In the special case where C_B is constant, Eq. 3 may be integrated to give:

$$a = a_0 - \frac{D(C_s - C_B)}{\rho h} t \qquad \text{(Eq. 4)}$$

where a_0 is the initial ($t = 0$) radius of the gallstone. Equation 4 may also be expressed on a weight basis:

$$W^{1/3} = W_0^{1/3} - \frac{D(C_s - C_B)}{\rho h} \left(\frac{4\pi\rho}{3}\right)^{1/3} t \qquad \text{(Eq. 5)}$$

where W_0 is the initial ($t = 0$) weight of the gallstone, and W is the weight at time t. Equation 5 is a form of the well-known Hixon-Crowell cube-root law (13).

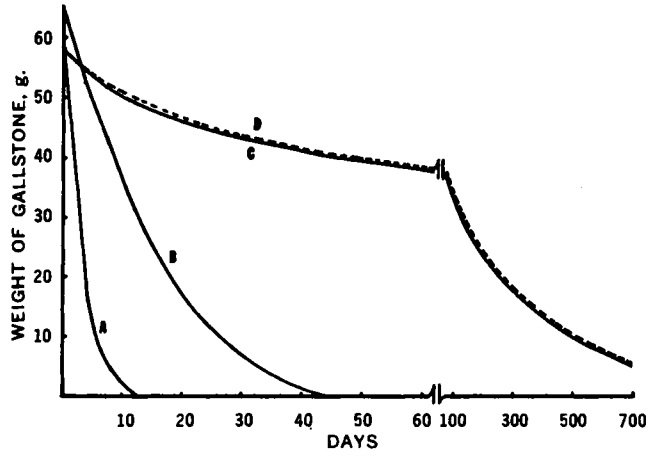

Figure 5—*Calculated dissolution of gallstone of radius* a_0 = *2.5 cm. and solubility* C_s = *26.4 mM/l. with A for Case I and* h = *50 μ, B for Case I and* h = *200 μ, C for Case II and* h = *50 μ, and D for Case II and* h = *200 μ.*

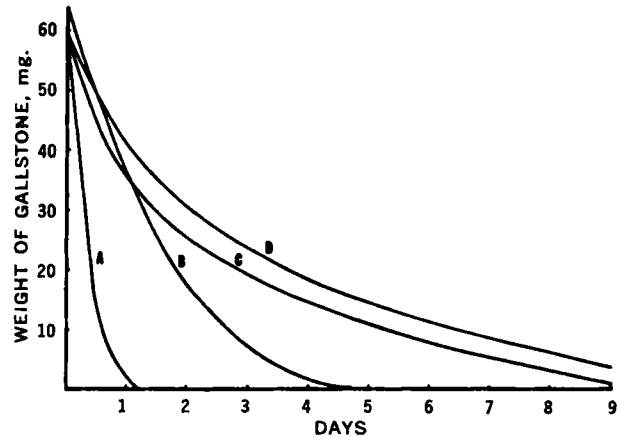

Figure 6—*Calculated dissolution of gallstone of radius* a_0 = *2.5 mm. and solubility* C_s = *26.4 mM/l. See Fig. 5 for meaning of A, B, C, and D.*

The general solution to Eq. 3, *i.e.*, where C_B is not a constant, may easily be obtained (13). If, for example, C_B changes appreciably during the dissolution period, it may be necessary to use the more general equation which is somewhat unwieldy. However, in most of the present discussion, Eqs. 1 and 4 are sufficient.

Case II: Leaching of Cholesterol from Uniform Matrix Model—If an insoluble, nondisintegrating, porous residue remains in place of the original gallstone substance when cholesterol dissolves into the solvent, this model may be appropriate. Figure 2 illustrates this problem for the sphere geometry case.

In this model, the dissolution rate is governed by diffusion of cholesterol from the surface ($r = a$, where r is the distance from the center of the sphere outward) of the cholesterol core through the solvent-filled but leached (no cholesterol) portion ($a \leq r \leq a_0$) of the gallstone and through the solvent diffusion layer of thickness h. It is again assumed that the solvent at $r = a$ is saturated with cholesterol. The rate of cholesterol transport, J, for this case is given by Eq. 6, where it is again assumed that C_B, the cholesterol concentration in the bulk solvent, remains constant during dissolution:

$$J = \frac{4\pi a_0^2 aD}{(\tau/\epsilon)a_0(a_0 - a) + ha}(C_s - C_B)t \qquad \text{(Eq. 6)}$$

where ϵ and τ are the porosity and tortuosity of the leached region ($a \leq r \leq a_0$), respectively. The other symbols have already been defined. Equation 6 thus considers both the effects of the solvent diffusion layer resistance and the matrix-diffusion resistance to cholesterol dissolution.

When Eq. 6 is combined with Eq. 2, one obtains the final expression which relates the size of the cholesterol core to time:

$$-2\left(\frac{h}{a_0} - \frac{\tau}{\epsilon}\right)\left(\frac{a}{a_0}\right)^3 - 3\frac{\tau}{\epsilon}\left(\frac{a}{a_0}\right)^2 + \frac{\tau}{\epsilon} + 2\frac{h}{a_0} = \frac{6D(C_s - C_B)}{a_0^2 S} \qquad \text{(Eq. 7)}$$

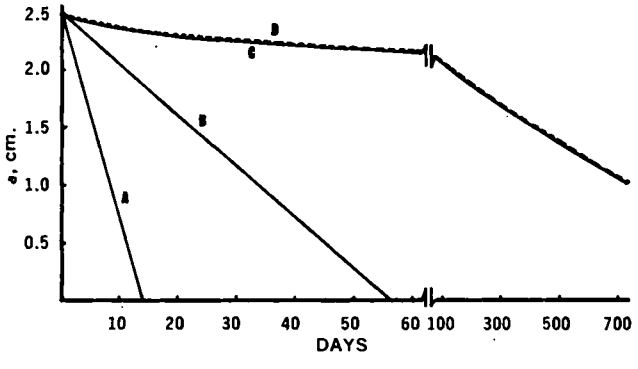

Figure 7—*Calculated dissolution of gallstone with radius* a versus *time* t. *Values of* a_0 = *2.5 cm. and* C_s = *26.4 mM/l. were used. See Fig. 5 for meaning of A, B, C, and D.*

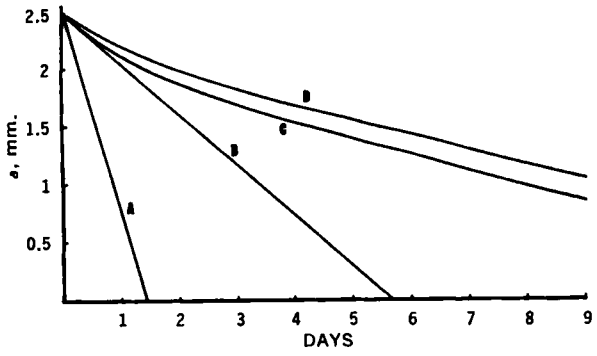

Figure 8—*Calculated dissolution of gallstone with radius* a versus *time* t. *Values of* a_0 = *2.5 mm. and* C_s = *26.4 mM/l. were used. See Fig. 5 for meaning of A, B, C, and D.*

where S = solid concentration of cholesterol in the gallstone matrix. Equation 7 may also be expressed on a weight basis:

$$-2\frac{(4\pi\rho)^{1/3}h}{(3W_0)^{1/3}}-\frac{W}{W_0}-3\frac{\tau}{\epsilon}\left(\frac{W}{W_0}\right)^{2/3}+\frac{\tau}{\epsilon}+\frac{2(4\pi\rho)^{1/3}h}{(3W_0)^{1/3}}=\frac{6(4\pi\rho)^{2/3}D(C_s-C_B)}{(3W_0)^{2/3}S} \quad \text{(Eq. 8)}$$

Case III: Interfacial Barrier or Coat Model I—Figure 3 illustrates a model that may be appropriate when: (*a*) a moderate degree of disintegration and/or dissolution of a residue (matrix) barrier (Case II) takes place, or (*b*) a reversible or collapsible barrier film is present on the stone surface during dissolution. Equation 9 describes the dissolution rate behavior for the sphere situation:

$$W^{1/3}=W_0^{1/3}-\frac{P(C_s-C_B)}{\rho}\left(\frac{4\pi\rho}{3}\right)^{1/3}t \quad \text{(Eq. 9)}$$

It is assumed that the permeability coefficient P of this barrier remains constant. All symbols in Eq. 9 have been defined. The physical meaning of the permeability coefficient P depends upon the particular situation (see *Discussion* section).

Case IV: Interfacial Barrier or Coat Model II—This situation (Fig. 4) might arise if a stable coating (*e.g.*, proteins, calcium phosphates, or calcium carbonate) is present on the stone surface. The outer dimensions do not change with time, while the inner cholesterol dissolves. Equation 10 describes the time change in the weight for this situation:

$$\frac{\epsilon}{\tau}+\frac{2(4\pi\rho)^{1/3}D}{P(3W_0)^{1/3}}-3\frac{\epsilon}{\tau}\left(\frac{W}{W_0}\right)^{2/3}+\left\{2\frac{\epsilon}{\tau}-\frac{2(4\pi\rho)^{1/3}D}{P(3W_0)^{1/3}}\right\}\frac{W}{W_0}=\frac{6(4\pi\rho)^{2/3}(C_s-C_B)\epsilon D}{\tau(3W_0)^{2/3}S} \quad \text{(Eq. 10)}$$

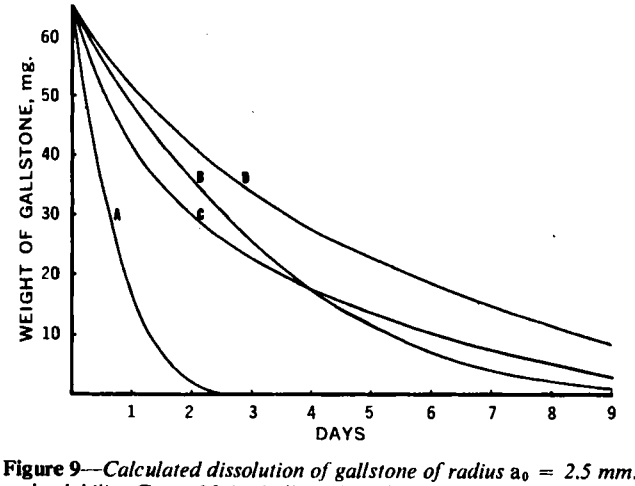

Figure 9—*Calculated dissolution of gallstone of radius* a_0 = *2.5 mm. and solubility* C_s = *26.4 mM/l. with A for Case III and* P = *2* × *10⁻⁴ cm./sec., B for Case III and* P = *5.0* × *10⁻⁵ cm./sec.; C for Case IV and* P = *2* × *10⁻⁴ cm./sec., and D for Case IV and* P = *5.0* × *10⁻⁵ cm./sec.*

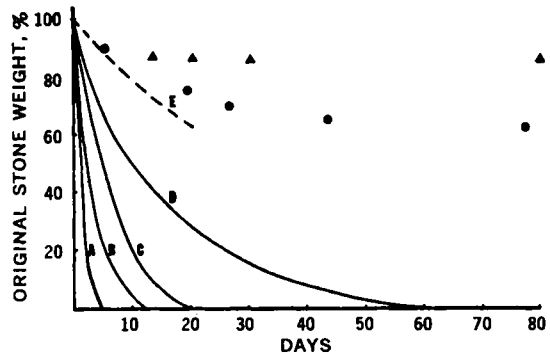

Figure 10—*Comparison of calculated percent gallstone dissolved for cases of* h = *200 μ and Small's (2) data with A for Case I and* C_s = *26.4 mM/l., B for Case II and* C_s = *26.4 mM/l., C for Case I and* C_s = *5.6 mM/l., and D for Case II and* C_s = *5.6 mM/l. Key (Small's data):* ▲, *dissolution in bile salt;* ●, *dissolution in bile salt–lecithin (2:1); and E, bile salt–lecithin corrected to sink condition by changes in* ΔC *with time.*

Here again the physical meaning of the permeability coefficient P depends upon the particular situation.

Other Models—Other models may be developed that relate to physical situations not already presented. Also, very complex combinations are possible. Before much serious consideration is given to very elaborate models, however, those presented in this paper should be evaluated thoroughly.

THEORETICAL CALCULATIONS

While the models and equations in the preceding section may be utilized in a rather rigorous and quantitative manner with experiments on "synthetic" and real gallstones, the present applications of the theoretical relations are concerned primarily with the identification of and "range-finding" in a number of situations. These "order-of-magnitude" calculations should be helpful in suggesting preliminary correlations and expectations and establishing limiting behavior.

Results Involving Case I—Some results of calculations with Eqs. 5 and 6 are shown in Figs. 5–8 (curves A and B). In these calculations, meaningful values for the parameters were selected that correlate to either *in vivo* or *in vitro* situations. The two values for h (50 and 200 μ) should represent reasonable[1] lower and upper limits for moderate and low agitation conditions (14). The two values for a_0, the initial stone radius, are typical of cholesterol stones. The value for the cholesterol solubility (C_s = 26.4 mmoles/l.) was reported to be that for gallbladder bile (15). For the diffusion coefficient D, a value of 1×10^{-6} cm.²/sec. was selected because this is close to that observed for bile salt–cholesterol micelles (16).

These calculations, being based on Case I and sink conditions ($C_B = 0$), represent optimum or maximum dissolution rates. Thus, it is probably significant from a clinical standpoint that it may take about a week to a month for a significant reduction in size of large gallstones ($a_0 \sim 2.5$ cm.) under such optimal conditions. The calculations predict that smaller stones ($a_0 \simeq 0.25$ cm.) may dissolve in a few days under these optimal (Case I and sink) conditions.

Results with Other Models—In curves C and D of Figs. 5–8, results of calculations with Eqs. 7 and 8 (Case II) are presented. As expected, the rates are lower than those for simple dissolution. The effect of agitation (*i.e.*, dependence upon h) is significant for small gallstones following this model but not for large stones.

Figure 9 shows the results of some calculations based on Cases III and IV.

DISCUSSION

The models considered and the equations deduced in this paper should serve as baselines for research on the dissolution kinetics of gallstones *in vitro* and *in vivo*. Experimental results in these laboratories have shown, for example, that gallstones dissolve according

[1] If the medium is much more viscous than water, however, these values should be greater.

to Model I in ethanol–water and acetone–water solvent mixtures. In 5% cholate, the rates appear to be somewhat slower than the predictions of Model I; in bile salt–lecithin solutions, the rates appear to be more than a factor of 10 slower. In Fig. 10, the data of Small (2) are compared to some theoretical calculations. As can be seen, rates based upon Model I appear to be significantly greater than Small's *in vitro* results. These preliminary comparisons of experimental results with the theoretical relationships show that under physiologically important conditions, the simple diffusion-controlled model may or may not be applicable and that careful scrutiny of the various factors is necessary.

From the clinical standpoint, the idea that a 2.5-mm. gallstone might be dissolved in a few days is very appealing. Therefore, the question of why the observed rates might be significantly slower than diffusion controlled is important clinically.

Mechanisms of Dissolution of Human Cholesterol Gallstones

WILLIAM I. HIGUCHI▲, SOMPOL PRAKONGPAN, and FUDAH YOUNG

Abstract □ Experiments were designed for investigating and comparing the *in vitro* dissolution kinetics of human cholesterol gallstones and cholesterol monohydrate compressed pellets. The dissolution rates were determined in 66% acetone–water, in 63% ethanol–water, in bile acids, and in bile acid–lecithin solutions. It was found that the rates of dissolution of the stones compared well with the dissolution rates obtained with the cholesterol monohydrate pellets in all solvents investigated. The dissolution rates for both stones and pellets in the organic–aqueous solvents were extremely rapid and of the order of magnitude expected for a bulk diffusion-controlled process. In sodium cholate solutions, the dissolution rates were about 2–3 times slower than rates predicted by diffusion theory and the data suggested a modest interfacial resistance to dissolution. The rates obtained in 2% bile acid–1% lecithin solutions were about 17 times slower than diffusion-controlled processes, and these results point to an interfacial barrier to dissolution that may be very important clinically.

Keyphrases □ Gallstones, human—mechanisms of dissolution, dissolution rates in different media, compared to prepared cholesterol pellets, existence of interfacial barriers □ Cholesterol gallstones, human—mechanisms of dissolution, dissolution rates in different media, compared to prepared cholesterol pellets, existence of interfacial barriers □ Dissolution, human cholesterol gallstones—mechanisms, dissolution rates in different media, compared to prepared cholesterol pellets, existence of interfacial barriers □ Diffusion—role in dissolution of human cholesterol gallstones, existence of interfacial barriers □ Interfacial barriers—as a factor in the dissolution of human cholesterol gallstones, mechanisms of dissolution

During recent years much research has been done to evaluate the thermodynamic equilibria existing in the bile acid–lecithin–cholesterol–water systems and their relation to cholelithiasis (1, 2). It has been shown that the degree of cholesterol saturation or supersaturation in gallbladder bile is a critical factor in the formation or dissolution of cholesterol gallstones *in vivo*. While it is now clear that thermodynamic factors can play important roles, relatively little is known about the kinetic factors involved. Questions concerning the *kinetics* of gallstone dissolution have become especially important since the finding of Thistle and Schoenfield (3) and Danzinger *et al.* (4) that oral administration of chenodeoxycholic acid in patients with gallstones can result in the simultaneous "normalization" of bile and the dissolution of stones.

The present article reports results of initial physicochemical investigations on the mechanisms of dissolution of cholesterol gallstones. An attempt was made to determine: (*a*) whether or not the rate of cholesterol gallstone dissolution *in vitro* compares closely to the dissolution rate of "synthetic" gallstones of compressed cholesterol monohydrate pellets, and (*b*) whether or not the dissolution rates of gallstones in various solvent media are governed by diffusion in the bulk or by interfacial factors (5).

to Model I in ethanol–water and acetone–water solvent mixtures. In 5% cholate, the rates appear to be somewhat slower than the predictions of Model I; in bile salt–lecithin solutions, the rates appear to be more than a factor of 10 slower. In Fig. 10, the data of Small (2) are compared to some theoretical calculations. As can be seen, rates based upon Model I appear to be significantly greater than Small's *in vitro* results. These preliminary comparisons of experimental results with the theoretical relationships show that under physiologically important conditions, the simple diffusion-controlled model may or may not be applicable and that careful scrutiny of the various factors is necessary.

Cholesterol monohydrate pellets	2.60	4.45	1.95	0.34	0.18

[a] Spherical gallstones of diameters ranging from 0.60 to 1.10 cm. were used. [b] Containing 0.1 *M* phosphate buffer. [c] o = dissolution from external surface of gallstone. [d] i = dissolution from cross-sectional cut surface of gallstone.

EXPERIMENTAL

Materials—Radioactive cholesterol monohydrate was prepared by mixing 5 g. of a three-times recrystallized cholesterol[1] with 50 μc. of benzene solution of ^{14}C-cholesterol[2] and drying *in vacuo*. The mixture was dissolved in 400 ml. of 95% ethanol at 60°. It was then seeded with a few crystals at room temperature. After 48 hr., the mixture was filtered and dried *in vacuo* overnight.

Various aqueous compositions of the following materials were used as solvent media. Sodium cholate and glycocholate[3] were used as received. Sodium taurocholate[4] was prepared by the method of Pope (6). Egg lecithin was prepared by the method of Small *et al.* (7), except that commercial egg lecithin of purified grade[5] was used as starting material. Human gallstones were obtained from Hofmann and his group[4].

Solubility Determination—The solubilities of cholesterol monohydrate in various media were determined by introducing an excess amount of radioactive cholesterol monohydrate of about 100 mg. into 20 ml. of a solvent in a 50-ml. volumetric flask. The flask was simultaneously flushed with nitrogen gas and shaken by a wrist-action shaker[6] in a water bath at 37°. An aliquot of 5 ml. was taken and filtered through a 0.22-μ filter[6] in a controlled atmosphere at 37°. Ten milliliters of scintillation fluid (8) was added to 1.0 ml. of the filtrate, and the radioactivity was determined in a scintillation system[7]. Aliquots were taken and assayed for cholesterol daily. Solubility of cholesterol monohydrate in the medium was obtained when the concentration in the filtrate reached a constant level.

Diffusion Coefficient Determination—Measurements were made at 37° in a diaphragm diffusion cell made of Lucite (Fig. 1) and by a method similar to that described by Keller *et al.* (9), except that the two reservoirs were separated by double silver filter membranes[8] of 1.2-μ pore size. The lower reservoir had a capacity of 3.4 ml. and was completely filled with a solution of radioactive cholesterol during operation. The upper reservoir was filled with the same amount of solvent medium. The stirring speed in both reservoirs was maintained at 150 r.p.m. A solution of 0.1 *N* KCl with a known diffusion coefficient[9] of 2.41 × 10^{-5} cm.^{2} sec.$^{-1}$ at 37° was used as standard in the measurements.

Dissolution Rate Determination—*Cholesterol Monohydrate or Benzoic Acid Pellets*—Pellets of radioactive cholesterol monohydrate or benzoic acid were prepared by directly compressing 300 mg. of the material in a die, 1.3-cm. (0.5-in.) i.d., under a force of 3000 lb. using a laboratory press[10]. The surface area of the resulting pellets was 1.267 cm.^{2}. The pellet was held firmly in a die by covering the inside surface with melted paraffin. This die was then mounted at the bottom of a water-jacketed cylinder, with the pellet facing a

[a] Containing 0.1 M phosphate buffer at pH 7.4.

stirring paddle inserted at the top of the cylinder (Fig. 2). The stirring speed was maintained at 150 r.p.m. during dissolution. Seventy milliliters of solvent preequilibrated at 37° was used. To measure the dissolution rates, the amount of cholesterol or benzoic acid dissolved in the solvent was analyzed against time.

Human Cholesterol Gallstones—Gallstones of various colors and sizes, ranging from 0.6 to 1.1 cm. in diameter, were used. Dissolution rates were measured from both the intact outer surface and the cross-sectioned inner surface by embedding a gallstone in a die with melted paraffin exposing half of the stone to the bulk solvent medium. The inner surface was obtained by cutting a spherical stone into halves cross sectionally. The surface areas for dissolution were estimated according to the specific geometry of the surfaces. The same apparatus and procedures as already described were then used. Samples of 5 ml. were taken and replaced with fresh solvent. Cholesterol in these samples was analyzed by the method of Dam *et al.* (11) or of Sperry and Webb (12) when lecithin was present in the medium.

RESULTS AND DISCUSSION

Figure 3 shows typical raw data obtained for the dissolution of human cholesterol gallstones in several solvent media. As can be seen, the dissolution in some solvents gave nearly linear plots; in these cases, the solvents remained much undersaturated with cholesterol during the dissolution period. In other solvents, apparent bending of the dissolution curves occurred as a result of the more rapid increase in cholesterol saturation with time.

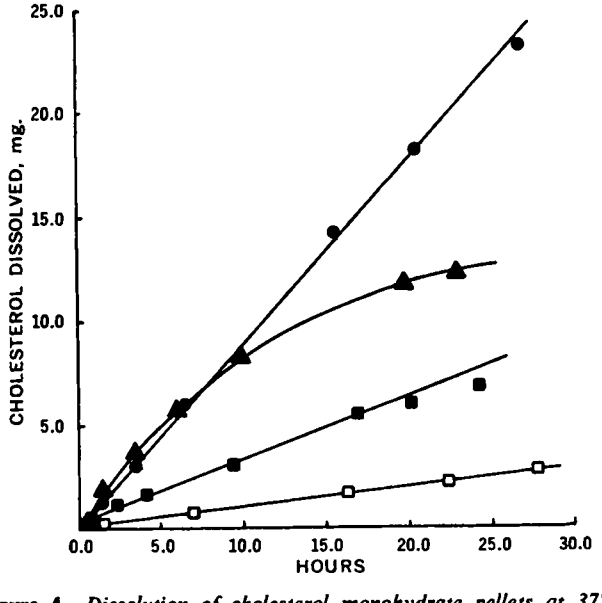

Figure 4—*Dissolution of cholesterol monohydrate pellets at 37°. Key: ●, in 5% cholate and 0.1 M phosphate buffer, pH 7.4; ■, in 2% cholate + 0.1 M phosphate buffer, pH 8.0; □, in 2% cholate + 1% lecithin + 0.1 M phosphate buffer, pH 8.0; and ▲, in 63% ethanol.*

The dissolution rate data of the compressed pellets of cholesterol monohydrate crystals are shown in Fig. 4. The dissolution patterns in Fig. 4 are similar to those in Fig. 3 for the gallstones. The dissolution rates (in mg. cm.$^{-2}$ sec.$^{-1}$) were obtained by taking the initial slopes of the dissolution curves such as those in Figs. 3 and 4 and correcting for the surface area.

Correlation between Gallstone and Cholesterol Monohydrate Dissolution Rates—The dissolution rates of various human gallstones and cholesterol monohydrate pellets in the organic-aqueous solvents and the bile media are shown in Table I. In each solvent studied, the dissolution rates of gallstones were found to compare closely with those for cholesterol monohydrate pellets. The variations in the gallstone dissolution rates, with a few exceptions, are well within a factor of two of the dissolution rates for the cholesterol monohydrate pellets in all solvents.

The dissolution rates determined from the inner cross-sectional surfaces were, in general, greater than those determined from the external surfaces. These differences and the variations found among the stones may be due to deposited film and matrix-forming substances derived from the biliary environment.

In view of the reported cholesterol content in human gallstones running as high as 98% (13), the consistent agreement between the dissolution rates of gallstones and cholesterol monohydrate pellets is not surprising. The data in Table I show that cholesterol monohydrate appears to be a good experimental model for the dissolution of the gallstones in these experiments. The presence of insoluble residues, bile pigments, mucus, and proteins may create physical situations where the rate of dissolution can be affected (5).

Diffusion-Controlled Model—In Table II, the experimental dissolution rate data for the cholesterol monohydrate pellets are compared to the dissolution rates predicted by the Nernst equation (14):

$$J = \frac{ADC_s}{h} \qquad \text{(Eq. 1)}$$

where A is the surface area of the pellet, D is the diffusivity of cholesterol in the solvent, C_s is the solubility of cholesterol monohydrate in the solvent, and h is the effective diffusion layer thickness. The theoretical rate calculations for J/A involved the use of Eq. 1 and the experimental D and C_s values, with an h value of 50 μ determined from a benzoic acid pellet dissolution experiment. This analysis points out several interesting aspects of the dissolution kinetics. First, the dissolution rates in the organic-aqueous solvents are maximal, *i.e.*, essentially diffusion controlled. Second, in the bile acid media, the rates are about 2–3 times slower than diffusion-controlled processes for the hydrodynamic situation prevailing in those experiments. Finally, when the solvent is 2% bile acid–1% lecithin, the rates are about 17 times slower than diffusion-controlled values and a very large interfacial barrier clearly dominates the kinetics.

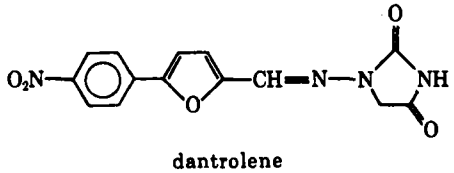
Dantrolene, a Direct Acting Skeletal Muscle Relaxant

K. O. ELLIS▲, A. W. CASTELLION, L. J. HONKOMP, F. L. WESSELS, J. F. CARPENTER, and R. P. HALLIDAY

Abstract □ Dantrolene causes skeletal muscle relaxation in animals without prominent CNS actions, and it has little or no measurable effect on smooth or cardiac muscle. Dantrolene reduces rigidity in decerebrate cats. Unlike centrally acting muscle relaxants, it has no preferential effect on polysynaptic flexor reflexes and still produces its maximum effect on the muscle twitch in an isolated, neurally intact, perfused hindlimb. Dantrolene blocks the twitch response when stimulated through the motor nerve in a way different from the action of tubocurarine or decamethonium. It inhibits direct twitch responses in denervated muscle and is equally effective in attenuating the direct and indirect twitch responses. It is hypothesized that dantrolene causes skeletal muscle relaxation by a direct action on muscle at a site beyond the neuromuscular junction.

Keyphrases □ Dantrolene—effects on skeletal muscle, CNS, and smooth or cardiac muscle □ Skeletal muscle relaxants, potential—dantrolene, proposed site of action

The synthesis of a series of 1-[(5-arylfurfurylidene)-amino]hydantoins and their identification as skeletal muscle relaxants were reported by Snyder *et al.* (1). One member of this series, dantrolene, 1-{[5-(*p*-nitrophenyl)furfurylidene]amino}hydantoin, subsequently received further evaluation (2, 3). This report details the general pharmacology of dantrolene and the proposed site of action as a skeletal muscle relaxant[1].



dantrolene

[1] Sodium dantrolene (Dantrium, Eaton Laboratories, Division of Norwich Pharmacal Co., Norwich, N. Y.) is now undergoing clinical trials as a skeletal muscle relaxant.

EXPERIMENTAL

Methods—*Gross Observational Evaluation*—Male albino mice[2], weighing 20–27 g., were used. The rating scale was similar to that described by Irwin (4). Dantrolene, suspended in 1% carboxymethylcellulose, was administered intraperitoneally and orally in logarithmically spaced doses.

Muscle Incoordination—A rotarod test similar to that reported by Dunham and Miya (5), except that the rod rotated at 20 r.p.m., was employed. The test drugs were administered intraperitoneally in groups of six previously trained mice (maximum of three training trials per animal), and the rotarod tests were conducted 15, 30, 60, and 180 min. following drug administration. The end-point for muscle incoordination was the animal's inability to stay on the rotarod for 30 sec. An ED_{50} (the dose of drug that caused 50% of the animals to fall off before 30 sec.) was estimated by probit analysis (6).

Flexor-Reflex Studies—Cats of either sex, weighing 2–4 kg., were anesthetized with an α-chloralose–urethan solution (50 and 500 mg./kg., respectively) in 50% propylene glycol with water administered intraperitoneally. Flexor-reflex preparations were prepared by a method similar to that of Berger (7), using the tibialis anticus muscle under a resting tension of 50 g. Sensory reflex muscle contractions were elicited by electrical stimulation of the central end of the cut tibial nerve. Motor nerve-induced contractions of the same muscle were obtained by electrical stimulation of the ipsilateral peroneal nerve. A pool of warm mineral oil bathed the nerves to prevent drying. Stimulus train durations of 50 msec. with a frequency of 100 Hz., a duration of 0.5 msec., and a voltage of 7–12 v. were applied to the tibial nerve. Motor nerve stimulation parameters were a duration of 1 msec., a frequency of 0.1 Hz., and a voltage adjusted so that the contraction response was comparable in magnitude to the tibial nerve-induced contraction. Nerve excitation was accomplished with bipolar platinum electrodes connected through a stimulus isolation unit[3] to a stimulator[4]. Contractions were recorded with a force-displacement transducer[5] on a polygraph[6].

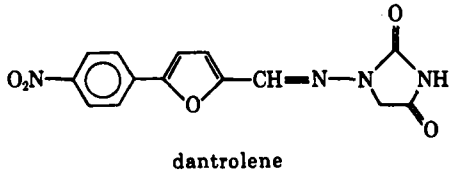
Dantrolene, a Direct Acting Skeletal Muscle Relaxant

K. O. ELLIS▲, A. W. CASTELLION, L. J. HONKOMP, F. L. WESSELS, J. F. CARPENTER, and R. P. HALLIDAY

Abstract □ Dantrolene causes skeletal muscle relaxation in animals without prominent CNS actions, and it has little or no measurable effect on smooth or cardiac muscle. Dantrolene reduces rigidity in decerebrate cats. Unlike centrally acting muscle relaxants, it has no preferential effect on polysynaptic flexor reflexes and still produces its maximum effect on the muscle twitch in an isolated, neurally intact, perfused hindlimb. Dantrolene blocks the twitch response when stimulated through the motor nerve in a way different from the action of tubocurarine or decamethonium. It inhibits direct twitch responses in denervated muscle and is equally effective in attenuating the direct and indirect twitch responses. It is hypothesized that dantrolene causes skeletal muscle relaxation by a direct action on muscle at a site beyond the neuromuscular junction.

Keyphrases □ Dantrolene—effects on skeletal muscle, CNS, and smooth or cardiac muscle □ Skeletal muscle relaxants, potential—dantrolene, proposed site of action

The synthesis of a series of 1-[(5-arylfurfurylidene)-amino]hydantoins and their identification as skeletal muscle relaxants were reported by Snyder *et al.* (1). One member of this series, dantrolene, 1-{[5-(*p*-nitrophenyl)furfurylidene]amino}hydantoin, subsequently received further evaluation (2, 3). This report details the general pharmacology of dantrolene and the proposed site of action as a skeletal muscle relaxant[1].



dantrolene

[1] Sodium dantrolene (Dantrium, Eaton Laboratories, Division of Norwich Pharmacal Co., Norwich, N. Y.) is now undergoing clinical trials as a skeletal muscle relaxant.

EXPERIMENTAL

Methods—*Gross Observational Evaluation*—Male albino mice[2], weighing 20–27 g., were used. The rating scale was similar to that described by Irwin (4). Dantrolene, suspended in 1% carboxymethylcellulose, was administered intraperitoneally and orally in logarithmically spaced doses.

Muscle Incoordination—A rotarod test similar to that reported by Dunham and Miya (5), except that the rod rotated at 20 r.p.m., was employed. The test drugs were administered intraperitoneally in groups of six previously trained mice (maximum of three training trials per animal), and the rotarod tests were conducted 15, 30, 60, and 180 min. following drug administration. The end-point for muscle incoordination was the animal's inability to stay on the rotarod for 30 sec. An ED_{50} (the dose of drug that caused 50% of the animals to fall off before 30 sec.) was estimated by probit analysis (6).

Flexor-Reflex Studies—Cats of either sex, weighing 2–4 kg., were anesthetized with an α-chloralose–urethan solution (50 and 500 mg./kg., respectively) in 50% propylene glycol with water administered intraperitoneally. Flexor-reflex preparations were prepared by a method similar to that of Berger (7), using the tibialis anticus muscle under a resting tension of 50 g. Sensory reflex muscle contractions were elicited by electrical stimulation of the central end of the cut tibial nerve. Motor nerve-induced contractions of the same muscle were obtained by electrical stimulation of the ipsilateral peroneal nerve. A pool of warm mineral oil bathed the nerves to prevent drying. Stimulus train durations of 50 msec. with a frequency of 100 Hz., a duration of 0.5 msec., and a voltage of 7–12 v. were applied to the tibial nerve. Motor nerve stimulation parameters were a duration of 1 msec., a frequency of 0.1 Hz., and a voltage adjusted so that the contraction response was comparable in magnitude to the tibial nerve-induced contraction. Nerve excitation was accomplished with bipolar platinum electrodes connected through a stimulus isolation unit[3] to a stimulator[4]. Contractions were recorded with a force-displacement transducer[5] on a polygraph[6].

[2] Taconic Farms.
[3] Grass SIU-5.
[4] Grass S88.
[5] Grass FT 10.
[6] Grass 7B.

Cross-Circulation Studies—Mongrel dogs of either sex were anesthetized with sodium pentobarbital (35 mg./kg. i.v.), tracheotomized, and prepared for trunk-to-limb cross-circulation studies similar to these described by Margolin *et al.* (8). Contractions of the tibialis cranialis muscle in the perfused hindlimb were induced and recorded as described for the cat flexor-reflex studies. Drugs were administered: (*a*) to the recipient animal to evaluate the central effects of the compounds, and (*b*) to the donor animal to test peripheral inhibition. Drugs administered to the recipient dog reached only the spinal cord, while drug administered to the donor reached the perfused hindlimb with its motor nerve and contracting muscle.

Indirect versus *Direct Muscle Stimulation*—Adult Sprague-Dawley male rats were anesthetized with allobarbital-urethan[7], 1 ml./kg. i.p., and artificially respired. Carotid blood pressure was monitored, and an external jugular vein was cannulated for drug injections. The Achilles tendon was isolated and detached with a piece of the calcaneous bone at its insertion, and the gastrocnemius muscle was freed from surrounding tissue. The free tendon was connected with a ligature to a force-displacement transducer[8], and muscle contractions were recorded on a dynagraph[9]. Indirect stimulation of the muscle was accomplished through the peripheral stump of the severed sciatic nerve. Square-wave stimuli of 10-msec. duration, 0.33 Hz., and at supramaximal voltage were delivered by the apparatus described in the cat flexor-reflex studies. The muscle was stimulated directly with stainless steel needle electrodes[10] inserted directly into the muscle, with the anode in the belly and the cathode in the Achilles tendon. Stimulus parameters were as already stated, but the voltage was adjusted so that magnitude of the contraction response approximated that produced with indirect stimulation. The nerve and muscle were kept moist with frequent applications of warm (37°) mineral oil saturated with Krebs-Ringer's solution.

Denervated Muscle (*9*)—Under ether anesthesia the right sciatic nerve in rats (adult Sprague-Dawley male) was severed and the animals were allowed to recover. Fifteen days later, gastrocnemius muscle contractions were elicited by direct muscle stimulation as already described.

Decerebrate Cat (*10*)—Cats were anesthetized with ether, and a midline incision was made from the base of the nose to the occiput. After trephination the skull bone was removed to expose the right cerebral hemisphere and, by using the tentorium as a guide, the brain stem was sectioned at this level with a spatula. The right hemisphere and then the left were removed, and the cranial vault was lightly packed with cotton.

Decerebrate rigidity ensued when the animal was positioned with its anterior-posterior axis vertical to the horizon and the head was allowed to fall backward.

Other Neuropharmacological Tests—Hexobarbital, 80 mg./kg. i.p., and paraldehyde, 0.8 ml./kg. i.p., "sleep" times were evaluated in mice by the methods of Cook *et al.* (11) and Iyer (12), respectively. Maximal electroshock seizures, produced by a method similar to that described by Swinyard *et al.* (13), and pentylenetetrazol- or strychnine-induced convulsions (14) were utilized as anticonvulsant tests in mice.

Local anesthetic activity was evaluated by the procedures of Wielding (16) on rabbit cornea and by an intradermal method in guinea pigs (17).

Autonomic Pharmacology—Anesthetized dogs (sodium pentobarbital, 35 mg./kg. i.v.) were tracheotomized and placed on artificial respiration, and a thoracotomy was performed through the fifth intercostal space. Coronary blood flow was measured with an extracorporeal flowmeter probe[11], and myocardial contractile force was evaluated with a strain gauge arch[12] in the usual manner. A femoral artery and vein were cannulated for recording of blood pressure and the injection of drugs, respectively. Doses of acetylcholine chloride (1 mcg./kg.), histamine phosphate (2 mcg./kg.), or epinephrine bitartrate (4 mcg./kg.) were administered several times before and at various times after dantrolene or vehicle (polyethylene glycol 300).

Nonvascular smooth muscle activity was evaluated on the GI tract of dogs by the procedures of Goldenberg and Burns (18).

Drugs—The compounds used were: acetylcholine chloride[13], physostigmine salicylate[13], allobarbital with urethan[7], α-chloralose[14], barium chloride[15], paraldehyde[15], dantrolene[16], decamethonium bromide[17], tubocurarine[17], histamine phosphate[17], epinephrine bitartrate[18], sodium hexobarbital[18], mephenesin[19], sodium pentobarbital[20], pentylenetetrazol[21], and strychnine sulfate[22].

RESULTS AND DISCUSSION

Dantrolene, at doses from 10 to 1600 mg./kg. i.p. in mice, induced dose-dependent decreases in spontaneous motor activity, muscle tone (leg and abdomen), and responsiveness to external stimuli. Movements became slow and occurred only when the

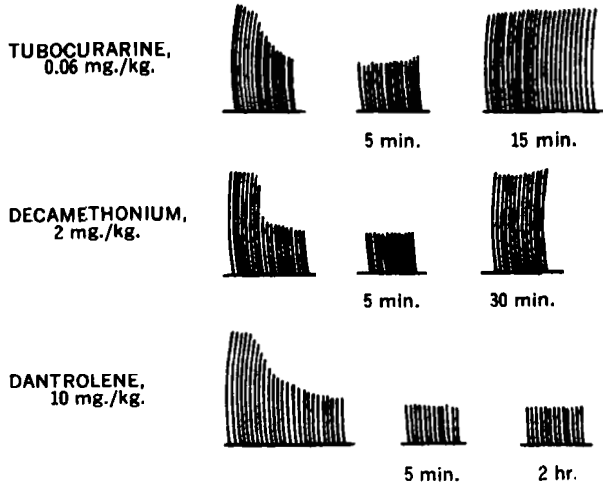

Figure 3—*A comparison of tubocurarine and decamethonium inhibition of the indirect twitch response in the rat with the inhibition caused by dantrolene.*

animals were prodded. Muscle relaxation at doses >200 mg./kg. was present for longer than 8 hr., and at doses >400 mg./kg. it was present for >18 hr. No deaths occurred after 72 hr. The only autonomic effects observed were increased frequency of urination and defecation. The urine was dark yellow following >40 mg./kg. i.p., and there were indications of chromodacryorrhea at >80 mg./kg. i.p. Similar effects in the whole animal were seen with other routes of administration (oral and intravenous) and in other species of animals (rats, cats, and dogs).

Dantrolene effects on motor coordination were evaluated using the rotarod (Fig. 1). The percentage of animals remaining on the rotarod for 30 sec. was plotted for four doses at time intervals up to 180 min. The time to peak drug effect was 60 min.; at that time, when the dose range was expanded, the ED_{50} for muscle incoordination was calculated as 153 mg./kg. i.p. with 19/20 confidence limits of 86 and 271 mg./kg. This ED_{50} for muscle incoordination was considerably above the intraperitoneal dose producing observable muscle relaxation (10–20 mg./kg.) and indicated that these two effects were readily separable.

Dantrolene's production of dose-dependent decreases in spontaneous motor activity, responsiveness to external stimuli, and skeletal muscle relaxation characterized a "sedative-like" profile. However, this profile was atypical in that sedation was secondary to muscle relaxation rather than the reverse, as characterizes sedative and hypnotic drugs. Muscle relaxation was the most pronounced and consistent feature. Unlike the centrally acting muscle relaxants and sedative and hypnotic drugs, dantrolene had no effect on the corneal and pinna reflexes and caused no loss of righting reflex.

Dantrolene (5–100 mg./kg. p.o.) increased the duration of hexobarbital and paraldehyde sleep times at doses >25 mg./kg. Since both methods are of a nonspecific nature and measure only the return of righting reflex, a long acting skeletal muscle relaxant would be expected to prolong such sleep times. Dantrolene (500–1500 mg./kg. p.o.) inhibited maximal electroshock seizures only 40% at 1500 mg./kg., but it had no effect on pentylenetetrazol-

[a] Dissolved in polyethylene glycol 300, all volumes <1.5 ml./kg.

or strychnine-induced convulsions at doses up to 500 mg./kg. p.o. or i.p. Decreased muscle strength was also observed in the rat analgesic test with 100–500 mg./kg. i.p. Although these doses produced significant muscle relaxation and slowed the reaction time for the tail withdrawal, the response was never blocked. No local anesthetic activity was observed with dantrolene (2–600 mg./ml.) as evaluated on rabbit cornea or by intradermal injections in guinea pigs.

No effect on blood pressure, coronary blood flow, heart rate, or contractile force was elicited by dantrolene (1–10 mg./kg. i.v.) in anesthetized dogs. Moreover, the cardiovascular responses induced by the various autonomic drugs were not affected by dantrolene. Only a slight increase and decrease of short duration in the contractile activity of the duodenum and colon, respectively, were observed after dantrolene (0.5–5 mg./kg. i.v.). There was no effect on the ileum. A slight antagonism of barium chloride-induced spasticity (19) of the ileum and colon was produced by dantrolene.

Dantrolene's muscle relaxant activity led to its being evaluated specifically as a skeletal muscle relaxant. Decerebrate cats that evidenced rigid extension of their legs and catatonic contraction of the trunk musculature were treated with dantrolene intravenously. At a dose of 1.8 mg./kg., the extensor rigidity was markedly reduced for a duration of 35 min., while 4.0 mg./kg. had the same effect for 85 min. Decerebrate rigidity was inhibited totally with 5 mg./kg. in two animals, whereas reduction in the rigidity and tremors, but not complete abolition, was observed in three other cats treated with the same dose. All animals treated with dantrolene (1.8–5 mg./kg.) exhibited at least some reduction in rigidity.

Centrally acting skeletal muscle relaxants are well known (7) for their preferential inhibition of polysynaptic reflex functions. This type of action is readily demonstrated in flexor-reflex preparations in which drug effects on monosynaptic and polysynaptic reflexes can be determined simultaneously. Dantrolene (0.25–10 mg./kg. i.v.) was studied in such preparations, and the results indicated that dantrolene had no preferential effect on polysynaptic reflex responses.

It was further demonstrated that dantrolene produced its effect on skeletal muscle without central actions (inhibition of polysynaptic transmission or otherwise) in the isolated perfused hindlimb of the dog in the cross-circulation preparation. Dantrolene (2.5 mg./kg.) was administered to the recipient dog and found to produce no effect (Table I) on either the sensory- or motor nerve-induced contractions. Mephenesin (30 mg./kg.) administered to the recipient dog for comparison inhibited contractions elicited *via* the polysynaptic pathway by 75%. Following mephenesin, when muscle contractions had returned to control levels (after 1 hr.), dantrolene (1.0 mg./kg.) was administered to the donor dog (periph-

Table II—Effect of Dantrolene, Tubocurarine, and Decamethonium on Denervated Rat Gastrocnemius Muscle

Compound	Dose, mg./kg. or ml./kg.	*n*	Percent Inhibition ± *SE*

Tubocurarine	0.05	6	4.0 ± 1.1
Decamethonium	1.0	6	61.3 ± 2.8
Saline control	1.0	3	0

eral) and the muscle contractions were reduced in the recipient dog by 63 and 84% at 1.0 and 2.5 mg./kg., respectively. This lack of effect in the recipient dog and the marked effect in the donor animals clearly demonstrated that only the peripheral elements of the twitch response were affected by dantrolene.

