitute aminoalkyl groups directly into the 2-position of III. Direct substitution into the ring appeared only recently in the literature (14), but this was not until several products had already been prepared.

DISCUSSION

Mannich Bases—It was envisioned that the synthesis of the alkylaminomethyl derivatives of *N*-methyl-2-phenylsuccinimide (IV, $n = 1$) may be accomplished by subjecting the parent compound (III) to Mannich conditions. A careful search of the literature revealed that there is no report of the successful application of the Mannich reaction to either *N*-substituted-2-phenylsuccinimides or *N,N*-disubstituted-2-phenylamides. Therefore, the authors became interested in establishing if, indeed, *N*-methyl-2-phenylsuccinimide (III) would undergo the Mannich reaction.

The most common solvent used in the Mannich reaction is ethanol. This solvent was initially employed, along with paraformaldehyde and dimethylamine hydrochloride under acidic conditions, in an attempt to prepare 2-dimethylaminomethyl-*N*-methyl-2-phenylsuccinimide hydrochloride (compound *1*, Table I). Several attempts under these conditions with various reaction times proved unsuccessful. Only starting material could be isolated. It was then decided to try higher boiling solvents which differ widely in their polarities. Four solvents were investigated: 2-butanol, glacial acetic acid, cyclohexanol, and toluene.

Substitution of 2-butanol for ethanol was also unrewarding. However, initial results were obtained when glacial acetic acid was used as the solvent; five Mannich bases were prepared: 2-dimethylaminomethyl - *N* - methyl - 2 - phenylsuccinimide hydrochloride (compound *1*, Table I), 2 - diethylaminomethyl - *N* - methyl - 2 - phenylsuccinimide hydrochloride (compound *2*, Table I), *N*-methyl-2-phenyl-2-(1-pyrrolidinomethyl) succinimide hydrochloride (compound *3*, Table I), *N*-methyl - 2 - (4 - morpholinomethyl) - 2 - phenylsuccinimide hydrochloride (compound *5*, Table I), and *N*-methyl-2-(4-methyl-1-piperazinomethyl)-2-phenylsuccinimide dihydrochloride (compound *7*, Table I). The yields, however, were generally poor.

Several attempts to synthesize *N*-methyl-2-phenyl - 2 - (1 - piperidinomethyl)succinimide hydrochloride (compound *4*, Table I) using the glacial acetic acid method failed, but this compound was finally obtained in cyclohexanol.

N - Methyl - 2 - phenyl - 2 - (1 - pyrrolidinomethyl)succinimide hydrochloride (compound *3*, Table I), which was prepared previously in glacial acetic acid, was obtained in a significantly higher yield in cyclohexanol. The synthesis of 2-(3-azabicyclo[3.2.2]non - 3 - ylmethyl) - *N* - methyl - 2-phenylsuccinimide hydrochloride (compound *8*, Table I) was also accomplished in cyclohexanol. The use of 3-azabicyclo[3.2.2]nonane as the amine in the Mannich reaction has been reported only in recent years (15).

Four Mannich bases (compounds *2*, *4*, *6*, and *8*, Table I) were prepared in toluene. In every case but one, the yields were substantially increased over those obtained in glacial acetic acid or cyclohexanol.

In reviewing the data, it was observed that in every case in which ethanol was used as the solvent, paraformaldehyde was the source of formaldehyde. Therefore, in order to ascertain if the source of formaldehyde might have made a difference, the synthesis of compound *2*, Table I, was again attempted in ethanol, but 36% formalin was substituted for paraformaldehyde. The product was obtained in a 49% yield which is significantly lower than the 67% yield obtained in toluene.

New Higher Homologs—The next higher homologs of the Mannich bases (IV, $n = 2$) were prepared according to the reaction shown in Scheme I.

[a] The starting amine, diethylamine, was used in the form of its hydrochloride; total reaction time was 4 hr. [b] Recrystallized from 95% ethanol. [c] 36% formalin. [d] Total reflux time 2 hr. [e] Recrystallized from isopropanol. [f] 95% paraformaldehyde. [g] Total reflux time 24 hr. [h] Isolated as free base and recrystallized from 95% ethanol. [i] Recrystallized from isopropanol. [j] Total reflux time 18 hr. [k] Dose level = 200 mg./Kg; see body of paper for experimental protocol.