The peripheral elements of the twitch response were studied in the gastrocnemius muscle stimulated through its motor nerve (Fig. 2). There was a wide effective dose range that caused twitch inhibition, and the dose–response relations were unique for this type of preparation in that the dose–response curve plateaued at less than 100% inhibition of twitch. Increasing the dose of dantrolene to 50 mg./kg. (five times the maximally effective dose) did not increase the level of twitch inhibition.

The inhibition of the indirect twitch response produced by dantrolene was not unlike that produced by neuromuscular blocking agents. This was studied further by comparing dantrolene (0.3–15.0 mg./kg.) with the competitive antagonist tubocurarine (0.01–0.1 mg./kg.) and the depolarizing blocker decamethonium (0.5–15 mg./kg.). The responses at roughly equieffective doses (producing 40–60% level of twitch inhibition) are illustrated in Fig. 3. The time course of the development of the twitch inhibition was similar for all three agents, but the duration of action of the dantrolene was much greater (>2 hr.) than that produced by either tubocurarine (15 min.) or decamethonium (30 min.). Complete abolition of the twitch response was never accomplished with dantrolene at any dose, whereas it was readily accomplished with curare and decamethonium at 0.075 and 15 mg./kg., respectively.

Anticholinesterase agents potentiate the twitch response and antagonize the twitch inhibition induced by competitive neuromuscular blockers such as tubocurarine (20). They do not antagonize the effects of depolarizing blocking agents such as decamethonium (20). The twitch inhibition produced by dantrolene was found to be similar to that of tubocurarine in that physostigmine (an anticholinesterase agent) reversed the twitch depression for a short time (Fig. 4). After the addition of physostigmine, the twitch response steadily increased for 2 min., at which time the twitch height was at the predantrolene level. The physostigmine effects lasted for 80 min., when the twitch response returned to the dantrolene-treated level.

Physostigmine antagonism of dantrolene twitch depression indicated that dantrolene did not produce a depolarizing blockade like decamethonium and implied that dantrolene had anticholinergic properties. However, this anticholinergic character was not substantiated when the effects on denervated muscle were studied. Dantrolene and decamethonium inhibited the twitch response, while curare did not (Table II). (Vehicle control values are included for comparison because of the extreme sensitivity of the preparation to twitch inhibition by a variety of chemical agents.)

The effectiveness of dantrolene in denervated muscle indicated that it did not require neuromuscular transmission to produce its effects and that the reversal of the twitch depression by physostigmine was a physiological type antagonism. Greater quantities of acetylcholine, causing twitch potentiation, masked the dantrolene depression until the effects of the anticholinesterase had disappeared after 80 min. and dantrolene twitch depression was again evident.

The physiological antagonism by physostigmine and the lack of neuromuscular blocking properties pointed to a site of action of dantrolene that was beyond the neuromuscular junction. This post-neuromuscular junction action of dantrolene was tested in experiments with direct and indirect twitch responses in the same preparation. At a dose of 2.5 mg./kg. i.v., dantrolene inhibited the direct twitch response by 56.8 ± 7.6%, while the indirect twitch responses were attenuated by 57.1 ± 3.0%. Although stimulation of the muscle undoubtedly released acetylcholine from some nerve terminals, the responses were >70% direct (75–80% of the direct response remained in the totally curarized muscle). Equal inhibition of both responses confirmed that the blocking action of dantrolene was beyond the neuromuscular junction.

CONCLUSIONS

Dantrolene is a new type of skeletal muscle relaxant. It has a specific action on skeletal muscle that is beyond the neuromuscular junction. It represents a new class of skeletal muscle relaxants and should be a useful tool for studying skeletal muscle contraction mechanisms.

Hypocholesterolemic Agents II: Inhibition of β-Hydroxy-β-methylglutaryl Coenzyme A Reductase by Arylalkyl Hydrogen Succinates and Glutarates

MARVIN R. BOOTS*▲, SHARON G. BOOTS*, CAROLE M. NOBLE†, and KENNETH E. GUYER†

Abstract □ A series of arylalkyl hydrogen succinates and glutarates was synthesized and assayed for inhibition of yeast β-hydroxy-β-methylglutaryl coenzyme A reductase. The following compounds were found to be particularly active as inhibitors: 1-(4-biphenylyl)-pentyl hydrogen succinate (5S), 1-(4-biphenylyl)-hexyl hydrogen succinate (6S), 1-(4-biphenylyl)-pentyl hydrogen glutarate (5G), 1-(2-fluorenyl)-pentyl hydrogen succinate (13S), and 1-(2-fluorenyl)-pentyl hydrogen glutarate (13G). Further studies with Compound 5S indicated that the inhibition was reversible and noncompetitive with respect to β-hydroxy-β-methylglutaryl coenzyme A and NADPH. Dixon and modified Hill plots were used to calculate a cooperativity number of 3 for 5S.

Keyphrases □ Arylalkyl hydrogen succinates and glutarates—synthesis, inhibition of yeast β-hydroxy-β-methylglutaryl-CoA reductase □ β-Hydroxy-β-methylglutaryl-CoA reductase—inhibition by arylalkyl hydrogen succinates and glutarates □ Inhibition of yeast β-hydroxy-β-methylglutaryl-CoA reductase—synthesis and evaluation of arylalkyl hydrogen succinates and glutarates □ Hypocholesterolemic agents—inhibition of β-hydroxy-β-methylglutaryl-CoA reductase by arylalkyl hydrogen succinates and glutarates

Atherosclerosis and its complications constitute a growing problem in public health. Although the term atherosclerosis is ill defined (1), it is generally agreed to include lipid accumulation within the arterial intima as one of its early causative factors.

The discovery of cholesterol in atherosclerotic arteries (2) coupled with the observation of experimentally induced atherosclerosis after cholesterol feeding (3) provided some of the first indications of the implication of cholesterol in atherosclerosis and a suggestion of its causative role.

Because of the importance attached to the plasma cholesterol level in atherosclerosis, many approaches (4, 5) have been investigated to control it. These methods may be summarized as: (*a*) decreased ingestion of cholesterol, (*b*) decreased absorption of cholesterol, (*c*) increased conversion of cholesterol to bile acids, and (*d*) decreased synthesis of cholesterol.

The inhibition of the endogenous cholesterol synthesis could lead to a lowering of the serum level. A brief outline of the biosynthetic pathway is shown in Scheme I.

The specific step of the biosynthetic pathway to be inhibited or blocked is an important factor (6). Inhibition of the first portion of the pathway (acetyl-CoA → acetoacetyl-CoA) is not desirable because acetoacetyl-coenzyme A (CoA) is involved in fatty acid biosynthesis. Antimetabolites related to acetoacetyl-CoA would possibly tend to inhibit fatty acid biosynthesis as well as β-hydroxy-β-methylglutaryl-CoA synthesis; thus the earliest feasible step for control would appear to be the conversion of β-hydroxy-β-methylglutaryl-CoA to mevalonic acid. Later possible sites of inhibition would involve the reaction sequence between mevalonic acid and squalene. However, it appears that any site after mevalonic acid requires almost a complete enzyme inhibition to affect significantly overall cholesterol biosynthesis (7). If the pathway is blocked after squalene synthesis, large amounts of the intermediate accumulate since the reactions after β-hydroxy-β-methylglutaryl-CoA synthesis are irreversible. This accumulation has led to serious toxic effects, as in the case of triparanol (6).

Thus, the conversion of β-hydroxy-β-methylglutaryl-CoA to mevalonic acid seems to be the ideal

point for the inhibition of cholesterol biosynthesis. The selection of this step is based on the following reasons:

1. All reactions prior to mevalonic acid synthesis are either reversible directly or reversible through other enzymatic pathways. Therefore, the problem of accumulation of intermediates is eliminated.

2. This conversion is the rate-limiting step in the synthesis of cholesterol.

3. The physiological regulation of hepatic cholesterogenesis appears to be the result of a feedback inhibition of this step (8, 9) by cholesterol or a lipoprotein containing cholesterol by decreasing the amount, rather than simply the activity, of β-hydroxy-β-methylglutaryl-CoA reductase (10).

The enzyme β-hydroxy-β-methylglutaryl-CoA reductase (E.C.1.1.1.34), which catalyzes this step, is readily available from yeast (11, 12). This enzymatic reduction can be measured spectrophotometrically and thereby provides an *in vitro* assay.

Palazzo *et al.* (13) and Bizzi *et al.* (14) reported that arylalkyl hydrogen succinates and glutarates (I) exhibited hypocholesterolemic activity in rats and also markedly inhibited the *in vitro* incorporation of acetate and mevalonate into both cholesterol and fatty acids. These data suggest that multiple sites of inhibition are involved. The similarity of β-hydroxy-β-methylglutaryl-CoA to the inhibitors (I) in terms of a free carboxyl group, an esterified carboxyl group, and the distance separating these two functional groups suggests that one site of inhibition may be the conversion of β-hydroxy-β-methylglutaryl-CoA to mevalonic acid. Therefore, a series of arylalkyl hydrogen succinates and

glutarates (I) were prepared and assayed as inhibitors of the reductase.

The synthetic scheme for the inhibitors is shown in Scheme II. Treatment of the appropriate Grignard reagent with an ethereal solution of a suitable aldehyde gave the desired alcohols (Table I). Acylation of the alcohols with succinic or glutaric anhydride in dry pyridine afforded the desired monoesters (Table II).

The monoesters[1] that failed to crystallize were chromatographed on silicic acid and characterized as their solid S-benzylthiuronium salts.

EXPERIMENTAL[2]

Preparation of Alkylarylcarbinols—The carbinols listed in Table I were prepared by treatment of the appropriate aromatic aldehyde with the required Grignard reagent. The preparation of 1-(4-biphenylyl)pentanol may serve as an example.

1-(4-Biphenylyl)pentanol (Compound 5)—The Grignard reagent was prepared from 4.1 g. (0.17 g.-atom) of magnesium turnings and 20 ml. (26 g., 0.192 mole) of *n*-butyl bromide in 100 ml. of ether. To the prepared Grignard was added dropwise, without heating or cooling, 25 g. (0.137 mole) of 4-biphenylcarboxaldehyde in 200 ml. of ether. The mixture was stirred at 25° for 45 min. after the addition was complete. A solution of saturated ammonium chloride, adjusted to pH 7 with ammonium hydroxide, was added dropwise with cooling until a heavy granular precipitate settled out. The mixture was filtered and the solvent was removed under reduced pressure to afford 29.5 g., 89%, of a white solid, m.p. 77–78°. Recrystallization from ethyl acetate–petroleum ether, b.p. 60–75°, afforded an analytical specimen, m.p. 78–79°. Table I lists the analytical data.

Preparation of Arylalkyl Hydrogen Succinates and Glutarates—The succinates and glutarates listed in Table II were prepared using a modification of the pyridine method described by Palazzo *et al.* (13). The preparation of 1-(4-biphenylyl)-pentyl hydrogen glutarate may serve as an example.

1-(4-Biphenylyl)-pentyl Hydrogen Glutarate (Compound 5G)—A mixture of 3.6 g. (0.015 mole) of the alcohol (Compound 5), 1.71 g. (0.015 mole) of glutaric anhydride, and 20 ml. of pyridine (distilled from and stored over barium oxide) was heated at reflux for 8 hr. The resulting solution was poured on an ice–hydrochloric acid mixture and then extracted with ether. The organic phase was washed twice with water and then twice with a 5% sodium hydroxide solution. The basic aqueous extract was acidified with a 5% hydrochloric acid solution and then was extracted with ether. The organic phase was washed with water, washed with a saturated sodium chloride solution, and then dried over anhydrous sodium sulfate. The solvent was removed under reduced pressure to give 2.9 g. of a colorless oil. The colorless oil was chromatographed on 50 g. of silicic acid. Elution with 20% ether–petroleum ether, b.p. 60–75°, afforded 2.5 g. of a colorless oil (Compound 5G), 46%. The NMR spectrum ($CDCl_3$) exhibited a 9:1 ratio of aromatic protons to the carboxyl proton, indicating the desired monoester. Analytical data were obtained for the solid monoesters, while the oily monoesters were characterized as their solid S-benzylthiuronium salts (Table II).

Preparation of S-Benzylthiuronium Salts—The method of Donleavy (15) was modified. To a solution of 0.17 g. (0.49 mmole) of 5G in 15 ml. of 95% ethanol was added 5.1 ml. of 0.095 *M* sodium hydroxide solution. To this solution was added 0.5 g. (2.4 mmoles) of 2-benzyl-2-thiopseudourea hydrochloride[3] in 5 ml. of hot 95% ethanol and then 20 ml. of water. The salt precipitated upon cooling to give 0.21 g. of a white solid. Two recrystallizations from ethyl acetate–petroleum ether, b.p. 60–75°, afforded an analytical specimen as white prisms, m.p. 122–123°. Table II lists the analytical data.

Enzyme Preparation—For the comparative inhibitor studies, β-hydroxy-β-methylglutaryl-CoA reductase was prepared from locally obtained baker's yeast[4] by the procedure of Durr and Rudney (11) as previously reported (12). The aqueous enzyme preparation was transferred to capped serum bottles and stored at −10° until used.

[1] The monoester 9S was characterized as an oil.

[2] Melting points, determined with a Thomas-Hoover capillary melting-point apparatus, are uncorrected. Microanalyses were performed by Galbraith Laboratories, Inc., Knoxville, Tenn. NMR spectra were obtained using a Varian A-60 NMR spectrophotometer.

14S	125	50	14G	125	50
15S	115	50	15G	130	50

[a] The inhibition index, I/S, equals the ratio of the nM concentration of the inhibitor to the nM concentration of substrate. The I/S ratios are reported for 50% inhibition unless the solubility properties of the inhibitor precludes this determination. If sufficiently soluble, a maximum ratio of 150 was used for compounds exhibiting a low order of inhibition. The $I/S_{10\%}$ ratios were determined by interpolation from a plot of percent inhibition *versus* log I/S ratio. At least three sets of duplicate determinations between 30 and 80% inhibition were used, and one set within 45–55% inhibition was used for confirmation.

Enzyme Inhibition—Enzyme activity was determined at 30° in a recording spectrophotometer[5] by measuring the decrease in absorbance at 340 nm. for the oxidation of NADPH (12). To each cell were added 1.6 ml. of 0.15 M NaH_2PO_4 (pH 7.0) containing 1 mM ethylenediaminetetraacetate, 0.2 ml. ethylene glycol monoethyl ether containing inhibitor, 0.5 ml. of a solution containing 6.8 mg. cysteine, 50 μl. reduced triphosphopyridine nucleotide (NADPH) solution containing 0.36 μmole NADPH, and 0.1 ml. enzyme solution (about 14 mg. protein/ml. in buffer). In control cells, ethylene glycol monoethyl ether was added without inhibitor. The absorbance was allowed to stabilize after stirring prior to adding 50 μl. of β-hydroxy-β-methylglutaryl-CoA solution containing 44 nmoles of *dl*-β-hydroxy-β-methylglutaryl-CoA (12) and stirring again.

Kinetic Studies—For the kinetic studies, a more highly purified enzyme was prepared from baker's yeast by a modification of the methods of Durr and Rudney (11) and Kirtley and Rudney (16) as reported previously (17). This procedure adds a 30–45% saturated ammonium sulfate precipitation and substitutes 1 mM dithiothreitol for cysteine.

Reversibility of inhibition by dialysis was also investigated. Various combinations of 5S, substrate, coenzyme, and enzyme were dialyzed for 6, 12, or 24 hr. against buffer; activity was compared to enzyme alone subjected to similar dialysis (Table IV).

RESULTS AND DISCUSSION

Thirty monoesters of succinic and glutaric acids were prepared and assayed as inhibitors of yeast β-hydroxy-β-methylglutaryl-CoA reductase (Table III). The compounds are composed of two series, the succinates (S) and the glutarates (G). This study involved the modification of the alcohol moiety of the ester function to determine what structural aspects were essential for activity. The complex alcohol moiety is composed of aromatic (R_1) and alkyl (R_2) groups (Structure I). To differentiate between the effects of the aromatic and alkyl groups, Compounds 1S–7S and 1G–7G were prepared and assayed. The aromatic group (R_1) was maintained as a biphenyl group with the alkyl group (R_2) being varied from hydrogen to hexyl. As the chain length is increased from R_2 = hydrogen to R_2 = *n*-hexyl, activity increases dramatically, with a maximum resulting when R_2 = *n*-butyl or *n*-pentyl (5S, 5G, 6G). In the glutarate series, the ethyl compound, 3G, begins to show

[5] Gilford.

Table IV—Dialysis of Enzyme in the Presence of Substrate, Coenzyme, and Inhibitor 5S[a]

	Hours of Dialysis: Experiment I, 6	Experiment I, 12	Experiment II, 12	Experiment II, 24
Control	100.0%	100.0%	100.0%	100.0%
Inhibitor (1.58 mM)	79.4	83.3	97.2	100.5
Inhibitor (1.58 mM), β-hydroxy-β-methylglutaryl-CoA (15.8 μM)	22.4	42.8	47.6	91.1
Inhibitor (1.58 mM), NADPH (144 μM)	80.9	93.3	104.7	94.2
Inhibitor (1.58 mM), β-hydroxy-β-methylglutaryl-CoA (15.8 μM), NADPH (144 μM)	34.0	51.7	68.8	102.1

[a] The indicated enzyme solutions containing 14.8 mg. enzyme were diluted to 6.0 ml. with phosphate buffer (pH 7.6) containing 1 mM dithiothreitol, mixed, incubated for 5 min. at 30°, and transferred to dialysis tubing. After dialysis at 5° against phosphate buffer (pH 7.6) containing 1 mM dithiothreitol for 6, 12, or 24 hr., enzyme activity was determined as before and calculated as a percentage of control activity (dialyzed without inhibitor, β-hydroxy-β-methylglutaryl-CoA, or NADPH).

reasonable activity ($I/S_{0.5}$ = 150), whereas the ethyl compound in the succinate series, 3S, indicates only minimal activity (I/S = 150, 16% inhibition). However, when R_2 = *n*-butyl in both series, 5S and 5G, the activities become equal. An additional methylene group, Compound 6S, fails to increase activity in the succinate series; in the glutarate series, Compound 6G, a slight decrease in activity results. A further increase of chain length of R_2 is precluded by solubility problems with Compounds 7S and 7G. Thus, it appears that a hydrophobic bonding area on the enzyme has such dimensions that it can accommodate a chain length up to

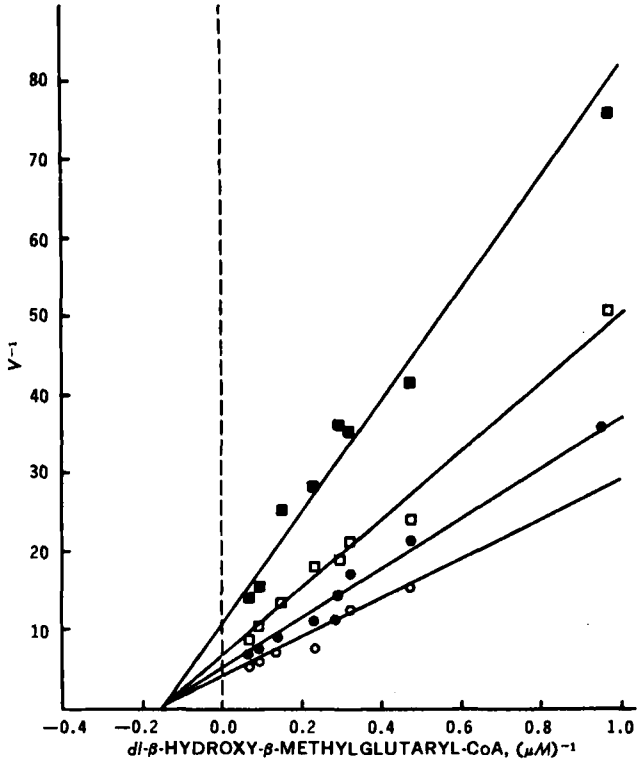

Figure 1—*Double-reciprocal plot of velocity* (ΔA_{340}/*min.*) versus *substrate concentration. All reaction mixtures consist of 7.4 mg. enzyme, 0.1 ml. ethylene glycol monoethyl ether, 2.4 ml. of 0.15* M *phosphate buffer containing 1* m*M dithiothreitol (pH 7.6), 0.36 μmole of NADPH, and varying amounts of substrate in a total volume of 2.5 ml. Key:* ○, *uninhibited;* ●, *0.79* m*M 5S;* □, *1.19* m*M 5S; and* ■, *1.58* m*M 5S.*

five carbon atoms.

The effects of the variation of the aromatic group (R_1) was investigated to determine if hydrophobic and electronic effects are important in binding of the inhibitor to the enzyme. The *n*-butyl chain (R_2) was retained in these inhibitors. The activity of Compounds 5S, 5G, 8S–10S, and 8G–10G appears to indicate that hydrophobic bonding is of primary importance in determining the degree of binding. As the hydrophobic bonding characteristics of the group (R_1) is increased (biphenyl > 3,4-dichlorophenyl > 4-chlorophenyl > phenyl), the activity of the monoesters increases. Coplanarity of the biphenyl group also appears to be important, as shown by the similar activity of the planar fluorenyl group, Compounds 13S and 13G, when compared to the biphenyl group, Compounds 5S and 5G.

In an attempt to determine if the position of attachment of the hydrophobic group (R_1) to the carbon atom bearing the ether oxygen of the ester was critical, the isomeric α- and β-naphthyl derivatives (11S, 11G, 12S, and 12G) were examined. No appreciable differences in activity were observed. An attempt also was made to detect electronic effects by evaluating positional isomers (14S, 14G, 15S, and 15G) containing an electron-donating substituent. This variation produced no significant change in activity.

In an effort to obtain more detailed information concerning the inhibition, Compound 5S was selected for additional studies on the type of inhibition, cooperativity, and reversal of inhibition by dialysis. From a double-reciprocal plot of velocity *versus* β-hydroxy-β-methylglutaryl-CoA (Fig. 1), it may be seen that the inhibition is noncompetitive with respect to substrate. A similar double-reciprocal plot of velocity *versus* NADPH (not shown) indicated that the inhibition is noncompetitive with respect to coenzyme as well.

A Dixon plot (18) and a modified Hill plot (19) were used to investigate cooperativity. A cooperativity number of 3 was calculated from the Dixon plot (Fig. 2) as well as a modified Hill plot (not shown). This is subject to a number of alternative explanations:

1. The enzyme molecules must combine with three molecules of inhibitor before any inhibition occurs.
2. The binding of one molecule of inhibitor to an enzyme molecule facilitates further binding of inhibitor to a total of three.
3. The molecules of enzyme which bind fewer than three molecules of inhibitor are quite unstable, either losing all of their bound inhibitor or binding up to their total of three.

Although subunits of this enzyme have not been reported, these data are compatible with an enzyme model consisting of subunits. However, subunits and their interactions are only one explanation of cooperativity.

It may be seen from Table IV that inhibition of the enzyme with inhibitor 5S is reversible by 24 hr. of dialysis. In the absence of substrate, however, inhibition is reversed in 12 hr. This would suggest the formation of a more stable ternary complex of enzyme, inhibitor, and substrate. The presence of NADPH appears to have little effect on the reversal of inhibition.

Biophasic Availability of Ophthalmic Carbachol I: Mechanisms of Cationic Polymer- and Surfactant-Promoted Miotic Activity

VICTOR F. SMOLEN[▲], JAMES M. CLEVENGER, EDWARD J. WILLIAMS, and MARK W. BERGDOLT

Abstract □ The influence of the topical application of cationic benzalkonium chloride and diethylaminoethyl dextran (mol. wt. $\simeq 2 \times 10^6$) adjuvants on the time variation of the miotic response intensity elicited by intraconjunctivally and intraaqueously administered carbachol was studied. The inclusion of either adjuvant in a 0.1% carbachol ophthalmic solution topically administered in the eye was observed to augment the miotic response activity attributable to direct transcorneal absorption into the biophase of the treated eye; the effect was nearly comparable to that achieved with similar dosing of a 2.0% solution containing carbachol alone. Simultaneous miotic activity in untreated control eyes of the rabbits, as well as other cholinergic side effects observed with the 2.0% carbachol solutions, did not occur with the 0.1% adjuvant-containing solutions, indicating that the enhanced local effects were not accompanied by a concomitantly promoted undesirable systemic absorption. The topical application of the adjuvants to the cornea following injection of the carbachol into the anterior chamber of the eye also appreciably promoted the miotic activity of the drug when it was administered by this mode. The principal mechanism of the observed adjuvant effects on carbachol biophasic availability is postulated as attributable to a promoted tissue permeability and release of the drug from corneal tissue binding sites; these occurrences result from an inductively implemented diminution of carbachol tissue binding affinities. The inductive effects originate and are propagated from fixed anionic corneal sites which interact with the cationic adjuvants. The impermeability of the cornea prevents the penetration of the adjuvant molecules to the deeper tissue layers where they could more directly influence carbachol tissue interactions.

Keyphrases □ Carbachol ophthalmic solutions—effect of cationic adjuvants on miotic activity □ Adjuvants, cationic—effect on miotic activity of carbachol solutions □ Miosis—effect of cationic adjuvants on carbachol activity □ Cationic adjuvant effect—miosis of carbachol ophthalmic solutions □ Ophthalmic solutions, carbachol—effect of cationic adjuvants on miotic activity □ Benzalkonium chloride—effect on miotic activity of carbachol solutions □ Diethylaminoethyl dextran—effect on miotic activity of carbachol solutions

Studies in this laboratory have been directed toward the elucidation of factors that influence the dynamic pharmacological response behavior of ophthalmic drugs (1–9) and the biophysical mechanisms by which they are operative (3, 6, 9). Since they are salutary to the development of an ultimate predictive capability with respect to the optimal control (7, 8) of drug response dynamics, quantitative treatments of observed phenomena in terms of pharmacokinetic and biophysical models have been developed and implemented whenever practicable. The requisite quantitative data have been derived from the implementation of two unique experimental methodologies, which allow results generally considered to be attainable only by destructive and *in vitro* techniques to be derived *in vivo* under normal physiological drug product use conditions without causing any injury. These methods thereby allow repeated measurements to be performed on the same subjects which can also serve as their own control. These techniques include a pharmacological method of drug absorption analysis (1–8, 10, 11) and a bioelectrometric method (9, 12–18) for the study of drug and other solute interactions with tissues or any other electrolytically conducting materials.

The bioelectrometric technique permits the determination of adsorption isotherms (12, 18) to describe drug–tissue interactions and the performance of kinetic studies of sorption and desorption (12, 18); the results can be quantitatively characterized in terms of thermodynamic and kinetic parameters (9, 12, 14, 18). The interpretation of results provided by the bioelectrometric method, concerning the dependency of the fixed-charge density of tissue surfaces on the composition of applied drug formulations, provides valuable insights into the submolecular mechanisms operative in drug–tissue interactions and transport across biological barriers; such information is generally unattainable by other techniques.

The use of transformed temporal pharmacological data (10) coupled with conventional pharmacokinetic approaches and/or techniques of engineering systems analysis and optimization (7, 8) provides a powerful approach to performing drug absorption analysis (1–5). The use of pharmacological data, as contrasted to the use of direct assay data derived by chemical or radiological assay, in addition to allowing the time course and rates of cumulative amounts of drug absorbed systemically to be determined, also permits the biophasic availability of the drug, *i.e.*, the amounts of drug that gain access to their sites of action, to be studied for any route of administration. The capability to compute the time course of drug absorption to a vicinal biophase adjacent to a site of topical administration, as well as the drug absorption profile for the quantities of drugs that simultaneously become systemically absorbed, renders this approach particularly valuable for ophthalmic drug bioavailability studies (1–6). Similar to the bioelectrometric method for the study of drug–tissue interactions, the use of pharmacological data for the study of drug transport is nondestructive and noninvasive.

The present report is the first of a series concerned with the kinetics and mechanisms of the biophasic availability of ophthalmically administered carbachol. Carbachol is an effective drug for the treatment of glaucoma. The seemingly erratic and sensitive dependency of its pharmacological response behavior on the formulation of the ophthalmic vehicle has contributed to its not being more commonly employed. However, it was hypothesized that the same and similar formula-

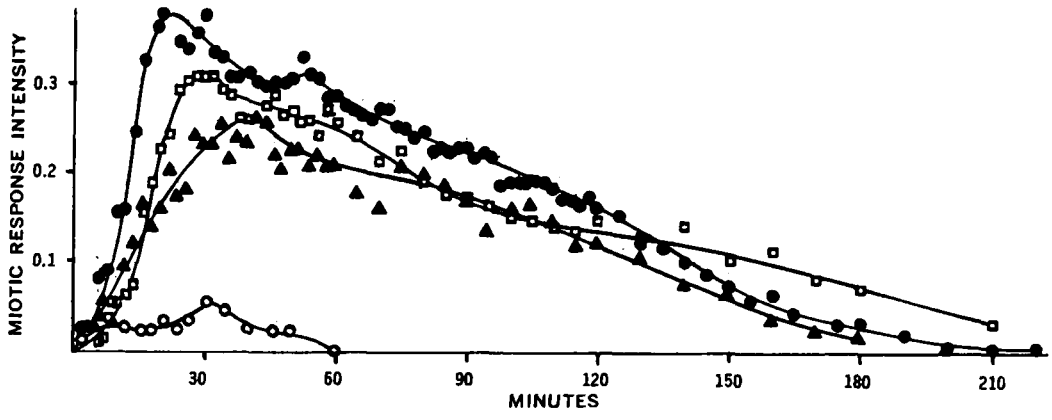

Figure 1—*Time variation of miotic response intensity following topical administration of 0.1 ml. of 0.1% carbachol (○), 2.0% carbachol (●), and 0.1% carbachol solutions containing 0.02% benzalkonium chloride (▲) and 0.06% diethylaminoethyl dextran (□). Each point represents the average of four replications performed on separate rabbits.*

tion factors to those responsible for the apparent erratic response behavior of ophthalmic carbachol, when properly understood, could conceivably provide the means by which to implement an optimal predictive control of the pharmacological response dynamics; this capability would permit a rational approach to the design of carbachol ophthalmic vehicle formulations.

The present report describes the results of relatively simple preliminary experiments concerned with the gross mechanistic nature of the very appreciable enhancement of the miotic activity observed to be induced by the inclusion of benzalkonium chloride (I) and diethylaminoethyl dextran (II) in carbachol ophthalmic vehicles. Subsequent reports will describe the quantitation of such results through the implementation of the bioelectrometric technique and the pharmacological method of drug bioavailability analysis.

EXPERIMENTAL

Materials—The ophthalmic solutions containing carbachol[1], I[2], and II[3], which were employed for topical and/or intraaqueous administration to the eye, were each prepared in a pH 7.4, isotonic phosphate buffer containing 0.1884 g./l. $NaH_2PO_4 \cdot H_2O$, 1.8293 g./l. $Na_2HPO_4 \cdot 7H_2O$, and 7.8910 g./l. NaCl. Distilled water was used and all the inorganic components were of reagent grade. The cationic dextran polymer has a supplier-reported molecular weight of approximately 2×10^6. The molecular weight of I was determined in this laboratory as 370 and 370.2 by UV spectrophotometry and chloride electroanalysis, respectively. It possessed a critical micelle concentration, determined by a liquid junction potential technique (19), of 8×10^{-4} *M*. The carbachol was at least USP grade. The solutions were prepared fresh prior to experimentation.

The apparent equivalent weight of the cationic polymer, II, was determined from Donnan potential measurements to have a value of 704 g. per equivalent of charge. The method involved separating a 5% (w/v) solution of II in pH 7.4 buffer from the buffered vehicle itself across a dialyzing membrane[4]. Dialysis equilibrium was achieved by storing the dialysis cell arrangement in a 37° water bath for 30 hr. with constant agitation until the Donnan potential, measured with a digital pH/voltmeter[5] using saturated calomel electrodes[6], became constant. The concentration of cationic charge in the solution resulting from the polymer and its equivalent weight was computed using previously reported (9, 12) theoretical expressions. By using these results, the 0.06% (w/v) II solution used in the present studies may be computed to be 8.5×10^{-4} *N* in polymer-contributed cation c charge. The normalities of the 0.02 and 0.03% I solutions are 5.4×10^{-4} and 8.1×10^{-4} equivalents of cationic charge per liter, respectively.

Approximately 4-month-old, male, New Zealand white rabbits, weighing 3.3–3.6 kg., were used as experimental animals. Twenty rabbits were screened on the basis of their similitude in pupillary accommodation to varying light intensity, magnitude of peak miotic response to test doses of carbachol administered intravenously, and clarity of pupil definition. Four of the rabbits were selected for use in the study.

Topical Administration to the Eye—The solutions administered intraconjunctivally to the rabbits contained 0.1 or 2.0% carbachol or 0.1% carbachol with 0.03% I or 0.06% (w/v) II. Solutions of 0.03% I and 0.06% II alone were also administered topically following intraaqueous dosing with carbachol.

Topical doses of 0.1 ml. of solution were instilled into the rabbit's eye using a 1.0-ml. syringe; the lower eyelid was retracted from the cornea and the solution was dropped into the conjunctival sac. The eyelids were held closed for 30–45 sec. following instillation to keep the rabbit from blinking, thereby preventing a large initial loss of the solution from the eye.

Intraaqueous Administration of Carbachol—Approximately 1 ml. of a 1%, isotonic, xylocaine solution[7] was dropped into the rabbit's eye to anesthetize the cornea. A 4-mcg./kg. dose of carbachol, contained in volumes of 0.05% (w/v) solutions ranging between 0.020 and 0.029 ml., was carefully injected through the cornea into the anterior chamber of the right eye. A similar injection of the same volume of solution vehicle alone provided a control. The influence of the adjuvants was studied by the topical instillation of 0.1 ml. of the 0.03% I or 0.06% II solution immediately following the intraaqueous injection.

Miotic Response Monitoring—The details of monitoring the time variation of pupillary diameters following dosing of rabbits were reported previously (1, 2). Briefly, however, the rabbits were restrained in a box during the procedure in which the diameter of the pupil was measured with a vernier caliper supported at a constant distance from the eye. A standard initial value of 4.5 mm. was obtained by adjusting the light intensity produced by two microscope lamps[8] using a rheostat. Subsequently, the eye was illuminated only during the time of the measurements (30–45 sec.) to avoid accommodation of the pupil to the light. The minimum pupil diameter during the period of illumination was recorded along with the time at which it was observed. Experience has demonstrated that this procedure, coupled with screening the rabbits prior to their selection for the study, considerably decreases both intrasubject and intersubject variations in the results. The miotic response intensity, I, was computed as: $I = 1 - (d_t/4.5)$, where d_t is the pupillary response at time t following dosing, and the value of 4.5 refers to the millimeter value of the pupillary diameter at time zero. The overall average relative error in the values of I obtained in this study is less than 6%. Since the variation in replicate experiments performed on the same animals was of the same magnitude as for replicates performed on different rabbits, results from different animals could be combined as averages.

RESULTS AND DISCUSSION

Adjuvant-Promoted Miotic Activity of Topically Administered Carbachol—Figure 1 presents the results of monitoring the time variation of miotic response following intraconjunctival administration. The results represent the averages of four replications performed on separate animals. The lowest curve depicts the miotic activity observed following the administration of 0.1% carbachol, which may be compared to the approximately eightfold increase in peak response intensity observed with an equal volume dose of a 2.0% carbachol solution. The middle curves demonstrate the influence of the inclusion of 0.02% I or 0.06% II in the ophthalmic solutions. The response *versus* time profiles clearly demonstrate the appreciable enhancement of miotic activity induced by the relatively small concentrations of these cationic adjuvants. Concentrations of II other than 0.06% were not studied. However, increasing the concentration of I beyond 0.02% up to 0.04%, which was the maximum level studied, causes further, although less pronounced, enhancement to the point where the response to the 0.1% carbachol solution is approximately tantamount to the results of administering the 2.0% carbachol solution alone. The details of all results with I will be presented in a subsequent report in the present series. It may be expected that an increase in the concentration of II would behave similarly to I in augmenting the response.

Except for topical dosing with the 2.0% carbachol solution without adjuvants, which produced a peak response in the left eye of 0.055–0.06 unit and a duration of approximately 100 min., the 0.1% carbachol solutions with and without adjuvants did not elicit any miotic activity in the left eyes of the rabbits used as carbachol-untreated controls. This observation and the observed relative lack of other systemic effects clearly indicate that the adjuvant-induced promotion of the pharmacological activity is attributable to an enhanced transcorneal biophasic availability directly to the sites of action as compared to an increase in the systemic bioavailability as can occur through schleral absorption, aqueous flow, and volume loss through the lacrimal-nasal drainage duct (3, 5, 6). By the latter routes, the drug enters the systemic circulation prior to gaining access to its biophase. Such systemic absorption is obviously undesirable because of the cholinergic side effects that can result from the systemic presence of carbachol. Inclusion of the adjuvants in the topically administered 0.1% carbachol solutions induced a local pharmacological activity nearly equivalent to the 2.0% carbachol, without apparent systemic activity. The significance of this observation with respect to the possibilities for the formulation of both safer and more effective carbachol ophthalmic preparations is apparent.

Adjuvant-Promoted Miotic Activity of Intraaqueous Injected Carbachol—Figure 2 presents the average results of the intraaqueous administration of 4-mcg./kg. doses of carbachol alone (lower curve) and the same dose followed by the topical administration of 0.1 ml. of 0.03% I (upper plot). Intraaqueous dosing results similarly obtained with the topical administration of II are shown in Fig. 3. In each case, a peak miotic response intensity was observed within 2–4 min. following dosing, after which an initially rapid decline in effect was apparent. The effects of the treatment with intraaqueous carbachol alone continued to diminish in a second phase, appearing between approximately 5 and 10 min., during which the decay was considerably slower. However, the miotic response observed in adjuvant-treated eyes again rose to a secondary maximum and plateau for a prolonged period in excess of the 180-min. interval over which the miotic activity was monitored. The pattern and magnitude of the influence of I and II were similar. Although the molar concentrations of I and II solutions are quite different, their normality with respect to cationic charge is nearly the same.

Mechanisms of Adjuvant-Promoted Miotic Activity—The topical application of the cationic adjuvants to the cornea has been demonstrated by the discussed results to augment the miotic activity of both topically and intraaqueously administered carbachol. Nonspecific physical mechanisms operative at the corneal surface—such as an increased viscosity of the vehicle or a Donnan exclusion effect which may be expected to be imparted by the positively charged polymeric II, or a lowering of surface tension attributable to the inclusion of the surface-active I—which could conceivably contribute to promoting the transcorneal absorption of carbachol following topical dosing, cannot reasonably be considered responsible for the enhanced activity observed following intraaqueous administration. Any explication in terms of a principal mechanism common to both routes of administration must obviously account for apparent transmission of the influence of the adjuvants through the thickness of the cornea to effect the disposition of the bolus of carbachol injected directly into the anterior chamber in such a manner as to promote the availability of pharmacologically active drug to its sites of action. The adjuvants themselves are miotically inactive; any appreciable penetration of the adjuvants across the minute lesional area in the periphery of the cornea resulting from the needle puncture may be considered as unlikely. The permeation of the highly charged II, possessing a molecular weight of approximately 2 million, across the corneal barrier to influence directly the interaction of carbachol with deeper tissue structures and thereby effect its disposition is untenable.

As a remaining alternative, it may be hypothesized that it is not necessary for the adjuvant molecules themselves to be physically transported into and through the cornea to effect changes in the nature of the interaction of carbachol with affected tissue structures; it is only required for the cationic adjuvants to interact with anionic corneal tissue surface sites. Such interactions can allosterically operate to induce changes which are inductively propagated (20, 21) by delocalization of mobile electrons to neighboring sites and deeper tissue levels where they alter tissue binding affinities for carbachol. These changes, in turn, result in the release of free, pharmacologi-

cally active drug. Although this postulation concerning the propagation of seemingly ethereal influences over relatively long ranges through tissues may initially appear highly speculative, it is consistent with theoretical considerations appearing in reports by other investigators (20–25) as well as from this laboratory (12, 13, 15, 16, 18). A further discussion and the details of experimental results which lend considerable credence to this hypothesis will be presented in subsequent reports. Briefly, however, it was found through the application of the pharmacological method of drug absorption analysis that larger quantities of carbachol were computed to be ultimately absorbed following topical administration with adjuvant-containing vehicles than were actually contained in the volume of solution with which the rabbits were dosed. This obviously violates the requirement for material balance. This anomaly does not occur when carbachol is administered alone, suggesting that the adjuvants act to displace and/or cause a release of tissue-bound, miotically inactive, carbachol from tissue binding sites. This action of the adjuvants is manifest in a lesser "apparent volume" of distribution; therefore, a higher concentration of free carbachol is available to its sites of action relative to that occurring in the absence of the influence of the adjuvants.

The above phenomenon may be further understood by considering an analogy to drug binding to plasma proteins. The volume of the plasma compartment computed as the ratio of an amount of drug known to be present in the plasma to the concentration of free drug for an extensively protein-bound drug will be determined as quite large. An adjuvant-induced release of the drug from its binding sites will obviously cause an increased free concentration of drug. When this concentration is multiplied by the value for an apparent volume of distribution determined in the absence of the adjuvant effect, values of apparent quantities of drug in excess of those which may be known to be actually present will be obtained. This is, in effect, analogous to what was observed with carbachol. The results of applying the bioelectrometric method to the study of adjuvant and carbachol interactions (to be reported later) also clearly imply further evidence that binding of cationic adjuvants to anionic corneal surface sites can profoundly influence the extent to which gangs of other anionic sites are occupied by cationic sorptates such as carbachol. Briefly, the results reveal a complex behavior in which I was observed to: (*a*) create new anionic tissue binding sites for carbachol through causing a cooperative, all-or-none type, deprotonation and/or release of other cations, *e.g.*, Na^+ and K^+, which can normally occupy these sites, (*b*) compete with carbachol for tissue binding sites, and (*c*) cause a sudden release of carbachol, as well as possibly other cations. This release occurs over nearly undiscernably small concentration ranges; such behavior is characteristic of cooperative mechanisms (21). The contribution of each of these phenomena to the tissue interaction behavior at any time was found to be dependent upon the relative magnitudes of carbachol and I concentrations simultaneously present.

SUMMARY AND CONCLUSIONS

In summary, the mechanism of the adjuvant effects is tentatively postulated on the basis of the present evidence as follows. Carbachol enters the corneal tissue through its surface following topical administration or back-diffuses into the cornea after intraaqueous dosing; the carbachol strongly binds to the tissues to a considerable extent. The bound, miotically inactive, drug could serve as a reservoir to prolong the activity, except that, under normal circumstances in the absence of adjuvants, the strongly bound drug is released too slowly to induce or contribute appreciably to observable levels of pharmacological activity. The interaction of the cationic adjuvants with anionic corneal surface sites results in the competitive displacement of bound carbachol from the surface and a diminution in the affinities of surface and deeper tissue binding sites. There is also a probable enhancement of the permeability of carbachol through the cornea (21). These effects permit the existence of relatively higher concentrations of the free drug to be available to its site(s) of action.

It is particularly notable that the observed adjuvant-induced augmentation of the miotic response activity apparently occurred by a promoted transcorneal absorption route rather than an enhanced systemic availability, which appeared to remain unaffected. The significance of this observation resides in an ability to formulate safer carbachol ophthalmic preparations using smaller concentrations of the drug, with a resulting diminution in systemic side effects; this can be accomplished without impairing the ophthalmic potency of the formulations.

Esters of Hydantoic Acids as Prodrugs of Hydantoins

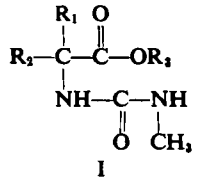
V. STELLA* and T. HIGUCHI▲

Abstract □ Hydantoins used as drugs possess low water solubility, which has led to erratic absorption patterns and dissolution patterns and possible precipitation in the blood after intravenous infusions of solutions of their sodium salts. The aim of this investigation was to elucidate the chemistry, physical properties, and pharmacological activity of some more water-soluble derivatives of hydantoins to determine the feasibility of their use as prodrugs. Various esters of the hydantoic acids of mephenytoin and 3-methylphenytoin were prepared and found to be quantitatively converted to the respective hydantoin under neutral to basic conditions. The β-*N'*,*N'*-diethylaminoethyl esters, in particular, were soluble in water up to pH 8 (presumably in the protonated form) and were converted to the respective hydantoin at pH 7.4 and 37°, with half-lives of under 20 min. At 25° and pH 6.0, the esters were stable for a few hours. An animal study using mice to test for anticonvulsant activity of the esters after intraperitoneal injection gave encouraging results (ED_{50} = 60 mg./kg., LD_{50} = 600 mg./kg.). The results suggested that β-*N'*,*N'*-diethylaminoethyl esters of hydantoic acids were candidates as water-soluble prodrugs of the respective hydantoin.

Keyphrases □ Hydantoic acid esters—evaluated as potential hydantoin prodrugs □ Hydantoin prodrugs—evaluation of water-soluble hydantoic acid esters □ Prodrugs for hydantoins—evaluation of water-soluble hydantoic acid esters

A number of hydantoins, including phenytoin, mephenytoin, and nitrofurantoin, are widely used as drugs. Their medical and veterinary usages, however, have been hampered by their low water solubility combined with their weakly acidic nature. Phenytoin, for example, has shown erratic absorption patterns and dissolution patterns as well as possible precipitation in the body after intravenous infusions of highly alkaline solutions of its sodium salt (1–4). Gastric upset associated with oral doses of sodium phenytoin similarly may be due to this necessary high alkalinity of aqueous solutions of the salt form.

The aim of this investigation was to determine the feasibility of obtaining transient prodrug (5) forms of these drugs which would confer acceptably high water solubility within the physiological pH range but convert to the desired active structure within the body system. Results obtained based on various esters (I) of the



I

R_3 = alkyl (simple esters) or $-C_2H_4N(C_2H_5)_2$ (amino esters)

respective hydantoic acid of the hydantoin, especially those esters that have an ionizable amino group in the alcohol portion of the ester grouping, are reported at this time. Esters of hydantoic acids are known to cyclize *via* an intramolecular reaction under basic conditions to their respective hydantoin (Scheme I), but no actual kinetic data are available. Kinetic data are available, however, on the cyclization of esters of the related *o*-ureidobenzoic acid under aqueous conditions in the neutral to alkaline pH range (6). Intramolecular cyclizations have been postulated as a means of latentiation by Levine *et al.* (7) in their work on the conversions of ω-haloalkylamines to their quaternary analogs. In the past, many derivatives of drugs formed through an ester linkage have been dependent on enzymatic reactions to release the parent compound (8, 9). Intramolecular reactions are known to be many thousand times faster than their intermolecular equivalent (10), forming a basis for the release of the parent compound at a speed that is not totally dependent on enzymatic mediation.

Table I lists the four esters investigated in the present study along with their compound numbers and formulas. Compounds IV and V cyclize to give mephenytoin, while II and III cyclize to give 3-methylphenytoin. Both mephenytoin and 3-methylphenytoin are anticonvulsant drugs.

EXPERIMENTAL

Equipment—A recording spectrophotometer[1] with a thermostated cell compartment capable of maintaining temperatures to ±0.1° was used for all spectroscopic measurements. The pH measurements were carried out using a research pH meter[2] standardized at 25° with phosphate buffer (pH 7.40 at 25°) and borate buffer (pH 9.18 at 25°). NMR spectra were measured on an NMR spectrometer[3].

Materials and Reagents—All chemicals used were of analytical or reagent grade. Mephenytoin was supplied commercially[4]. Buffers were made from triply distilled water and analytical grade phosphates and borates, with the ionic strength adjusted to unity with potassium chloride. Buffer concentration was 0.1 *M*.

The four esters were prepared *via* identical pathways. Analyses of the compounds are shown in Table II, and Table III gives some spectral data. An example of the synthetic procedure is listed here, and any differences associated with the synthesis of the other three esters are explained under the particular step.

Synthesis of V—*Step 1*—Ten grams (0.046 mole) of mephenytoin was placed in a plunging autoclave with 200 ml. of 20% NaOH under nitrogen. The mixture was heated at 180–190° for 24 hr., filtered through charcoal, and diluted to 500 ml. The solution was neutralized with glacial acetic acid and concentrated to 150 ml.

Table I—Hydantoic Acid Esters Studied with R_i (i = 1, 2, or 3) Referring to the Groups in Scheme I

Chemical Name	Compound Number	R_1	R_2	R_3
Ethyl 5-methyl-2,2-diphenylhydantoate	II	C_6H_5	C_6H_5	C_2H_5
β-N′,N′-Diethylaminoethyl 5-methyl-2,2-diphenylhydantoate	III	C_6H_5	C_6H_5	$C_2H_4N(C_2H_5)_2$
Methyl 2-ethyl-5-methyl-2-phenylhydantoate	IV	C_6H_5	C_2H_5	CH_3
β-N′,N′-Diethylaminoethyl 2-ethyl-5-methyl-2-phenylhydantoate	V	C_6H_5	C_2H_5	$C_2H_4N(C_2H_5)_2$

The crystalline material that precipitated was filtered and washed with 200 ml. of water and 200 ml. of ether. This gave a product of m.p. 288° dec., corresponding to 2,2-ethylphenylglycine (VI) [lit. (11) m.p. 275° dec.]. The yield was 5.5 g.

Step 2—Three grams (0.017 mole) of VI was dissolved in 30 ml. of 1 *N* NaOH. An excess of ethyl chloroformate (5 g., 0.047 mole) was added dropwise to this solution, while the pH of the solution was maintained alkaline by the addition of sodium hydroxide pellets. The solution was allowed to stir until no odor of ethyl chloroformate was detectable. After extraction with 2 × 50-ml. portions of ether (to remove any ether-soluble impurities), the aqueous layer was acidified with hydrochloric acid and again extracted with 4 × 50-ml. portions of ether. After drying over magnesium sulfate, the second ether extraction was evaporated by a rotary evaporator for 1 hr. Fifteen milliliters of benzene was added and warmed to complete solution. *n*-Hexane was added dropwise to cause cloudiness and precipitation of a white solid of m.p. 130–131° and a yield of 1.5 g. This was presumed to be *N*-ethoxycarbonyl-2,2-ethylphenylglycine (VII).

Step 3—Five milliliters of thionyl chloride was refluxed with VII (700 mg., 0.003 mole) for 1 hr. The excess thionyl chloride was removed by a rotary evaporator, leaving a yellow solid. The solid was taken up in benzene and precipitated with *n*-hexane, leaving a white compound of m.p. 99–101° and a yield of 550 mg. This was presumed to be 4,4-ethylphenyloxazolidinedione (2, 5) (VIII).

Step 4—To VIII (500 mg., 0.002 mole), freshly distilled diethylaminoethanol (400 mg., 0.003 mole) was added in a dry flask at 140°. An atmosphere of hydrogen chloride gas was passed over the melt. These conditions were maintained for 20 min. No product was actually isolated in this step.

If the ethyl or methyl esters were being prepared, VIII was refluxed in a solution of the appropriate alcohol which had hydrogen chloride gas passed through it.

Step 5—The syrupy melt of Step 4 was taken up in chloroform and extracted with 0.1 *N* NaOH and water. After drying, the chloroform layer was evaporated to 0.5 ml. and methylisocyanate was added (500 mg., 0.009 mole). The solution was allowed to stand for 20 min. and then evaporated to remove the excess methylisocyanate. The remaining oil was taken up in *n*-hexane and eventually precipitated as a solid of m.p. 83–87°. The solid was taken up in chloroform and extracted with 2 × 50-ml. portions of water. After drying and evaporating, the chloroform layer gave a white solid of m.p. 88–89°, corresponding by elemental analysis and NMR to β-N′,N′-diethylaminoethyl 2-ethyl-5-methyl-2-phenylhydantoate (V).

[a] All esters run in $CDCl_3$.

Kinetic Measurements—All kinetic measurements were carried out directly in the thermostated cell compartment of a recording spectrophotometer[1]. At the elevated temperatures, the buffer solution was placed in the cell compartment and allowed to equilibrate before the ester was introduced as a standard dioxane solution. For II and IV, the least water-soluble esters, the final concentration of dioxane was 5%; for III and V, the concentration of dioxane was 2%. The formation of the hydantoin was followed at 240 nm.; the rate constants were determined from plots of log ($A_\infty - A_t$) *versus* time, where A_∞ and A_t are the absorbance readings at infinity and at time t, respectively. Some rate constants were also determined by the Guggenheim (12) method. The closure rates in the presence and absence of horse serum cholinesterase[1], with a concentration of 2 mg./ml. of enzyme in pH 7.4 buffer, were followed directly in the cell compartment of the spectrophotometer.

Product Analysis—All of the esters gave their respective hydantoins on reaction with base. This was checked by spectral comparisons and TLC [solvent system of chloroform using microscopic slide technique (13)]. On heating in water, the four esters gave a near quantitative yield of the parent hydantoin.

Solubility Study—The solubility of the hydantoins and their derivatives in chloroform–carbon tetrachloride (1:3 v/v) at 25° was determined semiquantitatively using a gravimetric technique. The semiquantitative scale was necessary because of the small amounts of materials available. The partitioning of the esters and hydantoins between the chloroform–carbon tetrachloride nonaqueous layer and the pH 6.0 phosphate buffer was also estimated *via* the gravimetric technique by determining the amount of hydantoin or derivative in the nonaqueous layer before and after extraction with the aqueous buffer. The aqueous solubility of V and III in pH 6.0 phosphate buffer was estimated by placing 50-mg. fractions of the esters in 10 ml. of the buffer at room temperature until a saturated solution was obtained. This simple semiquantitative procedure was necessary, because even at 25° and pH 6.0 the esters are converted to their hydantoins with half-lives of under 10 hr.; since the hydantoins (the products of the reaction) are very water insoluble, they would show up as saturated solutions when only a simple observation was being used as the criterion for saturation.

Animal Studies—The animal studies presented here are not meant to represent a full comprehensive study but rather to show that the particular derivatives synthesized and studied in this work are, in fact, pharmacologically active and relatively nontoxic on a short-term scale.

[1] Sigma Chemical Co.

Table IV—Effect of Varying Borate Buffer Concentration on Cyclization[a] of IV at 25°, pH 9.0 (μ = 1.0)

Borate Concentration, M	k_{obs}, min.$^{-1}$
0.017	8.50×10^{-2}
0.029	8.65×10^{-2}
0.050	8.60×10^{-2}
0.100	8.16×10^{-2}
Average	8.58×10^{-2}

[a] k_2 for the cyclization of IV at 25° from the average value of k_{obs} at pH 9.0 is equal to 8.58×10^{3} M^{-1} min.$^{-1}$.

Random bred, albino, female mice, Ha/ICR, age 3–6 weeks, with an average weight of 11 g. (variation 8–15 g.), were obtained[6] and acclimatized for 3 days before use.

Toxicity Studies—Fifty mice were separated into lots of 10. Compound V was dissolved in a 0.1 *M* phosphate buffer of pH 5.9. The concentration of drug was such that when given intraperitoneally, ~0.1 ml. or ~0.2 ml. of the solution gave 100 mg./kg., 200 mg./kg., *etc.*, of drug; *i.e.*, all intraperitoneal injections were of 0.2 ml. or less. The animal weight was used to calculate what volume of solution was necessary to give the desired dose. With the first set of 10 animals, each animal received 100 mg./kg. of V. The second set was given 200 mg./kg. The other three sets were given 400 and 800 mg./kg. and the buffer solution, respectively.

Anticonvulsant Activity Tests—The ED_{50} anticonvulsant activity test is basically an electroshock test[7] where a supramaximal current of 20 ma. is applied across the ears of a mouse for 0.2 sec. to induce convulsion. Forty mice were separated into four sets of 10. Each mouse was submitted to the electroshock and any insensitive mice were discarded. All of the mice required severe resuscitation after the current was disconnected. The first set of mice was then given 50 mg./kg. i.p. of V, the second set 100 mg./kg., and the third set

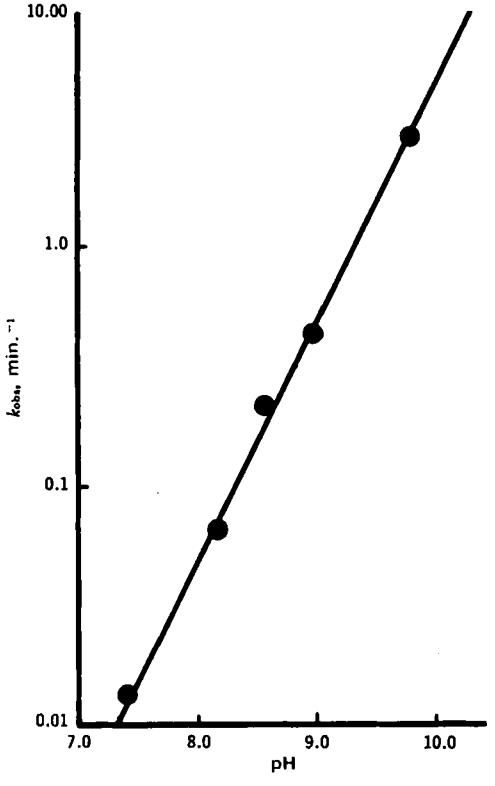

Figure 1—*Log* k_{obs} versus *pH profile for the closure of II at 37°* (μ = *1.0, with potassium chloride*).

0.029	1.48×10^{-1}
0.050	1.50×10^{-1}
0.100	1.46×10^{-1}
Average	1.48×10^{-1}

[a] k_2 for the cyclization of II at 25° from the average value of k_{obs} at pH 9.0 is equal to 1.48×10^4 M^{-1} min.$^{-1}$.

four esters cyclized *via* first-order kinetics to their respective hydantoins with the general reaction shown in Scheme II. All reactions were irreversible and complete, as evidenced by spectral comparisons, TLC, and near quantitative recovery of the hydantoins from boiling water solutions of the esters.

Plots of log k_{obs} *versus* pH for the cyclization of the four esters are shown in Figs. 1–4. For the simple esters, II and IV, plots of log k_{obs} *versus* pH (Figs. 1 and 2) gave straight lines whose slopes[b] were approximately one (0.98 and 0.96, respectively), suggesting that the reaction was first-order dependent on hydroxyl ions. For the amino esters, V and III, the plots (Figs. 3 and 4) were predictably nonlinear over part of the pH range studied but did approach linearity at the limits of the plots.

The rates of cyclization of all four esters were found to be buffer concentration independent at constant ionic strength (Tables IV and V), which, along with the log k_{obs} *versus* pH plots, suggest that like the esters of *o*-ureidobenzoic acid (6), the closures to the cyclic hydantoins are specific base catalyzed.

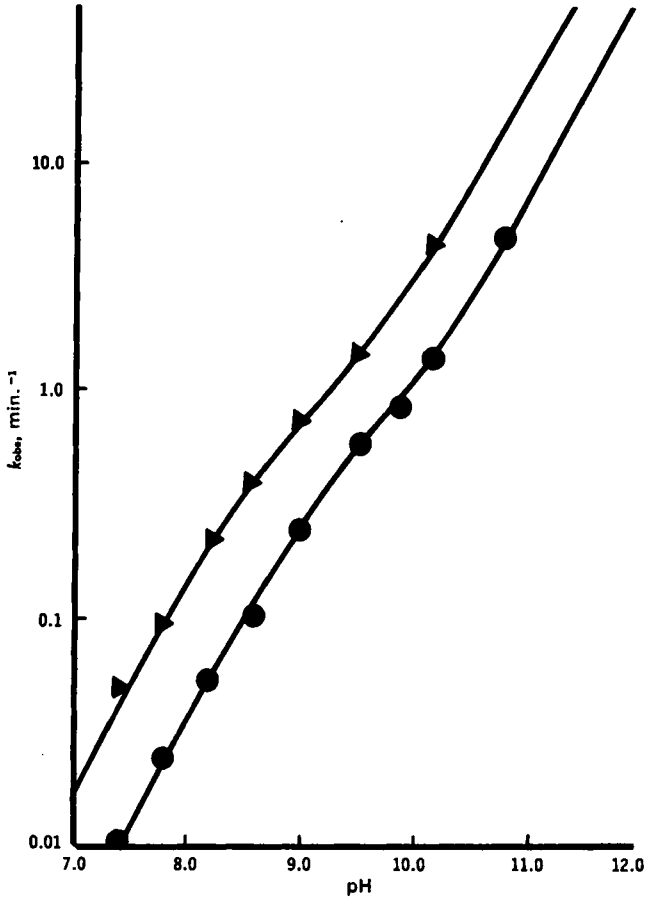

Figure 3—*Log* k_{obs} versus *pH profile for the closure of V at 25°* (●) *and 37°* (▲) (μ = *1.0, with potassium chloride*).

[b] Calculated by standard least-squares techniques, Olivetti Programma.

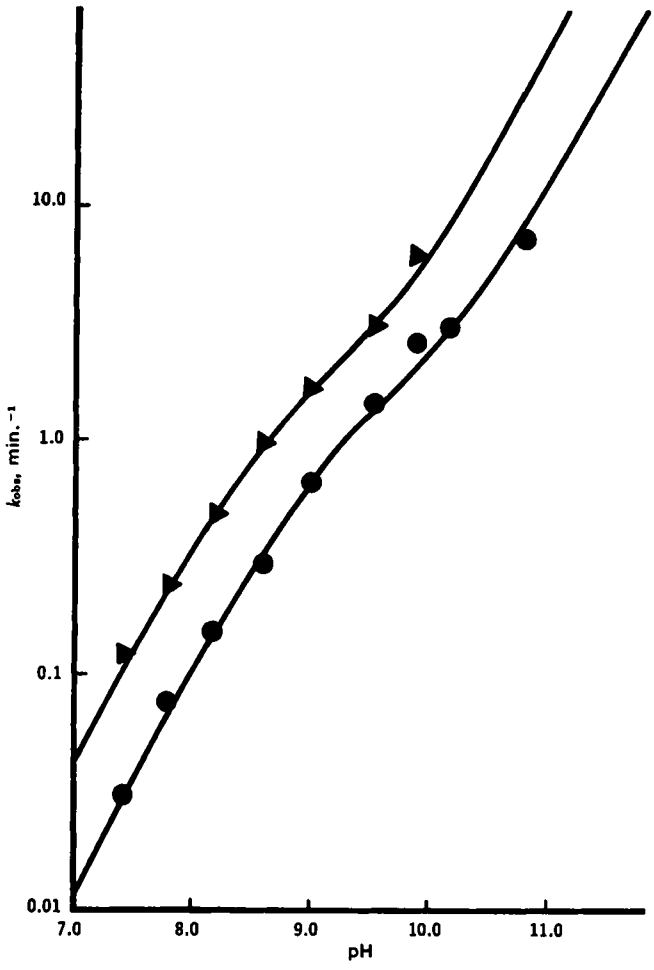

Figure 4—*Log* k_{obs} versus *pH profile for the closure of III at 25°* (●) *and 37°* (▲) (μ = *1.0, with potassium chloride*).

The results presented in Figs. 1–4 and Tables IV and V could be rationalized in terms of the general mechanistic Scheme II, where R_3 = alkyl or $-C_2H_4N(C_2H_5)_2$, and k_1' and k_2' are the spontaneous rate constants for the hydrolytic decomposition of X and XI.

The ionizations described by K_1 and K_2 are due to the microscopic ionization of the ureido group ($-NHCONHCH_3$) to the ureido anion ($-NHCON^-CH_3$). Both K_a and K_3 are due to the dissociation of the protonated amino group which can exist only for the amino esters; *i.e.*, Scheme II is complete for the amino esters but the terms IX, X, K_1, K_3, and K_a are all eliminated from Scheme II for the simple esters. If these terms are eliminated, then the rate of formation of the hydantoin, $d[P]/dt$, from the simple esters may be expressed as:

$$\frac{d[P]}{dt} = k_2'[XI] \quad \text{(Eq. 1a)}$$

$$= k_2'K_2[I]a_{OH^-} \quad \text{(Eq. 1b)}$$

$$= k_2a_{OH^-}[I] \quad \text{(Eq. 1c)}$$

where $k_2 = k_2'K_2$.

The total ester concentration is $[ester]_T = [I] + [XI]$, but since K_2 represents the ionization constant of the ureido group to the ureido anion and this constant is considered to be smaller than 10^{-14} (6), the term [XI] is negligible when compared to [I]. Therefore:

$$\frac{d[P]}{dt} = k_2[ester]_T a_{OH^-} \quad \text{(Eq. 2a)}$$

or:

$$k_{obs} = k_2a_{OH^-} \quad \text{(Eq. 2b)}$$

Since K_2 was not determinable, the results will be expressed in terms of k_2. The a_{OH^-} and a_{H^+} used later refer to the activity of hy-

Table VI—Second-Order Rate Constants and Ionization Constants for the Cyclization of Esters II–V to Their Respective Hydantoins at 25 and 37° in Aqueous Solution (μ = 1.0)

Ester	Temperature	k_1, × 10^{-4} (M^{-1} min.$^{-1}$)	k_2, × 10^{-4} (M^{-1} min.$^{-1}$)	pKa
II	25°	—	1.48	—
	37°	—	2.00	—
IV	25°	—	0.86	—
	37°	—	1.52	—
III	25°	10.5	1.10	9.20
	37°	17.3	1.93	8.65
V	25°	3.82	0.64	9.25
	37°	6.70	1.01	8.75

droxyl ion and hydrogen ion, respectively, which were calculated from pH measurements. Equation 2*b* predicts that a plot of log k_{obs} *versus* pH will be linear with a positive slope of unity, which is consistent with the present findings.

For the amino esters (III and V), the rate equation was more complex:

$$\frac{d[P]}{dt} = k_1'[X] + k_2'[XI] = k_1'[IX]K_1a_{OH^-} + k_2'[I]K_2a_{OH^-} \quad \text{(Eq. 3)}$$

The total ester concentration is:

$$[\text{ester}]_T = [IX] + [I] + [X] + [XI] \quad \text{(Eq. 4)}$$

Since K_1 and K_2 represent the ionization constants of the ureido group (substituted urea) and are considered to be smaller than 10^{-14} (6), the terms [X] and [XI] are negligible compared to [IX] and [I]. The fraction of ester present as [IX], expressed as β, therefore, can be defined as:

$$\beta = \frac{[IX]}{[I] + [IX]} = \frac{a_{H^+}}{a_{H^+} + K_a} \quad \text{(Eq. 5a)}$$

$$\frac{[dP]}{dt} = [\text{ester}]_T \{k_1a_{OH^-}\beta + k_2a_{OH^-}(1 - \beta)\} \quad \text{(Eq. 5b)}$$

$$k_{obs} = k_1a_{OH^-}\beta + k_2a_{OH^-}(1 - \beta) \quad \text{(Eq. 5c)}$$

where $k_1 = k_1'K_1$, and $k_2 = k_2'K_2$.

Since K_1 and K_2 could not be determined, the results will be expressed in terms of k_1 and k_2. Equation 5*c* predicts that plots of log k_{obs} *versus* pH for the amino esters will be complex and nonlinear in the pH range where β does not approximately equal zero or one. The plot resulting from such an equation has been adequately described (14) and will not be discussed here.

The rate and equilibrium constants consistent with the experimental results are shown in Table VI. Variation of pKw with temperature was taken into account in the calculation of the rate and equilibrium constants. The solid lines drawn in Figs. 1–4 have been calculated by substituting the rate and equilibrium constants shown in Table VI into Eqs. 2*b* and 5*c*.

The rate constant k_1 has been defined by Scheme II and Eq. 5*c* as the second-order base-catalyzed rate constant for the attack of the ureido group on the protonated amino ester. However, its kinetic equivalent, the spontaneous attack of the neutral ureido group on the free base form of the ester, cannot be fully discounted.

In summary, the cyclization of esters of hydantoic acid in neutral to alkaline solution appears to be a specific base-catalyzed intramolecular closure, with the rate-determining transition state involving the attack of the ureido anion at the ester carbonyl group.

V	16.9	1710

[a] pH 7.4 and 37°. [b] pH 6.0 and 25°. [c] Estimated from Figs. 3 and 4 and Tables IV and V.

It appears that the diethylamino moiety helped increase the ester's rate of closure at pH's below the pKa of the amino group. For example, k_{III}/k_{II} at pH 7.40 and 37° is 8.5. This increased rate of closure over the simple esters and the free base form of the amino esters may be due to electrostatic stabilization of the negatively charged reaction center (see XII), although the possibility of intramolecular general acid catalysis cannot be discounted. The transition states for the esters where $-C_2H_4N^+(-H)(C_2H_5)_2$ is replaced by a simple alkyl group or $-C_2H_4N(C_2H_5)_2$ would be the same as XII, except that no electrostatic stabilization of the negative reaction center would be possible.

Hegarty and Bruice (6) recently demonstrated the intramolecular nucleophilicity of the ureido group. They showed a rate acceleration of 1.5 × 10^5-fold for the attack of the ureido group in the intramolecular cyclization of the methyl ester of *o*-ureidobenzoic acid to that of its intermolecular equivalent. The results and conclusion presented here are in perfect accordance with their findings.

Table VII shows the half-lives for the conversion of the four esters to their hydantoin at pH 7.4 and 37°, suggesting that at least under *in vitro* conditions the esters are quickly converted to their hydantoin, while at pH 6.0 and 25° the conversion is quite slow. This means that the esters could be used in a reconstitutable injection if they are water soluble. The solubility of the esters will be discussed later.

Because the derivatives appeared promising, a test was run to observe the effect of an esterase enzyme on the product and rate of cyclization of one of the esters, III. Horse serum cholinesterase[5] at a concentration of 2 mg./ml. in buffer solution did not affect the hydrolytic intramolecular closure of the ester. The $t_{1/2}$ values at pH 7.43 and 23.6° with and without enzyme were 31.1 and 31.9 min., respectively. The products of the two reactions, *i.e.*, with and without enzyme, gave the same final UV spectrum corresponding to 3-methyl-5,5-diphenylhydantoin. Of particular importance was the enzyme's inability to cleave the ester linkage before the intramolecular reaction was able to take place. The product of such a

Table VIII—Results of LD_{50} Study of V[a]

Dose, mg./kg.	Mortality, %	Observations
100	0	All mice acted quite normal with no observable toxic effects over 4 hr.
200	0	Slightly sedated and ataxic over 4 hr. but no critical effects.
400	0	After 1 hr., the mice were very ataxic and it did appear that a few of them may die. Their breathing appeared normal, but there was kicking of the hindlegs. After 4 hr., all the mice had recovered and appeared normal.
800	100	All mice died within 10–15 min. They became very ataxic, with increased breathing rate and kicking of the hindlegs, indicative of convulsions.
Buffer solution (no drug)	0	All mice appeared quite normal.

[a] The mice given III in the ED_{50} experiment at a dose of 25 mg./kg. appeared quite normal over a 3-hr. range with no obvious toxic effects.

reaction would have been the hydantoic acid, and the hydantoic acid under *in vitro* physiological conditions is closed very slowly to the hydantoin (15).

Solubility Studies—The order of solubility of the esters in chloroform–carbon tetrachloride (1:3 v/v) on a molar basis compared to the hydantoins was found to be amino ester (in the free base form) > parent hydantoin > simple ester. A study of the partitioning between chloroform–carbon tetrachloride (1:3 v/v) and 0.1 *M* phosphate buffer (pH 6.0) showed that very little of the hydantoin and the simple ester passed into the aqueous layer from the organic layer in which they were dissolved, whereas virtually all the amino ester did pass into the aqueous layer presumably in the protonated form. The aqueous solubility of V and III in 0.1 *M* phosphate buffer (pH 6.0) was estimated at 2 and 1% w/v, respectively. An accurate estimate could not be made because of the fast cyclization of the esters to the hydantoins. It appears, therefore, that the diethylamino moiety not only helped increase the esters' rate of closure under *in vitro* physiological conditions but also helped increase the aqueous solubility of the esters below their pKa.

Toxicity and Activity Studies—A problem that may arise when attempting chemical modification of a drug is that the derivative itself may possess increased toxicity or have a pharmacological effect of its own. The β-*N'*,*N'*-diethylaminoethyl moiety is found in a diverse group of compounds: local anesthetics, cholinergic drugs, antiasthmatics, and tranquilizers.

Table VIII shows the results of LD_{50} determinations on mice *via* intraperitoneal injections of V dissolved in 0.1 *M* phosphate buffer (pH 5.9). Table IX shows the results of an anticonvulsant activity ED_{50} determination on mice *via* intraperitoneal injections of V dissolved in the same buffer used for the LD_{50} determination. The results of one run using III at a concentration of 25 mg./kg. is also given.

The results displayed in Tables VIII and IX suggest that the ED_{50} of V against electroshock in mice after intraperitoneal injection is approximately 60 mg./kg. and its LD_{50} is between 400 and 800 mg./kg. For III an ED_{50} and LD_{50} could not be estimated; but at 25 mg./kg., 16% protection was observed. In the ED_{50} experiments with doses that gave only slight or no protection, the animals after convulsion did not require any resuscitation, whereas the mice not given the drug had to be revived for breathing to begin. This suggests that even at low doses the drugs were having an effect. Efforts to compare solutions of V and III with the parent hydantoins were not successful, because the hydantoins were not soluble in the buffer of pH 5.9. Suspensions of the hydantoin given intraperitoneally through a wide bore needle and tested for anticonvulsant activity after 1 hr. offered no protection, *i.e.*, the lack of protection against electroshock was probably due to the method of administration.

SUMMARY

The results of the present study showed that esters of hydantoic acids may be of use as prodrugs for the respective hydantoin. The β-*N'*,*N'*-diethylaminoethyl esters in particular showed superior physical properties to those of the parent hydantoin. Their cyclization rates, half-lives of under 20 min., under physiological conditions were unaffected by an esterase enzyme, and a preliminary animal study showed interesting and encouraging results. The amino esters may be of use as components of a reconstitutable injection, because their rate of cyclization and aqueous solubility at physiological pH would not lead to the precipitation in the bloodstream that was seen with the sodium hydantoin. Similarly, because solutions can be maintained at around neutral pH, the solution would be more compatible in intravenous infusions with other possible components of the infusion.

Normally, prodrugs formed through the formation of an ester linkage require enzyme mediation to regenerate the parent drug. Intramolecular nucleophilic ureido participation at an ester linkage has been shown to give a rate acceleration of 10^5-fold over the intermolecular equivalent. If the product of the intramolecular reaction happens to be the parent drug, then the acylic ester is a chemical modification whose closure rate is independent of the need of enzymatic mediation. In the present study, an ionizable group has been built into the alcohol portion of a hydantoic acid ester, giving it increased aqueous solubility and an increased rate of closure under physiological conditions. These desirable properties make V and III possible candidates as prodrugs of their respective hydantoin.

Hydrolytic Behavior of *N*-Acyl Phthalimides

V. STELLA* and T. HIGUCHI▲

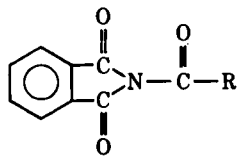
Abstract □ The hydrolysis of *N*-acyl phthalimides was studied to determine the effect of the *N*-acyl moiety on the hydrolytic rate and hydrolytic products, *i.e.*, whether hydrolysis leads to the regeneration of the parent phthalimide or to formation of the corresponding *N*-acyl phthalamic acid. A series of *N*-acyl phthalimides was prepared and their hydrolysis was observed in the neutral to alkaline pH range at 25°. It was found that *N*-acetyl-, *N*-propionyl-, *N*-(ethoxycarbonyl)-, and *N*-(morpholinocarbonyl)phthalimides gave their corresponding *N*-acyl phthalamic acid as their major hydrolytic product while *N*-chloroacetyl- and *N*-bromoacetylphthalimides gave phthalamide and the corresponding carboxylic acid. The change in path depending on the *N*-acyl group was rationalized in terms of the susceptibility of the appropriate carbonyls to attack.

Keyphrases □ *N*-Acyl phthalimides—hydrolysis, effect of *N*-acyl moiety on rate and formation of phthalimide parent or *N*-acyl phthalamic acid □ Phthalimides, *N*-acyl—hydrolysis, effect of *N*-acyl moiety on rate and formation of phthalimide parent or *N*-acyl phthalamic acid □ Hydrolysis of *N*-acyl phthalimides—effect of *N*-acyl moiety on rate and phthalimide or phthalamic acid products □ Imides (phthalimides)—formation by hydrolysis of *N*-acyl phthalimides

Imides form a group of compounds which have found wide use in the pharmaceutical and chemical industries. The major pharmaceuticals having the imide functionality within their structural formulas are glutethimide and thalidomide (sedatives), ethosuximide and phensuximide (anticonvulsants), bemegride (barbiturate antagonist), and a number of antibiotic, antiviral, and carcinostatic agents (1).

The present study was concerned with the hydrolysis of *N*-acyl phthalimides (I) and the possible use of acylimides as prodrugs of imides. The aim of the work was to observe the effect of the *N*-acyl moiety on the hydrolytic rate and hydrolytic products of *N*-acyl phthalimides, *i.e.*, whether hydrolysis leads to the regeneration of the imide or to formation of the corresponding *N*-acyl phthalamic acid. If *N*-acyl imides are to be considered for prodrugs of imides, they must regenerate the imide on hydrolysis.

The solvolysis and aminolysis of *N*-acyl cyclic imides under various conditions were the subjects of a limited number of studies (2–9), most of which were intended as observations of the acylating power of the acylated imides; however, no quantitative kinetic data were presented. There also appears to be some confusion as to the mechanism of reaction because the products vary depending on the nucleophile, solvent, and temperature of reaction.



I

R = alkyl, alkoxy, or amino

EXPERIMENTAL

Equipment—A recording spectrophotometer[1], with a thermostated cell compartment maintained at 25 ± 0.1°, was used for all kinetic and product measurements. NMR spectra were obtained using spectrometers[2] with all spectra run in $CDCl_3$. IR spectra were acquired using an IR spectrometer[3]. All pH measurements were obtained on a research pH meter[4] at 25°, standardized with standard phosphate and borate buffers.

Reagents and Materials—Dioxane and phthalimide were purified according to the method of Perrin *et al.* (10). All other chemicals were of analytical or reagent grade and were used without further purification. A TLC sorbent[5] was used. *N*-Ethoxycarbonylphthalimide (II) was obtained commercially[6], and all other phthalimide derivatives studied were synthesized.

Synthesis of *N*-Acetylphthalimide (III)—Five grams (0.034 mole) of phthalimide was dissolved in 25 g. (0.250 mole) of acetic anhydride. The solution was refluxed for 2 hr. and then fractionally distilled (30-cm. vigreux column). The first distillate was collected at 123° (acetic acid plus acetic anhydride), and the reaction was terminated when the distillate temperature rose to 138°. The residue was then taken up in toluene, hot filtered through charcoal, and, on cooling, diluted with 50 ml. of ether. The resulting white precipitate was recrystallized three times from the toluene–ether mixture to give a solid of m.p. 136–137° [lit. (11) m.p. 135–136°]. NMR showed a symmetrical A_2B_2 pattern at 7.92 and 7.98δ (four protons) and a singlet at 2.69δ (three protons), confirming *N*-acylation. The IR spectrum gave a large peak area between 1800 and 1600 $cm.^{-1}$, and the UV spectrum gave peaks at 270 and 295 nm.

Synthesis of *N*-Propionylphthalimide (IV)—This was prepared in a similar manner to *N*-acetylphthalimide, except that propionic anhydride was used in place of acetic anhydride. A product of m.p. 153–155° was obtained [lit. (12) m.p. 143–144°]. NMR showed a symmetrical A_2B_2 pattern at 7.92 and 7.96δ (four protons), a triplet at 1.29δ (three protons), and a quartet at 3.10δ (two protons), confirming *N*-acylation. The IR spectrum gave a large peak area between 1800 and 1600 $cm.^{-1}$, and the UV spectrum gave peaks at 270 and 295 nm.

Synthesis of *N*-Chloroacetylphthalimide (V)—To a solution of 10 g. (0.059 mole) of chloroacetic acid was added 6.1 g. (0.059 mole) of dicyclohexylcarbodiimide in 120 ml. of tetrahydrofuran. After standing for 4 hr., the urea was filtered off, leaving a solution of the anhydride of approximately 10% (w/v). Two grams of potassium phthalimide was added to 20 ml. of the solution, and the suspension was refluxed for 5 hr. with stirring. The solution was filtered and evaporated to 10 ml., and the precipitate was collected. After three recrystallizations from tetrahydrofuran, a white compound was collected, m.p. 177–179° [lit. (13) m.p. 179–180°]. NMR showed a symmetrical A_2B_2 pattern at 7.92 and 7.98δ (four protons) and a singlet at 4.70δ (two protons), confirming *N*-acylation.

Synthesis of *N*-Bromoacetylphthalimide (VI)—The synthesis was identical to that of V, except that bromoacetic acid was used in the initial step. A product of m.p. 153–155° was obtained.

Anal.—Calc. for $C_9H_{10}BrNO_3$: C, 44.94; H, 2.27; N, 5.24. Found: C, 45.24; H, 2.49; N, 5.37.

NMR showed a symmetrical A_2B_2 pattern at 7.92 and 7.98δ (four protons) and a singlet at 4.60δ (two protons), confirming *N*-acylation.

Synthesis of *N*-(Morpholinocarbonyl)phthalimide (VII)—This compound was synthesized according to the method of Grigat (14), except that the starting material was *N*-(ethoxycarbonyl)phthalimide instead of *N*-(phenoxycarbonyl)phthalimide. The product showed m.p. 204–205° [lit. (14) m.p. 207–208°]. NMR showed a sym-

Table I—Delivery Volume as a Function of Pressure

Liquid	Rate, ml./p.s.i. (10^3)	Total Volume Delivered, ml. 1400 p.s.i.	2100 p.s.i.	2800 p.s.i.
Calcium carbonate, 5%	6.7	10	14.7	19
Syrup USP	7.1	10	15	20
Water	6.8	12	16.8	21.5
Alcohol USP	7.1	13	18	23

EXPERIMENTAL

Materials and Equipment—The liquids used in this study were: distilled water; syrup USP; shellac, 2.7 kg. (6 lb.) cut; 5, 15, and 35% (w/v) aqueous suspensions of calcium carbonate; and a 2% (w/v) solution of methylcellulose[1], 500 cps.

The equipment utilized to evaluate the factors involved in an automated tablet-coating system was a self-programming automated tablet-coating system with two automatic spray guns[2] as previously described (4).

Fluid Delivery Studies—Fluid delivery experiments were conducted to ascertain the influence of pressure, spray tip orifice size, and type of liquid on the volume of spray delivered.

The volume of fluid delivery in milliliters was determined from 1400 to 2800 p.s.i. nozzle pressure in 140 p.s.i. pressure increments. The tip orifice sizes varied from 0.023 cm. (0.009 in.) to 0.053 cm. (0.021 in.) in diameter. All experiments were conducted in an air conditioned room at approximately 25° and 30–40% relative humidity.

Three-second fluid spray delivery cycles were used, and five replicate samples of each liquid under study were collected, at each pressure and nozzle tip size, in a 100-ml. graduated cylinder; the resulting volumes were recorded.

Spray Pattern Characteristics—Spray patterns were determined for the liquids studied, each containing 1% (w/v) FD&C Red No. 2 dye for contrast. The spray from the activated gun of the automated tablet-coating system was directed at a specially designed target which consisted of a 61-cm. square pane of glass with five concentric circles painted 10 cm. apart. The tip of the spray gun was positioned 30 cm. from the glass surface and at the center point of the target. The spray cycle was set for a 0.25-sec. solution delivery. The patterns were subsequently observed at 1400-, 1960-, and 2800-p.s.i. nozzle pressure (the lower, middle, and upper pressure range, respectively) for all tip sizes ranging from 0.023 cm. (0.009 in.) to 0.053 cm. (0.021 in.) in orifice diameter. After each spray, the pattern dimensions were taken and pattern uniformity was noted.

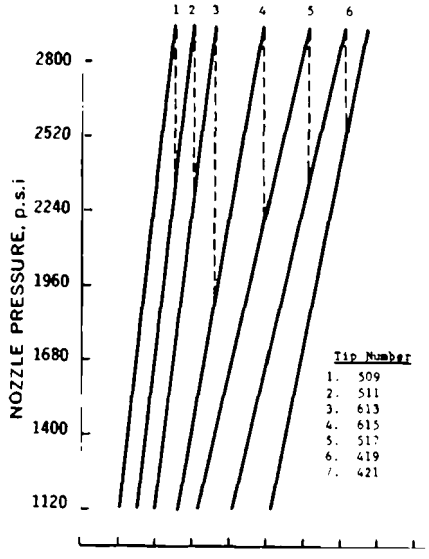

Figure 4—*Fluid delivery curves, 3-sec. cycle.*

RESULTS AND DISCUSSION

Fluid Delivery—The pressure–volume curves in Fig. 1, constructed from fluid delivery data obtained with a 0.023-cm. (0.009-in.) spray tip and a 3-sec. delivery, show that the change in fluid volume delivered as a function of pressure was constant. The curves are representative of some of the liquids studied, and each shows excellent linearity. The rate of change of delivery (Table I) for the liquids represented in Fig. 1 was essentially the same.

A 3–4-ml. difference in total volume delivered at each pressure increment was found between the four liquids studied. These small volume differences do not appear to be significant, but the data show a trend toward a decrease in volume delivered with an increase in fluid viscosity and solids content when comparing syrup and calcium carbonate with water and alcohol. A significant difference would be expected at a much lower or at atmospheric pressure. The data, therefore, indicate that fluid volume delivery is essentially independent of the physical properties of the fluid at very high pressures.

Fluid delivery curves for the three calcium carbonate suspensions, which varied from a "watery" to an "ointment-like" consistency (Fig. 2)[3], are in essence identical and confirm that the elevated pressures used in the study obliterated the effects of the physical properties of the fluids delivered.

In Fig. 3, the volume of water delivered in 3 sec. *versus* tip orifice diameter shows a good linear relationship within the range of 0.030 cm. (0.012 in.)–0.053 cm. (0.021 in.). This finding is unusual because one would expect an orifice–volume relationship based on

Figure 5—*Spray patterns with water. Left: 0.023-cm. (0.009-in.) tip size and 30 × 9-cm. pattern size. Right: 0.053-cm. (0.021-in.) tip size and 40 × 30-cm. pattern size.*

[3] Data points for Fig. 2 were omitted for the purpose of clarity.

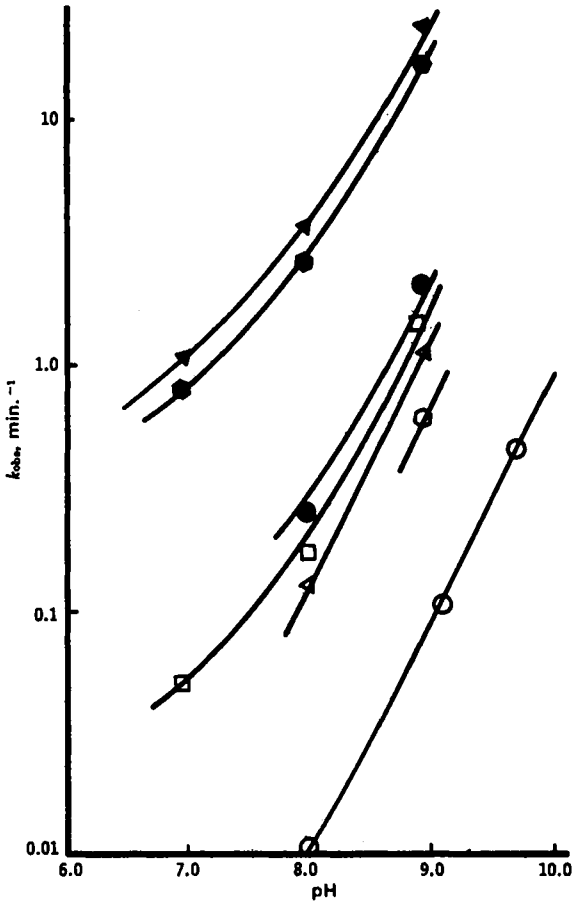

Figure 1—*Plot of log* k_{obs} versus *pH for hydrolysis of* N-*acyl phthalimides. Key:* ○, $R = N(CH_3)_2$[a]; ○, *R = morpholino;* △, $R = C_2H_5$; □, $R = C_2H_5O$; ●, $R = CH_3$; ●, $R = CH_2Br$; *and* ▲, $R = CH_2Cl$. *(For definition of R, see Scheme I.)* ([a]*Unpublished data, T. Higuchi and F. Kametani.*)

(*b*) help disperse any negative charge built up on the nitrogen in the transition state.

Similarly, for the reactions that took place at the *N*-acyl carbonyl, the rates were found to be proportional to the electron-withdrawing power of R, again referring to R in Scheme I.

Effects of R on Reaction Path—If the rates for the attack of base at the phthalimide carbonyls are to be compared to those at the *N*-acyl carbonyl, it is important to consider that there are two phthalimide carbonyls as compared to one *N*-acyl carbonyl. Statistical considerations, therefore, predict that more of the *N*-acyl phthalamic acid would be formed than phthalimide.

Which path (Path I or II) provides the better leaving group could be a matter for further discussion. However, for the task at hand, the route of reaction can be explained on the basis of the susceptibility of the various carbonyl groups to attack by a nucleophile. A close look at the compounds that hydrolyzed *via* Path I revealed a common property. The R group for each of the compounds was electron donating to the *N*-acyl carbonyl; *i.e.*, dimethylamino and morpholino can donate electrons to the *N*-acyl carbonyl by resonance because the amine group possesses a free pair of electrons. Where R is a methyl or an ethyl group, electrons are donated to the *N*-acyl carbonyl by induction. If R is an ethoxy group, a carbamate linkage results. The specific interactions of the R group with the *N*-acyl carbonyl actually change the character of the reaction centers, making the comparison of attack at the phthalimide carbonyls to the *N*-acyl carbonyl difficult. All these R groups deactivate the *N*-acyl carbonyl while, at the same time, as the *N*-acyl group (RCO), they activate the phthalimide carbonyls by being electron withdrawing at those carbonyls.

Phthalimide–acyl cleavage occurs only if the *N*-acyl carbonyl is sufficiently activated by electron-withdrawing R groups, such as $-CH_2Br$ and $-CH_2Cl$, so it can compete with attack at the phthalimide carbonyls. Thus, the product of reaction appears to be determined by susceptibility of the appropriate carbonyl to attack. The slightest activation of the *N*-acyl carbonyl, even by the phenoxymethylene R group (9), has been shown to lead to reaction at the *N*-acyl carbonyl. The idea that the carbonyl activation is the product-determining factor in the hydrolysis of *N*-acyl phthalimides may be best explained in terms of free energy of activation. Electron-withdrawing *N*-acyl groups lower the free energy of activation for Path I. Proportionally, however, there may be greater effect on the free energy of activation for Path II by the changes in R; *i.e.*, for VII, $\Delta G^{\ddagger}_{\text{Path II}} >>> \Delta G^{\ddagger}_{\text{Path I}}$, whereas for III, $\Delta G^{\ddagger}_{\text{Path II}} > \Delta G^{\ddagger}_{\text{Path I}}$. For V and VI, $\Delta G^{\ddagger}_{\text{Path I}} \gg \Delta G^{\ddagger}_{\text{Path II}}$, thus predicting that compounds like *N*-(phenylacetyl)phthalimide with a poor electron-withdrawing R group should degrade *via* Paths I and II, *i.e.*, both pathways being detectable.

In summary, chemical modification of imides through *N*-acylation requires a detailed study of the products of the *in vitro* hydrolysis because it cannot be assumed that the product will be the parent imide. This study has shown that *N*-acylated imides, when hydrolyzed, can regenerate the parent imide if the *N*-acyl carbonyl is sufficiently activated to compete with possible reaction at the imide carbonyls.