The addition of III to a suspension of commercial lithium amide in anhydrous toluene generated its lithium salt, which was allowed to react with the appropriately substituted β-chloroethylamine hydrochlorides. Since the starting amines were used in the form of their hydrochlorides, it was necessary to use at least two equivalents of the lithium amide. In subsequent preparations of some of the compounds, it was found that an increase in the number of equivalents of lithium amide used in the reaction produced an increase in the yields of the products. In specific cases the increases were quite significant (Table II).

EXPERIMENTAL

All melting points have been determined on either a Fisher-Johns block or the Kofler micro-hot stage and have been corrected. The infrared spectra were obtained using a Beckman IR-8 spectrophotometer. All imide derivatives displayed the two characteristic carbonyl stretching frequencies between 1775 and 1690 $cm.^{-1}$ (16–18). Also, the "ammonium bands" characteristic of tertiary amine hydrochlorides were present between 2700 and 2250 $cm.^{-1}$ (19).

The elemental analyses were performed by Galbraith Laboratories, Inc., Knoxville, Tenn., and Micro-Analysis, Inc., Wilmington, Del.

All chemicals were obtained commercially unless specified otherwise.

Intermediates

2-Phenylsuccinic Acid—The preparation of this compound was according to the method of Allen *et al.* (20).

N-Methyl-2-phenylsuccinimide (III)—Made by the procedure of Miller and Long (4).

4-Methyl-1-(2-hydroxyethyl)piperazine—The following procedure is a modification of Ratouis, Boissier, and Dumont's method for the preparation of phenoxyalkylpiperazines (21). A mixture of 23.0 Gm. (0.230 mole) of *N*-methylpiperazine, 16.0 Gm. (0.200 mole) of 2-chloroethanol, 31.8 Gm. (0.230 mole) potassium carbonate, and 700 ml. of 2-butanol was heated to 100° for 15 hr. The mixture was allowed to cool to room temperature and filtered to remove the inorganic salts. The 2-butanol was then removed *in vacuo*. The residue, 4-methyl-1-(2-hydroxyethyl)piperazine, was used without further purification in the following procedure.

4-Methyl-1-(2-chloroethyl)piperazine Hydrochloride—The 4-methyl-1-(2-hydroxyethyl)piperazine, prepared by the procedure above, was treated according to the method of Billinghurst (22). That is, a chloroform solution of the alcohol was treated with thionyl chloride and the solid product was recrystallized from methanol to yield 22.4 Gm. (78%, based on 2-chloroethanol) of the title compound.

3-(2-Chloroethyl)-3-azabicyclo[3.2.2]nonane Hydrochloride—The procedure of Eastman Chemical Products, Inc., was modified in the preparation of this compound (23). To 31.2 Gm. (0.250 mole) of 3-azabicyclo[3.2.2]nonane was added, dropwise, 20.1 Gm. (0.250 mole) of 2-chloroethanol over a period of 20 min. After the addition was complete the reaction mixture was warmed on a steam bath. The entire reaction mixture formed a solid mass after 5 min. To this dark solid was added, with stirring, 150 ml. of a 10% solution of sodium hydroxide and 50 ml. of ether. The layers were separated and the basic aqueous solution was washed twice with 25-ml. portions of ether. The combined ethereal washings were dried over anhydrous mag-

nesium sulfate and filtered. The ether was removed *in vacuo* to give 30.1 Gm. (71.2%) of 3-(2-hydroxyethyl)-3-azabicyclo[3.2.2]nonane, which was used without further purification in the next step.