Drug Permeation through Membranes II: Simultaneous Dissolution and Permeation of Drug from Solid Dosage Forms

EDWARD G. LOVERING[▲] and KEN B. McRAE

Abstract □ The simultaneous dissolution and permeation of a drug from solid oral dosage forms were analyzed by a treatment based on Fick's second law of diffusion. The analysis shows that dissolution rate constants can be obtained from the permeation lag time, while the coefficients of permeability are estimated, as usual, from the rate of drug transfer across the membrane under steady-state conditions. Drug–excipient interactions, if any, would be expected to affect the rate of drug transfer across the membrane. Therefore, from a single experiment, the dissolution rate and the extent of drug–excipient interaction can be obtained. The equation was tested by dissolution–permeation measurements on two amobarbital formulations.

Keyphrases □ Drug permeation—membranes, amobarbital, analysis of dissolution and permeation from solid oral dosage forms, application of Fick's second law of diffusion, relevance to drug–excipient interactions, equations □ Drug–excipient interactions—application of Fick's second law of diffusion to determine both dissolution and membrane permeation, amobarbital from a solid oral dosage form, equations □ Dissolution–membrane permeability data—generated by application of Fick's second law of diffusion, relevance to drug–excipient interactions, amobarbital from solid oral dosage form, equations □ Permeation, membrane—used to evaluate drug–excipient interactions and drug dissolution by application of Fick's second law of diffusion, amobarbital from a solid oral dosage form □ Membrane permeation–dissolution data—generated by application of Fick's second law of diffusion, relevance to drug–excipient interactions, amobarbital from a solid oral dosage form, equations

It is now well recognized that the *in vivo* dissolution characteristics of drug formulations may have a pronounced effect on their bioavailability. Because *in vivo* dissolution rates are difficult to measure directly, attempts to assess this aspect of drug quality are commonly made from *in vitro* dissolution rate data. Dissolution specifications *in vitro* have been promulgated for a number of drugs (1, 2), and attempts to correlate these with bioavailability have met with varying degrees of success (3–5).

In addition to *in vivo* dissolution, bioavailability depends upon transfer of the drug across the GI membrane. For typical oil-soluble drugs, the transfer rate depends upon the concentration of free, unionized drug in the GI tract. The concentration may be adversely affected by adsorption, absorption, reprecipitation, partitioning into bile micelles or fat particles, or any other factor that reduces the concentration of free drug (6). Substances having an adverse effect on absorption rates may be endogenous to the GI tract or may be introduced as nutrients or tablet excipients. *In vitro* assessment of the latter can be made by comparing the permeation rate of unformulated drug to that of drug released from formulations dissolved, or dispersed, in an appropriate buffer. Drug–excipient interactions may account for the low bioavailabilities observed in some formulations.

This paper describes a method for the simultaneous determination of the dissolution rate constant of drug in a formulation and the permeability coefficient of the drug in that formulation.

THEORETICAL

The experiment involves dissolution of drug from a solid dosage form, followed by drug transfer across the membrane of a permeation cell mounted in the dissolution vessel. The term permeation refers to transfer of drug from the aqueous solution in which it dissolves, across the membrane, and into the aqueous solution within the permeation cell, while diffusion refers to movement of drug molecules within the cell membrane.

Movement of drug within a homogeneous membrane can be described by Fick's second law of diffusion:

$$\frac{\partial C^*}{\partial t} = D\frac{\partial^2 C^*}{\partial x^2} \qquad \text{(Eq. 1)}$$

where C^* is concentration of drug within the membrane, t is time, D is the diffusion coefficient, and x is the space coordinate normal to the surface of the membrane (7). For a membrane of thickness l, x lies between zero and l. On the absorbing side of the membrane, where $x = 0$, the concentration of drug is time dependent and given by:

$$C^* = C_0^* G(t) \qquad \text{(Eq. 2)}$$

where C_0^* is the drug concentration in the membrane at $x = 0$ when the dosage form has completely dissolved, and $G(t)$ is a particular driving function with range [0, 1]. The drug concentration is zero when time is zero. On the desorbing side, where $x = l$, the drug concentration is maintained at zero by buffering the desorbing solution at an appropriate pH. These considerations lead to the following boundary conditions:

$$C^*(l,t) = 0 \qquad \text{(Eq. 3)}$$

$$C^*(x,0) = 0 \qquad \text{(Eq. 4)}$$

$$C^*(0,t) = C_0^* G(t) \qquad \text{(Eq. 5)}$$

Solution of Eq. 1 for C^* as a function of x and t is given in *Appendix I*. The rate at which drug diffuses across the plane of the membrane at $x = l$ is given by:

$$-D\left.\frac{\partial C^*}{\partial x}\right|_{x=l} \qquad \text{(Eq. 6)}$$

so that, for a membrane of unit area, the quantity of drug crossing the plane during the time interval from 0 to t is:

$$q = -D\int_0^t \left(\frac{\partial C^*}{\partial x}\right)_{x=l} dt \qquad \text{(Eq. 7)}$$

The particular driving function, $G(t) = (1 - e^{-\alpha t})$, was chosen to represent the rate of drug dissolution from a solid dosage form. It probably represents actual dissolution behavior as well as any other function and it is convenient to handle mathematically. The

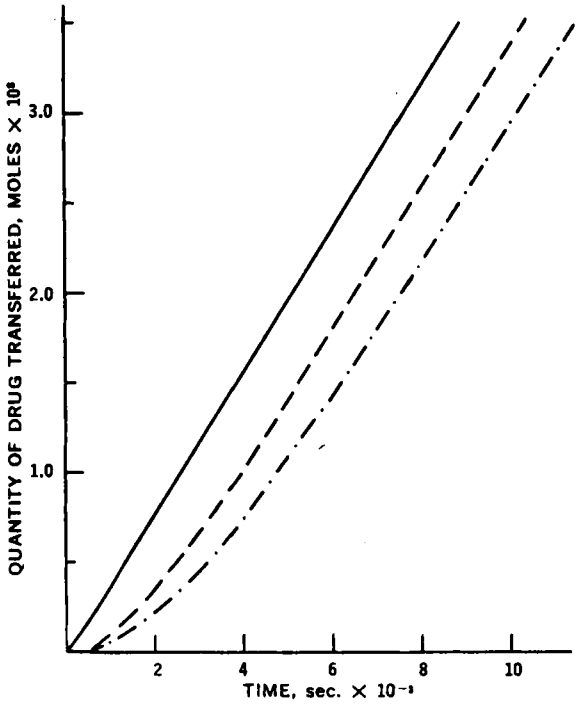

Figure 1—*Plots of theoretical* q versus t *for various half-times of dissolution. Key:* ——, $t_{1/2}$ = *0 min.;* - - -, $t_{1/2}$ = *16.6 min.;* -.-., $t_{1/2}$ = *30 min.;* P = 10^{-6} *cm.*^{2} *sec.*$^{-1}$, C* = 10^{-6} *mole cm.*$^{-3}$, *and* l = 2.54×10^{-3} *cm.*

constant κ is characteristic of a given dosage form and is a measure of the rate at which it dissolves. Solution of Eq. 1 for this particular case is given in *Appendix II*. Differentiation with respect to x at $x = l$ and integration over time lead to:

$$q = C_0^* \left\{ \frac{Dt}{l} - \frac{l}{6} - \frac{D}{\kappa l} + \frac{e^{-\kappa t}}{\sqrt{\kappa/D}\sin\{l\sqrt{\kappa/D}\}} + \frac{2\kappa l}{\pi^2 D}\sum_{n=1}^{\infty}\frac{(-1)^n}{n^2}\frac{e^{-(n\pi/l)^2 Dt}}{(n\pi/l)^2 - \kappa/D}\right\} \quad \text{(Eq. 8)}$$

provided that $(l/\pi)\sqrt{\kappa/D} \neq n = 1, 2, 3 \ldots$.

If the limit of q in Eq. 8 is taken as t becomes large, then:

$$q = \frac{C_0^* AD}{l}t - C_0^* A\left(\frac{l}{6} + \frac{D}{\kappa l}\right) \quad \text{(Eq. 9)}$$

where A is the surface area of the membrane. To apply Eq. 9 to permeation, it is necessary to replace DC_0^* by PC_0, where P is the permeation coefficient and C_0 is the concentration of drug in solution when dissolution is complete. Thus, the partition coefficient,

[a] Dissolution half-times determined by direct measurement.

K_p, is C_0^*/C_0. This substitution assumes that the concentration of drug in the membrane at $x = 0$ is proportional to the concentration of drug in solution. The term P includes diffusion of the drug across the aqueous boundary layer in contact with the membrane. Thus:

$$q = \frac{C_0 AP}{l}t - C_0 A\left(\frac{l}{6} + \frac{P}{\kappa l}\right) \quad \text{(Eq. 10)}$$

Equation 10 is applicable to dissolution–permeation experiments of sufficient duration to reach the steady state, where the plot of q *versus* t is linear. Under these conditions:

$$P = \frac{(dq/dt)l}{C_0 A} \quad \text{(Eq. 11)}$$

and:

$$\kappa = \left(t^* - \frac{l^2}{6D}\right)^{-1} \quad \text{(Eq. 12)}$$

where t^*, the lag time, is the value of t when q is zero.

Before attempting to use Eqs. 8–12 to determine κ and P from experimental measurements of q and t, it is important to know whether κ and P vary significantly with changes in the experimental parameters. Figure 1 gives curves of q *versus* t for various κ's between 10^3 and 3.851×10^{-4} sec.$^{-1}$, corresponding to a range in half-times of dissolution from 0 to 30 min. Clearly, the curves and lag times are well separated with the lag time increasing from 2 to 45 min. It is, therefore, feasible to determine κ by this technique. Plots of Eq. 8 for various values of P (not shown) demonstrate that while t^* depends on P, the change in t^* is less than a factor of 2 when P is varied over an order of magnitude. However, highly permeable membranes are preferred since the time required to carry out an experiment increases as P decreases.

The significance of changes in lag time can be visualized by recasting Eq. 12:

$$t^* = \frac{l^2}{6D} + \frac{1}{\kappa} \quad \text{(Eq. 13)}$$

showing t^* to be made up of a diffusion term and a dissolution term. As l becomes smaller, the contribution of the first term to t^* decreases, enhancing the relative importance of κ^{-1} and facilitating its determination. In addition, small values of l reduce the time required to reach the steady state and, hence, the overall time of the experiment. The effect of an increase in l on q is to decrease the drug transfer rate, increase the lag time, and prolong the period required to reach a steady state.

EXPERIMENTAL

Dissolution–permeation experiments were carried out in a 1-l. resin kettle at 37 ± 1°. The kettle contained a wire basket of the

type used in the USP dissolution procedure (1) placed near the rim of the kettle, about halfway down, and rotated at 150 r.p.m. A diffusion cell of the type described by Garrett and Chemburkar (8), equipped with 0.014-cm. membranes of polydimethylsiloxane, was placed opposite the rotating basket.

Dissolution–permeation experiments were carried out on two tablet formulations of amobarbital, A and B. The experiment was started by placing 900 ml. of acetate buffer, pH 5, in the kettle and 15 ml. of borate buffer in the diffusion cell. A tablet was put into the wire basket at time zero; at appropriate time intervals, the concentration of amobarbital in the diffusion cell was measured by UV spectroscopy at 240.5 nm., following the procedure already described (6). Tablet dissolution rates were measured directly by sampling the resin kettle at appropriate time intervals. These samples were diluted with borate buffer, and the amobarbital concentration was read spectrophotometrically.

RESULTS AND DISCUSSION

To measure the dissolution constant κ and the permeability coefficient P by the method described, it is necessary for the transfer rate of drug across the membrane to reach the steady state. The steady state cannot be achieved before the tablet has completely dissolved. The time taken to reach the steady state also increases as the membrane thickness increases.

The dissolution constant κ for two brands of amobarbital, A and B, was determined in the dissolution–permeation apparatus by two methods: (*a*) from the lag time as described in this paper, and (*b*) by measurement of the drug concentration in the dissolving medium.

The results (Table I) show $t_{1/2}$ as determined by the two methods to be in agreement, remembering that large intralot variations in tablet dissolution times are commonly observed. The permeability coefficients are, within experimental error, the same as those reported previously for amobarbital (6). The component of the lag time due to the nature of the drug and the membrane thickness, $l^2/6D$, in Eq. 13 is about 425 sec. for this experiment. The difference between this quantity and t^*, the experimentally observed lag time, is a reflection of the time required for the tablet to dissolve.

Equation 8 was tested by calculating the theoretical curve of q *versus* t for an amobarbital tablet with a dissolution half-time of 37 min. and plotting the experimental points of Tablet 4, Formulation B, on the same graph (Fig. 2). It is evident that the experimental results are adequately described by Eq. 8.

In conclusion, it was possible to determine the dissolution constant and the permeability coefficient of a drug in a solid dosage form by a single experiment. The time required to determine κ by this method is greater than in a single dissolution experiment, but additional information is gained. Comparison of P as determined from tablet dissolution, with P for the pure drug in question, indicates whether or not a portion of the drug is unavailable for membrane transfer. Drug availability could be reduced by interaction with tablet excipients. Further studies are planned to determine if dissolution–permeation experiments are of value in monitoring drug quality and whether the results can be correlated with human bioavailability data.

APPENDIX I

Suppose $C^*(x,t)$ is well defined for $0 < x < l$, $t > 0$, so that for fixed x, $C^*(x,t)$ is sectionally continuous in every finite interval $0 < t < N$ and of exponential order γ for $t > N$, where N and γ are finite numbers. Then by the method of Laplace transformations (9), the partial differential Eq. 1 can be transformed into the ordinary differential equation:

$$sc^*(x,s) - C^*(x,0) = D\frac{d^2c^*}{dx^2} \qquad \text{(Eq. A1)}$$

where the Laplace transformation of $C^*(x,t)$ is denoted by the lower case function $c^*(x,s) \overset{\text{defn}}{\equiv} \int_0^\infty e^{-st}\, C^*(x,t)\, dt$.

The Laplace transforms of boundary conditions (Eqs. 3–5) are, respectively:

$$c^*(l,s) = 0 \qquad \text{(Eq. A2)}$$

$$c^*(x,0) = 0 \qquad \text{(Eq. A3)}$$

$$c^*(0,s) = C_0^* g(s) \qquad \text{(Eq. A4)}$$

The general solution of Eq. A1 after the substitution of Eq. 4 is given by:

$$c^*(x,s) = \kappa_1 \cosh \sqrt{s/D}x + \kappa_2 \sinh \sqrt{s/D}x \qquad \text{(Eq. A5)}$$

Using boundary condition A2, one finds:

$$\kappa_2 = \kappa_1 \cosh\{\sqrt{s/D}l\}/\sinh\{\sqrt{s/D}l\} \qquad \text{(Eq. A6)}$$

and:

$$c^*(x,s) = \kappa_1 \sinh\{\sqrt{s/D}(l-x)\}/\sinh\sqrt{s/D}l \qquad \text{(Eq. A7)}$$

After imposing boundary condition A4, one has:

$$c^*(x,s) = C_0^* g(s) \sinh\{(l-x)\sqrt{s/D}\}/\sinh\sqrt{s/D}l \qquad \text{(Eq. A8)}$$

The solution to the partial differential equation is given by the inverse Laplace transformation of Eq. A8 and can be found by use of the convolution theorem. That is:

$$C^*(x,t) = L^{-1}\left\{C_0^* g(s)\frac{\sinh(l-x)\sqrt{s/D}}{\sinh l\sqrt{s/D}}\right\} = \int_0^t \left(L^{-1}\frac{\sinh(l-x)\sqrt{s/D}}{\sinh l\sqrt{s/D}}\bigg|_{x=u}\right) C_0^* G(t-u)\,du = \frac{2\pi D}{l^2} C_0^* \sum_{n=1}^{\infty}(-1)^{n-1} n \int_0^t e^{-(n\pi/l)^2 Du} G(t-u)du \times \sin n\pi(l-x)/l \qquad \text{(Eq. A9)}$$

The rate of transfer at $x = l$ at time t is given by:

$$-D\frac{\partial C^*}{\partial x}\bigg|_{x=l}$$

so that the quantity of diffusing substance during the interval $[0,t]$ is:

$$q = -D\int_0^t \left(\frac{\partial C^*}{\partial x}\right)_{x=l} d\tau \qquad \text{(Eq. A10)}$$

APPENDIX II

For the particular driving function $G(t) = (1 - e^{-\kappa t})$, it is necessary to evaluate:

$$\int_0^t e^{-(n\pi/l)^2 Du}\{1 - e^{-\kappa(t-u)}\}\,du = \int_0^t e^{-(n\pi/l)^2 Du}\,du - e^{-\kappa t}\int_0^t e^{-\{(n\pi/l)^2 D-\kappa\}u}du = [(1-e^{-\kappa t})/\{(n\pi/l)^2 D - \kappa\}] - [\kappa\{1 - e^{-(n\pi/l)^2 Dt}\}/(n\pi/l)^2 D\,\{(n\pi/l)^2 D - \kappa\}] \qquad \text{(Eq. A11)}$$

provided $(n\pi/l)^2 D \neq \kappa$. Substituting into Eq. A9, one has:

$$C^*(x,t) = \frac{2C_0^*\pi D}{l^2}\left[(1-e^{-\kappa t})\sum_{n=1}^{\infty}\frac{(-1)^{n-1}n}{(n\pi/l)^2 D - \kappa}\times \sin\frac{n\pi(l-x)}{l} + \kappa\sum_{n=1}^{\infty}\frac{(-1)^n n}{\{(n\pi/l)^2 D - \kappa\}(n\pi/l)^2 D}\times \{1 - e^{-(n\pi/l)^2 Dt}\}\sin n\pi(l-x)/l\right] = C_0^*(1-e^{-\kappa t})\times \frac{\sin(l-x)\sqrt{\kappa/D}}{\sin l\sqrt{\kappa/D}} + \frac{2\kappa C_0^*}{\pi D}\sum_{n=1}^{\infty}\frac{(-1)^n}{\{(n\pi/l)^2 - \kappa/D\}n}\times \{1 - e^{-(n\pi/l)^2 Dt}\}\sin\frac{n\pi(l-x)}{l} \qquad \text{(Eq. A12)}$$

where the first summation was executed by series 557 in Jolley (10).

After differentiating Eq. A12 with respect to x and using summation formula 558 in Jolley (10), one obtains:

$$\left(\frac{\partial C^*}{\partial x}\right)_{x=l} = C_0^* \left\{\sqrt{\frac{\kappa}{D}}\frac{e^{-\kappa t}}{\sin l\sqrt{\kappa/D}} - \frac{1}{l} + \frac{2\kappa}{Dl}\sum_{n=1}^{\infty}\frac{(-1)^n e^{-(n\pi/l)^2 Dt}}{(n\pi/l)^2 - \kappa/D}\right\} \quad \text{(Eq. A13)}$$

Consequently, upon integration and simplifying by means of series 337 and 558 in Jolley (10), one obtains Eq. 8. Under experimental conditions, l, D, and κ will be rational numbers while π^2 is irrational so that $l^2\kappa/\pi^2 D \neq 1, 4, 9, 16, \ldots$. However, it may be sufficiently close to an integer to cause "round off" difficulties in computing the infinite sum.

Acute Effects of Narcotic Analgesics on Behavioral Arousal in the Rat

W. MARVIN DAVIS▲ and CALVIN C. BRISTER*

Abstract □ Locomotor activity measured by photocell actometers was taken as an index of behavioral arousal in rats following acute administration of pentazocine, morphine, methadone, levorphanol, and meperidine. The intraperitoneal doses tested were 1.25, 2.5, 5.0, 10, and 20 mg./kg. The low doses of morphine and methadone and an intermediate dose of pentazocine produced an early (1st hr.) increase in motility. Higher doses of these three drugs and the lowest dose of levorphanol caused a delayed excitation (2nd–3rd hr.). An early inhibition of activity was seen for the higher doses of morphine, methadone, meperidine, and levorphanol but not for pentazocine. Meperidine did not elicit significant locomotor excitation in these doses. The enhanced motility after pentazocine and the narcotic analgesics was blocked by pretreatment with α-methyltyrosine.

Keyphrases □ Locomotor activity—effect of pentazocine and narcotic analgesics, compared to morphine, pretreatment with α-methyltyrosine, rats □ Pentazocine and narcotic analgesics—effect on locomotor activity, compared to morphine, pretreatment with α-methyltyrosine, rats □ Analgesics, narcotic (methadone, meperidine, levorphanol)—effect on locomotor activity, compared to morphine, pretreatment with α-methyltyrosine, rats □ Methadone—effect on locomotor activity, rats □ Meperidine—effect on locomotor activity, rats □ Levorphanol—effect on locomotor activity, rats □ α-Methyltyrosine pretreatment—effect of pentazocine and narcotic analgesics on locomotor activity, rats

Previous reports from this laboratory have analyzed the occurrence of locomotor stimulation following low doses of morphine in nontolerant rats (1–4). This effect had been little emphasized and had not been systematically evaluated in earlier works, which did, however, describe repeatedly an enhancement of motility by morphine occurring after an interval of repeated dosing in the study of tolerance and/or physical dependence (5–9). Certain studies have cited gross observations or limited data concerning such an effect in nontolerant rats (9–12). Locomotor excitation provides evidence for behavioral arousal in response to morphine in the nontolerant rat despite the classification of this species among those showing predominantly a response of depression and behavioral inhibition (13, 14).

Interest in this excitatory component of the CNS pharmacology of the opiates led to a consideration of the generality of the motility response seen with low doses of morphine. Specifically, it was of interest whether similar effects might be found not only after the synthetic narcotic analgesics but also after an agent of the narcotic antagonist–analgesic class. Therefore, methadone, meperidine, levorphanol, and penta-

where the first summation was executed by series 557 in Jolley (10).

After differentiating Eq. A12 with respect to x and using summation formula 558 in Jolley (10), one obtains:

$$\left(\frac{\partial C^*}{\partial x}\right)_{x=l} = C_0^* \left\{\sqrt{\frac{\kappa}{D}}\frac{e^{-\kappa t}}{\sin l\sqrt{\kappa/D}} - \frac{1}{l} + \frac{2\kappa}{Dl}\sum_{n=1}^{\infty}\frac{(-1)^n e^{-(n\pi/l)^2 Dt}}{(n\pi/l)^2 - \kappa/D}\right\} \quad \text{(Eq. A13)}$$

Consequently, upon integration and simplifying by means of series 337 and 558 in Jolley (10), one obtains Eq. 8. Under experimental conditions, l, D, and κ will be rational numbers while π^2 is irrational so that $l^2\kappa/\pi^2 D \neq 1, 4, 9, 16, \ldots$. However, it may be sufficiently close to an integer to cause "round off" difficulties in computing the infinite sum.

zocine were examined to compare their actions to that of morphine. In addition to measuring the locomotor response to such agents alone, their interaction was tested with α-methyl-*p*-tyrosine, an agent that was previously found to be an effective inhibitor of the motor excitatory response to morphine in nontolerant rats (3, 4).

EXPERIMENTAL

Experimental subjects were male Wistar rats[1], which were assigned randomly on receipt to treatment groups and housed three per cage in metal cages (41 × 24.5 × 18 cm.) with food and water available *ad libitum*. They were placed in a room with an altered light cycle of 4:00 p.m. to 4:00 a.m., and 7–9 days was allowed for adaptation to the environmental conditions. Most rats attained a desired weight range of 225–235 g. by the time the locomotor activity study was begun. Each rat received only one dose of only one drug.

The photocell actometer units used (15) consisted of a circular alley, 7.6 cm. wide and 15 cm. high, with an external diameter of 37.5 cm. The inner wall held a container for food and a water bottle. Photocells of this apparatus cannot be deactivated several times in succession. An adjacent photocell must be subsequently deactivated to reset the first one, so that only large horizontal movements may be recorded. The actometers were located in a windowless, sound-shielded room, which also contained a masking white-noise generator to attenuate further any outside sounds. The temperature was generally maintained at 24 ± 1°.

Experiments began 1.5–2 hr. after light onset. On the 1st day, all rats were injected with saline, placed in actometer units individually, and allowed 24 hr. for adaptation to the actometer. On the 2nd day, they were injected with saline or with the test drug. Beginning immediately following injection, motility data were recorded hourly for 8 hr. Statistical analyses tested for differences between the saline control and each treatment group at each hourly observation period by means of one-way analysis of variance and Duncan's multiple range test (16).

The locomotor activity responses to several dosages of morphine and its surrogates were evaluated first. With the exception of methadone, all drugs were tested at the same five levels: 1.25, 2.5, 5.0, 10, and 20 mg./kg. For methadone the highest dosage was reduced to 16 mg./kg. because of toxicity. Each of the six treatment groups was composed of 18 subjects. During every actometer session (a 48-hr. period), three rats were tested from each treatment group.

Subsequent experiments tested for a relationship between central adrenergic function and the excitation produced by morphine and certain surrogates by determining the effect of α-methyltyrosine pretreatment on drug-induced motility. For this purpose, a dose of each analgesic agent was chosen that had produced the greatest activity response at the 1st hr. after treatment. For comparison, the effect of α-methyltyrosine on the activity evoked by 1.0 mg./kg. dextroamphetamine also was tested. These studies utilized four treatment groups: saline–saline, α-methyltyrosine–saline, saline–drug, and α-methyltyrosine–drug. On the 2nd day of the experimental session, saline or α-methyltyrosine pretreatment was administered 3.5–4 hr. prior to the injection of the test drug or saline. For the interaction study with dextroamphetamine, α-methyltyrosine was administered in a dose of 50 mg./kg. However, in experiments with analgesics, 100 mg./kg. was used.

A total recording period of only 4 hr. was utilized for the interaction studies because earlier data showed that the maximum activity produced by the selected dosages occurred within the first 3 hr. postinjection. Analysis of variance was applied to the cumulative motility counts over the first 3 hr. and separately for the 2nd and 3rd hr., but only the former values are reported here.

For each individual experiment, a solution or suspension of the drugs to be used was freshly prepared. Saline (0.9%) was used to

prepare solutions of morphine sulfate, levorphanol tartrate, and dextroamphetamine sulfate and a suspension of D,L-α-methyl-*p*-tyrosine[1]. Solutions of methadone hydrochloride, meperidine hydrochloride, and pentazocine lactate were prepared by dilution of commercial injectable solutions with saline. All drugs were administered in a volume of 1.0 ml./kg. As a control for each drug, an equal volume of 0.9% saline was injected. All injections were by the intraperitoneal route. Dosages given are in terms of the salts used.

RESULTS

Dose–Response Relationships for Analgesics on Locomotor Activity—Graphical presentations of results are given in Figs. 1–5. Saline-treated control rats characteristically displayed a moderate level of activity during the 1st hr., which is attributable to a combined effect of handling and injection procedures and of the behavioral arousal evoked by being removed from and returned to the actometer. Activity fell greatly in the 2nd hr. and remained low throughout the remaining 6 hr. of recording, except for a slight rise often found between the 3rd and 6th hr.

The activity patterns over time for several dosage levels of morphine are shown in Fig. 1. These are in close agreement with previous results from this laboratory (1, 2). The three lower doses produced a high initial excitatory response. For the lower two the peak activity was at the 1st hr., with significant activity continuing only during the 2nd hr. With the 5.0-mg./kg. dose, the peak was observed at the 2nd hr., and the duration was greater since a lower but still significant activity was evident at the 3rd hr. A further delay in peak activity was produced by increasing the dosage to 10 and 20 mg./kg. The former dose had no significant effect at the 1st hr. but caused peak activity at the 2nd hr., which was maintained with only slight reduction through the 3rd hr. The response to 20 mg./kg. suggested a biphasic effect: initial depression followed by excitation. A biphasic pattern has been more clearly demonstrated in other observations for which the 24-hr. adaptation was omitted so that activity at the 1st hr. was elevated. Peak excitation occurred at the 3rd hr., and high activity continued through the 4th hr.

The activity patterns for all of the other analgesics except meperidine showed a general similarity to that of morphine. The only apparent differences were in the level of peak activity achieved, in the duration of either depressant or stimulatory phase, and in the dosage producing a particular response pattern.

Methadone never showed as high a peak excitation as morphine (Fig. 2). The response to a 2.5-mg./kg. dose was like that of morphine at 1.25 or 2.5 mg./kg., while the response to 5.0 mg./kg. resembled morphine at 10 mg./kg. The response to methadone at 10 mg./kg. matched that with 20 mg./kg. morphine, and at 16 mg./kg. it was comparable to activity found in another study (2) for 40 mg./kg. morphine.

Levorphanol in doses of 1.25 and 2.5 mg./kg. (Fig. 3) produced responses closely resembling those after 10 and 20 mg./kg. of morphine, respectively. There was a suggestion of a biphasic response after levorphanol doses of 2.5, 5.0, and 10 mg./kg., while 20 mg./kg. clearly caused initial depression followed by excitation. No dose caused as high a degree of excitation as did morphine. There was a delay in time of peak excitatory response and an increased duration of excitation as the levorphanol dose was increased from 1.25 to 20 mg./kg.

Pentazocine at 1.25 and 2.5 mg./kg. had no significant effects (Fig. 4). However, the time-activity curves after 5.0 and 10 mg./kg. were very similar to those of morphine at 1.25 and 2.5 mg./kg., respectively. The pattern of activity following 20 mg./kg. pentazocine was comparable to that of 10 mg./kg. morphine.

Results with meperidine were not comparable to morphine at any dose tested (Fig. 5). Only 10 mg./kg. gave a small but significant increase in activity at the 2nd hr. The 20-mg./kg. dose showed a significant 1st hr. depressant effect along with a small but significant increase in activity at the 3rd hr.

[1] Regis Chemical Co., Chicago, Ill.

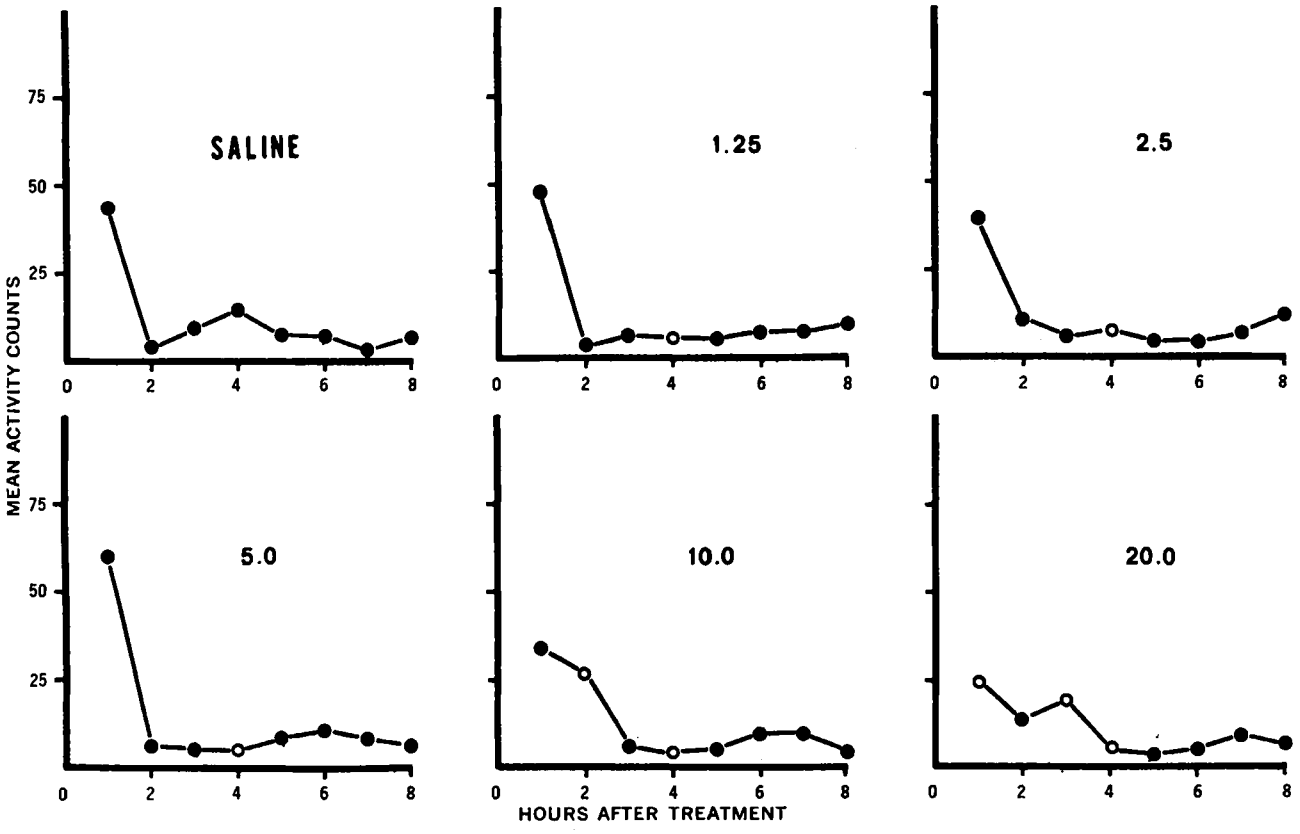

Figure 5—*Locomotor activity of rats following saline or several doses of meperidine hydrochloride as indicated on the individual graphs (1.25–20.0 mg./kg.). Open circles represent hourly totals differing significantly from corresponding values of saline controls at* $p \leq 0.05$. *For each point,* $N = 18$.

Thus, these results indicate that characteristic dose–activity patterns observed with morphine were matched by methadone at about one-half, by levorphanol at about one-tenth, and by pentazocine at 2–4 times the morphine dosage. On the other hand, meperidine failed to show clearly any pattern corresponding to those found with morphine.

Effect of α-Methyltyrosine on Locomotor Activity—The inhibition by α-methyltyrosine of the initial excitatory response to dextroamphetamine and to selected dosages of the analgesics (except for meperidine) is shown in Fig. 6. Statistical comparisons between means for total activity over the first 3 hr. after drug showed that in all cases α-methyltyrosine blocked the drug-induced excitatory response; *i.e.*, the activity of the combination did not differ from the saline controls or α-methyltyrosine–saline groups. Although the 3-hr. means for the α-methyltyrosine control groups were, in most instances, somewhat lower than saline controls, the differences were nonsignificant, and the apparent deficit in activity occurred mainly during the 1st hr.

DISCUSSION

While morphine in low doses (1, 2) has been known to stimulate motility of nontolerant rats, reports of such an effect have been lacking for the synthetic analgesics (methadone, levorphanol, and meperidine), although all have shown such activity in mice (17). One previous report of increased motility in the rat after a narcotic antagonist analgesic appeared recently for pentazocine (18). This work showed that α-methyltyrosine pretreatment blocked the motility response to pentazocine, another result that is confirmed by the present study. In addition, the morphine data of this study, both alone and in combination with α-methyltyrosine, provide confirmation for earlier findings (3, 4) in a different strain of rat.

The activity response to methadone and levorphanol was qualitatively similar to that after morphine, although of lesser magnitude. With both drugs the rats displayed a progressive delay in onset of peak activity with increasing dosage, as has been found characteristic of morphine (2). Pentazocine caused a maximum activation comparable in magnitude to that of morphine, but the shift over time with increasing dosage was less clearly evident in this dosage range. Meperidine in the doses reported here caused no consistent elevation of activity over controls. However, a later supplementary study with a dose of 30 mg./kg. gave a result very similar to that shown here for 20 mg./kg. of levorphanol (Fig. 3), having a quite delayed onset and peak of activity. Even with this observation, the pattern of response to meperidine in rats clearly differed from that of the other analgesics.

It has been postulated that locomotor excitatory effects of morphine are elicited through an action at a receptor site which is separate from and more sensitive than the one that causes locomotor inhibitory effects (2). The similarity in response patterns between morphine and the analgesics tested here (except meperidine) would allow the extension of this concept to these morphine surrogates. Such quantitative differences as were found could be attributed largely to differences in rates of metabolic inactivation. In view of these results in rats, it is interesting to note that meperidine in mice also caused the least increase in motor activity among several narcotic analgesics including morphine, methadone, and levorphanol (17). A difference in relative affinities for excitatory and inhibitory receptor sites could possibly explain the differing response pattern of meperidine compared to the other narcotic analgesics.

While a 50-mg./kg. dose of α-methyltyrosine blocked most of the motility response to dextroamphetamine, a dose of 100 mg./kg. was required to block completely the response to the four analgesics. The latter dose was the same that Holtzman and Jewett (18) found effective against the motility effects of pentazocine. The failure of morphine, methadone, levorphanol, and pentazocine to produce locomotor excitation after α-methyltyrosine suggests the dependence of their stimulatory effects upon a release of brain catecholamines. The same supposition was made earlier for morphine on the basis of a lowering of brain catecholamine levels during its action (9, 14, 17) as well as the interaction of morphine and α-methyltyrosine (4). In the case of pentazocine, this supposition also was put forth recently on the basis of both types of data (18). However, differences were observed in brain amine effects and

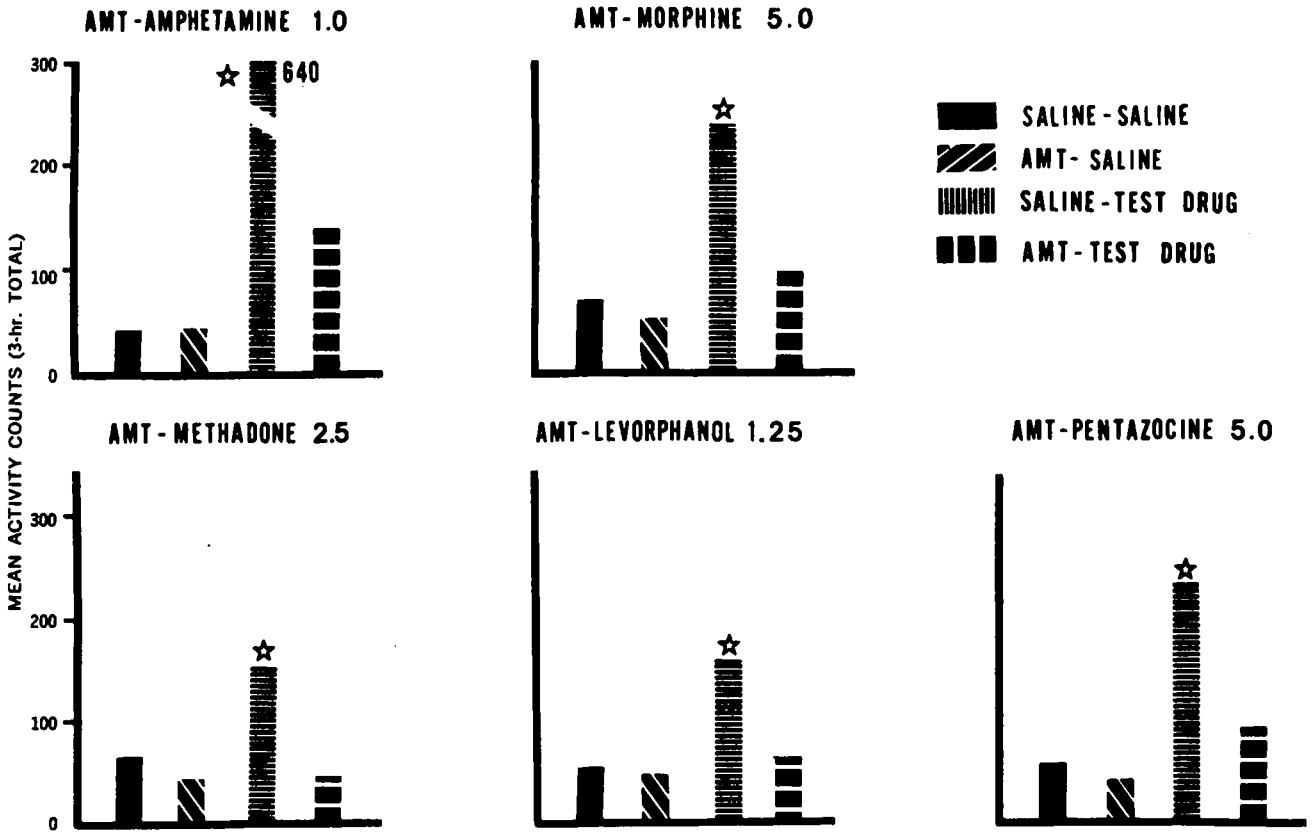

Figure 6—*Effect of α-methyltyrosine (I, AMT) on drug-induced locomotor activity of rats. Saline or I was injected intraperitoneally 3.5–4 hr. before each test drug. Dosages of drugs tested were dextroamphetamine, 1.0 mg./kg.; morphine sulfate, 5.0 mg./kg.; methadone hydrochloride, 2.5 mg./kg.; levorphanol, 1.25 mg./kg.; and pentazocine lactate, 5.0 mg./kg. Values indicated by stars were the only ones differing significantly* ($p \leq 0.05$) *among the respective treatment groups. For each group,* $N = 18$.

interactions with naloxone, which were taken to suggest that some agonist actions of pentazocine are mediated by receptors distinct from those on which morphine acts (18). The present data do not provide a basis for speculation on that point but do indicate some qualitative similarity in the responses to the agonist actions of morphine and pentazocine in terms of a locomotor activity measure.

Polarography of Cephalosporin C Derivatives I: 3-(5-Methyl-1,3,4-thiadiazol-2-ylthiomethyl)-7-[2-(3-sydnone)-acetamido]-3-cephem-4-carboxylic Acid, Sodium Salt

D. A. HALL

Abstract □ 3-(5-Methyl-1,3,4-thiadiazol-2-ylthiomethyl)-7-[2-(3-sydnone)acetamido]-3-cephem-4-carboxylic acid, sodium salt was found to be polarographically reducible in acidic medium, producing two polarographic waves: the first a two-electron reduction, and the second a six-electron reduction. Both waves are diffusion controlled; however, only the first can be used to follow acid and base hydrolysis and β-lactamase degradation of the compound.

Keyphrases □ 3-(5-Methyl-1,3,4-thiadiazol-2-ylthiomethyl)-7-[2-(3-sydnone)acetamido]-3-cephem-4-carboxylic acid, sodium salt—polarographic reduction □ Cephalosporin C derivatives—polarographic reduction of 3-(5-methyl-1,3,4-thiadiazol-2-ylthiomethyl)-7-[2-(3-sydnone)acetamido]-3-cephem-4-carboxylic acid, sodium salt □ Polarography—reduction of 3-substituted cephalosporin C derivatives [3-(5-methyl-1,3,4-thiadiazol-2-ylthiomethyl)-7-[2-(3-sydnone)acetamido]-3-cephem-4-carboxylic acid, sodium salt]

The initial report of the polarographic reducibility of cephalosporins, specifically, cephalosporin C and two of its derivatives, cephalothin [7-(thiophene-2-acetamido)-cephalosporanic acid] and cephaloridine [7-(2-thienylacetamido)-3-(1-pyridylmethyl)-3-cephem-4-carboxylic acid betaine], was that of Jones *et al.* (1). The polarographic reduction wave of cephaloridine was used for quantitative analysis, while those of cephalothin and cephalosporin C were used for qualitative comparison.

This paper reports the d.c. polarographic reduction of 3-(5-methyl-1,3,4-thiadiazol-2-ylthiomethyl)-7-[2-(3-sydnone)acetamido]-3-cephem-4-carboxylic acid, sodium salt (I) and its analytical utilization for control and stability assays.

EXPERIMENTAL

Apparatus—Polarograms were recorded by an IR compensating automatic recording polarograph[1], employing a water-jacketed three-compartment polarographic cell (the indicating-electrode compartment was between the reference and counter-electrode compartments). The cell was maintained at 25.0 ± 0.2° and contained a saturated calomel reference electrode and a platinum foil auxiliary electrode. The compartments of the cell were separated by medium-porosity sintered-glass disks and 4% agar-saturated potassium chloride salt bridges. The dropping mercury electrode had an $m^{2/3}t^{1/6}$ value of 1.555 at open circuit in air-saturated 0.1 *M* potassium chloride solution, unless noted otherwise.

Coulometric runs were made using a mercury pool cathode in the same polarographic cell. Stirring was accomplished by means of a 600-r.p.m. synchronous rotator[2] and a one-turn screw-type impeller.

Procedure—Test solutions were prepared by weighing approximately 2.5 mg. of the compound of interest into a 25-ml. volumetric flask, adding the buffer, and diluting to the mark with deionized water; the pH of this solution was measured. Without delay, about 12 ml. of test solution was transferred to the polarographic cell, purged with argon[3] for about 10 min., and polarographed. The half-wave potential, $E_{1/2}$, and the diffusion current, i_d, were determined graphically using the maximum of the recorder trace.

Buffer solutions were prepared from analytical reagent grade chemicals. Phosphate–citric acid–potassium chloride buffers were used at constant ionic strengths (2) of 0.4 and 0.6 *M* over the pH range of 2.3–6.0. A hydrochloric acid–potassium chloride buffer was used for pH 1.6 and was 0.1 *N* in hydrochloric acid. All buffer solutions were polarographically clean within the potential region of interest.

The total number of coulombs passed during coulometry was determined graphically. All coulometric runs were corrected for background current and were considered completed when the current was equivalent to the steady-state coulometric current of the background electrolyte.

RESULTS

Effect of pH—Compound I exhibits two polarographic waves (Fig. 1, solid lines), and both half-wave potentials are pH dependent. The results of the pH study at a concentration of 0.43 m*M* are shown in Table I. Waves I and II at this concentration show a pH dependence of $E_{1/2} = -0.45$–0.09 pH and $E_{1/2} = -0.76$–0.10 pH, respectively. As can be seen from Table I, the pH range in which both reduction waves are present is very narrow. A pH of 2.3 and an ionic strength of 0.6 *M* were selected for analytical purposes and were used throughout the rest of the study, unless noted otherwise.

Effects of Temperature and Mercury Height—Both waves I and II show a temperature dependence of +1.0% per degree. Waves I and II are dependent on the square root of the mercury height, corrected for back-pressure, within a relative standard deviation of ±1.6 and ±4.1%, respectively. These results indicate that both reduction waves are diffusion controlled.

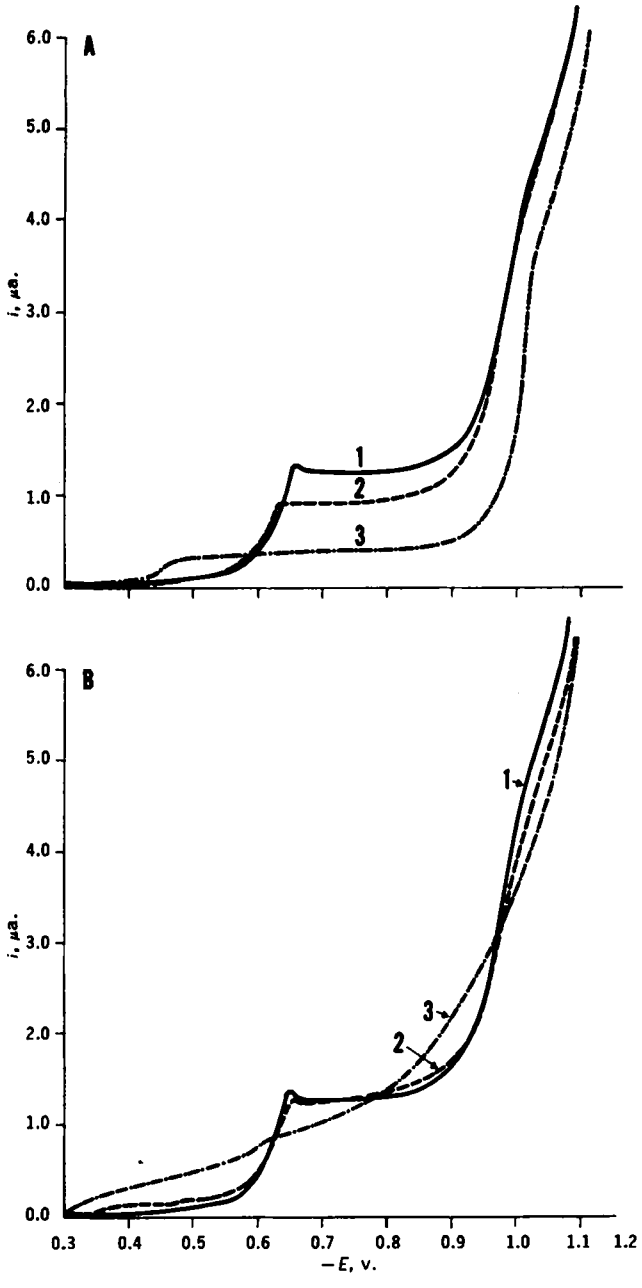

Figure 1—*(A) Polarography of acid hydrolysis sequence. Key: 1, initial; 2, 10 min. at 60°; and 3, 20 min. at 80°. (B) Polarography of base hydrolysis sequence. Key: 1, initial; 2, 0.1 meq. NaOH for 10 min. at room temperature; and 3, 0.1 meq. NaOH for 10 min. at 45°. All solutions were 0.22 m*M *in 1 at pH 2.0. The* $m^{2/3}t^{1/6}$ *of the dropping mercury electrode at open circuit in air-saturated 0.1* M *potassium chloride is 1.720.*

Concentration Dependence—The half-wave potentials of waves I and II are dependent on concentration, becoming more negative with increasing concentration (Table II). Wave I exhibits what appears to be a maximum of the first kind (3) that decreases more rapidly than the diffusion current with decreasing concentration and shows a negative dependence on surfactant[4] concentration; however, the addition of surfactant results in wave II merging with background. An increase in the ionic strength of the buffer from 0.4 to 0.8 *M* had no effect on the maximum. All data reported are in the absence of surfactant.

In the concentration range examined, *i.e.*, 0.07–0.43 m*M*, the diffusion currents of waves I and II are directly proportional to concentration (Table II). The dependences are i_{dI} = 4.41 μa./m*M* + 0.03 μa. and i_{dII} = 12.63 μa./m*M* − 0.15 μa., respectively. The *RSD* of waves I and II for four individually weighed 0.20 m*M*, 0.6 *M* ionic strength, pH 2.3 samples are ±2.6 and ±2.4%, respectively.

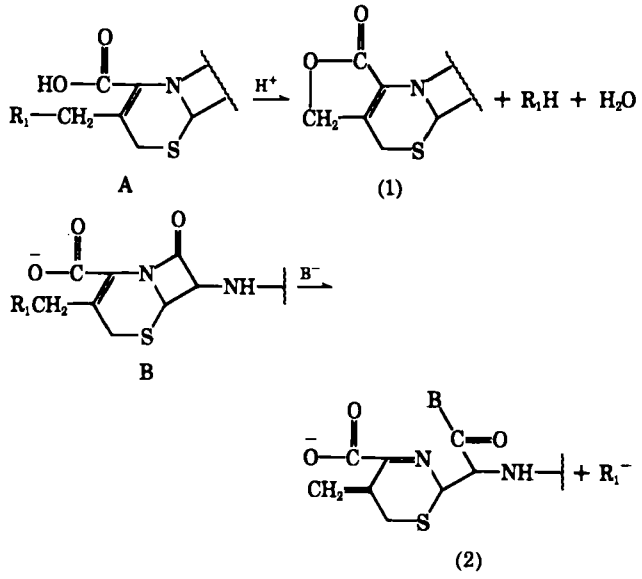
Acid Hydrolysis Stability—A 0.22 m*M*, 0.6 *M* ionic strength, pH 2.0 solution of I was subjected to three heating conditions. Results of two are shown in Fig. 1A. The polarograms show a decrease in wave I, essentially no effect on wave II, and the development of a reduction wave at −0.45 v. The third hydrolysis at 25° for 1 hr. did not detectably degrade I. A 1.95 m*M*, pH 2.3 solution of I was degraded at 80° for 15 min. and examined by an iodometric β-lactam assay and TLC. The iodometric assay, as compared to nondegraded I, indicated a 61% reduction in iodine uptake and a very large increase in the blank iodine uptake. The blank of the degraded material used approximately 1.7 times the iodine absorbed by the nondegraded sample. TLC in acetic acid–dioxane–acetone (1:2:8) on silica gel indicated a total loss of I, some material at the point of application, and two spots, both more mobile than I (iodine chamber development). The lead spot corresponded in R_f to the thiol-thiadiazole side chain of I. The less mobile spot corresponded to the lactone of I (Scheme IA) (1).

Base Hydrolysis Stability—Two 5.5-mg. samples of I were reacted with 0.1 meq. of base as 0.05 *N* NaOH under two different heating conditions. Polarograms of the resulting material at a concentration of 0.22 m*M* with respect to I and at a pH of 2.0 are shown in Fig. 1B. There is a decrease in both waves I and II and development of two ill-defined reduction waves at −0.35 and −0.48 v. A 2.5-mg. sample of I was degraded in 6 ml. of 0.17 *N* NaOH for 80 min. at room temperature. TLC, using the system previously described, revealed two new spots. The spot more mobile than I corresponded to the thiol-thiadiazole side chain of I. The second spot was less mobile than I and could be better described as a smear, most probably made up of material containing degraded β-lactam (see *Discussion*).

β-Lactamase Stability—Treatment of I with β-lactamase from *B. cereus* at pH 7 and 25° resulted in a 54% decrease in the diffusion current of wave I at pH 2.3 over 2 hr. The degradation produced a very small reduction wave at −0.36 v.

Polarography of 5-Methyl-1,3,4-thiadiazole-2-thiol (II)—Since II is indicated as a product of at least two different degradation paths of I and is also a probable intermediate in the synthesis of I (see *Discussion*), it seemed reasonable to try to develop a polarographic method to determine II. The compound is not reducible; therefore, it was decided to look into the possibility of an oxidation. The McIlvaine buffers used to determine I contain chloride ion, which results in an early anodic discharge at the dropping mercury electrode. However, II gives a well-defined anodic wave in pH 5.7, 0.7



Scheme I—Cephalosporin degradative pathways: A, acid hydrolysis; and B, base hydrolysis

M acetate buffer which is proportional to concentration within a relative standard deviation of ±6.0% (Table III). The half-wave potential is quite concentration dependent. The oxidation is assumed to involve the formation of an insoluble mercurous salt. This oxidation can be used as a supplemental analytical method to follow the degradation pathways of I which involve the loss of II and also as a control method for II in nondegraded I.

Coulometry—Coulometric reduction of I in pH 2.3 buffer on the limiting current plateau of wave I resulted in *n* values of 1.85 and 1.94. No anodic waves corresponding in $E_{1/2}$ to wave I were found in the electrolyzed solutions. Wave II was considered to be too close to background discharge for coulometric *n* value determination. However, comparison of diffusion currents for waves I and II indicates a five- or six-electron transfer for wave II.

Polarography of 3-Acetoxymethyl-7-[2-(3-sydnone)acetamido]-3-cephem-4-carboxylic Acid, Sodium Salt (III)—A 0.54 m*M* solution of III, in which an acetoxy group has been substituted for the thiol-thiadiazole group, in pH 2.3 McIlvaine buffer exhibits only one reduction wave at −1.01 v. with an *i/C* value of 14.3 μa./m*M*.

Polarography of 7-(Thiophene-2-acetamido)cephalosporanolactone (IV)—Compound IV, with a thiophene in place of a sydnone and an α,β-unsaturated lactone at the 3–4 position (Scheme IA) (1), showed no reduction waves in pH 2.3 McIlvaine buffer.

DISCUSSION

Cephaloridine, cephalothin, and cephalosporin C, as reported by Jones *et al.* (1), each exhibit one reduction wave. The polarographic $E_{1/2}$'s of the three compounds are pH dependent and concentration dependent, and the reduction wave of cephaloridine is diffusion controlled. Compound I exhibits two reduction waves, both showing the same characteristics with respect to pH and concentration as has been demonstrated. The $E_{1/2}$ concentration dependence of all four compounds is indicative of a polarographically irreversible reduction. Final solutions, completely electrolyzed with respect to the first reduction wave of I, showed no anodic wave with an $E_{1/2}$ corresponding to that of wave I, further proof of an irreversible reduction. Based on preliminary diffusion current data, Jones *et al.* (1) assumed that cephaloridine was reduced *via* a two-electron transfer. Coulometry, on the first reduction of I, confirms a net two-electron transfer for the compound and, based on *i/C* data, suggests a five- to six-electron transfer for the second reduction wave.

Jones *et al.* (1) made no attempt to assign the functionality in cephaloridine that undergoes reduction. Comparison of the reduction patterns of I and cephaloridine shows similar half-wave potentials for the second reduction of I and the reduction of cephaloridine. However, the former is a five- to six-electron transfer, and the latter is assumed to be a two-electron transfer. Sydnones, as reported by Zuman (4), are reduced in a single six-electron step under acidic conditions, which supports a hypothesis that wave II represents the reduction of the sydnone side chain of I, a functionality not present in cephaloridine.

Table III—Effect of Concentration on the $E_{1/2}$ and i_d of II

Concentration, m*M*	$-E_{1/2}$, v.	$-i_d$, μa.
0.30	0.09	0.76
0.60	0.11	1.67
0.91	0.12	2.64
1.21	0.12	3.52
1.51	0.13	4.41

The acid hydrolysis of I, as followed by TLC, results in the loss of II and the formation of the lactone of I. Polarographically, acid hydrolysis results in the loss of the first reduction wave and the retention of the second reduction wave. These two observations point to the first reduction of I as involving the side chain (II) at the 3-position. This conclusion is supported by the fact that III, which has an acetoxy group in the 3-position in place of the thiol-thiadiazole and the same acetamido grouping at the 7-position, exhibits only one reduction wave at −1.01 v., corresponding to the proposed sydnone reduction of I. Compound II is not reducible under similar conditions.

It was recently reported (5) that cephalosporin C, upon macroelectrolysis at a mercury pool electrode at pH 6.6, is converted to the deacetoxy compound, *i.e.*, the acetoxy group at the 3-position is reductively eliminated. It seems reasonable to assume, then, that the first reduction wave of I represents a similar elimination in which the thiol-thiadiazole group is expelled from the molecule. Conclusions from an extension of these arguments to the reduction waves of cephalosporin C and cephalothin, as reported by Jones *et al.* (1), are obvious. The reduction of cephaloridine, which probably also involves the 3-position side chain, may be complicated by its zwitterion character. Moreover, the first reduction wave of I is approximately 300 mv. more positive than the reduction wave of cephaloridine and approximately 600 mv. more positive than the reductions of cephalosporin C and cephalothin at the same pH. This indicates a substituent effect on the reduction caused by the functionality at the 3-position.

Cephalosporins, in general, easily undergo acid (6) and base (7) hydrolysis (Scheme I). Acid hydrolysis results in the loss of the R group at the 3-position and formation of an α,β-unsaturated lactone. Base hydrolysis opens the β-lactam moiety and simultaneously eliminates the R group at the 3-position. TLC has tentatively supported these degradation pathways for I. Enzymatic deactivation of cephalosporins is believed (7) to follow a reaction path similar to that of base hydrolysis, again with loss of the R group. As can be seen from Figs. 1A and 1B, the acid and base hydrolysis of I can be followed by polarography. The enzymatic degradation also results in loss of wave I of I. The key to this specificity is believed to be the loss of the R group at the 3-position. The identities of the new polarographic waves produced *via* the three degradation paths have not been established. The lactone functionality, from the polarography of IV, is not responsible for any of them. However, Structure 2 in Scheme IB could be polarographically reducible.

As mentioned under the polarography of II, II should also be a contaminant in nondegraded I. This conclusion is based on the reported (7) method of synthesis of compounds containing R groups at the 3-position other than —H or —$OCOCH_3$. The reaction is a nucleophilic displacement wherein an excess of free side chain is used to replace the naturally occurring —$OCOCH_3$ function of the fermentation product, cephalosporin C. The oxidation of II, therefore, should not only be useful in following the degradation of I, and presumably other cephalosporins with similar 3-position substituents, but should also be useful in examining newly synthesized cephalosporin for side-chain contaminant.

CONCLUSION

The polarographic reduction of I consists of two waves. The first is believed to be the two-electron reductive elimination of the 3-position substituent. The second is believed to be the six-electron reduction of the sydnone acetamido 7-position substituent. Both waves can be utilized as control methods for the analytical determination of I. Only the first wave, however, can be used to follow the

acid, base, and enzymatic degradations of I which involve the loss of the 3-position substituent.

When taking into consideration the work of Jones *et al.* (1), it is believed that the polarographic method should be generally applicable to all cephalosporins containing a leaving group at the 3-position. Those free leaving groups containing a thiol functionality should also be amenable to polarographic determination *via* oxidative mercurous salt formation.

4-Anilidopiperidine Analgesics I: Synthesis and Analgesic Activity of Certain Ring-Methylated 1-Substituted 4-Propananilidopiperidines

THOMAS N. RILEY▲, DANNY B. HALE*, and MARVIN C. WILSON†

Abstract □ In view of the potency-enhancing effect of methyl substitution of the piperidine ring of the 4-phenylpiperidine analgesics and the alkylene chain of the acyclic basic anilide analgesics, the 1-methyl, 1-benzyl, and 1-phenylethyl derivatives of 2-methyl-, 3-methyl-, and 2,5-dimethyl-4-propananilidopiperidine were prepared. The analgesic activity of these compounds indicates that 3-methylation has the greatest effect in enhancing analgesic potency whereas 2-methyl and 2,5-dimethyl substitution is detrimental to analgesic activity.

Keyphrases □ 4-Anilidopiperidine analgesics—synthesis and activity of ring-methylated 1-substituted 4-propananilidopiperidines □ Analgesics, potential—synthesis of ring-methylated 1-substituted 4-propananilidopiperidines, structure–activity relationships □ Structure–activity relationships—4-anilidopiperidines and analgesic activity, effect of ring methylation

Fentanyl[1] (I, R = $C_6H_5CH_2CH_2$) is a potent narcotic analgesic which possesses a rapid onset and short duration of action (1). Its pharmacological profile is very similar to other morphinomimetic compounds, except that fentanyl is a considerably more potent narcotic analgesic (2). Structurally, fentanyl may be characterized as a 4-anilidopiperidine derivative. This class of synthetic narcotic analgesics exhibits structural features also found in the acyclic basic anilide analgesics (II) and the 4-phenylpiperidine analgesics (III).

In general, studies of structure–activity relationships in the 4-anilidopiperidine class (3–6) indicate that structural requirements for analgesic activity are similar to those established for both the acyclic basic anilides and the 4-phenylpiperidines. One aspect of the structure–activity relationships of the 4-anilidopiperidines that has not as yet been reported is the effect of piperidine ring methylation in this class. It is well established that methylation of the piperidine ring of the 4-phenylpiperidine analgesics (*e.g.*, the prodines) results in a significant increase in analgesic activity. In addition, introduction of a methyl substituent on the alkylene chain of the acyclic basic anilides provides for compounds of high analgesic activity. In this regard, however, it is important to note that the increase in analgesic activity in these analogs is highly dependent on the position of the methyl substituent relative to the basic nitrogen. In the 4-phenylpiperidines, 3-methylation and 2,3-, 2,5-, and 3,5-dimethylation result in high analgesic activities (7). Other methyl substitution patterns in this class generally reduce analgesic activity. In the acyclic basic anilide analgesics, methyl substitution α to the basic nitrogen affords the greatest enhancement of analgesic activity (3).

IV V VI

R = (*a*) CH_3, (*b*) $C_6H_5CH_2$, or (*c*) $C_6H_5CH_2CH_2$

These considerations prompted this study of the effect of ring methylation in conjunction with 1-substitution on the analgesic activity of the 4-propananilidopiperidines. The 1-substituted 2-methyl analogs (IV) possess structural features shown to confer high analgesic activity on the acyclic basic anilides. The 1-substituted 3-methyl-4-propananilidopiperidines (V) and 2,5-dimethyl-4-propananilidopiperidines (VI) exhibit structural features important for potent analgesic activity in the 4-phenylpiperidine class.

SYNTHESIS

Literature schemes for the synthesis of 4-anilidopiperidines usually proceed through the 1-substituted 4-piperidones with the formation of the Schiff base with aniline, followed by reduction and subsequent acylation of the 4-anilino moiety (5, 8). In this study, however, the desired 4-anilidopiperidines were most readily accessible *via* the appropriate 4-anilinopyridines (XI, Scheme I). These key intermediates were prepared according to literature procedures (9) *via* nucleophilic displacement of chloride by aniline from the appropriate 4-chloropyridine *N*-oxides (IX) or 4-chloropyridine hydrochlorides (X). Syntheses of X proved to be more facile than the preparation of IX, and treatment of X with aniline hydrochloride gave higher yields of the desired 4-anilinopyridines.

The propananilides (XII, Scheme II) were obtained by heating the 4-anilinopyridines (XI) in propionic anhydride. Hydrogenation of the pyridine ring in XII was achieved using 10% palladium-on-charcoal in glacial acetic acid in a catalyst to a compound ratio of 1:3. The use of platinum oxide as a catalyst in this conversion proved unsatisfactory because of partial pyridine ring reduction and reduction of the aniline ring.

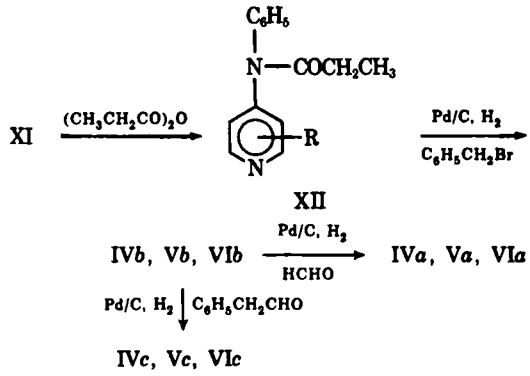
Scheme I



XI XII IV*b*, V*b*, VI*b* IV*a*, V*a*, VI*a* IV*c*, V*c*, VI*c*

Scheme II

The ring-methylated 4-propananilidopiperidines obtained from the reduction of the 4-anilidopyridines proved very difficult to purify. Preparation of the 1-benzyl-4-propananilidopiperidines provided products that could be easily purified by adsorption chromatography. The other two series of 1-substituted 4-propananilidopiperidines were conveniently prepared by catalytic hydrogenolysis of the 1-benzyl derivatives in the presence of either formaldehyde or phenylacetaldehyde.

The synthetic procedures employed for the preparation of the ring-methylated 4-anilidopiperidines of this study undoubtedly gave rise to diastereomeric mixtures of the products. Isomeric mixtures were indicated in certain cases by separation during chromatographic purification. However, in all cases that this was observed the isomers were combined to give homogeneous products with regard to elemental analyses. The results with adsorption chromatography will be of value in future studies of the isomers of these compounds.

ANALGESIC ACTIVITY

The analgesic activity of the ring-methylated 4-anilidopiperidines prepared in this study was determined in rats by the D'Amour–Smith (10) tail-flick method. The compounds were tested as the hydrochloride salts and were dissolved in normal saline immediately prior to intraperitoneal injection. The ED_{50} value for the compound studied is defined as the dose of the drug which, in 50% of the animals tested, increased the reaction time by 50% at 40 min. postinjection. Compounds were deemed inactive if the rats did not exhibit significant analgesia at dose levels of 100 mg./kg.

EXPERIMENTAL[2]

4-Anilino-2-methylpyridine (XI*a*)—A mixture of 8.2 g. (0.05 mole) of 4-chloro-2-methylpyridine hydrochloride (X*a*) [prepared by standard procedures by treatment of 2-methylpyridine *N*-oxide (VII*a*) with phosphorus oxychloride] and 10.3 g. (0.08 mole) of aniline hydrochloride was placed in a sealed vessel and heated for 4 hr. at 130°. The resulting tarry material was purified by steam distillation. After 800 ml. of distillate had been collected, the residue was filtered and the filtrate was treated with charcoal and filtered through diatomaceous earth[3]. The filtrate was extracted with chloroform and the chloroform was dried (sodium sulfate) and evaporated *in vacuo*, leaving 5.2 g. (56%) of XI*a* as white crystals, m.p. 146–147°; NMR ($CDCl_3$): δ 8.40 (d, 1, C-6 H), 7.45–7.85 (m, 5, N—C_6H_5), 7.28 (s, 1, C-3 H), 7.20 (d, 1, C-5 H), 6.78 (broad s, 1, N—*H*), and 2.50 (s, 3, C-2 CH_3).

[2] All melting points were determined on a Thomas-Hoover melting-point apparatus and are uncorrected. The IR spectra for all compounds were as expected. The NMR spectra were taken using a C-60HL Jeolco instrument, using tetramethylsilane as the internal standard. Elemental analyses were performed by Chemlytics, Inc., Tempe, Ariz. Hydrochloride salts of amine oxides were formed by dissolving the amine oxide in dilute aqueous hydrochloric acid and evaporating *in vacuo*.

Anal.—Calc. for $C_{15}H_{13}N_3$: C, 78.26; H, 6.52; N, 15.22. Found: C, 78.21; H, 6.67; N, 14.64.

4-(*N*-Propananilido-2-methylpyridine) (XII*a*)—An 18.4-g. (0.10-mole) sample of XI*a* was dissolved in 100 ml. of propionic anhydride and heated at 80° for 12 hr. The excess propionic anhydride was removed *in vacuo*, and the dark residue was purified in 10-g. quantities by passage through a 1000 × 25-mm. chromatographic column packed with 190 g. of silica gel. Elution was carried out with ethyl acetate and 30-ml. fractions were collected. Fractions 11–20 were found to contain the product. This procedure gave 19.5 g. (81%) of XII*a* as a light oil; NMR ($CDCl_3$): δ 8.40 (d, 1, C-6 H), 7.40–7.85 (m, 5, N—C_6H_5), 7.31 (s, 1, C-3 H), 7.25 (d, 1, C-5 H), 2.54 (s, 3, C-2 CH_3), 2.48 (m, 2, $COCH_2CH_3$), and 1.25 (t, 3, $COCH_2CH_3$). The hydrochloride salt was prepared by standard procedures and recrystallized from ethanol–ether, m.p. 152°.

Anal.—Calc. for $C_{15}H_{16}N_2O \cdot HCl$: C, 65.10; H, 6.15; N, 10.13. Found: C, 64.91; H, 6.22; N, 9.64.

1-Benzyl-2-methyl-4-(*N*-propananilido)piperidine (IV*b*)—A 15.6-g. (0.064-mole) sample of XII*a* was dissolved in 150 ml. of glacial acetic acid, and 4.0 g. of 10% palladium-on-charcoal was added to the solution. The mixture was hydrogenated for 24 hr. at 75°. The catalyst was removed by filtration, and the filtrate was carefully basified with sodium hydroxide and then extracted with chloroform. The chloroform extract was dried (sodium sulfate) and concentrated *in vacuo*, giving a viscous oil. This oil was dissolved in acetonitrile, and 13.3 g. (0.078 mole) of benzyl bromide was added. The solution was refluxed for 11 hr. followed by concentration *in vacuo*. The residual oil was taken up in a saturated solution of potassium carbonate and extracted with chloroform. The chloroform extract was dried (sodium sulfate) and concentrated *in vacuo* to yield a yellow oil, which was then passed through a 500 × 25-mm. chromatographic column packed with 90 g. of silica gel. Elution with ethyl acetate gave 10.5 g. (48%) of IV*b* as a clear oil; NMR ($CDCl_3$): δ 7.20–7.75 (m, 10, N—C_6H_5 and N—$CH_2C_6H_5$), 4.50–5.05 (m, 1, C-4 H), 3.15 and 4.33 (*AB* quartet, 2, N—$CH_2C_6H_5$), and 0.80–1.45 (m, 6, $COCH_2CH_3$ and C-2 CH_3). The picrate of IV*b* was recrystallized from ethanol, m.p. 210–212°.

Anal.—Calc. for $C_{22}H_{28}N_2O \cdot C_6H_3N_3O_7$: C, 59.46; H, 5.50; N, 12.38. Found: C, 59.72; H, 5.40; N, 12.36.

1-(2-Phenylethyl)-2-methyl-4-(*N*-propananilido)piperidine (IV*c*)—A 3.0-g. (0.009-mole) sample of IV*b* was mixed with 1.44 g. (0.012 mole) of phenylacetaldehyde and 0.5 g. of 10% palladium-on-charcoal in ethanol and hydrogenated for 4 hr. at room temperature. The reaction mixture was filtered and concentrated *in vacuo*, leaving a dark oil. The oil was purified by passing it through a 500 × 25-mm. chromatographic column packed with 90 g. of silica gel. Elution with ethyl acetate provided 2.24 g. (71%) of IV*c* as an oil; NMR ($CDCl_3$): δ 7.20–7.85 (m, 10, N—C_6H_5 and N—$CH_2CH_2C_6H_5$), 4.33–4.80 (m, 1, C-4 H), and 0.80–1.50 (m, 6, $COCH_2CH_3$ and C-2 CH_3). The oil formed a picrate which was recrystallized from ethanol, m.p. 207–208°.

Anal.—Calc. for $C_{23}H_{30}N_2O \cdot C_6H_3N_3O_7$: C, 60.09; H, 5.74; N, 12.08. Found: C, 59.90; H, 5.75; N, 12.12.

1,2-Dimethyl-4-(*N*-propananilido)piperidine (IV*a*)—A mixture of 2.0 g. (0.006 mole) of IV*b*, 0.90 g. (0.01 mole) of 37% formaldehyde solution, and 0.5 g. of 10% palladium-on-charcoal was hydrogenated for 4 hr. The reaction mixture was filtered, concentrated *in vacuo*, and passed through a 250 × 20-mm. chromatographic column packed with silica gel. Elution with ethyl acetate gave 1.2 g. (79%) of viscous oil; NMR ($CDCl_3$): δ 7.20–7.75 (m, 5, N—C_6H_5), 4.50–5.00 (m, 1, C-4 H), 2.07 (s, 3, N—CH_3), and 0.80–1.50 (m, 6, $COCH_2CH_3$ and C-2 CH_3). The oil formed a picrate which was recrystallized from ethanol, m.p. 194–196.5°.

Anal.—Calc. for $C_{16}H_{24}N_2O \cdot C_6H_3N_3O_7$: C, 53.98; H, 5.56; N, 14.31. Found: C, 54.00; H, 5.68; N, 14.76.

4-Anilino-3-methylpyridine (XI*b*)—A mixture of 7.2 g. (0.05 mole) of 4-chloro-3-methylpyridine *N*-oxide (IX*b*), prepared by standard procedures from the 4-nitro derivative (VIII*b*) (9), and 9.3 g. (0.10 mole) of aniline was heated in a sealed vessel at 130° for 4 hr. The deep-violet tar obtained from this procedure was purified as described in the synthesis of XI*a*, leaving a green crystalline solid which was recrystallized from ethanol–water (1:3) to yield 3.51 g. (38%) of product, m.p. 119–120° [lit. (9) m.p. 122°].

4-(*N*-Propananilido)-3-methylpyridine (XII*b*)—A 20.3-g. (0.11-mole) sample of 4-anilino-3-methylpyridine (XI*b*) dissolved in 100 ml. of propionic anhydride was stirred and heated at 80° for 12 hr. Purification by the procedure described for XII*a* gave 21.1 g. (80%) of a light-yellow oil; NMR ($CDCl_3$): δ 8.63 (d, 1, C-6 H), 8.70 (s, 1, C-2 H), 7.55–7.80 (m, 5, N—C_6H_5), 7.35 (d, 1, C-5 H), 2.45 (m, 2, $COCH_2CH_3$), and 1.20 (t, 3, $COCH_2CH_3$). The hydrochloride salt of XII*b* was formed in the usual way and recrystallized from ethanol–ether, m.p. 136–137°.

Anal.—Calc. for $C_{15}H_{16}N_2O \cdot HCl$: C, 65.09; H, 6.15; N, 10.12. Found: C, 64.94; H, 6.25; N, 9.98.

1-Benzyl-3-methyl-4-(*N*-propananilido)piperidine (V*b*)—A 9.6-g. (0.04-mole) sample of XII*b* was dissolved in 100 ml. of glacial acetic acid, and 4.0 g. of 10% palladium-on-charcoal was added to the solution. The mixture was hydrogenated for 24 hr. at 75°. After filtration, basification, and concentration, the residual oil was refluxed with 11.9 g. (0.07 mole) of benzyl bromide in acetonitrile. The oil obtained by this procedure was purified as described for IV*b*, yielding 7.8 g. (58%) of V*b* as a clear oil; NMR ($CDCl_3$): δ 7.45 (s, 5, $CH_2C_6H_5$), 7.30–7.80 (m, 5, N—C_6H_5), 4.45–4.80 (m, 1, C-4 H), 3.55 (s, 2, N—$CH_2C_6H_5$), and 1.10 (d, 3, C-3 CH_3). The hydrochloride salt of V*b* was prepared and recrystallized from ethanol–ether, m.p. 202.5–204°.

Anal.—Calc. for $C_{22}H_{28}N_2O \cdot HCl \cdot H_2O$: C, 67.59; H, 7.99; N, 7.17. Found: C, 67.83; H, 7.55; N, 7.02.

1-(2-Phenylethyl)-3-methyl-4-(*N*-propananilido)piperidine (V*c*)—A 4.0-g. (0.012-mole) sample of V*b* was mixed with 1.0 g. (0.016 mole) of phenylacetaldehyde and treated according to the procedure described for the synthesis of IV*c*, resulting in 3.32 g. (79%) of V*c* as a clear oil; NMR ($CDCl_3$): δ 7.42 (s, 5, N—$CH_2CH_2C_6H_5$), 7.30–7.77 (m, 5, N—C_6H_5), 4.40–4.80 (m, 1, C-4 H), and 1.10 (d, 3, C-3 CH_3). The hydrochloride salt of V*c* was prepared and recrystallized from ethanol–ether, m.p. 164–166°.

Anal.—Calc. for $C_{23}H_{30}N_2O \cdot HCl$: C, 71.38; H, 8.08; N, 7.24. Found: C, 71.01; H, 8.24; N, 6.95.

1,3-Dimethyl-4-(*N*-propananilido)piperidine (V*a*)—A mixture of 4.0 g. (0.012 mole) of V*b* and 0.13 g. (0.015 mole) of formaldehyde solution (37%) was treated according to the procedure described in the preparation of IV*a* to yield 2.6 g. (82%) of V*a* as a clear oil; NMR ($CDCl_3$): δ 7.10–7.65 (m, 5, N—C_6H_5), 4.24–4.75 (m, 1, C-4 H), 2.23 (s, 3, N—CH_3), and 1.10 (d, 3, C-3 CH_3). The picrate of V*a* was prepared in the usual manner, m.p. 164°.

Anal.—Calc. for $C_{16}H_{24}N_2O \cdot C_6H_3N_3O_7$: C, 53.98; H, 5.56; N, 14.31. Found: C, 54.04; H, 5.56; N, 14.73.

4-Chloro-2,5-dimethylpyridine (X*c*)—A 154.5-g. (0.88-mole) sample of 2,5-dimethylpyridine *N*-oxide hydrochloride was prepared by standard procedures and added to 475 g. (3.10 moles) of phosphorus oxychloride. The reaction was heated to 120° for 1 hr. and then refluxed for 4 hr. The solution was allowed to cool and poured into ice. The solution was basified (potassium carbonate) and extracted with ether, and the ethereal extracts were dried (sodium sulfate) and concentrated *in vacuo*, leaving an impure liquid which was distilled at 40–50° (1 mm.) to give 89.7 g. (72%) of X*c*; NMR ($CDCl_3$): δ 8.60 (s, 1, C-6 H), 7.15 (s, 1, C-3 H), 2.50 (s, 3, CH_3), and 2.40 (s, 3, CH_3). The hydrochloride of X*c* was prepared, m.p. 240–241°.

Anal.—Calc. for $C_7H_8ClN \cdot HCl$: C, 47.21; H, 5.09; N, 7.69. Found: C, 47.29; H, 5.55; N, 7.74.

4-Anilino-2,5-dimethylpyridine (XI*c*)—Following the procedure used to prepare XI*a*, 81.6 g. (0.63 mole) of aniline hydrochloride and 80.1 g. (0.45 mole) of X*c*·HCl reacted to yield XI*c* as a gray solid. Recrystallization from dioxane yielded 61.2 g. (49%) of a white solid, m.p. 145°; NMR ($CDCl_3$): δ 7.05–7.90 (m, 6, C-3 H and N—C_6H_5), 2.50 (s, 3, CH_3), and 2.40 (s, 3, CH_3).

Anal.—Calc. for $C_{13}H_{14}N_2$: C, 78.78; H, 7.07; N, 14.14. Found: C, 78.70; H, 7.15; N, 14.16.

4-(*N*-Propananilido)-2,5-dimethylpyridine (XII*c*)—A 29.7-g. (0.15-mole) sample of XI*c* was heated in 150 ml. of propionic anhydride for 12 hr. at 80°. The reaction was worked up as described for XII*a* to give 31.7 g. (83%) of XII*c* as an oil which solidified on standing at room temperature. Recrystallization of this solid from ether gave white crystals, m.p. 87–89°; NMR ($CDCl_3$): δ 8.15 (s, 1, C-6 H), 7.20–7.55 (m, 5, N—C_6H_5), 7.13 (s, 1, C-3 H), 2.57 (s, 3, C-2 CH_3), 2.26 (s, 3, C-5 CH_3), 2.33 (m, 2, $COCH_2CH_3$), and 1.16 (t, 3, $COCH_2CH_3$).

Anal.—Calc. for $C_{16}H_{18}N_2O$: C, 75.79; H, 7.09; N, 11.02. Found: C, 75.53; H, 6.90; N, 10.77.

1-Benzyl-4-(*N*-propananilido)-2,5-dimethylpiperidine (VI*b*)—A solution of 10.1 g. (0.04 mole) of XII*c* in 120 ml. of glacial acetic acid was hydrogenated and then treated with 8.5 g. (0.05 mole) of

Table I—Analgesic Activities of 4-Propananilidopiperidines

benzyl bromide, as previously described for the preparation of IV*b*, to yield 7.3 g. (52%) of VI*b* as a clear oil; NMR ($CDCl_3$): δ 7.20–7.75 (m, 10, N—C_6H_5 and N—$CH_2C_6H_5$), 4.30–4.75 (m, 1, C-4 H), 2.95–4.20 (*AB* quartet, 2, N—$CH_2C_6H_5$), and 0.80–1.40 (m, 9, C-2 CH_3, C-5 CH_3 and $COCH_2CH_3$). The oil formed a picrate which was recrystallized from ethanol, m.p. 209–210°.

Anal.—Calc. for $C_{23}H_{30}N_2O \cdot C_6H_3N_3O_7$: C, 60.09; H, 5.74; N, 12.08. Found: C, 59.71; H, 5.68; N, 11.81.

1-(2-Phenylethyl)-2,5-dimethyl-4-(*N*-propananilido)piperidine (VI*c*)—A solution of 1.0 g. (0.008 mole) of phenylacetaldehyde and 2.0 g. (0.006 mole) of VI*b* was hydrogenated over 10% palladium-on-charcoal. The product was purified, as previously described in the preparation of IV*c*, to provide 1.16 g. (53%) of VI*a* as a clear oil; NMR ($CDCl_3$): δ 7.35–7.75 (m, 10, N—C_6H_5 and N—$CH_2CH_2C_6H_5$), 4.30–4.75 (m, 1, C-4 H), and 0.80–1.40 (m, 9, C-2 CH_3, C-5 CH_3 and $COCH_2CH_3$). The oil formed a hydrochloride salt which was recrystallized from ethanol–ether, m.p. 235.5–237°.

Anal.—Calc. for $C_{24}H_{32}N_2O \cdot HCl$: C, 71.88; H, 8.30; N, 6.99. Found: C, 71.70; H, 8.24; N, 6.96.

4-(*N*-Propananilido)-1,2,3-trimethylpiperidine (VI*a*)—Two grams (0.006 mole) of VI*b* and 0.9 g. (0.01 mole) of formaldehyde were hydrogenated. The product was purified, as previously described in the preparation of IV*a*, to yield 1.28 g. (78%) of VI*a* as a clear oil; NMR ($CDCl_3$): δ 7.20–7.75 (m, 5, N—C_6H_5), 4.30–4.75 (m, 1, C-5 H), 2.07 (s, 3, N—CH_3), and 0.80–1.40 (m, 9, C-2 CH_3, C-5 CH_3 and $COCH_2CH_3$). The oil formed a picrate which was recrystallized from ethanol, m.p. 242–244°.

Anal.—Calc. for $C_{17}H_{26}N_2O \cdot C_6H_3N_3O_7$: C, 54.86; H, 5.81; N, 13.91. Found: C, 55.86; H, 5.95; N, 14.13.

RESULTS AND DISCUSSION

Analgesic activities of the ring-methylated 4-propananilidopiperidines prepared in this study are given in Table I. The results of analgesic activities of the 4-propananilidopiperidines in this study are in accord with previous findings of structure–activity relationships for morphinomimetic compounds in that phenethylation of a basic nitrogen in these agents provides compounds of the highest analgesic activity. The results further indicate that 3-methylation of the piperidine ring of the 4-propananilidopiperidines significantly enhances analgesic activity, whereas 2-methylation and 2,5-dimethylation lead to a significant reduction in analgesic activity. It is interesting to correlate the effect of 1-substitution on the analgesic activities of the 4-propananilidopiperidines. In the fentanyl (I) and the 2,5-dimethylated (VI) series, potency is observed to decrease in the order $C_6H_5CH_2CH_2 > C_6H_5CH_3 > CH_3$, whereas in the 3-methylated series (V) the dependence of analgesic activity on the 1-substituent is in the order $C_6H_5CH_2CH_2 > CH_3 > C_6H_5CH_2$. These relationships suggest that introduction of a methyl substituent in the piperidine ring of the 4-propananilidopiperidine analgesics results in a fundamental alteration of the analgesic activity of these compounds which is possibly related to the mode of binding of the molecules at the analgesic receptor.

A meaningful interpretation of the nature of the interaction of the 4-propananilidopiperidines with the analgesic receptor is rather difficult to derive from the analgesic activities given in Table I. In addition to reflecting differences in receptor affinities, these results also reflect differences in distribution and metabolism of the various compounds. These latter factors can result in significant differences in biophase concentrations and, hence, apparent differences in analgesic activities (11).

Introduction of a ring methyl into the 4-propananilidopiperidines results in chiral molecules. In view of the reported stereoselectivity of the narcotic analgesic receptor (12), it is anticipated that separation of the geometric and optical isomers of the compounds in this study will provide even more potent compounds and will afford pertinent information with regard to the nature of the drug–receptor interaction. Studies on stereostructure–activity relationships for the ring-methylated 4-propananilidopiperidines are currently underway in these laboratories.

Reaction of Helenalin with Hydrogen Chloride

KUO-HSIUNG LEE[▲], HIROSHI FURUKAWA*, SUN-HYUK KIM, and CLAUDE PIANTADOSI

Abstract □ Reaction of helenalin (I) with hydrogen chloride–chloroform and deactivated neutral alumina yielded three products: mexicanin A (II), 1-epiallohelenalin (IV), and a new oxide (V). These products were formed *via* intermediates (VII, IX, and VIII, respectively) by the initial addition of hydrogen chloride to the exocyclic methylene grouping of the γ-lactone followed by elimination of hydrogen chloride upon treatment with neutral alumina. Exposure of II to hydrogen chloride–chloroform gave the same intermediates (VII, IX, and VIII) which, upon treatment with the neutral alumina, regenerated II, IV, and V, respectively. Thus, II was the common intermediate for IV and V in the reaction of I with hydrogen chloride–chloroform and neutral alumina. The conversion of IV to its intermediate [11,13-dihydro-13-chloro-1-epiallohelenalin (IX)] with hydrogen chloride–chloroform and the complete recovery of the starting material (IV) with neutral alumina were also observed. Treatment of I with concentrated hydrochloric acid afforded 2,3-dihydro-2-chlorohelenalin (X). Compound X was also readily converted to I upon treatment with either neutral alumina or water. Further reaction of I with deactivated neutral alumina in chloroform led to the direct formation of II. The structures of these compounds were assigned on the basis of chemical as well as spectral evidence. The mode of formation of these compounds was also postulated.

Keyphrases □ Helenalin—reaction with hydrogen chloride–chloroform, identification of products and intermediates, mechanism of formation □ Sesquiterpene lactones—reaction of helenalin with hydrogen chloride–chloroform, identification of products and intermediates □ Hydrogen chloride—reaction with helenalin, identification of products and intermediates, mechanism of formation

The conversion of helenalin (I) to a mixture of mexicanin A (II) and neohelenalin (III) by treatment with hydrogen chloride–chloroform was previously reported (1–3). In connection with the study of the structure–activity relationship among the helenalin-related sesquiterpene lactones for cytotoxic or antitumor activity (4–6), this reaction was repeated; the chemical as well as spectroscopic data on the resulting products provided some interesting information on their structures and the mode of their formation.

When helenalin (I) was dissolved in anhydrous chloroform saturated with hydrogen chloride at room temperature and the resulting products were chromatographed on deactivated neutral alumina according to Herz *et al.* (1), the expected mexicanin A (II) was obtained in 25% yield as reported (1); but instead of neohelenalin (III)[1] accompanying II, traces of 1-epiallohelenalin (IV) and a new compound, an oxide (V), isolated in 5% yield, were obtained. However, these compounds (II, IV, and V) were not obtained before the treatment of the reaction products with neutral alumina. This finding will be covered later.

DISCUSSION

Compound V, m.p. 188–190°, had the composition $C_{15}H_{18}O_4$ and showed a molecular ion peak at *m/e* 262 in the mass spectrum. Compound V revealed IR bands at 1760 and 1655 cm.$^{-1}$ and a pair of low-field doublets in the NMR spectrum at 6.29 (1H, J = 3), and 5.61 (1H, J = 3). This is characteristic of a γ-lactone conjugated with an exocyclic methylene grouping, a feature common to helenalin (I) and mexicanin A (II). The NMR spectrum of V showed the lactonic proton at C-8 as a multiplet at 4.60. Two methyl groups at C-10 and C-5 in V were seen as a doublet at 1.18 (3H, J = 6) and a sharp singlet at 1.07 (3H), respectively. The presence of a cyclopentanone ring system in V was first suggested by the appearance of a strong IR band at 1740 cm.$^{-1}$ and substantiated by the absence of the characteristic conjugated cyclopentenone olefinic protons.

The IR spectrum of Compound V taken in mineral oil showed the absence of a hydroxyl group. This was further confirmed by the fact that V could not be acetylated with acetic anhydride in pyridine. This evidence, coupled with the fact that the empirical formula of Compound V ($C_{15}H_{18}O_4$) was identical with those of helenalin and mexicanin A, would indicate that the remaining fourth oxygen must form an oxide ring. Models show that one of the two possible structures, V or VI, can be assigned to this compound[2]. The former is regarded as the most likely because the signal for the proton at H-2 in Structure V appeared as a multiplet at 4.76, and it would be expected to move further downfield if Structure VI is assigned since H-3 in VI is adjacent to the C-4 carbonyl group. The upfield shift of the oxide proton at C-6 (3.79, 1H, d, J = 5.3) in V, compared with that in the NMR spectrum of helenalin (I) in which the H-6 signal appeared at 4.45 (1H, d, J = 4.5), might be due to the anisotropic effect of the α-methylene grouping of the γ-lactone.

The foregoing evidence suggests the assignment of Structure V with complete stereochemistry for the oxide.