In 200 ml. of chloroform was dissolved 20.1 Gm. (0.178 mole) of the crude 3-(2-hydroxyethyl)-3-azabicyclo[3.2.2]nonane. To this solution was added slowly 30 ml. of thionyl chloride dissolved in 200 ml. of chloroform. The reaction was exothermic. After the addition was complete, the mixture was refluxed for 3 hr. and then allowed to stand at room temperature overnight. The solid was collected by filtration and recrystallized from absolute ethanol to yield 14.3 Gm. (35.8%) of 3-(2-chloroethyl) - 3 - azabicyclo[3.2.2]nonane hydrochloride, m.p. 214–215° dec.; lit. m.p. 198–225°.

Mannich Bases (Table I)

Method A—To 25 ml. of cold glacial acetic acid was added slowly, with stirring, 0.120 mole of the amine as a 40% aqueous solution (for an exception, see compound *2*, Table I). To this solution was added 10 ml. of 36% formalin (0.12 mole formaldehyde), followed by 18.9 Gm. (0.100 mole) of *N*-methyl-2-phenylsuccinimide. The mixture was heated on a steam bath for 1–2 hr.

The reaction mixture was cooled in an ice bath and made basic with 10% sodium hydroxide solution, and then extracted with chloroform. The chloroform extracts were dried over anhydrous magnesium sulfate and filtered, and the solvent was removed *in vacuo*. The residue was dissolved in anhydrous ether and filtered to remove any undissolved material. The ethereal solution was saturated with dry hydrogen chloride and the solid was collected by filtration, washed with anhydrous ether, and recrystallized from absolute ethanol.

Method B—A mixture of 0.10 mole of the amine, 18.9 Gm. (0.100 mole) of *N*-methyl-2-phenylsuccinimide, 60 ml. of toluene, and either 8.0 ml. of 36% formalin (2.9 Gm., 0.10 mole formaldehyde) or 3.4 Gm. (0.10 mole, calculated as formaldehyde) of 95% paraformaldehyde was heated at reflux for 20–24 hr. The volatile liquids were then removed *in vacuo*. An ethereal solution of the residue was dried over anhydrous magnesium sulfate, filtered, and saturated with dry hydrogen chloride. Sometimes a tacky material precipitated, which upon further addition of dry hydrogen chloride, with stirring, usually solidified to a white solid. However, if this treatment failed, then triturating the material with fresh anhydrous ether accomplished the same thing. The hydrochlorides were recrystallized from either 95% ethanol or isopropanol.

Method C—The amine (0.055 mole), 5.0 ml. (1.8 Gm., 0.060 mole formaldehyde) of 36% formalin and 9.4 Gm. (0.050 mole) of *N*-methyl-2-phenylsuccinimide were added to 50 ml. of cyclohexanol. The mixture was heated at reflux for several hours and then allowed to cool to room temperature.

The mixture was then dissolved in ether and the resulting solution was washed four times with 50-ml. portions of 10% hydrochloric acid solution. The combined acidic solutions were made basic with 10% sodium hydroxide solution, which usually precipitated an oil. The basic mixture was then extracted with ether, and the ethereal layer was dried over anhydrous magnesium sulfate, filtered, and saturated with dry hydrogen chloride. The solid was recrystallized from absolute ethanol. As in the previous method, occasionally a tacky material precipitated from the acidified ethereal solution. Treating the material in a manner similar to that in method *B* yielded an amorphous solid which then could be easily recrystallized from absolute ethanol.

Method D—Since only 2-diethylaminomethyl-*N*-methyl-2-phenylsuccinimide hydrochloride (compound *2*, Table I) was prepared by this method, the detailed procedure follows. To 3.7 Gm. (0.050 mole) of diethylamine were added 5.0 ml. (1.8 Gm., 0.060 mole formaldehyde) of 36% formalin, 9.4 Gm. (0.50 mole) of *N*-methyl-2-phenylsuccinimide, and 50 ml. of 95% ethanol. The solution was heated at reflux for 24 hr., and the volatile liquids were then removed *in vacuo*. An ethereal solution of the residue was dried over anhydrous magnesium sulfate, filtered, and saturated with dry hydrogen chloride. The solid was recrystallized from absolute ethanol to yield 2-diethylaminomethyl-*N*-methyl-2-phenylsuccinimide hydrochloride.