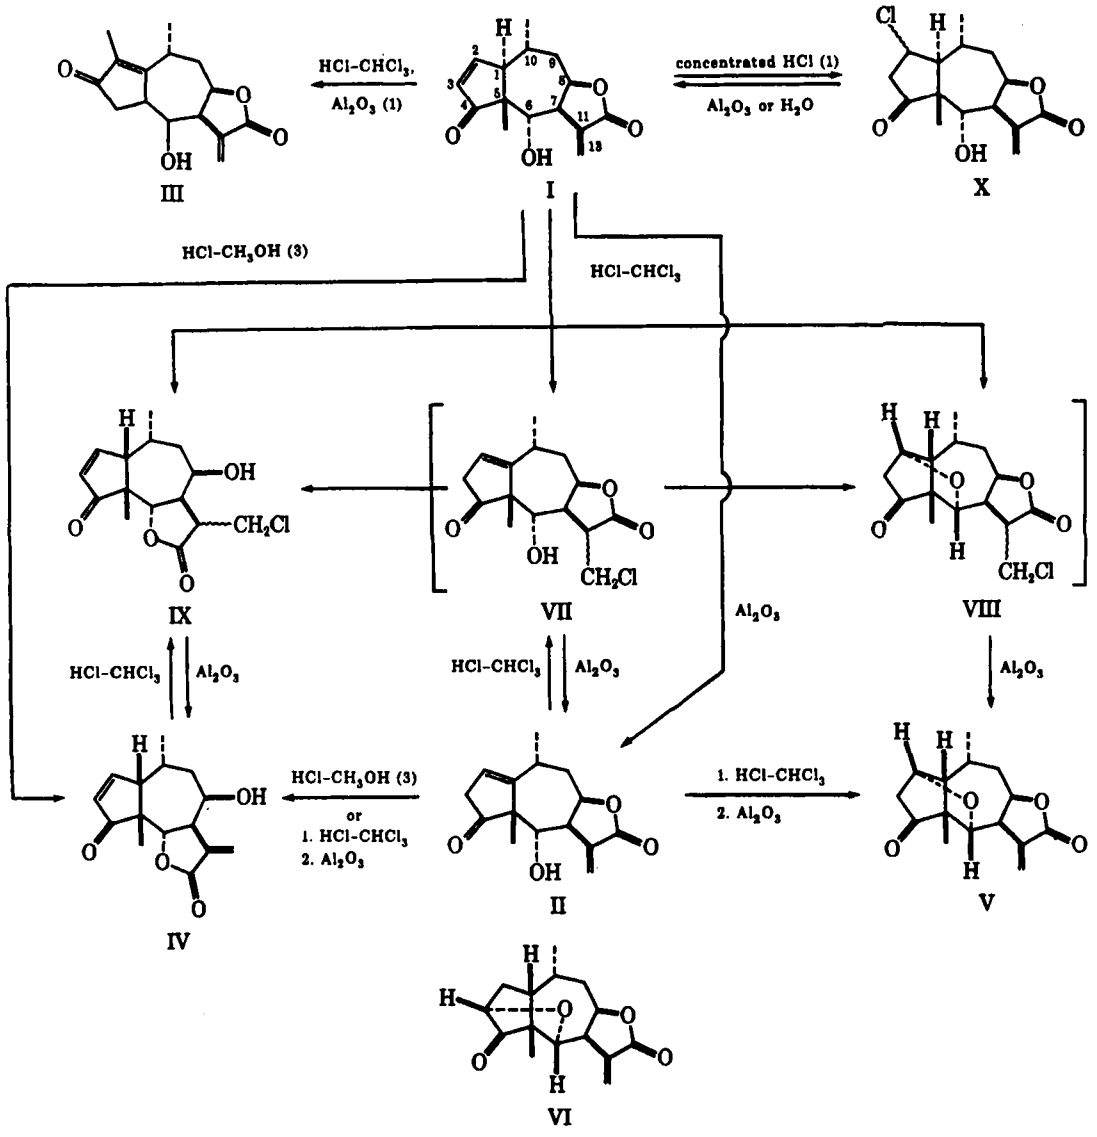
The other product besides II and V in this reaction of I with hydrogen chloride–chloroform and neutral alumina was the 1-epiallohelenalin (IV). This compound was obtained in only about 2% yield and was shown to be identical with the major product obtained by the treatment of I with hydrogen chloride–methanol as reported previously (3).

As already mentioned, during the action of hydrogen chloride–chloroform on helenalin, it was found that the initial reaction products prior to chromatography on neutral alumina were not mexicanin A (II), 1-epiallohelenalin (IV), and the oxide (V). They were mainly the new intermediates that resulted from the addition of hydrogen chloride to the exocyclic methylene grouping of the γ-lactone. These observations were verified by the fact that the intermediates were obtained in almost quantitative yield and showed the characteristic isotopic molecular ions at *m/e* 298 and 300 ($C_{15}H_{19}{}^{35}ClO_4$ and $C_{15}H_{19}{}^{37}ClO_4$) in the ratio of approximately 3:1, indicating the incorporation of 1 mole of hydrogen chloride into the molecule. These intermediates have proven to be elusive as far as separation is concerned[3], but their isolation as a mixture (likely Compounds VII, VIII, and IX) was easily achieved by silica gel chromatography. The NMR spectrum of this mixture further confirmed the absence of the characteristic pair of low-field doublets which corresponds to the α-methylene-γ-lactone grouping. Treatment of mexicanin A (II) with hydrogen chloride–chloroform in a manner similar for helenalin (I) gave reaction products whose NMR spectrum was completely identical with the one obtained from the

[1] Analysis of the crude reaction mixture in high concentration by NMR spectroscopy revealed the absence of any detectable vinyl methyl protons in the high field region (1.60 ~ 2.10). Neohelenalin was reported to show a vinyl methyl group at C-2 as a doublet at 1.68 (J = 2) (1).

[2] Dreiding models indicate that the formation of such an oxide ring between C-6 and C-2 or C-3, as shown in V or VI, requires the inversion of the asymmetric center at C-1 of helenalin. No other oxygen bridge could be constructed when H-1 is in an α disposition. As shown in Structure V, the oxide bridge involved C-6 α, C-2 α bonds.

[3] These mixtures were not very stable and tended to generate mexicanin A gradually upon prolonged sitting at room temperature.



Scheme I

reaction of I with hydrogen chloride–chloroform and yielded products II, IV, and V upon chromatography on neutral alumina.

In conclusion, the results obtained indicate that mexicanin A (II) is the common intermediate for the 1-epiallohelenalin (IV) and the oxide (V) in the reaction of helenalin with hydrogen chloride–chloroform and neutral alumina (Scheme I).

Similar treatment of 1-epiallohelenalin (IV) with hydrogen chloride–chloroform led to the formation of the corresponding hydrogen chloride adduct of the α-methylene-γ-lactone grouping (IX) in quantitative yield. Compound IX, m.p. 234–236°, analyzed for $C_{15}H_{19}ClO_4$, showed a molecular ion peak at *m/e* 298 along with an isotopic ion at *m/e* 300. The NMR spectrum of IX showed the disappearance of the characteristic exocyclic methylene protons and the generation of a new two-proton multiplet at 3.80, attributable to the protons attached to chlorine atom. Compound IX regenerated IV upon treatment with neutral alumina.

Reaction of helenalin (I) with concentrated hydrochloric acid elaborated 2,3-dihydro-2-chlorohelenalin (X) in quantitative yield. The following evidence supported Structure X for this reaction product: the presence of the isotopic molecular ions at *m/e* 298 and 300 in the mass spectrum, the absence of signals corresponding to the olefinic protons at C-2 and C-3 as found in I, and the presence of the well-defined pair of low-field doublets ascribed to the γ-lactone-α-methylene protons in the NMR spectrum. Further treatment of X with neutral alumina or water led to the complete recovery of I. Further reaction of I with deactivated neutral alumina in chloroform led to the direct formation of II in 15% yield.

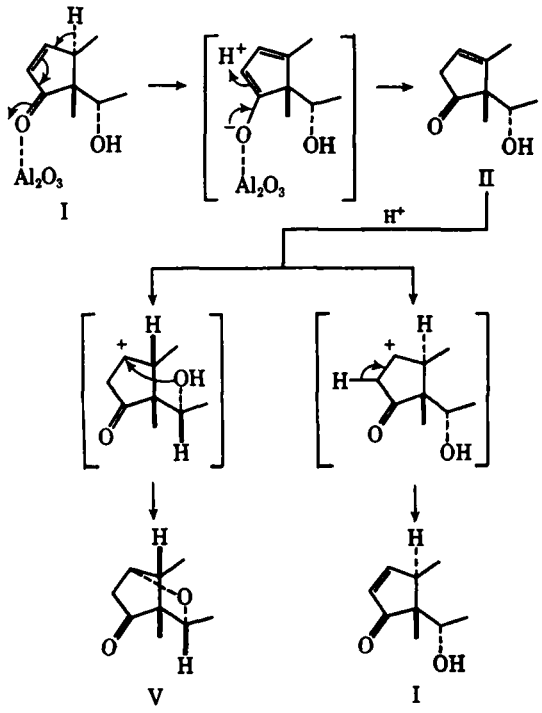
The formation of II and V can be accounted for by the mechanism postulated in Scheme II in which alumina is considered to act as a Lewis acid.

EXPERIMENTAL[4]

Helenalin (I) was obtained from extracts of either *Helenium microcephalum* or *Balduina angustifolia* as previously reported (4, 7).

Treatment of Helenalin (I) with Hydrogen Chloride–Chloroform: Compounds VII, VIII, and IX—This reaction was carried out in the same manner as that reported in the literature (1); *i.e.*, a solution of helenalin (1 g.) in anhydrous chloroform saturated with hydrogen chloride (35 ml.) was allowed to stand at room temperature overnight. The mixture was further refluxed for 30 min., and the product

[4] Melting points were determined on a Thomas-Hoover melting-point apparatus and are corrected. Unless otherwise specified, IR spectra were determined in mineral oil mulls with a Perkin-Elmer 257 grating IR spectrophotometer. NMR spectra were measured in $CDCl_3$ with a Jeolco C 60 HL NMR spectrometer, using tetramethylsilane as an internal standard. All chemical shifts were reported in δ (p.p.m.) values and the coupling constants were reported in hertz values. Signals are characterized in the usual way: s, singlet; d, doublet; t, triplet; q, quartet, and m, multiplet. Mass spectra were determined on an A.E.I. MS-902 instrument at 70 ev. using a direct inlet system. Silica gel for column chromatography refers to Baker A.R. No. 3405, and silica gel for TLC refers to Merck silica gel G developed with chloroform–acetone (3:1) and visualized by spraying with concentrated sulfuric acid and heating. Deactivated neutral alumina for column chromatography refers to neutral alumina AG-7 (100–200 mesh), Bio-Rad, activity grade III. Elemental analyses were performed by Atlantic Microlab, Inc., Atlanta, Ga.



Scheme II

was washed with 5% sodium hydroxide, washed with water, dried over anhydrous sodium sulfate, and evaporated *in vacuo* to yield a brown syrup. The syrup showed the characteristic isotopic molecular ions at *m/e* 298 and 300 as described in the text. It was chromatographed on silica gel (1.3 × 30 cm.) activated at 120° and impregnated with 10% of water using *n*-hexane–benzene (1:1), benzene, and ethyl acetate as the developing solvents, successively. Thirty-one 25-ml. fractions were collected, and the composition of the fractions was determined by examining thin-layer chromatograms. The first hexane–benzene (1:1) eluate (fractions 1–19) yielded, after evaporation of the solvent, a colorless oil (380 mg.), which appeared as a single fast moving spot. The NMR spectrum of this substance indicated that this was a mixture of the hydrogen chloride adducts, *i.e.*, Compounds VII, VIII, and IX. The subsequent benzene (fractions 20–26) (180 mg.) and ethyl acetate (fractions 27–31) (400 mg.) eluates all contained a mixture of mainly the above-mentioned, fast moving spot and traces of others, and they were not investigated further.

Treatment of Helenalin (I) with Hydrogen Chloride–Chloroform and Deactivated Neutral Alumina—The brown syrup obtained from the repetition of the above experiment with I (1 g.) and hydrogen chloride–chloroform (35 ml.) was chromatographed on deactivated neutral alumina (1.5 × 25 cm.). Elution was effected in 2-ml. fractions with benzene, benzene–chloroform, chloroform, and acetone.

The Oxide (V)—The first benzene eluates (fractions 1–10) afforded, after evaporation of the solvent, a crystalline residue. This residue was recrystallized from dichloromethane–absolute ethanol to give V as colorless needles (50 mg., 5%), m.p. 188–190°. The relevant (IR, NMR, and mass) characteristics have been described in the text.

Anal.—Calc. for $C_{15}H_{18}O_4$: C, 68.68; H, 6.92. Found: C, 68.46; H, 7.01.

Mexicanin A (II)—The subsequent benzene–chloroform (1:1) and chloroform eluates (fractions 11–25) provided a crystalline material, which was recrystallized from acetone–ether to furnish II as colorless prisms (250 mg., 25%), m.p. 140–142° [lit. (1) m.p. 138–140° (acetone–ether)]. The IR spectrum of II was identical with that of mexicanin A as described in the literature (1). The NMR spectrum exhibited signals at 1.21 (3H, s, C-5 CH_3), 1.32 (3H, d, J = 6, C-10 CH_3), 3.59 (1H, d, J = 7.5, H-6), 4.67 (1H, dt, J = 3, 8.3, H-8), 5.89 (1H, q, J = 3.8, 1.5, H-2), 6.02 (1H, d, J = 3, H-13), and 6.35 (1H, d, J = 3, H-13) and was in complete agreement with the indicated structure (II), *i.e.*, mexicanin A.

1-Epiallohelenalin (IV)—The final acetone eluates (fractions 26–39) gave an oily residue, which was seeded with one crystal of 1-epiallohelenalin obtained from the treatment of helenalin with hydrogen chloride–methanol (q.v.). The colorless crystals which formed were collected and recrystallized from dichloromethane–ether to yield 20 mg. of IV, m.p. 179–180°. The identity of IV was established by direct comparison with an authentic sample of 1-epiallohelenalin by mixed melting point, TLC, and superimposable IR and NMR spectra.

Attempted Acetylation of Oxide (V)—A solution of V (35 mg.) in acetic anhydride–dry pyridine (2:1) (0.5 ml.) was kept at room temperature overnight. The product, recovered by working up the reaction mixture in the usual way, was the unchanged starting material (33 mg.).

Treatment of Mexicanin A (II) with Hydrogen Chloride–Chloroform and Deactivated Neutral Alumina: Compounds VII, VIII, and IX and Compounds II, V, and IV—Compound II (300 mg.) was treated with anhydrous chloroform saturated with hydrogen chloride (15 ml.) in an analogous manner as that for helenalin, furnishing a brown oily residue. The residue was identified as the mixture of Compounds VII, VIII, and IX by their superimposable NMR spectra in comparison with the reaction products of helenalin and hydrogen chloride–chloroform already described. The oily residue was chromatographed on deactivated neutral alumina (1.5 × 12 cm.). Elution with benzene (20 ml.) afforded V (30 mg., 10%). Elution with benzene and chloroform–ether (1:1) (25 ml.) yielded II (180 mg., 60%). Elution with chloroform–ether (1:2) (20 ml.) gave IV (18 mg., 6%).

Treatment of 1-Epiallohelenalin (IV) with Hydrogen Chloride–Chloroform: 11,13-Dihydro-15-chloro-1-epiallohelenalin (IX)—Compound IV (100 mg.) was treated with anhydrous chloroform–hydrogen chloride (5 ml.) in an analogous manner as described for helenalin. The oily residue resulting from the removal of solvent crystallized upon trituration with a small amount of anhydrous ether. Recrystallization from dichloromethane–ether gave IX as white crystals in quantitative yield, m.p. 234–236° dec. The IR bands were at 3420 (OH), 1775 (saturated γ-lactone), 1690, and 1590 (cyclopentenone) cm.$^{-1}$. The NMR spectrum exhibited signals at 1.22 (3H, d, J = 6.8, C-10 CH_3), 1.38 (3H, s, C-5 CH_3), 3.80 (2H, m, CH_2Cl), 4.05 (1H, m, H-8), 4.77 (1H, d, J = 8, H-6), 6.33 (1H, dd, J = 6, 2.3, H-3), and 7.82 (1H, dd, J = 6, 2.3, H-2).

Anal.—Calc. for $C_{15}H_{19}ClO_4$: C, 60.29; H, 6.41. Found: C, 60.25; H, 6.51.

1-Epiallohelenalin (IV) from 11,13-Dihydro-13-chloro-1-epiallohelenalin (IX) and Neutral Alumina—Chromatography of IX (20 mg.) on deactivated neutral alumina (1.2 × 7 cm.) and elution with chloroform afforded IV as colorless needles in quantitative yield. Compound IV showed undepressed melting point on admixture of an authentic sample, and their IR and NMR spectra were identical.

Treatment of Helenalin (I) with Concentrated Hydrochloric Acid: 2,3-Dihydro-2-chlorohelenalin (X)—A solution of I (100 mg.) in concentrated hydrochloric acid (1 ml.) was heated at 40° for 5 min. The colorless crystalline product that deposited was filtered and dried to give quantitative yield of X, m.p. 134–135° dec. [lit. (3) m.p. 143–145° dec.]. Compound X showed IR bands at 3480 (OH), 1765 (sh), 1752, 1650 (α-methylene-γ-lactone), and 1735 (cyclopentanone) cm.$^{-1}$. Compound X also displayed NMR (dimethyl sulfoxide-d_6) signals at 0.87 (3H, s, C-5 CH_3), 1.15 (3H, d, J = 6, C-10 CH_3), 5.86 (1H, d, J = 3, H-13), and 6.19 (1H, d, J = 3, H-13).

Helenalin (I) from 2,3-Dihydro-2-chlorohelenalin (X)—Chromatography of X (50 mg.) on deactivated neutral alumina (1.7 × 7 cm.) with elution with acetone (50 ml.) recovered I quantitatively. Compound I was also obtained by extraction of X with water and chloroform. The chloroform extract was dried and evaporated to yield a crystalline residue, which was recrystallized from benzene–ether to give I as colorless needles, m.p. 170–172°. The IR spectrum of this compound was identical with that of helenalin.

Treatment of Helenalin (I) with Deactivated Neutral Alumina: Mexicanin A (II)—A solution of I (70 mg.) in chloroform (5 ml.) was added to deactivated neutral alumina (1 g.). The reaction mixture, after standing at room temperature for 3 days with occasional shaking, was filtered and evaporated to yield an oil[5]. Preparative TLC on silica gel[6] furnished mexicanin A (II) (10.5 mg., 15%), m.p. 140–142°, identical (IR and mixed melting point) with an authentic sample, and unreacted I (43 mg.).

[5] Examination of this oil by TLC revealed the absence of Compounds IV and V.

[6] Merck silica gel GF-254 with chloroform–acetone (3:1).

Quantitative Fluorometric Determination of Pancreatic Lipase in Pharmaceuticals

S. S. WAGLE▲ and D. G. HOUSE

Abstract □ A rapid and reliable assay for pancreatic lipase is described. The method utilizes microquantities of enzyme and a fluorescent substrate. Among the many fluorescent substrates available, 4-methylumbelliferone laurate was chosen as the most suitable for this method. The rate of hydrolysis at different enzyme levels was determined at 25°. Interference due to nonspecific esterases and the effect of some pharmaceutical agents were evaluated. The fluorometric assay procedure was compared to the NF XIII potentiometric method. Pancreatic lipase in concentrations as low as 0.15 NF unit of activity could be detected. Various complex pharmaceutical preparations were compared using the fluorometric and the potentiometric methods. The fluorometric procedure was found to be reproducible and useful in determining content uniformity.

Keyphrases □ Pancreatic lipase—quantitative fluorometric determination in pharmaceuticals □ Fluorometry—quantitative determination of pancreatic lipase in pharmaceuticals □ Enzymes, pancreatic lipase—quantitative fluorometric determination in pharmaceuticals

For many years, pancreatic enzymes have been used as digestive aids. A number of pharmaceutical preparations contain pancreatic enzymes alone or in combination with other therapeutic agents. Many assay procedures have been devised to determine the potencies and activities of the lipolytic enzymes in these preparations. Aldridge (1) first described a manometric method utilizing carbon dioxide liberation from bicarbonate buffer to detect lipases in biological extracts. However, titrimetric measurement of acid liberation from natural fats was found to be more convenient (2, 3). Over the years, this procedure has been greatly modified and refined to improve its reliability and reproducibility (4). The potentiometric titration method, although reliable, is cumbersome and time consuming for routine analysis. This procedure also lacks the versatility needed for testing complex pharmaceutical preparations and ascertaining content uniformity.

Fluorometric procedures have a distinct advantage over other methods in that they are very sensitive. For a number of years, biochemists and clinical chemists detected minute amounts of esterase in microorganisms by utilizing fluorogenic substrates such as 1-naphthyl esters (5). Most fluorometric procedures for hydrolytic enzymes involve hydrolyzing a nonfluorescent substrate to a highly fluorescent product. 1-Naphthyl phosphate, a nonfluorescent substrate, is readily hydrolyzed by the enzymes, acid phosphatase and alkaline phosphatase, producing the free fluorescent product, 1-naphthol, which is then measured quantitatively by the fluorometric method. Similarly, umbelliferone and 4-methylumbelliferone are highly fluorescent compounds while their ester derivatives are nonfluorescent. These derivatives are ideal substrates for many enzymes (6). Recently, a number of investigators (6–8) reported new derivatives of fluorescein and 7-hydroxy-4-methylcoumarin to detect and locate minute quantities of lipase in plants

and biological fluids. The suitability of the fluorogenic substrates for quantitative analysis of pancreatic lipase in pharmaceutical preparations has not been investigated.

This paper reports a systematic study of some fluorogenic substrates and a simple fluorometric assay procedure for rapid and quantitative determination of lipase in pharmaceutical preparations.

EXPERIMENTAL

Apparatus—The rate of hydrolysis of the fluorogenic substrate is measured as the rate of increase in fluorescence and is simultaneously recorded by a fluorometer[1] with a recorder attachment. Clear fused Pyrex glass cells (10 × 10 × 65 mm.) were used as reaction vessels, and the instrument supplier's slit arrangement No. 1 was used throughout the work. The excitation and fluorescent wavelengths used for various substrates are listed in Table I.

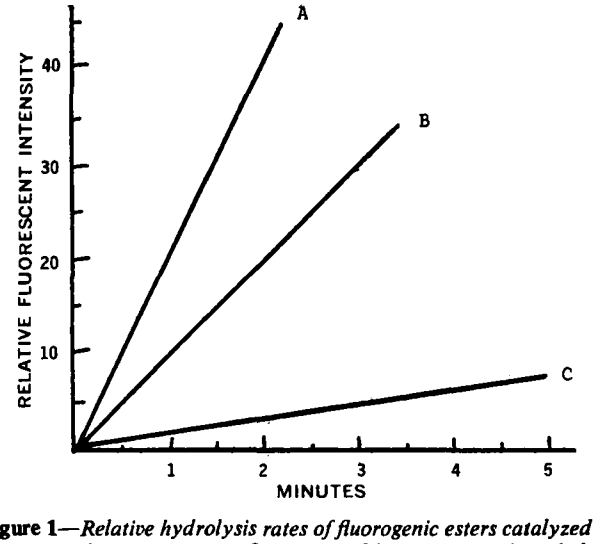

Figure 1—*Relative hydrolysis rates of fluorogenic esters catalyzed by pancreatic lipase. Key: A, fluorescein dibutyrate; B, 4-methylumbelliferone laurate; and C, 1-naphthyl acetate.*

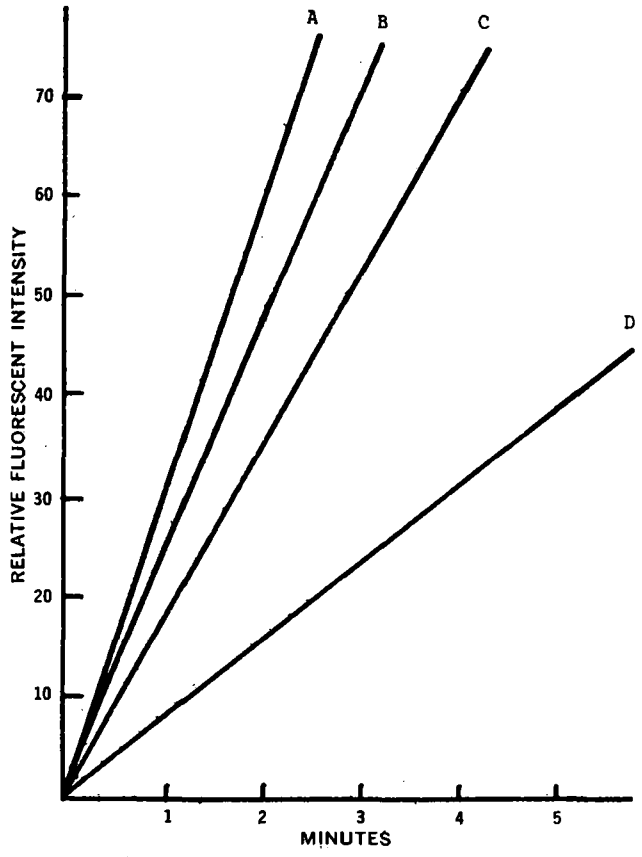

Figure 2—*Lipolysis of 4-methylumbelliferone laurate. Incubation mixture contained 5 × 10^{-5} mole of substrate and varying amounts of pancreatic lipase standard. Key: A, 0.6 NF unit; B, 0.45 NF unit; C, 0.30 NF unit; and D, 0.15 NF unit, in a total volume of 5 ml. of 0.05* M *phosphate buffer, pH 9.0, at 25°.*

Reagents and Chemicals—Stock solutions (1×10^{-2} *M*) of 1-naphthyl acetate[2], fluorescein dibutyrate[2], and 4-methylumbelliferone laurate[3] were prepared in 2-methoxyethanol[4]. These stock solutions are stable for at least 1 year when frozen. A fresh working solution (1×10^{-5} *M*) was made by diluting 1 ml. of the stock solution to 1 l. with 0.05 *M* disodium hydrogen phosphate buffer, pH 9.0.

Samples—At least 20 capsules (or tablets) were emptied into a beaker and mixed well, and a quantity equivalent to one capsule content was accurately weighed into a beaker and mixed thoroughly with 2–3 drops of glycerin. When the contents were thoroughly wet, 25 ml. of phosphate buffer (0.05 *M*) was added. The mixture was stirred for 5–10 min., quantitatively transferred into a centrifuge tube, and spun at 3000×*g* for 10 min. The supernatant liquid was transferred into a suitable flask and diluted with phosphate buffer to obtain a desired concentration of lipase activity.

Standard Solution—One hundred milligrams of the NF pancreatin reference standard (for protease and lipase activity) was accurately weighed and was treated in the same manner as the sample to obtain a desired concentration.

Other Pharmaceutical Agents—Dioctyl sodium sulfosuccinate USP, hyoscyamine sulfate NF, sodium taurocholate NF, and trypsin[5] were either dissolved or suspended in 0.05 *M* phosphate buffer, pH 9.0.

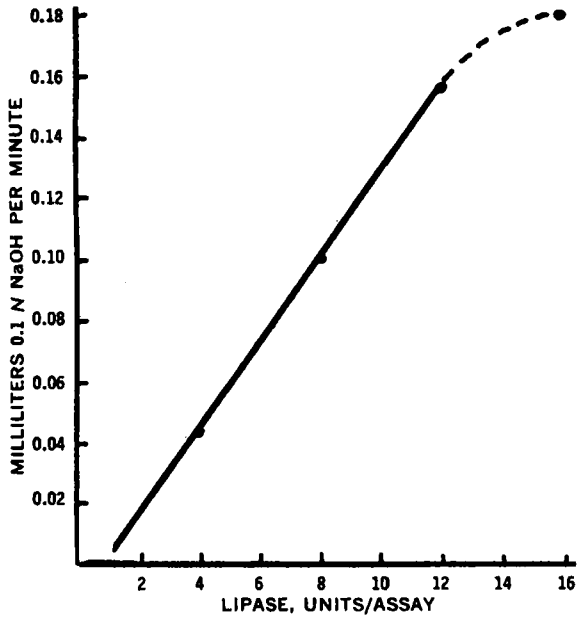

Figure 3—*Representative standard curve for pancreatic lipase by NF method.*

Procedure—Enzymatic reactions were conducted at 25° in the fluorometer cells. The reaction mixture contained 1 ml. of the substrate (1×10^{-5} *M*), with or without inhibiting or potentiating agents, and variable amounts of lipase (between 0.2 and 0.6 NF unit of activity per assay) in a total volume of 5 ml. The cell was placed immediately in a fluorometer, and the increase in fluorescence was recorded for the next 5–7 min. The rate of hydrolysis was calculated from the slope of the curve. For comparison, the potentiometric assay for lipase was performed as described in the second supplement of NF XIII (4).

RESULTS AND DISCUSSION

The effects of temperature and pH on lipolysis of fluorogenic substrates have been extensively studied by several investigators (6, 7, 11). In the present investigation, the hydrolytic reaction was conducted in phosphate buffer at pH 9.0 to reduce the possible deactivation of lipases by proteolytic enzymes which may be present in the formulations. No special precautions were necessary to control the cell temperature since the study indicated that the temperature of the reaction mixture varied less than a degree during the entire procedure.

Three fluorogenic esters were investigated as possible lipase substrates. Several important criteria, such as substrate sensitivity and specificity and enzyme inhibition and potentiation by pharmaceutical agents normally employed in the enzyme preparations, were tested and evaluated. To demonstrate hydrolysis at a very low enzyme concentration, the substrate should possess a relatively high fluorescence after hydrolysis. Table I shows the relative fluorescence of the three prospective fluorogenic substrates and their hydrolysis products. All fluorogenic substrates tested were hydrolyzed by lipase; however, fluorescein dibutyrate and 1-naphthyl acetate produced the highest and the lowest fluorescence, respectively, after hydrolysis and the latter exhibited the lowest hydrolytic rate (Fig. 1).

Table III—Comparative Analysis of Commercial Preparations by NF Method and Fluorometric Method[a]

Product	NF Method	Fluorometric Method[b]	Variation, %
A	16.49	16.8 ± 0.28	1.87
B	14.69	15.0 ± 0.40	2.11
C	20.80	22.2 ± 0.44	6.73

[a] Assay values presented in NF units. [b] Mean of at least six determinations.

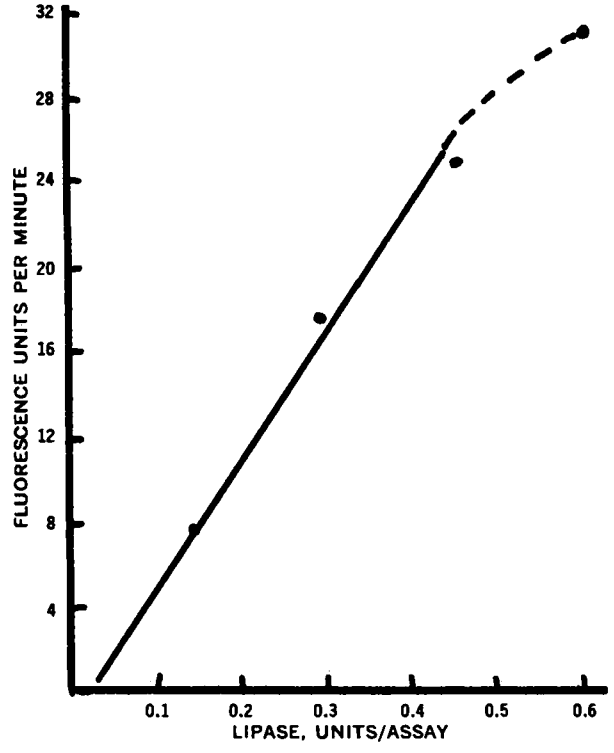

Figure 4—*Representative standard curve for pancreatic lipase by fluorometric method.*

It is imperative that minute quantities of pharmaceutical agents and excipients employed in the formulation have a minimal effect on the lipolysis of the substrate. The effects of some pharmaceutical agents and other interfering enzymes are summarized in Table II.

Trypsin is found in significant amounts in pancreatic extracts and possesses high esterase activity. Many substrates used in fluorometric assays are nonspecific and are hydrolyzed by both esterases and lipases. Therefore, a substrate that is specific for lipase will have a distinct advantage. Experiments revealed that fluorescein dibutyrate was readily hydrolyzed by both trypsin and lipase. 4-Methylumbelliferone laurate, on the other hand, was specifically hydrolyzed by lipase and was least affected by trypsin (Table II).

Some pharmaceutical and medicinal agents exhibit biological activity by virtue of their potentiating or inhibiting actions on enzyme catalysis (9). Bile salts and other surfactants are commonly used to enhance lipolysis of olive oil or other fatty esters (10). The data, however, indicate that sodium taurocholate had no potentiating effect on the rate of hydrolysis of fluorescein dibutyrate or 4-methylumbelliferone laurate. Another potent surfactant, dioctyl sodium sulfosuccinate, at 25-mcg./ml. concentration, enhanced the lipolysis of fluorescein dibutyrate 400%, but no such effect could be demonstrated on the hydrolysis of 4-methylumbelliferone laurate. Belladonna alkaloids, particularly hyoscyamine sulfate, are frequently formulated in combination with digestive enzymes. Hyoscyamine sulfate inhibited the enzymatic hydrolysis of fluorescein dibutyrate but had no apparent effect on the hydrolysis of 4-methylumbelliferone laurate. The data summarized in Table II clearly suggest that 4-methylumbelliferone laurate is a preferable substrate for fluorometric determination of lipase.

Figure 2 shows a typical continuous recorder tracing of hydrolysis of 4-methylumbelliferone laurate at different concentrations of NF lipase standard. The slope of the curve thus represented the rate of hydrolysis. This, when plotted against the concentration of enzyme, provided a standard curve for quantitative estimation of lipase. Using the NF lipase standard, comparison was made of the rates of hydrolysis obtained by the NF method and the fluorometric method. The data show that essentially the same linear rate was obtained using either method (Figs. 3 and 4). The fluorometric method, however, was 10–20 times more sensitive than the potentiometric procedure.

Comparative analyses were conducted on commercial preparations using potentiometric and fluorometric methods. All products

tested contained, in addition to lipases, other hydrolytic enzymes of pancreatic, plant, or microbial origin mixed with lactose and smaller quantities of lubricants. The data were analyzed statistically, and excellent agreement between the two methods was observed (Table III). The reproducibility of the method was evaluated by performing repeated analysis of the same enzyme solution. The precision of the method was determined from the variability obtained upon repeated analysis of lipase standard or samples. A standard deviation of 0.76, with a coefficient of variation of 3.05%, was obtained.

CONCLUSION

The advantages of a fluorometric procedure are many. In contrast to earlier methods, the fluorometric assay is more sensitive and requires smaller amounts of substrate and enzyme. The lipolytic measurements can be made at such a great dilution that interfering enzymes and other excipients are frequently diluted out. 4-Methylumbelliferone laurate was found to be a most suitable substrate for the fluorometric assay, because it was unaffected by a number of pharmaceutical agents and enzymes tested.

The method shows a high degree of precision and accuracy. The procedure is simple and requires little preparation. The substrate is stable under the experimental conditions and can be stored frozen for long periods. The method may be valuable in determining content uniformity of pharmaceutical preparations containing lipase.

Sensitive Colorimetric Determination of Isoniazid

HENRY S. I. TAN

Abstract □ A sensitive colorimetric method was developed for the assay of isoniazid. The method is based on measuring the absorbance at 467 nm. of the orange-colored product produced by the interaction of isoniazid with 7-chloro-4-nitrobenzo-2-oxa-1,3-diazole in the presence of sodium tetraborate in absolute methanol. The Beer–Lambert law was obeyed over the concentration range of 0.3–5 mcg./ml, and the color was stable for at least 90 min. The coefficient of variation as determined on nine replicate samples containing 2 mcg. isoniazid/ml. was 0.87%. Applied to the assay of isoniazid tablets and syrups, the method gave results comparable to those obtained by the USP XVIII method. It also afforded improvements in sensitivity, ease, and speed over the official method. It was established that the major metabolites of isoniazid (acetylisoniazid and isonicotinic acid) produced no color with the reagent under the proposed experimental conditions.

Keyphrases □ Isoniazid—colorimetric analysis, compared to compendial method □ Colorimetry—analysis, isoniazid, compared to compendial method

Isoniazid (isonicotinyl hydrazine, I) is a remarkably effective drug which is now considered a primary drug for the chemotherapy of tuberculosis. It is not surprising that the determination of this drug has been, and is still, the subject of much investigation (1, 2). The need for further investigation is evidenced by the fact that many of the assay procedures reported appear not to be very satisfactory. For example, the current official assay method for isoniazid employs an iodometric titration in the presence of sodium bicarbonate (3). This method, originally developed by Canbäck (4), involves a slow reaction; 90 min. is needed for the completion of the reaction before a back-titration of the excess iodine can be performed. In addition, at several stages during the assay period, loss of iodine by volatilization can occur. The USP XVIII method for the assay of isoniazid tablets is time consuming and laborious; *at least* 2.5 hr. is required for the extraction of the drug from the tablet mass, evaporation of the extract, and completion of the reaction (5).

Several methods for the analysis of isoniazid in the microgram range have been developed using 1-chloro- or 1-fluoro-2,4-dinitrobenzene as the reagent (6, 7). Reisch *et al.* (8) recently reported the use of a similar reagent for visualization of isoniazid spots on thin-layer chromatoplates. This reagent, 7-chloro-4-nitrobenzo-2-oxa-1,3-diazole (II)[1], gave a colored product

tested contained, in addition to lipases, other hydrolytic enzymes of pancreatic, plant, or microbial origin mixed with lactose and smaller quantities of lubricants. The data were analyzed statistically, and excellent agreement between the two methods was observed (Table III). The reproducibility of the method was evaluated by performing repeated analysis of the same enzyme solution. The precision of the method was determined from the variability obtained upon repeated analysis of lipase standard or samples. A standard deviation of 0.76, with a coefficient of variation of 3.05%, was obtained.

CONCLUSION

The advantages of a fluorometric procedure are many. In contrast to earlier methods, the fluorometric assay is more sensitive and requires smaller amounts of substrate and enzyme. The lipolytic measurements can be made at such a great dilution that interfering enzymes and other excipients are frequently diluted out. 4-Methylumbelliferone laurate was found to be a most suitable substrate for the fluorometric assay, because it was unaffected by a number of pharmaceutical agents and enzymes tested.

The method shows a high degree of precision and accuracy. The procedure is simple and requires little preparation. The substrate is stable under the experimental conditions and can be stored frozen for long periods. The method may be valuable in determining content uniformity of pharmaceutical preparations containing lipase.

Sensitive Colorimetric Determination of Isoniazid

HENRY S. I. TAN

Abstract □ A sensitive colorimetric method was developed for the assay of isoniazid. The method is based on measuring the absorbance at 467 nm. of the orange-colored product produced by the interaction of isoniazid with 7-chloro-4-nitrobenzo-2-oxa-1,3-diazole in the presence of sodium tetraborate in absolute methanol. The Beer–Lambert law was obeyed over the concentration range of 0.3–5 mcg./ml, and the color was stable for at least 90 min. The coefficient of variation as determined on nine replicate samples containing 2 mcg. isoniazid/ml. was 0.87%. Applied to the assay of isoniazid tablets and syrups, the method gave results comparable to those obtained by the USP XVIII method. It also afforded improvements in sensitivity, ease, and speed over the official method. It was established that the major metabolites of isoniazid (acetylisoniazid and isonicotinic acid) produced no color with the reagent under the proposed experimental conditions.

Keyphrases □ Isoniazid—colorimetric analysis, compared to compendial method □ Colorimetry—analysis, isoniazid, compared to compendial method

Isoniazid (isonicotinyl hydrazine, I) is a remarkably effective drug which is now considered a primary drug for the chemotherapy of tuberculosis. It is not surprising that the determination of this drug has been, and is still, the subject of much investigation (1, 2). The need for further investigation is evidenced by the fact that many of the assay procedures reported appear not to be very satisfactory. For example, the current official assay method for isoniazid employs an iodometric titration in the presence of sodium bicarbonate (3). This method, originally developed by Canbäck (4), involves a slow reaction; 90 min. is needed for the completion of the reaction before a back-titration of the excess iodine can be performed. In addition, at several stages during the assay period, loss of iodine by volatilization can occur. The USP XVIII method for the assay of isoniazid tablets is time consuming and laborious; *at least* 2.5 hr. is required for the extraction of the drug from the tablet mass, evaporation of the extract, and completion of the reaction (5).

Several methods for the analysis of isoniazid in the microgram range have been developed using 1-chloro- or 1-fluoro-2,4-dinitrobenzene as the reagent (6, 7). Reisch *et al.* (8) recently reported the use of a similar reagent for visualization of isoniazid spots on thin-layer chromatoplates. This reagent, 7-chloro-4-nitrobenzo-2-oxa-1,3-diazole (II)[1], gave a colored product

with isoniazid. The color of the product seemed to be pH dependent.

This work served as the basis for the present study, in which II in alkaline medium was used for the quantitative colorimetric assay of isoniazid.

EXPERIMENTAL[2]

Materials and Reagents—The following were used:

Isoniazid—Highest purity grade isoniazid[3] recrystallized from 80% methanol and dried under reduced pressure for 24 hr., m.p. 172–172.5°.

Methanol—Acetone-free absolute methanol containing 0.008% water[4].

Isonicotinic Acid—Isonicotinic acid[5], m.p. 310–315°.

1-Isonicotinyl-2-acetylhydrazine—Prepared by a slightly modified procedure of Fox and Gibas (9). To a stirred solution of 4 g. isoniazid in 25 ml. warm glacial acetic acid was added dropwise 3 ml. of acetic anhydride. The mixture was heated in a boiling water bath for 30 min., cooled, and evaporated under reduced pressure. Upon treatment of the residue with 35 ml. benzene, a white precipitate (4.5 g.) was formed. Recrystallization from isopropyl alcohol–ethyl acetate afforded fine needles, m.p. 161–162.5° [lit. (9) m.p. 162–163°].

[2] A Beckman Acta V UV-visible double-beam spectrophotometer (Beckman Instruments, Fullerton, Calif.), with 1-cm. Bausch and Lomb cells and a slit width of 0.36 mm., was used for the absorption measurements. A Blue M Magniwhirl model MW 1110A-1 constant-temperature water bath (Blue M Electric Co., Blue Island, Ill.) and a Mettler type H18 analytical balance (Mettler Instrument Corp., Princeton, N. J.), were also utilized in the assay procedure.

[4] Matheson, Coleman and Bell, Norwood, Ohio.

[5] Aldrich Chemical Co., Milwaukee, Wis.

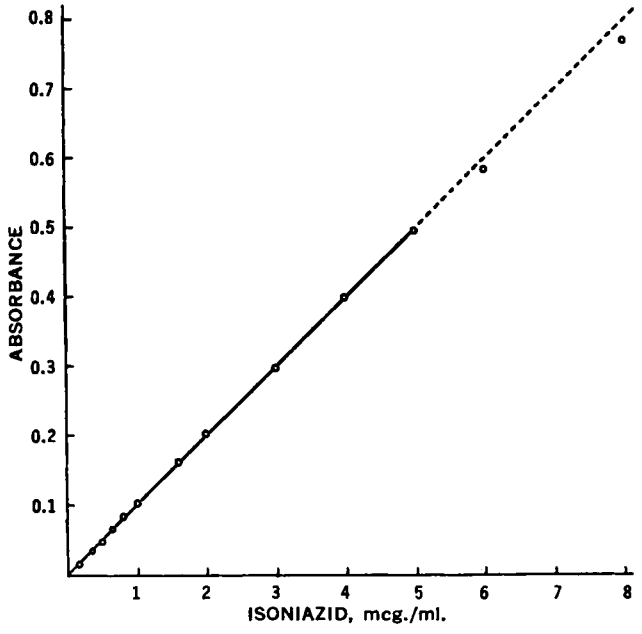

Figure 2—*Relationship between absorbance and concentration of isoniazid.*

Color Reagent—A 0.10% (w/v) solution of II (m.p. 97–99°)[6] in methanol. This reagent is stable for 2 weeks if kept under refrigeration.

Borax Solution—A 2.5% solution of sodium tetraborate decahydrate (ACS grade)[3] in methanol.

Preparation of Standard Curve—A stock solution of isoniazid was prepared by dissolving 50.0 mg. of isoniazid in 100 ml. of methanol. Further dilutions were made to obtain standard solutions, each containing 1.6, 2.0, 3.2, 4.0, 5.0, 6.4, 8.0, 10.0, 12.0, 16.0, 20.0, 30.0f 40.0, 50.0, 60.0, 80.0, and 100.0 mcg. isoniazid/ml. One milliliter or each solution was utilized for color development as described unde, *Assay Procedure for Isoniazid.* The stock and standard solutions must be freshly prepared.

Assay Procedure for Isoniazid—Pipet 1.0 ml. of a methanolic solution containing 3–50 mcg. of isoniazid into a 10-ml. glass-stoppered volumetric flask. To this solution, add successively 1 ml. of color reagent and 2 ml. of borax solution. Dilute the mixture to the mark with methanol. Stopper the flask tightly and place in a constant-temperature water bath at 60 ± 1° for 1 hr. Allow the mixture to cool to room temperature by immersing the flask in a tap-water bath (3–5 min.). Adjust the volume with methanol, if necessary, and measure the absorbance at 467 nm. against a blank prepared as already described but omitting the isoniazid. Obtain the amount of isoniazid present from a calibration curve.

Assay Procedure for Isoniazid Tablets—Weigh and finely powder 20 tablets. Weigh accurately a portion of powder, equivalent to about 100 mg. of isoniazid, and transfer to a 100-ml. volumetric flask. Add methanol to the mark and shake well for about 5 min. Filter the mixture quickly through a dry filter into a dry flask, rejecting the first 10 ml. of filtrate and keeping the funnel covered during the filtration. Pipet 1.0 ml. of the filtrate into a 50-ml. volumetric flask and make up to volume with methanol. Pipet 1.0 ml. of the resulting solution into a 10-ml. glass-stoppered volumetric flask and proceed as described in the *Assay Procedure for Isoniazid*, beginning with: "To this solution, add . . .."

Assay Procedure for Isoniazid Syrups—Transfer an accurately measured volume of syrup, equivalent to about 100 mg. of isoniazid, to a 100-ml. volumetric flask. Add methanol to the mark and shake well for about 1 min. Pipet 1.0 ml. of the resulting solution into a 50-ml. volumetric flask and make up to volume with methanol. Pipet 1.0 ml. of the latter solution into a 10-ml. glass-stoppered volumetric flask and proceed as described in the *Assay Procedure for Isoniazid*, beginning with: "To this solution, add . . .."

Effect of Reagents on Color Formation—*Color Reagent*—A series of 10-ml. glass-stoppered volumetric flasks, each containing 1.0 ml. of a methanolic solution of isoniazid (20 mcg./ml.), was prepared. Varying volumes of 0.05% II in methanol were added to each flask.

[a] Each value is the average of three replicate assays.

After 2 ml. of borax solution was added to each flask and the mixture was diluted to the mark with methanol, the flasks were warmed at 60 ± 1° for 1 hr. The flasks were cooled to room temperature, the volume of the solution was adjusted, if necessary, and the absorbance was measured at 467 nm. against a blank[6].

Borax Solution—A series of 10-ml. glass-stoppered volumetric flasks, each containing 1.0 ml. of a methanolic solution of isoniazid (20 mcg./ml.) and 1 ml. of color reagent, was prepared. Varying volumes of 2.5% borax solution were added to each flask, and the experiment was completed as described for the color reagent. The absorbance of each solution was measured at 467 nm. against a blank[6].

Effect of Isonicotinic Acid and Acetylisoniazid on Assay Results of Isoniazid—Two solutions of isonicotinic acid in methanol containing 20 and 40 mcg./ml., respectively, were prepared. Two solutions of acetylisoniazid in methanol containing 20 and 40 mcg. acetylisoniazid/ml., respectively, were also prepared. One milliliter of each solution was assayed as described under *Assay Procedure for Isoniazid.*

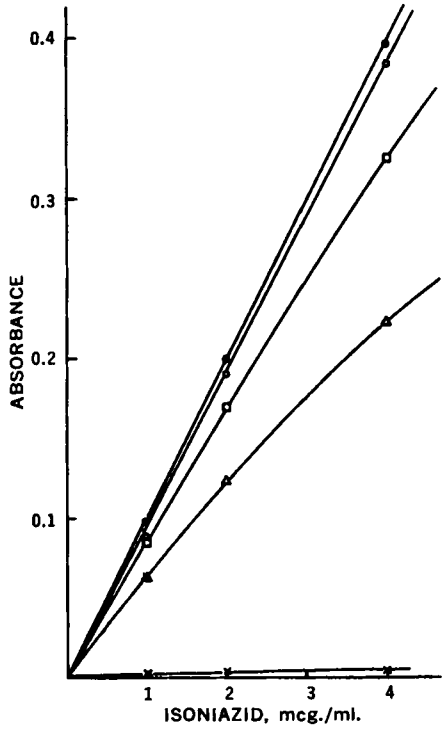

Figure 3—*Effect of heating on color development. Key: ×, 30 min. at room temperature; △, 30 min. at 50°; □, 60 min. at 50°; ○, 30 min. at 60°; and ●, 60 min. at 60°.*

[6] Each blank contained the same amount of II and sodium tetraborate as in the solution studied but contained no isoniazid.

RESULTS AND DISCUSSION

The orange-colored product obtained from the interaction between isoniazid and II in alkaline medium shows an absorption peak at 467 nm. in its absorption spectrum (Fig. 1). At concentrations above 3 mcg. isoniazid/ml., another peak appears around 445 nm. This absorption maximum shifts gradually toward lower wavelengths as the concentration of isoniazid is increased. As might be expected, absorbances measured at this second peak are not proportional to the concentrations of isoniazid. At 467 nm., however, the procedure as described shows adherence to the Beer–Lambert law up to 5 mcg. isoniazid/ml. A typical standard curve is shown in Fig. 2. Under the experimental conditions described in the assay procedure, the molar absorptivity, ϵ, is 13,715 l. mole^{-1} cm.$^{-1}$. Since isoniazid has a molecular weight of 137.15, an absorbance value of 0.100 corresponds to a concentration of 1 mcg./ml.

The interaction between isoniazid and II in the presence of sodium tetraborate in methanol was favored by heating. The time and tem-

perature of heating affected the color formation. At room temperature, hardly any color was formed (Fig. 3). Since heating at 60° required about 60 min. to obtain satisfactory absorbance values, attempts were made to speed up the reaction time by increasing the reaction temperature. Heating at temperatures above the boiling point of methanol presented problems since screw-capped tubes must be used to prevent significant evaporation of the solvent. Furthermore, heating at these high temperatures caused a shift in the absorption maximum to 462.5 nm. At this wavelength, adherence to the Beer–Lambert law could not be observed. Therefore, 60° was chosen as the heating temperature.

The time of heating was determined by following the color development. Absorbance values increased through 70 min. and then decreased. It was found that a heating period of 1 hr. at 60 ± 1° was quite satisfactory. The color produced appeared to be stable for at least 90 min. after the heating. Under these conditions the reference blank showed a pale-yellow coloration.

Gosh and Whitehouse (10) reported the determination of certain amino acids with II in aqueous solutions. When using water or 95% ethanol as solvents for the assay of isoniazid with II, it was found that the color formation was greatly accelerated. However, variations in color intensity occurred with the use of these solvents. The presence of water in the system caused nonreproducibility of the results. In these cases, a deep-yellow color was obtained with the reference blank.

The effect of the concentrations of reagent and sodium tetraborate on color formation was also studied. Higher absorbance values were obtained with the increasing amount of II used. At the same time the reference blank also exhibited a more intense yellow color. This caused a decrease in the sensitivity of the proposed procedure and made the determination of isoniazid at the lower limits of the concentration range obeying the Beer–Lambert law less reliable. The presence of more than 5 mg. sodium tetraborate/ml. in the assay solution caused a decrease in the absorbance value. In view of these results, 1 ml. 0.10% II and 2 ml. 2.5% sodium tetraborate were selected as optimum concentrations for the assay.

The stability of the color reagent solution was evaluated by recording its UV spectrum (λ_{max} 335 nm.) over an extended period. Molar absorptivities remained unchanged for 14 days, indicating that the reagent preparation, when kept refrigerated, could be kept for 2 weeks without significant deterioration.

As little as 0.16 mcg. isoniazid/ml. can be detected by the proposed procedure. The method, however, is reliable only for concentrations above 0.2 mcg./ml. The percent recoveries of known samples analyzed at 0.16- and 0.20-mcg. isoniazid/ml. levels were only 87.5 and 95.0%, respectively, with relative standard deviations from the mean of 38.5 and 3.5%, respectively. Very good recovery data were obtained for the concentration levels of 0.3–5 mcg./ml. The recovery experiments were performed by dissolving an accurately weighed amount of about 50 mg. isoniazid in 100 ml. methanol. Appropriate dilutions were then prepared to afford different concentrations (Table I) which were assayed by the proposed method. The recovery experiments were also conducted on 100 and 200 mg. isoniazid. Data presented in Table I indicate the accuracy of the method; the results were reproducible and quantitative. It was found that slight changes in absorbance reading can result in fairly substantial changes in percent recovery. The overall percent recovery for the six samples was 100.3%, with a standard deviation of ± 0.88%. In comparison, the average percent recovery for two samples analyzed by the USP XVIII method was 99.3%.

The precision of the analytical method was determined by running replication studies on nine 1.00-ml. aliquots of a standard isoniazid solution containing 2.0 mcg./ml. These solutions were assayed by the proposed procedure. The coefficient of variation for the nine replicate samples was 0.87% (Table II).

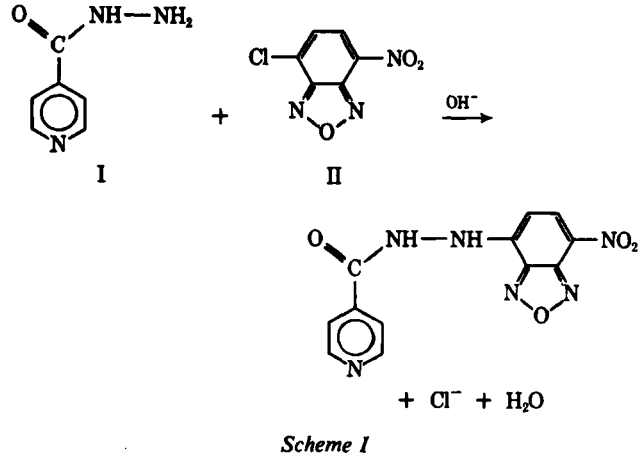
Results obtained by applying the assay procedure to commercially available isoniazid tablets are presented in Table III. Comparison of the experimental data with those obtained by the official method shows a relatively good correlation. The proposed extraction of the drug by shaking the tablet mass with methanol at room temperature for 5 min. appeared to be complete. In contrast, the official method requires heating on a steam bath for 30 min. Generally speaking, the present method offers ease and speed over the official method.

Table III also shows that the proposed colorimetric procedure is applicable for the assay of isoniazid syrups. The results of the proposed method are in agreement with those obtained by the USP XVIII procedure. Since the amount of water in the final assay solution is very low due to the two-step dilution procedure, it does not interfere with the reaction. Commercial Syrup D (Table III) also contained a flavoring agent and a yellow dyestuff. It appeared that these agents do not affect the absorbance measurements.

Several workers (6, 11) have suggested that, analogous to the König reaction, 1-chloro- or 1-fluoro-2,4-dinitrobenzene reacts with the pyridine nitrogen of isoniazid to form a polymethine dyestuff. The structurally related II may be expected to react with isoniazid in a similar fashion. Present studies revealed that neither acetylisoniazid nor isonicotinic acid produced any color with II under the experimental conditions described (Table IV). This would indicate that a free amino function in the molecule is necessary for the reaction with II. These findings are in agreement with those of Poole and Meyer (7), who stated that the reactivity of 1-fluoro-2,4-dinitrobenzene with the pyridine nitrogen of isoniazid is not probable.

Table IV—Effect of Acetylisoniazid and Isonicotinic Acid on Assay Results of Isoniazid

Compound	Concentration Assayed, mcg./ml.	Absorbance at 467 nm.
Acetylisoniazid	2.0	0.000
Acetylisoniazid	4.0	0.000
Isonicotinic acid	2.0	0.001
Isonicotinic acid	4.0	0.000



Scheme I

Therefore, it is concluded that the reaction between isoniazid and II under the experimental conditions of the assay method likely proceeds as depicted in Scheme I.

The present method can be modified to make it applicable to the determination of *free* isoniazid in biological fluids since none of the most important metabolites of isoniazid that have been identified (acetylisoniazid, isonicotinic acid, isonicotinylglycine, pyruvic acid isonicotinylhydrazine, and α-oxoglutaric acid isonicotinylhydrazine) (12) possesses a free amino function in the molecule. Further studies are in progress, and the results will be reported at a later date.

Potentiometric Titration of Antithyroid Drugs with Mercuric Acetate Solution

SERGIO PINZAUTI▲, VITTORIO DAL PIAZ, and ENZO LA PORTA

Abstract □ A simple and accurate potentiometric titration procedure for the analysis of five antithyroid drugs is described. The drugs dissolved in aqueous solution at particular pH values are titrated with 0.01 *M* mercuric acetate. The end-point is determined potentiometrically by the use of three different indicating electrodes (mercury drop, amalgamated gold, and silver). Quantitative recoveries are reported.

Keyphrases □ Thyroid inhibitors—analysis, potentiometric titration with mercuric acetate □ Methimazole—analysis, potentiometric titration with mercuric acetate □ Thiobarbituric acid—analysis, potentiometric titration with mercuric acetate □ Thiouracil—analysis, potentiometric titration with mercuric acetate □ Methylthiouracil—analysis, potentiometric titration with mercuric acetate □ Propylthiouracil—analysis, potentiometric titration with mercuric acetate □ Potentiometric titrimetry—analysis of five thyroid inhibitors using mercuric acetate □ Mercuric acetate—used in potentiometric titration of five thyroid inhibitors

Methimazole (1-methylimidazole-2-thiol), 2-thiobarbituric acid, 2-thiouracil, 6-methyl-2-thiouracil, and 6-propyl-2-thiouracil are commonly employed in treatment of hyperthyroidism. Many types of titrimetric procedures for their determination have been proposed (1–15). The mercurimetric method of Abbot (4) was the basis in the BP monographs (16) for the determination of 6-methyl-2-thiouracil and 6-propyl-2-thiouracil. Accordingly, thiouracil (0.35 g.) is dissolved in an excess of sodium hydroxide and the resulting disodium salt is titrated in a buffered acetate system with mercuric acetate (0.05 *M*); the end-point is determined by the use of diphenylcarbazone as the indicator. Although satisfactory results are attainable by this method, the indicator change is not sharp and the procedure is not suitable for other antithyroid thiols, *e.g.*, methimazole.

In the present study, a simple, rapid, and accurate direct potentiometric titration is reported for the determination of methimazole USP, thiouracil, methylthiouracil BP, propylthiouracil USP and BP, and 2-thiobarbituric acid. The use of three different indicating electrodes is described.

EXPERIMENTAL

Apparatus—Titrations were performed potentiometrically with a pH meter[1] equipped with a mercury drop electrode (17) and mercurous sulfate electrode[2]. An amalgamated gold electrode (a gold flag dipped into metallic mercury for 20 sec.) or a silver electrode (a silver coil) was also employed as indicating electrodes. The mercury drop and amalgamated gold electrodes can be used for many titrations if rinsed with water between titrations.

Reagents and Solutions—Pure drug samples (listed in Table I) were obtained from commercial sources. Analysis by the USP assay for methimazole indicated a purity of better than 98%. Analysis by the BP assay for methylthiouracil and propylthiouracil indicated a purity of better than 98%.

Borax (0.025 M)—Dissolve 9.535 g. of $Na_2B_4O_7 \cdot 10H_2O$ (reagent grade) in sufficient water to make 1000 ml.

Phosphate Buffer (pH 7.2)—Dissolve 17.337 g. of $Na_2HPO_4 \cdot 12H_2O$ (reagent grade) and 2.485 g. of KH_2PO_4 (reagent grade) in sufficient water to make 1000 ml.

Acetate Buffer (pH 4.6)—Dissolve 3.28 g. of CH_3COONa (reagent

Potentiometric Titration of Antithyroid Drugs with Mercuric Acetate Solution

SERGIO PINZAUTI▲, VITTORIO DAL PIAZ, and ENZO LA PORTA

Abstract □ A simple and accurate potentiometric titration procedure for the analysis of five antithyroid drugs is described. The drugs dissolved in aqueous solution at particular pH values are titrated with 0.01 *M* mercuric acetate. The end-point is determined potentiometrically by the use of three different indicating electrodes (mercury drop, amalgamated gold, and silver). Quantitative recoveries are reported.

Keyphrases □ Thyroid inhibitors—analysis, potentiometric titration with mercuric acetate □ Methimazole—analysis, potentiometric titration with mercuric acetate □ Thiobarbituric acid—analysis, potentiometric titration with mercuric acetate □ Thiouracil—analysis, potentiometric titration with mercuric acetate □ Methylthiouracil—analysis, potentiometric titration with mercuric acetate □ Propylthiouracil—analysis, potentiometric titration with mercuric acetate □ Potentiometric titrimetry—analysis of five thyroid inhibitors using mercuric acetate □ Mercuric acetate—used in potentiometric titration of five thyroid inhibitors

Methimazole (1-methylimidazole-2-thiol), 2-thiobarbituric acid, 2-thiouracil, 6-methyl-2-thiouracil, and 6-propyl-2-thiouracil are commonly employed in treatment of hyperthyroidism. Many types of titrimetric procedures for their determination have been proposed (1–15). The mercurimetric method of Abbot (4) was the basis in the BP monographs (16) for the determination of 6-methyl-2-thiouracil and 6-propyl-2-thiouracil. Accordingly, thiouracil (0.35 g.) is dissolved in an excess of sodium hydroxide and the resulting disodium salt is titrated in a buffered acetate system with mercuric acetate (0.05 *M*); the end-point is determined by the use of diphenylcarbazone as the indicator. Although satisfactory results are attainable by this method, the indicator change is not sharp and the procedure is not suitable for other antithyroid thiols, *e.g.*, methimazole.

In the present study, a simple, rapid, and accurate direct potentiometric titration is reported for the determination of methimazole USP, thiouracil, methylthiouracil BP, propylthiouracil USP and BP, and 2-thiobarbituric acid. The use of three different indicating electrodes is described.

EXPERIMENTAL

Apparatus—Titrations were performed potentiometrically with a pH meter[1] equipped with a mercury drop electrode (17) and mercurous sulfate electrode[2]. An amalgamated gold electrode (a gold flag dipped into metallic mercury for 20 sec.) or a silver electrode (a silver coil) was also employed as indicating electrodes. The mercury drop and amalgamated gold electrodes can be used for many titrations if rinsed with water between titrations.

Reagents and Solutions—Pure drug samples (listed in Table I) were obtained from commercial sources. Analysis by the USP assay for methimazole indicated a purity of better than 98%. Analysis by the BP assay for methylthiouracil and propylthiouracil indicated a purity of better than 98%.

Borax (0.025 M)—Dissolve 9.535 g. of $Na_2B_4O_7 \cdot 10H_2O$ (reagent grade) in sufficient water to make 1000 ml.

Phosphate Buffer (pH 7.2)—Dissolve 17.337 g. of $Na_2HPO_4 \cdot 12H_2O$ (reagent grade) and 2.485 g. of KH_2PO_4 (reagent grade) in sufficient water to make 1000 ml.

Acetate Buffer (pH 4.6)—Dissolve 3.28 g. of CH_3COONa (reagent

Table I—Results of Potentiometric Titration of Antithyroid Drugs with Mercuric Acetate and Three Different Indicating Electrodes

Drug	Weighed Range, mg.	Proposed Method, % Recovery with Mercury Drop Electrode	Proposed Method, % Recovery with Amalgamated Gold Electrode	Proposed Method, % Recovery with Silver Electrode	BP Method, % Recovery
Methimazole	20.20–57.05	99.90 ± 0.22[a]	99.78 ± 0.27[a]	99.69 ± 0.15[a]	—
Thiouracil	21.06–55.34	99.67 ± 0.36	99.58 ± 0.24	99.71 ± 0.38	—
Methylthiouracil	23.20–62.15	99.83 ± 0.38	99.70 ± 0.16	99.59 ± 0.33	99.26 ± 0.25[a]
Propylthiouracil	20.90–56.50	100.06 ± 0.33	100.03 ± 0.25	100.37 ± 0.18	99.20 ± 0.16
2-Thiobarbituric acid	24.84–67.56	100.14 ± 0.29	100.36 ± 0.32	99.93 ± 0.40	—

[a] Standard deviation based on six analyses.

grade) in 200 ml. of water; add 2.3 ml. of glacial acetic acid and sufficient water to make 400 ml.

Mercuric Acetate (0.01 M)—Dissolve 800 mg. of mercuric acetate (reagent grade) in 250 ml. of water, and add 0.3 ml. of glacial acetic acid to prevent hydrolysis. Titrate the solution potentiometrically with 0.01 *M* ethylenediaminetetraacetic acid in pH 4.6 acetate buffer, using a mercury drop–mercurous sulfate electrode system.

Procedure—*Assay of Methimazole*—About 20–60 mg. of methimazole, accurately weighed, was dissolved in 50 ml. of 0.025 *M* borax. The solution, magnetically stirred, was titrated potentiometrically with 0.01 *M* mercuric acetate. The end-point in the titration was determined from the inflection in the curve obtained by plotting milliliters of titrant *versus* millivolt readings. Each milliliter of 0.01 *M* mercuric acetate is equivalent to 2.283 mg. of methimazole.

Assay of Methylthiouracil and Propylthiouracil—About 20–60 mg. of the drug, accurately weighed, was dissolved in 50 ml. of pH 7.2 phosphate buffer, with warming to complete solution. After cooling to room temperature, titration was performed in the same way (as for methimazole). Each milliliter of 0.01 *M* mercuric acetate is equivalent to 2.844 mg. of methylthiouracil or 3.405 mg. of propylthiouracil.

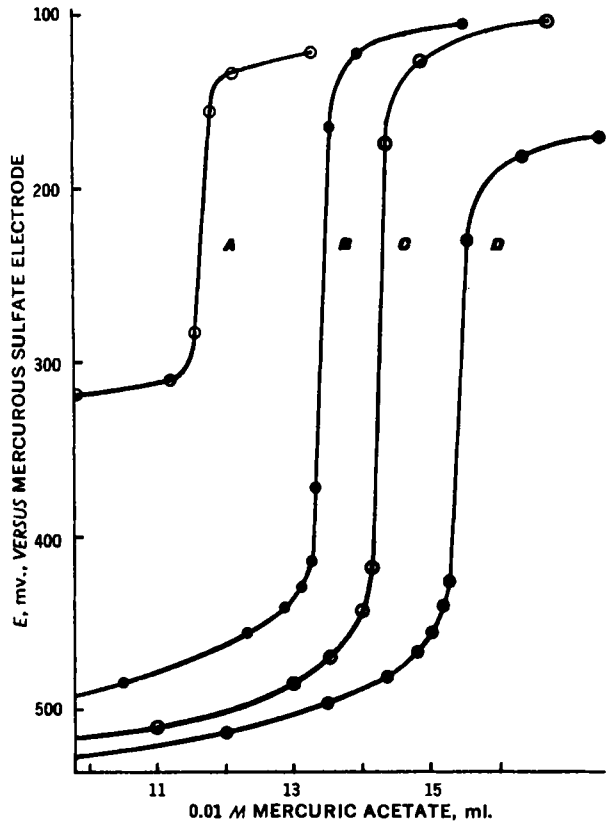

Figure 1—*Typical titration curves for antithyroid drugs. Key: A, 2-thiobarbituric acid, 33.82 mg. (silver electrode); B, methylthiouracil, 38.25 mg. (silver electrode); C, propylthiouracil, 48.50 mg. (amalgamated gold electrode); and D, methimazole, 35.46 mg. (mercury drop electrode).*

Assay of Thiouracil—About 20–60 mg. of the drug, accurately weighed, was dissolved in 50 ml. of pH 4.6 acetate buffer, with warming to complete solution. After cooling to room temperature, titration was performed as already described. Each milliliter of 0.01 *M* mercuric acetate is equivalent to 2.563 mg. of thiouracil.

Assay of 2-Thiobarbituric Acid—About 20–60 mg. of the drug, accurately weighed, was dissolved in 50 ml. of water. The solution was adjusted to pH 1 with nitric acid (20% w/w), and titration was performed as already described. Each milliliter of 0.01 *M* mercuric acetate is equivalent to 2.883 mg. of 2-thiobarbituric acid.

RESULTS AND DISCUSSION

Table I shows the results of mercurimetric determination of five antithyroid agents with potentiometric end-point detection. The recoveries by the proposed method are satisfactory, and only small amounts of drug are required for analysis. A mercury drop electrode, an amalgamated gold electrode, and a silver electrode were used with success as pHg indicators for the potentiometric titration. The silver electrode behaves as reversible with respect to the anion RS^-.

For the analysis of methylthiouracil, propylthiouracil, and methimazole, the largest change in potential at the end-point [about 200 mv./0.1 ml. Hg^{+2} (0.01 *M*)] was observed using the amalgamated gold electrode (Fig. 1). However, the sharp rise produced with the mercury drop and silver electrodes was also sufficiently steep (about 160 mv./0.1 ml. of titrant). In the titration of thiouracil, a lower rise in the potential was noted with each electrode used (about 90 mv./0.1 ml. of titrant). In the assay of 2-thiobarbituric acid, the best results were obtained with the silver electrode (about 160 mv./0.2 ml. of titrant), but the inflections observed with the mercury drop or amalgamated gold electrode (about 100 mv./0.2 ml. of titrant) were also analytically useful.

Antithyroid thiols react with mercuric acetate to form very slightly soluble sulfides. Two moles of the sulfido form (RS^-) of the thiol reacts with 1 mole of the mercuric titrant. The quantitative presence of the sulfido form is pH dependent (20). In preliminary experiments for methimazole in the pH 4–6.8 region, no detectable end-point was apparent. The best results for the assay of methimazole were attained at pH 8.2–9.4, using borax dilute solutions. Methylthiouracil and propylthiouracil gave the most satisfactory titraton curves at pH 7.2–8 (phosphate buffer). The greater sensitivity in end-point detection was noted for 2-thiouracil at pH 4.6 and for 2-thiobarbituric acid in the pH range of 1–2.2.

The potential of the mercury electrode depends on pH by formation of mercuric oxide (18) (the electrode reaction may be written as: $Hg + 2OH^- \leftrightharpoons HgO + H_2O + 2e^-$). In the case of methylthiouracil, propylthiouracil, and methimazole, the solubility products of the precipitate sulfides are evidently lower than HgO ($pSP_{HgO} = 25.5$) (19), permitting sharp breaks in the titration curves under alkaline conditions.

Determination of Dopa in Pharmaceutical Dosage Forms Based on Oxidation at Tubular Carbon Electrode

WILLIAM D. MASON

Abstract □ A method for the determination of dopa [3-(3,4-dihydroxyphenyl)alanine] in pharmaceutical dosage forms based on electrochemical oxidation at the tubular carbon electrode is presented. A comparison with a colorimetric method shows this new method to be considerably faster and simpler without a significant loss in precision or accuracy. Between 25 and 30 samples may be determined each hour, for which the variance due to the method results in a standard deviation no greater than ±0.9%.

Keyphrases □ Dopa—analysis in dosage forms, electrochemical oxidation at tubular carbon electrode □ Electrochemical analysis—dopa in dosage forms, tubular carbon electrode

The problems associated with the fluorometric or colorimetric determination of levodopa [(−)-3-(3,4-dihydroxyphenyl)-L-alanine] in pharmaceutical dosage forms were recently summarized (1). Although highly sensitive and specific, these methods are inconvenient due to lengthy procedures involving separation and other manipulative steps. A new colorimetric method by Maggi and Cometti (1), designed specifically for the determination of levodopa in dosage forms, eliminates separatory steps but requires a number of manipulations including a precisely controlled reaction for color formation. A possible alternative to the colorimetric approach may be an electrochemical method similar to the one presented for ascorbic acid (2).

The method for ascorbic acid is based on continuous analysis in flowing streams by oxidation of the drug at the tubular carbon electrode (3). This electrochemical method has advantages over other commonly employed methods of being extremely fast and simple without any significant loss in accuracy or precision. Studies (4) of the electrochemical oxidation of catecholamines, similar in structure to levodopa, suggested that the drug may be assayed in this manner. Thus, an investigation of the oxidation of levodopa at the tubular carbon electrode was undertaken with the idea of developing an analytical method. In this paper a method for the determination of dopa in pharmaceutical dosage forms is presented and compared to the colorimetric method of Maggi and Cometti (1). In addition, the utility of the new electrochemical method in continuously monitoring the dissolution of solid dosage forms is demonstrated.

EXPERIMENTAL

Instrumentation—The electrode assembly, flow system, pump, and polarography system were the same as reported earlier (2). The tablet dissolution apparatus was described by Levy and Hayes (5).

Chemicals—All chemicals were of the highest quality commercially available. Standard solutions of dopa were prepared using the powder[1].

Procedures—Current–voltage curves were determined using a tubular carbon electrode (TCE) which had previously been cleaned with ethyl acetate. Volume flow rates between 4 and 10 ml./min. were commonly employed and were controlled to ±1%. The voltage was scanned anodically from 0 v. *versus* the saturated calomel electrode (SCE) at 0.20 v./min. Standard buffers (6) were used to determine the effect of pH on the oxidation half-wave potential of the compounds studied.

Solid dosage forms were assayed by dissolving weighed quantities in sufficient 0.1 *N* HCl to give approximately 10^{-4} *M* dopa solutions. The sample solutions were pumped through a pledget of glass wool to the TCE (with the potential set at 0.90 v. *versus* the SCE) and the limiting currents were recorded. A calibration plot of the limiting current *versus* concentration was determined daily, and intermittent standards were run to check and adjust the calibration.

The accuracy of the TCE method was evaluated by comparison with a colorimetric method (1). Three tablets were weighed and powdered, and weighed aliquots were taken for analysis; the capsules were emptied and weighed, and similar aliquots were taken. The sample aliquots were dissolved in 1 ml. of 1 *N* HCl and diluted to 1 l. with water; then each aliquot was assayed by the colorimetric method three times. These same aliquots were then

Table I—Current–Voltage Scans of Possible Interfering Substances

Compound	Half-Wave Potential[a] ±0.005 v. *versus* SCE
Levodopa	0.250
3-Amino-L-tyrosine	0.230
Hydroquinone	0.135
Resorcinol	N.W.[b]
Tryptophane	N.W.
Tyrosine	N.W.

[a] Determined at pH 6.0, and subject to slight variance due to electrode history. [b] No wave (N.W.) before 0.60 v. *versus* the SCE.

Table II—Dopa Analysis

Dosage Form	Amount Declared per Sample, mg.	—Mean Amount, mg. ± *SD*[a]— TCE[b] Method	Colorimetric Method[c]
Tablet (250 mg.)	20.1	20.1 ± 0.1	20.1 ± 0.1
	42.7	42.8 ± 0.2	42.6 ± 0.1
Capsule (250 mg.)	20.0	20.1 ± 0.1	20.1 ± 0.1
	38.9	38.7 ± 0.2	39.0 ± 0.2

[a] Calculated on the basis of three assays of a single aliquot. [b] With 0.1 *N* HCl as medium. [c] *Reference 1.*

diluted with 0.1 *N* HCl to about 10^{-4} *M* and assayed by the TCE method.

For the dissolution study the beaker was filled to 1 l. with 0.1 *N* HCl and the propeller was set at 60 r.p.m. The solution was pumped through a Swinnex-25 unit[2] without a filter to the TCE and returned to the beaker. After setting the electrode potential at +0.90 v. *versus* the SCE and establishing a baseline current, a tablet was added and the limiting current was recorded as a function of time. From a previously determined calibration plot, the chart paper was labeled in terms of percent dissolution (taking the plateau current to represent 100%) as well as microamperes.

RESULTS AND DISCUSSION

A typical current–voltage curve for the oxidation of levodopa at the TCE is shown in Fig. 1. The limiting current was linear with respect to concentration over the 10^{-6}–10^{-3} *M* range. With the volume flow rate at 5 ml./min., a typical calibration plot has a slope of 6.9 μa./10^{-4} *M* with a zero intercept. A plot of the logarithm limiting current *versus* logarithm flow rate had a slope of 0.33,

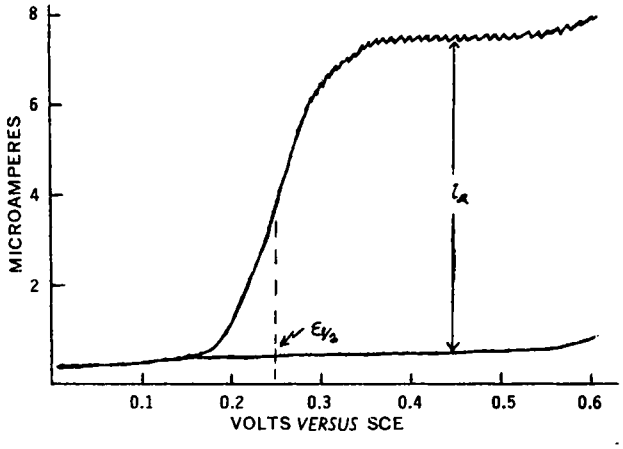

Figure 1—*Levodopa current–voltage curve; run at pH 6. (See text for details.)*

[2] Millipore Corp., Bedford, Mass.

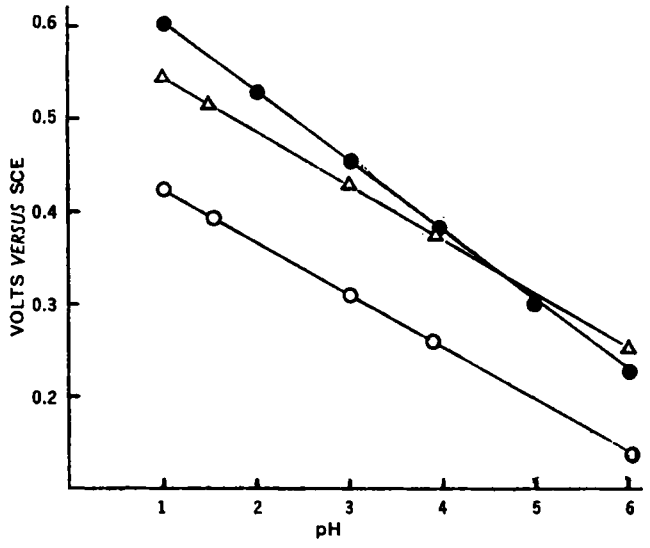

Figure 2—*Half-wave potential as a function of pH. Key:* ○, *hydroquinone;* △, *levodopa; and* ●, *3-amino-L-tyrosine.*

which agrees with theoretical considerations of the tubular electrode geometry (7).

Current–voltage scans on 10^{-4} *M* solutions of the compounds listed in Table I show only 3-amino-L-tyrosine to have a half-wave potential ($E_{1/2}$) close to that for levodopa. The other compounds listed, all of which have been suggested as possible interferences formed during synthesis of levodopa, have half-wave potentials significantly different from that of dopa or do not show an oxidation wave. From Fig. 2 it is evident, within the limits of experimental error, that the half-wave potentials for dopa and hydroquinone fit the relationship $E_{1/2} = E° - 0.059$ pH, while the pH dependence of the 3-amino-L-tyrosine oxidation is greater. Indeed, in 1.5 *M* H_2SO_4 the half-wave potential for levodopa is 0.73 v. *versus* the SCE while the oxidation of 3-amino-L-tyrosine occurs about 0.10 v. more anodic. Although a more in-depth study was not attempted, it is surmised that the oxidation of 3-amino-L-tyrosine is suppressed by protonation of the amino group on the benzene ring. Thus, samples suspected of containing this impurity may be assayed in strong acid media. Current–voltage curves for dopamine and norepinephrine were observed to have essentially the same half-wave potential as dopa. If these compounds or other 3,4-dihydroxyphenylethylamine derivatives are considered as possible contaminants in a sample, a separation procedure must precede analysis at the TCE.

The accuracy of the TCE method in determining the dopa content of solid dosage forms is shown in Table II. It is evident that the new method gives data in agreement with the colorimetric method

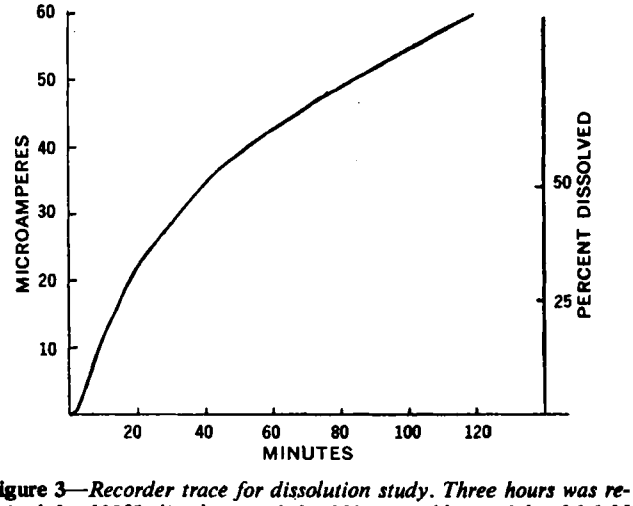

Figure 3—*Recorder trace for dissolution study. Three hours was required for 100% dissolution of the 250-mg. tablet in 1 l. of 0.1* N *HCl.*

and that comparable precision is obtained. In comparison with the colorimetric method, the TCE method is faster and simpler. Once the sample solutions were prepared, between 25 and 30 determinations could be run each hour. The reproducibility of the TCE, as determined by repeatedly assaying a single sample dilution, is indicated by a deviation of the mean ±0.90% for six determinations.

Figure 3 shows the current–time curve for the dissolution study. Once the tablet was placed in the beaker, no further manipulative steps were required to record continuously the tablet dissolution. Although not included here, the dissolution could be determined as a function of pH using the same analytical procedure.

In summary, it is concluded that the electrochemical method for the determination of dopa presented in this paper is more convenient, faster, and simpler to use than previously available methods without any significant loss in precision and accuracy. Although automation was not employed in this study, the method may readily be incorporated into automated or semiautomated systems because it employs continuous analysis on a flowing stream of sample. And, finally, the applicability of the analytical method in the direct and continuous monitoring of tablet dissolution is demonstrated.

PHARMACEUTICAL TECHNOLOGY

Soft Gelatin Capsules I: Factors Affecting Capsule Shell Dissolution Rate

F. S. HOM▲, S. A. VERESH, and J. J. MISKEL

Abstract □ A method to study the relationship between various factors influencing the dissolution rate of the soft gelatin capsule shell is reported. The gelatin disk method makes use of the current USP rotating-basket dissolution apparatus. The effects of agitation, temperature, dissolution medium, and shell composition on the capsule shell dissolution rate are illustrated and discussed. A knowledge of these factors and their influence on dissolution should be of assistance in the formulation of soft gelatin capsule shells for various purposes.

Keyphrases □ Dissolution rate of soft gelatin capsules—effects of agitation, temperature, dissolution medium, and shell composition □ Capsules, soft gelatin—effects of agitation, temperature, dissolution medium, and shell composition on dissolution rate □ Gelatin capsules, soft—effects of agitation, temperature, dissolution medium, and shell composition on dissolution rate

Although soft gelatin capsules have been in mass production (1) since the introduction of the rotary die process (2), little or no work has been reported on the relationship between formulation design and dissolution rate of the capsule shell. Nevertheless, several formulations designed for specific uses have been patented (3–8) in this country. Recently, studies on comparisons of dissolution rates of drugs from soft gelatin capsules and tablets were reported (9, 10). The present report deals with a method to study the relationship between various factors influencing the dissolution rate of the soft gelatin capsule shell.

In the design and formulation of soft gelatin capsule dosage forms, one should consider the effects of components and other parameters on the dissolution rate of the capsule shell. A method that is simple, fast, able to differentiate minor but meaningful changes in dissolution rate, and readily reproducible is of great utility. Eckert *et al.* (11), concerned with drug availability, advocated the use of the *in vitro* initial-release rate to reflect this factor in the monitoring of soft gelatin capsule manufacture. The initial-release rate is adequate for such a purpose, but it lacks the sensitivity and simplicity based on the criteria of the present proposal. A more appropriate method was developed in this laboratory.

Many factors that influence the dissolution rate of the soft gelatin capsule shell may be adequately studied by the use of the Nelson (12) modification of the Noyes–Whitney equation. Using the Noyes–Whitney equation, one may write:

$$\frac{dW}{dt} = KS(C_s - C) \qquad \text{(Eq. 1)}$$

where W is the amount dissolved, t is the time, K is the solution rate constant with dimensions of distance/

and that comparable precision is obtained. In comparison with the colorimetric method, the TCE method is faster and simpler. Once the sample solutions were prepared, between 25 and 30 determinations could be run each hour. The reproducibility of the TCE, as determined by repeatedly assaying a single sample dilution, is indicated by a deviation of the mean ±0.90% for six determinations.

Figure 3 shows the current–time curve for the dissolution study. Once the tablet was placed in the beaker, no further manipulative steps were required to record continuously the tablet dissolution. Although not included here, the dissolution could be determined as a function of pH using the same analytical procedure.

In summary, it is concluded that the electrochemical method for the determination of dopa presented in this paper is more convenient, faster, and simpler to use than previously available methods without any significant loss in precision and accuracy. Although automation was not employed in this study, the method may readily be incorporated into automated or semiautomated systems because it employs continuous analysis on a flowing stream of sample. And, finally, the applicability of the analytical method in the direct and continuous monitoring of tablet dissolution is demonstrated.

Soft Gelatin Capsules I: Factors Affecting Capsule Shell Dissolution Rate

F. S. HOM▲, S. A. VERESH, and J. J. MISKEL

Abstract □ A method to study the relationship between various factors influencing the dissolution rate of the soft gelatin capsule shell is reported. The gelatin disk method makes use of the current USP rotating-basket dissolution apparatus. The effects of agitation, temperature, dissolution medium, and shell composition on the capsule shell dissolution rate are illustrated and discussed. A knowledge of these factors and their influence on dissolution should be of assistance in the formulation of soft gelatin capsule shells for various purposes.

Keyphrases □ Dissolution rate of soft gelatin capsules—effects of agitation, temperature, dissolution medium, and shell composition □ Capsules, soft gelatin—effects of agitation, temperature, dissolution medium, and shell composition on dissolution rate □ Gelatin capsules, soft—effects of agitation, temperature, dissolution medium, and shell composition on dissolution rate

Although soft gelatin capsules have been in mass production (1) since the introduction of the rotary die process (2), little or no work has been reported on the relationship between formulation design and dissolution rate of the capsule shell. Nevertheless, several formulations designed for specific uses have been patented (3–8) in this country. Recently, studies on comparisons of dissolution rates of drugs from soft gelatin capsules and tablets were reported (9, 10). The present report deals with a method to study the relationship between various factors influencing the dissolution rate of the soft gelatin capsule shell.

In the design and formulation of soft gelatin capsule dosage forms, one should consider the effects of components and other parameters on the dissolution rate of the capsule shell. A method that is simple, fast, able to differentiate minor but meaningful changes in dissolution rate, and readily reproducible is of great utility. Eckert *et al.* (11), concerned with drug availability, advocated the use of the *in vitro* initial-release rate to reflect this factor in the monitoring of soft gelatin capsule manufacture. The initial-release rate is adequate for such a purpose, but it lacks the sensitivity and simplicity based on the criteria of the present proposal. A more appropriate method was developed in this laboratory.

Many factors that influence the dissolution rate of the soft gelatin capsule shell may be adequately studied by the use of the Nelson (12) modification of the Noyes–Whitney equation. Using the Noyes–Whitney equation, one may write:

$$\frac{dW}{dt} = KS(C_s - C) \qquad \text{(Eq. 1)}$$

where W is the amount dissolved, t is the time, K is the solution rate constant with dimensions of distance/

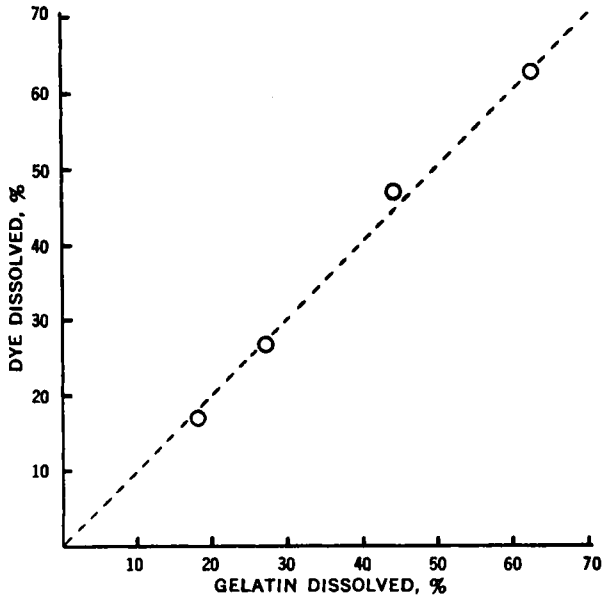

Figure 1—*Plot showing the correlation of the percent dye and gelatin dissolved in simulated gastric fluid without pepsin at 37° and 100 r.p.m. for a given dissolution time in the gelatin disk method. The dashed line is drawn for a theoretically perfect correlation.*

time, S is the surface area of the dissolving solid, C_s is the concentration of dissolving solid at the liquid–solid interface, and C is the concentration in the dissolution medium. At very low percent saturations of dissolving substance in dissolution medium, Nelson (12) showed that the C term may be ignored so Eq. 1 reduces to:

$$\frac{dW}{dt} = KSC_s \qquad \text{(Eq. 2)}$$

Integration, with S considered a constant, yields:

$$W = KSC_s t \qquad \text{(Eq. 3)}$$

By dividing both sides of Eq. 3 with S and setting $KC_s = k$, one then has:

$$\frac{W}{S} = kt \qquad \text{(Eq. 4)}$$

A plot of W/S *versus* t yields a straight line going through the origin. The slope of the line equals k. Equation 4 is valid for initial dissolution rates and at dilute solutions, which is the case in the beginning of each dissolution experiment.

EXPERIMENTAL

Materials—Gelatins used were Type A USP and Type B USP, with gel strength in Bloom grams of 264 ± 4[1], 195 ± 3[2], 27 ± 1[3], and 77 ± 2. The last was a blend of a higher and of a lower gel strength gelatin. The gelatins were sieved to obtain a particle size between U. S. Standard 20- and 40-mesh screens. The following were also used: glycerin USP[4], sorbitol solution USP[5], hexaglycerol[6], FD&C certified Blue No. 1[7], lysine hydrochloride[8], and analytical reagent grade urea[9] and chemicals. Commercial grades of additives were used where reagent grades were not available.

Table I—Repetitive Determinations of Dissolution Rate Constants of Gelatin A and B Type Soft Gelatin Capsule Shell Samples in Simulated Gastric Fluid T.S. without Pepsin at 37° and 100 r.p.m.

	Gelatin Type A Shell, mg./cm.² min.	Gelatin Type B Shell, mg./cm.² min.
	1.83	2.74
	2.07	2.76
	2.03	2.65
	1.98	2.81
	2.09	2.84
Average ± *SD*	2.00 ± 0.12	2.76 ± 0.08

Gel Strength—Gelatin gel strengths, measured in Bloom grams by the use of a Bloom gelometer (13), are averages of duplicate runs.

Dissolution Medium—The aqueous solution pH values were as follows: pH 1.2 simulated gastric fluid T.S. with or without pepsin (14), pH 1.2–2.0 USP standard buffer solutions (14), pH 7.5 simulated intestinal fluid T.S. without pancreatin (14), pH 2.2–5.0 McIlvaine's standard buffer solution (15), and pH 9.9 carbonate buffer solution (16).