Next Higher Homologs (Table II)

To a suspension of lithium amide in 60 ml. of anhydrous toluene, under nitrogen, was added 4.7 Gm. (0.025 mole) of *N*-methyl-2-phenylsuccinimide. The mixture was heated at reflux for 5 hr., and then allowed to cool to room temperature. The amine hydrochloride (0.028 mole) was then added. After having been heated at reflux for several hours, the mixture was cooled in an ice bath and hydrolyzed with 20 ml. of water. The layers were separated and the organic layer was washed with water until the aqueous extracts were neutral. The toluene solution was dried over anhydrous magnesium sulfate, filtered, and the toluene removed *in vacuo*.

An ethereal solution of the residue was saturated with dry hydrogen chloride. If a tacky material precipitated, it was treated according to one of the procedures mentioned under *Method B*. The products were recrystallized from either absolute ethanol or isopropanol.

In some subsequent preparations it was found that if the number of equivalents of lithium amide were increased, the yields could also be increased.

PHARMACOLOGY

Pharmacological tests were conducted to determine if the tertiary amino derivatives of III were effective in abolishing the tonic hind leg extensor seizure of convulsions induced electrically and by pentylenetetrazol. A comparative pharmacological study was conducted on all the experimental compounds using male, albino, Charles River mice weighing 19–26 Gm. The mice were divided into groups of 10 and were fasted for 24 hr. before intraperitoneal injection of the test compound. All the compounds were soluble in water except compound *8* (Table I) which, like III, was suspended in a 7% solution of gum acacia. One hour after the compounds were administered, the mice were challenged with electroshock or pentylenetetrazol.

The electroschock procedure used in this study was a modification of the supramaximal seizure technique of Toman *et al.* (24). A 60-c. alternating current of fixed voltage was delivered for 0.2 sec. to each mouse through two attached ear clips. In order to screen the compounds for antipentylene-

tetrazol activity, 100 mg./Kg. of pentylenetetrazol was injected subcutaneously into each mouse. This dose is considered to be approximately twice the CD_{50} in untreated mice (25). In both tests, an animal was considered protected if the tonic extensor component of the seizure was abolished. The control animals, which were injected with 7% gum acacia or distilled water, showed 0% protection against electroshock and subcutaneous pentylenetetrazol.

All of the test compounds were evaluated at a dose level of 200 mg./Kg. with the exception of compound 4 (Table II, 100 mg./Kg.). However, none of the derivatives of III were shown to be effective in preventing the tonic hind leg extension produced by pentylenetetrazol. It was not possible to test higher doses of the experimental compounds since amounts greater than 200 mg./Kg. produced toxic symptoms.

The results from the electroshock testing demonstrated that several of the analogs were more protective against electroshock than was the parent compound (III). At a dose level of 200 mg./Kg., III protected 20% of the test animals against electroshock. The electroshock data appear in Tables I and II.

Survival of *Pseudomonas aeruginosa* in Fluorescein Solution

Preservative Action of PMN and EDTA

By MICHAEL R. W. BROWN

Colony counts were made for a year on washed and unwashed cells of *Ps. aeruginosa* inoculated into fluorescein sodium solution, 2 percent in water (pH 8.6), into nutrient broth, into tris buffer (pH 8.6), and into water. Broth exerted a protective effect in all storage liquids (22°) and also supported growth, depending on the amount of broth. Water-washed inocula lost viability in less than a day in fluorescein solution. Viability of broth inocula was maintained for more than a year in all vehicles. Fluorescein solution preserved with PMN-sterilized inocula of about 10^6/ml. *Ps. aeruginosa* cells within 5 hr. EDTA in combination with PMN was less effective.

PSEUDOMONAS AERUGINOSA causes general problems of cross infection (1, 2) and is a particular hazard in ophthalmology (3, 4). Dale *et al.* (5) have reviewed many reports of *Ps. aeruginosa* as a contaminant of fluorescein eye drops.

The B.P.C. recommendation of phenylmercuric nitrate (PMN) as an ophthalmic preservative is supported by many studies, nearly all of which