Preparation of Sample—Soft gelatin capsule shell disks, containing about 0.25% on dry basis of FD&C Blue No. 1 with either Type A or B gelatin and varying amounts of plasticizer such as glycerin, may be made in the following manner. As an example, mix 60.25 g. gelatin with 31.50 g. glycerin in a 500-ml. filtering flask fitted with a stopcock. Add 33 ml. cold, aqueous solution of 250 mg. FD&C Blue No. 1 dye and additive, if any, and mix well. Reduce pressure of system to deaerate contents, and close off stopcock to maintain a reduced pressure. Heat system on a steam bath to dissolve contents and to obtain a flowable mass. Mix well by swirling flask contents without creating bubbles in the molten mass. Vent flask and pour flask contents on a clean glass plate. Immediately level mass with a constant-thickness doctor blade. The formed film should be homogeneous and free of bubbles. Allow film to set at room temperature for 1 hr., and then mount film between two plastic brackets to keep it flat along edges. Allow film to equilibrate for at least 2 weeks in a desiccator containing solid calcium chloride in equilibrium with a saturated solution of calcium chloride. Just before a dissolution run, cut a disk of the gelatin film with a No. 13

cork borer. Determine the weight of the disk on an analytical balance, and calculate the surface area from measurements of diameter and thickness.

Dissolution Apparatus—The USP XVIII rotating-basket dissolution apparatus (14) is used. A modification of this method was described recently (17) which facilitates faster determinations of dissolution rates. Throughout this study, the temperature of the dissolution medium was kept constant at the indicated temperature ±0.1° by use of a constant-temperature circulator[10].

Dissolution Procedure—Place a weighed soft gelatin disk sample flat on the bottom of the stainless steel basket, and secure with fine stainless steel wires inserted crosswise immediately above the sample. Assemble to stirring motor and raise dissolution vessel to predetermined height by use of a laboratory jack. The temperature of the vessel and its contents is kept constant at the desired temperature ±0.1°. Add 500 ml. simulated gastric fluid T.S. (with or without pepsin as the case may be) maintained at the same desired temperature. To start dissolution, turn on stirring motor set at a predetermined revolutions per minute. At suitable time intervals, determine the absorbance of the dissolution medium at 630 nm. *versus* water in a suitable spectrophometer. A 3-ml. aliquot may be withdrawn for this purpose. However, absorbance is best determined by continuous analysis in a spectrophotometer flow cell assembly. The amount of soft gelatin film dissolved in time t, W_t, is equal to that fraction of the disk dissolved in time t. One may write:

$$W_t = \frac{A_t M}{A_\infty} \qquad \text{(Eq. 5)}$$

where M is the weight of the plug in milligrams, and A_t and A_∞ are the absorbance values at 630 nm. for time t and infinity (completed dissolution), respectively. In this manner, the term W/S may be determined for corresponding values of time. The dissolution constant, k, is obtained from the slope of the straight line in a plot of W/S *versus* t and will have the dimensions of mg./cm.² min., where S is measured in cm.² and t in minutes. The results are averages of at least duplicate runs.

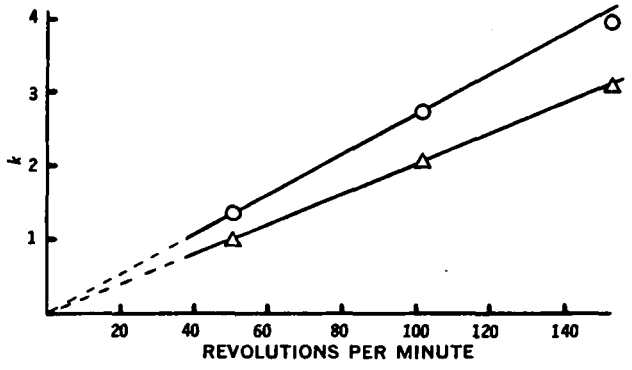

Figure 3—*Effect of agitation (r.p.m.) on the dissolution rate constant (mg./cm.² min.) of soft capsule shells made from gelatin Types A (Δ) and B (○) in simulated gastric fluid at 37°.*

Without pepsin	2.29 ± 0.08	1.50 ± 0.19

Validity of Method—The use of soft gelatin capsule shell disks in the method ensures that each test sample presents uniform and constant surface to the dissolving medium. The sample disk has the additional advantage in being relatively simple to prepare. Since it is difficult to prepare soft gelatin capsule shell films containing the same amount of water, the conditioning of the film in a constant relative humidity atmosphere before a dissolution rate determination is important because an unconditioned, freshly made sample has a relatively higher initial dissolution rate and this rate decreases to a constant value under controlled humidity storage condition. The incorporation of the water-soluble dye permits ready appraisal of dissolution of the gelatin. The relatively simple absorbance measurement of the dye in the dissolution medium renders the method amenable to the use of the present USP XVIII rotating-basket dissolution apparatus.

Apparently the water-soluble dye is distributed uniformly throughout the gelatin shell, and there is no indication that the dye diffuses from the matrix at a rate greater than the dissolution of gelatin. The diffusion of the dye out of the gelatin matrix is measurable only with nearly insoluble samples, where dissolution is extremely slow or at low temperatures and low agitations. Nevertheless, this rate is considerably less than normal dissolution and does not contribute significantly to the measurements discussed. Furthermore, visual observations indicate that the amount of dye dissolved is proportional to the amount of the gelatin mass dissolved. This was confirmed by analyses of both dye and gelatin dissolved for a given dissolution time. The percent gelatin dissolved was calculated from the relative amounts of nitrogen in solution as determined by a slightly modified USP XVIII Method II (14). The described dissolution procedure was used with the exception that 100 ml. instead of the 500 ml. of simulated gastric fluid made without pepsin was used. Figure 1 shows that the results fall on top of the theoretical, perfect correlation line.

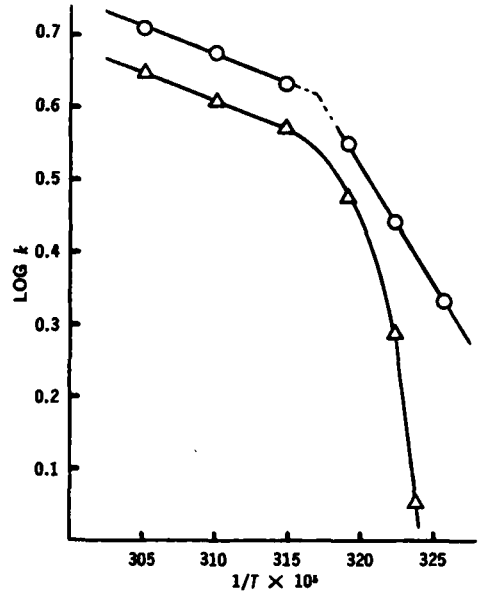

Figure 4—*Arrhenius plot showing the effect of temperature on the dissolution rate constant, k, of soft capsule shells made from gelatin types A (Δ) and B (○) in simulated gastric fluid at 100 r.p.m.*

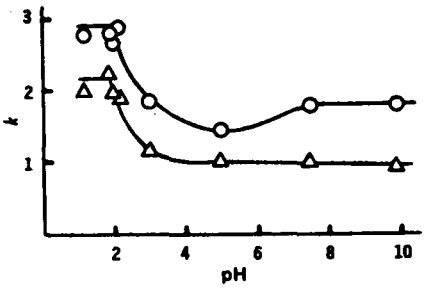

Figure 5—*Effect of pH of the medium on the dissolution rate constant (mg./cm.² min.) of soft capsule shells made from gelatin Types A (△) and B (○) at 100 r.p.m. and 37°.*

In separate experiments, the blue soft gelatin film, when dissolved in an acid dissolution medium at the concentrations of the dissolution experiments, obeyed Beer's law at the wavelength of 630 nm. The FD&C Blue No. 1 was chosen for its high absorptivity and water solubility. Although it is not the only dye that can be used in the method, the present report is limited to its use.

Gas bubbles clogging the dissolution basket wire screen were observed to slow the dissolution rate measurably, but this source of error was eliminated by the removal of dissolved gas. The addition of a small piece of stainless steel screen or a piece of boiling stone helped the dissolved gas to nucleate and to grow into larger gas bubbles. Gentle agitation under reduced pressure removed the gas bubbles. This treatment, before each dissolution rate determination, produced results that were reproducible and typical of those shown in Table I.

RESULTS AND DISCUSSION

Stirring Rate—Figure 2 shows plots of *W/S versus* time in minutes at 50, 100, and 150 r.p.m. of the rotating basket for gelatin Type B soft gelatin capsule shells in simulated gastric fluid T.S. without pepsin at 37°. It can be seen that the lines are straight, but they do not seem to extrapolate linearly to the origin as predicted by Eq. 4. These observed differences or apparent lag times may be explained by the inefficiency of mixing at lower stirring rates. This postulation is supported by the smaller apparent lag times at higher revolutions per minute values. However, these apparent initial lag times seem to have little or no effect on the values of the dissolution rate constants as shown in Fig. 3. The linear relationship as depicted in the plot of dissolution rate constant, *k*, *versus* revolutions per minute is in accord with a diffusion-controlled dissolution process (18). Both Figs. 2 and 3 show the importance of agitation on the dissolution rate of the soft gelatin capsule shell. Withey and Mainville (19) came to a similar conclusion after they tested a soft gelatin capsule sample.

Temperature—Because of the abilities of gelatin to form thermally reversible rigid gels and to hydrogen bond, temperature may be expected to have a marked effect on the dissolution rate of soft gelatin capsule shells. Indeed, this is the case, especially below about 42°, as shown by the Arrhenius plots in Fig. 4 of log *k versus* the reciprocal of the absolute temperature. In the regions of the curves below 42°, the activation energy varies from 71 to 15 kcal./mole for the gelatin Type A and Type B soft gelatin capsule shell. By contrast, the activation energy above 42° is relatively constant at 3.6–3.7 kcal./mole. Unfortunately, most of the dissolution rate determinations are at 37°. Consequently, the temperature of the medium during a dissolution rate determination must be kept precisely constant.

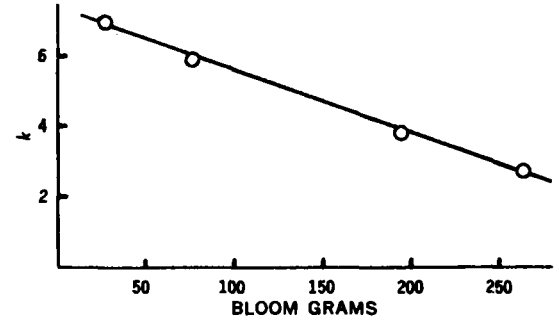

Figure 6—*Effect of gelatin gel strength in Bloom grams on the dissolution rate constant (mg./cm.² min.) of soft capsule shells made from Type B gelatins in simulated gastric fluid at 37° and 100 r.p.m.*

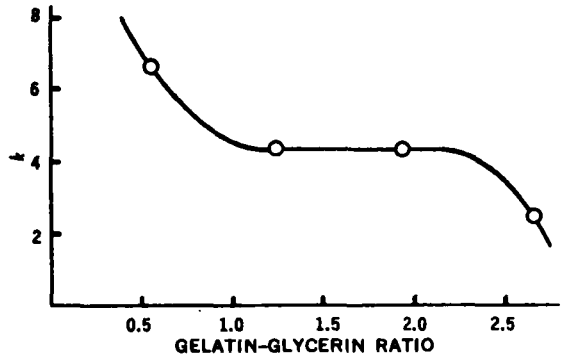

Figure 7—*Effect of gelatin-glycerin ratio in a capsule formulation on the dissolution rate constant (mg./cm.² min.) of soft capsule shells made from a Type B gelatin in simulated gastric fluid at 37° and 100 r.p.m.*

Dissolution Medium—The influence of pH of the medium on the dissolution rate constant for gelatin Type A and Type B soft gelatin capsule shells is shown in Fig. 5. The pH seems to have little effect above a value of 3 on dissolution rate constants of both types of soft gelatin capsule shells. Also, there appears to be a minimum at pH 5 for the Type B gelatin in the pH dissolution profile. The pH of the minimum seems to coincide with the isoelectric point (pH 4.7–5.1) of gelatin Type B. As the pH values decrease from 3 to 1, the dissolution rate constants seem to approach a higher plateau. This increase in dissolution rate may be due to the protonation of amino groups that have pKa values in this pH range.

Small amounts of salts such as sodium or potassium chloride may or may not have an effect on the dissolution rate constants of soft gelatin capsule shells, depending on the type of gelatin used and the pH of the medium. Both sodium and potassium chloride at concentrations from 0 to 0.30 *M* and a pH value of 5.0 seem to have no effect on the dissolution rate constant of both Types A and B soft gelatin capsule shells. However, at a pH value of 1.2, both salts seem to have a small negative effect on the dissolution rate constants of both types of gelatin shells (Table II).

In most instances the use of pepsin in the simulated gastric fluid T.S. has little or no effect on the dissolution rate constant of the soft gelatin capsule shell. This is particularly true for relatively unaged and fast dissolving samples. However, in certain aged and relatively slow dissolving samples, the use of enzyme may increase the dissolution rate. This is illustrated by the results listed in Table III for a 2-year-old sample and a relatively slow dissolving Type A soft gelatin capsule shell sample. It can be seen that in this instance there is no significant difference between the dissolution rate of a slow

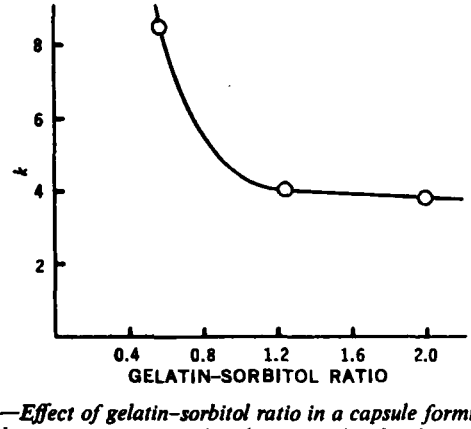

Figure 8—*Effect of gelatin-sorbitol ratio in a capsule formulation on the dissolution rate constant (mg./cm.² min.) of soft capsule shells made from a Type B gelatin in simulated gastric fluid at 37° and 100 r.p.m.*

Table IV—Normal Gelatin–Glycerin Ratio Values for Several Different Capsule Shell Formulations and Their Suggested Uses

0.4–1.0	Suppositories

dissolving sample in simulated gastric fluid T.S. with or without the use of pepsin. However, there is a small difference in the dissolution rate of the aged sample. In a case of an aged soft gelatin capsule where dissolution rate was a problem, pellicle formation was observed. A thin membrane on the inner side of the capsule shell seemed to be responsible for the delay in dissolution time. Apparently the pepsin in the simulated gastric fluid helped to accelerate the dissolution of the pellicle and the subsequent liberation of the encapsulated drug. Pellicle formation in gelatin capsules has been encountered with aldehydes and/or aldehyde-containing liquids, such as in perfumes and flavors. The use of aldehyde, *e.g.*, formaldehyde, to render gelatin less water soluble is the basis of a technique (3) to produce delayed-release soft gelatin capsules.

Gelatin Gel Strength—For a given soft gelatin capsule, there is an optimum gelatin Bloom strength to use when all factors are taken into account. One of these factors is the dissolution rate of the capsule shell. The effect of Bloom strength on the dissolution rate constant of the Type B gelatin capsule shell in simulated gastric fluid without pepsin at 37° and 100 r.p.m. is shown in Fig. 6. It is not surprising to observe a linear relationship, since the same types of gelatin may be blended to obtain a desired property, such as Bloom strength. The straight line with a negative slope indicates a reverse linear relationship: the lower the Bloom the higher the dissolution rate and the higher the Bloom the lower the dissolution rate. This relationship holds true provided other factors are constant. For example, gelatins with higher Bloom values have greater physical strength; therefore, thinner films or ribbons may be made from them. Capsules made with thinner ribbons have faster apparent dissolution. In most instances, soft gelatin capsules are made with Type B gelatin having Bloom strength values between 150 and 200 g.

Plasticizer—The plasticizer is an important part of the soft gelatin capsule shell formulation. Not too many compounds may be used to replace glycerin as the plasticizer of gelatin. Glycerin is relatively pure, commercially available in large quantities, relatively inexpensive, and nontoxic. Propylene glycol and polyethylene glycol 400 can be used, but they have no advantage over glycerin. Sorbitol has limited uses as a plasticizer for gelatin. Usually it is used to replace part of the glycerin in cases where a low glycerin content is desirable in a particular formulation. Hexaglycerol and its family of polymers are not commercially available at present. They have properties similar to glycerin as plasticizers for gelatin. The plasticizer in a

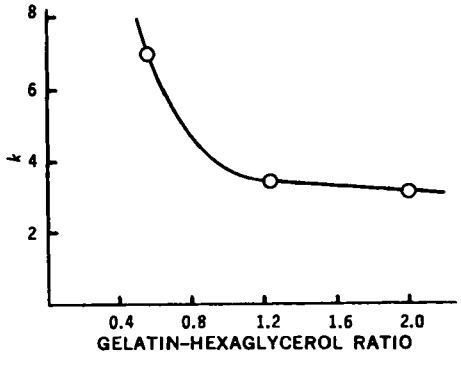

Figure 9—*Effect of gelatin–hexaglycerol ratio in a capsule formulation on the dissolution rate constant (mg./cm.² min.) of soft capsule shells made from a Type B gelatin in simulated gastric fluid at 37° and 100 r.p.m.*

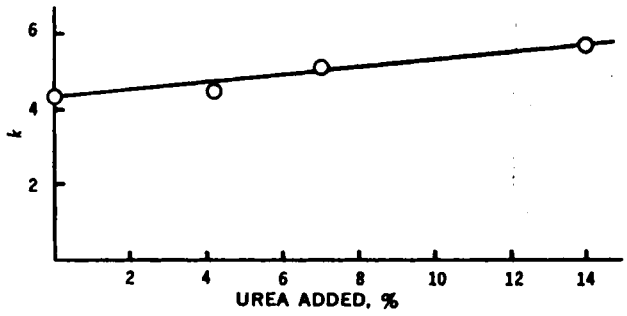

Figure 10—*Effect of percent urea added to a capsule formulation on the dissolution rate constant (mg./cm.² min.) of soft capsule shells made from a Type B gelatin in simulated gastric fluid at 37° and 100 r.p.m.*

formulation, expressed as the gelatin–plasticizer ratio, controls the consistency of the soft gelatin capsule. Hence, the gelatin–plasticizer ratio reflects the projected use of the capsule. Figures 7–9 show the influence of the gelatin–plasticizer ratio on the dissolution rate constant of the Type B gelatin capsule shell. It is surprising to see that the gelatin–plasticizer ratios for glycerin, sorbitol, and hexaglycerol have similar effects on the dissolution rate constant, in particular in the region between 1.2 and 2.0 ratios where the plasticizer seems to have little influence on dissolution. Table IV shows a tabulated list of normal gelatin–glycerin ratio values for several different capsule shell formulations and their suggested uses.

Additives—The influence of certain additives on the dissolution rate constant of the soft gelatin capsule shell in simulated gastric fluid without pepsin at 37° at 100 r.p.m. has been investigated. Figure 10 reflects the increased dissolution rate, which may be attributable to the hydrogen bond breaking effect of urea in a plot of dissolution rate constant *versus* percent urea added to the capsule shell. The increase in dissolution rate is small for the amount of urea added. A somewhat greater increase with lysine hydrochloride, probably due to acidity, is illustrated in Fig. 11. For ease of comparison, a list of additives tabulating the changes in the dissolution rate constant realized through the addition of 1% of each to a standard soft gelatin capsule shell formulation is compiled in Table V. Most of the compounds caused only a slight change in the dissolution rate constant. Acid salts and mineral and organic acids seem to cause the largest change in dissolution rate, probably due to acid hydrolysis of the polypeptide in the gelatin.

SUMMARY AND CONCLUSIONS

A simple method is described to study the effects of various factors on the dissolution rates of soft gelatin capsule shells. The method involves the use of the current USP XVIII dissolution apparatus and the spectrophotometric determination of the amount of dye dissolved from a blue, soft gelatin capsule shell disk placed in the rotating basket. The validity of the gelatin disk method was confirmed by a correlation study of the percent dye and gelatin dissolved for any given dissolution time. Dissolution rate constants may be obtained from a plot of the amount of the soft gelatin

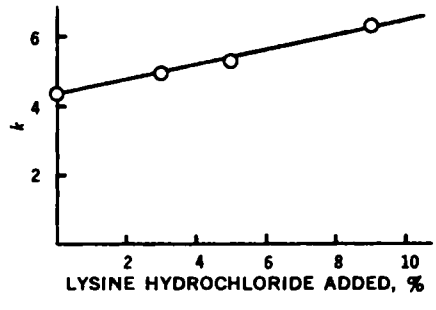

Figure 11—*Effect of percent lysine hydrochloride added to a capsule formulation on the dissolution rate constant (mg./cm.² min.) of soft capsule shells made from a Type B gelatin in simulated gastric fluid at 37° and 100 r.p.m.*

capsule shell dissolved, which is directly proportional to the dye dissolved, divided by the dissolving solid surface area *versus* time.

The use of the gelatin disk method has permitted the present investigation of the influence of agitation, temperature, dissolution medium, gelatin gel strength, plasticizer, and certain additives on the dissolution rate of the capsule shell. Gelatin gel strength, when measured in Bloom grams, appeared to have an inverse linear relationship with dissolution rate. The plasticizer plays an important role, and its effect on dissolution rate seems to depend on the gelatin–plasticizer ratio in a particular formulation. Acid salts and mineral and organic acids seem to cause a greater change in dissolution rate, probably due to acid hydrolysis of gelatin.

In conclusion, various factors have been demonstrated to influence soft gelatin capsule shell dissolution rates. A knowledge of these relationships is helpful in the formulation of soft gelatin capsule shells for various purposes.

4-Methanesulfonyloxybutanol: Hydrolysis of Busulfan

P. W. FEIT▲ and N. RASTRUP-ANDERSEN

Abstract □ The hydrolysis of busulfan (1,4-dimethanesulfonyloxybutane) was investigated by means of NMR spectroscopy. The final hydrolysis product was found to be tetrahydrofuran. The rather unstable intermediate, 4-methanesulfonyloxybutanol, was synthesized and proved to undergo cyclization to tetrahydrofuran by intramolecular alkylation. The half-life of this first-order reaction in aqueous solution at 37° was determined to be approximately 12 min. at pH 3 as well as at pH 7.4. From the present data, it is concluded that 4-methanesulfonyloxybutanol is unlikely to be responsible for the biological action of busulfan.

Keyphrases □ Busulfan—hydrolysis, NMR determination of hydrolysis intermediate as 4-methanesulfonyloxybutanol □ 4-Methanesulfonyloxybutanol—synthesis, identified as an unstable intermediate in the hydrolysis of busulfan, NMR □ NMR spectroscopy—identification of 4-methanesulfonyloxybutanol as an unstable intermediate in the hydrolysis of busulfan

In connection with an investigation of the genetic action of busulfan (1,4-dimethanesulfonyloxybutane), it has been found that aqueous solutions of hydrolyzed busulfan, as well as solutions of a compound assumed to be 4-methanesulfonyloxybutanol (III), induced mutations to a greater extent than busulfan itself (1). Compound III, formerly a monofunctional alkylating agent, was of potential interest as an intermediate in the hydrolysis of busulfan with reference to the discussion of the mechanism of the biological effects of busulfan. To our knowledge, the synthesis and stability of III have not been described in the literature[1]. For this reason, it seemed justified to synthesize the intermediate III and to investigate its behavior. Furthermore, the partial saponification and hydrolysis of busulfan were followed by NMR spectroscopy.

EXPERIMENTAL[2]

Synthesis—*4-Benzoyl-1-methanesulfonyloxybutane* (II)—To a stirred mixture of 4-benzyloxybutanol (I) (2) [9 g., 0.05 mole, b.p. 157–160° (12 mm.)] and methanesulfonyl chloride (6.9 g., 0.06 mole), pyridine (20 ml.) was added dropwise while keeping the temperature below 40° by cooling. After additional stirring for 1 hr., the reaction mixture was poured into a mixture of ice and 4 *N* HCl. It was extracted with chloroform and the organic layer was washed with 4 *N* HCl, dried (magnesium sulfate), and evaporated *in vacuo*. The residue was suspended in water, and the excess methanesulfonyl chloride was hydrolyzed at room temperature at pH 7 using an automatic end-point titrator (11.2 ml. of 1 *N* NaOH). It was extracted with chloroform, washed with water, dried (magnesium sulfate), and evaporated *in vacuo*, yielding crude II (12 g., 93%). Crude II (3 g.) was chromatographed on a dry silica gel column[3]. The fractions, shown by TLC[3] to be homogeneous, were combined and evaporated *in vacuo*. After drying of the residue *in vacuo* (1 mm.) for 2 hr. at 22°, II was obtained as a colorless oil (2.1 g.); NMR ($CDCl_3$, tetramethylsilane): CH_2CH_2 (m, 1.78, 4H), CH_3O_2SO (s, 2.94, 3H), CH_2CH_2O (t, 3.52, 2H), CH_2OSO_2 (*t*, 4.26, 2H), $C_6H_5CH_2O$ (s, 4.51, 2H), and C_6H_5 (s, 7.36, 5H).

Anal.—Calc. for $C_{12}H_{16}O_4S$ (mol. wt. 258.32): C, 55.80; H, 7.02; S, 12.38. Found: C, 55.67; H, 7.04; S, 11.92.

4-Methanesulfonyloxybutanol (III)—A solution of II (1 g., 3.9 mmoles) in dry ethanol (15 ml.) was hydrogenated at room temperature after addition of 10% palladium-on-charcoal (0.15 g.). After the uptake became negligible, the catalyst was removed by filtration. The filtrate was evaporated *in vacuo* in a bath not exceeding 15° to yield III as a colorless oil. All operations including analyses were performed within 6 hr., and III was kept below −10° when possible. The NMR spectrum of III is given in Fig. 1.

Anal.—Calc. for $C_5H_{12}O_4S$ (mol. wt. 168.21): C, 35.70; H, 7.20; S, 19.05. Found: C, 35.46; H, 7.59; S, 18.92.

Half-Life Studies—The half-life of III was obtained by titration of liberated methanesulfonic acid in 0.1-mmole solution of III at pH 7.4 and 3, respectively, using 0.33 *N* NaOH. The titration curve was recorded until the sodium hydroxide consumed had become negligible. The reaction order and the half-life were determined as usual.

Hydrolysis of Busulfan—*Acidic Conditions*—A suspension of busulfan (0.025 g., 0.1 mmole) in deuterium oxide (D_2O) (0.4 ml.) was kept in a sealed NMR test tube at 70° and shaken occasionally until a solution was obtained (24 hr.). The NMR spectrum was recorded to show the signals of IV. The formation of IV was verified and the absence of 1,4-butanediol was proved by NMR spectra taken after the addition of IV and the diol successively to the desealed NMR tube.

Alkaline Conditions—The experiment was performed as described under *Acidic Conditions*, except that 2.4 *N* NaOD (0.1 ml.) was added to the suspension prior heating to show IV as the reaction product.

Partial Saponification—To a mixture of busulfan (0.125 g., 0.5 mmole), D_2O (1 ml.), and $(CD_3)_2CO$ (3 ml.), 2.4 *N* NaOD (0.2 ml., 0.48 mmole) was added and the mixture was refluxed for 4 hr. The NMR spectrum of the still alkaline reaction mixture was examined, and the presence of IV along with the starting material was proved as described under *Acidic Conditions*.

RESULTS AND DISCUSSION

Experiments to provide 4-methanesulfonyloxybutanol (III) by partial saponification of busulfan, as well as total hydrolysis under acidic and alkaline conditions, were followed by NMR spectroscopy. No reaction products but tetrahydrofuran (IV) could be detected. Fast cyclization of III to IV by intramolecular alkylation was the only explanation for this result and was consistent with the described cyclization of partially mesylated or tosylated polyalcohols under acidic (3, 4) and alkaline (5) conditions. The same type of cyclization occurs during the recently reported (6) formation of

[1] The authors were not successful in obtaining the details of the original method of preparation of the compound (1) alleged to be the monomesyl derivative III.

[2] The NMR spectra were obtained on a Varian A-60 A spectrometer. The titration curves were obtained on a Radiometer titrator, Type TTT 1a, equipped with a Radiometer titrigraph, SBR 2b.

[3] HF_{254}, Merck; C_6H_{12} (three parts), ethyl acetate (one part); detection by UV.

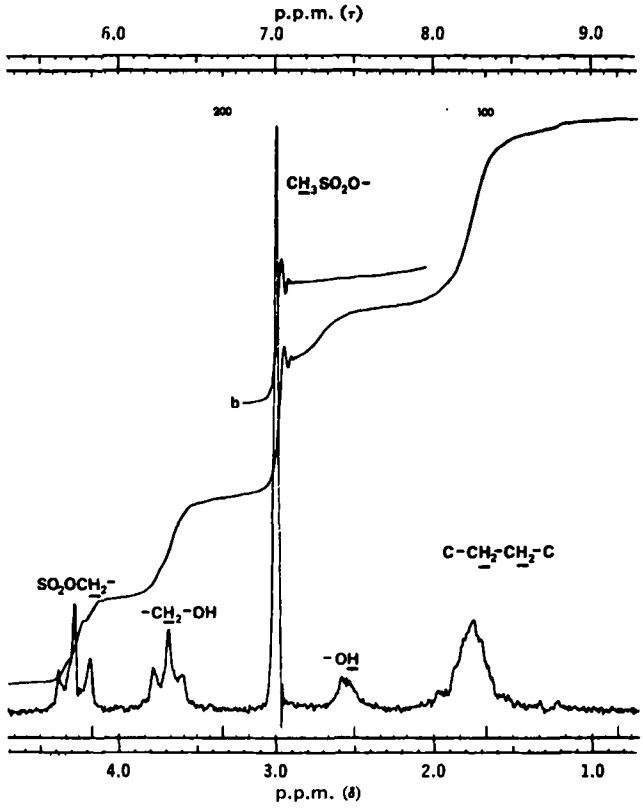

Figure 1—*NMR spectrum of III, 10% (CDCl₃, tetramethylsilane). The integral* b *is recorded after shaking the NMR solution with* D_2O.

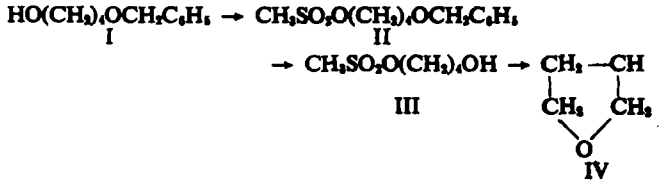
2,5-dimethyltetrahydrofurans from their corresponding 2,5-bis-methanesulfonyloxyhexanes. For these reasons, the synthesis of III was based on a temporary protection of the hydroxyl function as outlined in Scheme I. The reductive debenzylation as the last step resulting in III was advantageous since it could be performed under mild conditions to yield III quantitatively as a colorless, analytically pure, and unstable oil. The structure was proved by its NMR spectrum in $CDCl_3$ (Fig. 1). When the NMR test tube was left for 46 hr. at room temperature, an almost quantitative for-



Scheme I

mation of IV and methanesulfonic acid was observed. In water, III has a half-life of approximately 12 min. at 37° both at pH 7.4 and 3, and it was transformed to IV both in the neutral and acidic solutions in a first-order reaction. The cyclization could conveniently be followed by titration of liberated methanesulfonic acid.

The presented results proved that the hydrolysis of busulfan leads to tetrahydrofuran (IV) through the intermediate III, which is in contrast to the reported formation of 1,4-butanediol (7). When one considers the high rate of cyclization of the monomesyl compound, III, it is unlikely that this compound is responsible for the biological action of busulfan.

Antitumor Activity and Preliminary Phytochemical Examination of *Tagetes minuta* (Compositae)

G. R. ICKES, H. H. S. FONG, P. L. SCHIFF, Jr.*, R. E. PERDUE, Jr.†, and N. R. FARNSWORTH▲

Abstract □ A random collection antitumor screening program revealed that the whole flowering plants of *Tagetes minuta* were significantly active against the Lewis lung carcinoma *in vivo*. In the present phytochemical examination of this plant, the flavone glycosides quercetagetrin and patuletrin were isolated in addition to the monomethyl ester of fumaric acid and syringic acid.

Keyphrases □ *Tagetes minuta* (Compositae)—phytochemical study, antitumor activity □ Antitumor activity—isolation and testing of constituents of *Tagetes minuta* □ Medicinal plants—phytochemical study of *Tagetes minuta*, antitumor activity

Extracts from *Tagetes minuta*[1] were found to elicit significant activity against the Lewis lung carcinoma *in vivo*. Results of a preliminary phytochemical investigation of this plant are reported here.

Prior phytochemical studies on *T. minuta* were limited to the isolation and characterization of insecticidally active compounds such as 5-(3-buten-1-ynyl)-2,2′-bithienyl, α-terthienyl (1), 5-(but-1-chloro-2-ol-3-ynyl)-2,2′-bithienyl, *cis*-5-(1-acetoxy-but-3-enyl)-2,2′-bithienyl, 5-(but-1-en-3-ynyl)-2,2′-bithienyl, 5-(4-chloro-3-hydroxy-but-1-ynyl)-2,2′-bithienyl, and 5-(but-1-yn-4-olyl)-2,2′-bithienyl (2), in addition to the terpenes ocimene, *d*-limonene, estragole, tagetone, and α-dimethyl-Δ^{α}-octen-ε-one (3, 4). A number of rather rare flavonoids, *i.e.*, patuletin, patuletrin, quercetagetin, quercetagetrin, tagetiin, and kaempferitrin (5–8), in addition to a number of carotenoids, *i.e.*, helinine, violaxanthin, rubichrome, rubixanthin epoxide, lutein, antheraxanthin, α-cryptoxanthin, phytofluene, α-carotene, β-carotene, and helenien (9–11), have been isolated from other tagetes species but not *T. minuta*.

EXPERIMENTAL[2]

Plant Material—Originally, the aerial parts of the plant[3] *T. minuta* L. (Compositae) were collected along an open sunny bank, below the Harar-Jijiga road, near the southeastern limits of Harar, Hararge Province, Ethiopia, in December 1964. The collection was made at latitude 9° 18′ N., longitude 42° 7′ E. at an elevation of 2134 m. (7000 ft.). A second collection of plant material (PR-15256), on which the current investigation is based, was collected along the Acachi River in Shoa Province, Ethiopia, 17 km. south of Addis Ababa [elevation 2082 m. (6830 ft.), latitude 8° 52′ N., longitude 38° 50′ E.] in January 1968. This material corresponded in every detail with the original collection.

Extraction and Initial Fractionation—A 6.0-kg. sample of milled aerial parts of *T. minuta* was extracted with hexane[4] in a Lloyd extractor for 24 hr. The resulting extract was concentrated and removed from the extractor; fresh solvent was added and the extraction was continued for an additional 24 hr. This procedure was repeated two additional times, and the extracts were pooled and concentrated to a thick syrup (39.8 g., Fraction A).

The defatted plant material was then air dried, placed back into the extractor, and extracted with 95% ethanol in a similar manner as for the hexane extraction. After removing the ethanol from the extract, a fraction (B) weighing 372 g. was obtained. Fraction B was then partitioned between 2 l. each of chloroform and water, and the aqueous phase was separated and extracted with three additional 2-l. volumes of chloroform. All chloroform extracts were combined and taken to dryness *in vacuo*, and a third fraction (C) weighing 43.5 g. was obtained. Entrained chloroform was removed from the aqueous phase *in vacuo*, and the fraction was frozen and lyophilized to yield 329.5 g. of Fraction D.

Fraction D was dissolved in a convenient volume of distilled water, and a flavonoid fraction was prepared by several extractions with ethyl acetate. The ethyl acetate extraction was continued until a negative cyanidin reaction was obtained (12). In this manner, 59.3 g. of Fraction E was obtained. Further extraction of Fraction D with ethyl acetate–methanol (95:5 and 8:2) yielded only negligible quantities of residue. Finally, Fraction D was exhaustively extracted with *n*-butanol, which yielded 190 g. of Fraction F.

Fraction E, following TLC on polyamide plates using methanol as the developing solvent and 25% aqueous lead subacetate solution as the spray reagent, showed the presence of three yellow-orange spots at R_f 0.90, 0.41, and 0.59 when the chromatograms were viewed under UV light.

Isolation and Identification of Patuletrin—An aqueous slurry of polyamide (370 g.) was prepared and poured into a glass chromatographic column (4 × 7 cm.). A charge of 18.05 g. of Fraction E was absorbed on 10 g. of polyamide, and this was placed on top of the prepared column as a dry powder. Elution was initiated with water, then with water containing increasing amounts of methanol, and finally with methanol. Fifty-milliliter fractions were collected from the column, and these fractions were monitored on cellulose TLC plates, using *n*-butanol–acetic acid–water (4:1:5) as the developing solvent. Fractions were grouped and pooled on the basis of TLC patterns after spraying the plates as previously described.

Fractions 50–69, which were eluted from the column with water–methanol (1:1), were pooled and taken to dryness to yield 1.01 g. of residue. The residue was dissolved in 500 ml. of hot methanol and this was reduced *in vacuo* to 50 ml. and filtered; then the filtrate was allowed to evaporate spontaneously at room temperature. In this manner, three crops of amorphous material were harvested, which were shown to be identical by TLC. The material consisted of two major components, giving flavonoid reactions, at R_f 0.66 (major) and 0.77 (minor). The precipitate was crystallized from methanol to give 20 mg. of crystals. However, the crystals still contained a small amount of the R_f 0.77 substance, which was separated from the major component by TLC on cellulose plates. Elution of the mixture was with *n*-butanol–acetic acid–water (4:1:5). The zone at R_f 0.66 was removed by scraping, dissolved in methanol, and crystallized in the usual manner to yield microcrystals having, after drying *in vacuo* at 100° for 24 hr., m.p. 254–256°. An IR spectrum of the isolate showed absorption maxima at 3380 (s), 2940 (sh), 1660 (m), 1595 (m), 1485 (s), 1375 (m), 1200 (m), 1070 (s), 990 (s), and 700 (s) $cm.^{-1}$.

Direct comparison of the aglycone of the isolate by UV and IR analyses and by TLC analysis in three different systems showed it to be identical with patuletin. The glycone, analyzed after acid hydrolysis, was shown to be D-glycose. Attachment of the D-glucose at the 7-position was determined by UV analysis when no bathochromic shift in the UV spectrum from 259 nm. (observed) for the intact glycoside was observed after treatment with sodium acetate

[1] Collected in Ethiopia as part of the anticancer screening program of the U. S. Department of Agriculture and the National Cancer Institute.

[2] Melting points were taken on a Thomas-Hoover apparatus and are uncorrected. The UV spectra were obtained using a Beckman model DK-2 spectrometer, and the IR spectra were determined in KBr pellets using a Beckman model IR-8 instrument.

[3] A voucher specimen is in the Herbarium of the U. S. National Arboretum and in Kew Herbarium. The original specimen was determined at Kew.

[4] Skellysolve B.

(14). It was thus concluded that the isolated flavone was 3,5,3′,4′-tetrahydroxy-6-methoxyflavone-7B-D-glucopyronoside (patuletrin).

Isolation and Identification of Quercetagetrin—TLC on cellulose plates of combined fractions 96–115 from the column, which were eluted with water–methanol (1:3), showed the presence of one major flavonoid at R_f 0.16 and five minor flavonoids. The fraction (0.74 g.) was dissolved in a minimum volume of methanol and was applied to several thick-layer cellulose plates (0.5 mm.); it was separated, using *n*-butanol–acetic acid–water (4:1:5), by triple development of the plates. The major component (R_f 0.16) was removed and eluted from the cellulose matrix with methanol to give 410 mg. of one-spot material as evidenced by TLC. After drying *in vacuo* at 100° for 24 hr., the isolate exhibited a melting point of 237–238°. An IR spectrum (KBr) of the isolate showed absorption bands at 3400 (s), 2940 (w), 1655 (s), 1605 (s), 1485 (s), 1385 (m), 1250 (w), 1070 (s), 990 (sh), 855 (w), and 825 (w) cm.$^{-1}$. The isolate exhibited an unusual dull black color under UV light on paper and thin-layer chromatograms, which is an unusual characteristic for flavonoids but which has been described previously for two rather rare flavonoids, *i.e.*, quercetagetrin and its aglycone (16). This isolate was also shown to be a flavonol as evidenced by the typical UV absorption at 363 nm. (methanol), and the *o*-dihydroxy grouping was demonstrated to be present as a result of a hypsochromic shift of 56 nm. in aluminum chloride when compared with the absorption in aluminum chloride–hydrochloric acid.

A comparison of the UV, IR, and TLC data of the isolate with those of quercetagetrin proved the two compounds to be identical. Thus, the isolate was shown to be 3,5,6,3′,4′-pentahydroxyflavone-7B-D-glucopyranoside (quercetagetrin).

Isolation and Identification of Monomethyl Fumarate—An additional portion of Fraction E (41.25 g.) was dissolved in water containing only enough methanol to effect complete solution. This solution was then extracted several times with ether; the ether fractions were pooled, dried over anhydrous sodium sulfate, and taken to dryness to give 7.11 g. of residue. This residue was dissolved in chloroform and applied to a chloroform slurry-packed column of silicic acid (400 g.), and 20-ml. fractions were collected. TLC of each fraction from the column revealed that fractions 113–118 contained a single substance. The pooled fractions (113–118) were taken *in vacuo* to a syrupy consistency (510 mg.), and the addition of benzene to this syrup resulted in a copious formation of colorless needles. The needles were recovered by filtration, in addition to a second crop from the mother liquor. A total of 35 mg. of colorless needles was obtained which, after drying *in vacuo* for 24 hr., gave a melting point of 144.5°; IR (KBr): 3100 (s), 2975 (w), 2700 (w), 2530 (w), 1720 (s), 1685 (s), 1351 (s), 1285 (sh), 1275 (s), 1265 (s), 995 (s), 920 (m), 895 (m), 765 (m), and 650 (m) cm.$^{-1}$. The UV spectrum of the isolate, in ethanol, showed only end-absorption at 208 nm. (ϵ = 7333). A mass spectrum taken at 70 ev. showed the molecular weight of the isolate to be 130. Mass tables (17) were consulted for various combinations of C, H, and O having this molecular weight. Five formulas were found: $C_5H_6O_4$, $C_6H_{10}O_3$, $C_7H_{14}O_2$, $C_8H_2O_2$, and $C_8H_{16}O$. Since the IR spectrum indicated the presence of both an unsaturated acid and an unsaturated ester, all compounds with less than four O atoms were not considered further. This left only the formula $C_5H_6O_4$. The mass spectrum showed that the compound was a methyl ester, as evidenced by the large M − 31 ion at *m/e* 99. When the IR spectrum of the isolate was compared with that of a synthetic sample of the monomethyl ester of fumaric acid, they were found to be identical. The melting point of the isolate was 144.5°, which is in agreement with the literature value for the monomethyl ester of fumaric acid (18). A mixed melting point of the isolate and a synthetic sample of the monomethyl ester of fumaric acid showed no depression. These data confirmed the identification of this isolate as the monomethyl ester of fumaric acid.

Isolation and Identification of Syringic Acid—Fractions 161–204, obtained from the silicic acid column previously described, were combined and concentrated *in vacuo* to a thick syrup and placed into a vacuum oven to dry at 50°. After several hours, colorless needles were observed projecting from the syrup. These crystals were removed and dissolved in 10 ml. of methanol for recrystallization. Three milligrams of pure, colorless needles were obtained from this solution which, after drying for 72 hr. in a vacuum desiccator at 25°, exhibited a melting point of 197–199°.

An IR spectrum of the isolate (KBr) showed absorptions at 3300 (s), 2980 (w), 2930 (w), 1695 (s), 1610 (s), 1515 (s), 1455 (s), 1415 (s), 1365 (m), 1240 (m), 1200 (s), 1025 (w), 905 (m), 860 (m), 795 (w), 765 (s), and 680 (s) cm.$^{-1}$. The carbonyl absorption at 1695 cm.$^{-1}$ was suggestive of an unsaturated aromatic acid.

The UV spectrum, in methanol, showed bands at 267 (ϵ = 4812) and 217 (ϵ = 9375) nm. On addition of a potassium hydroxide solution to the sample, a bathochromic shift to 300 (ϵ = 5937) and 224 (ϵ = 7812) nm. was observed, indicating the presence of an enolizable moiety in the isolate, perhaps due to a phenol group.

In consideration of these data, a search was made of previously isolated constituents to obtain a list of organic acids having a molecular weight of 198 (as evidenced by a mass spectrum of the isolate) and a melting-point range of 197–200°. Syringic acid (3,5-dimethoxy-4-hydroxybenzoic acid), and 2,4,5-trihydroxyphenylglyoxylic acid were the only two compounds that fulfilled these criteria. Since the IR spectrum did not show the two different carbonyl absorptions necessary for the substituted phenylglyoxylic acid, and since the literature melting point for 2,4,5-trihydroxyphenylglyoxylic acid was 193°, syringic acid was tentatively assumed to be the isolated compound.

Supporting evidence that this selection was correct is found if one examines the UV spectrum again. Comparing the theoretical maximum for syringic acid, an excellent correlation is found. If one uses a base value of 239 nm. for benzoic acid, adding 25 nm. for a *para*-substituted hydroxyl group and 7 nm. each for two *meta*-substituted methoxyl groups, one arrives at a calculated value of 269 nm. for syringic acid (19). This compares favorably with the observed value of 267 nm. for the isolate.

Mass spectra of the isolate and a reference sample of syringic acid were identical.

In addition to these data, TLC in three different solvent systems gave identical R_f values when the isolate was simultaneously chromatographed with a reference sample of syringic acid. Also, the IR spectra of the isolate and syringic acid were superimposable.

Antitumor Activity of *T. minuta*—Each crude fraction (A–D) was submitted to the Drug Research and Development Branch, National Cancer Institute, for bioassay using established protocols (23) in the PS leukemia, L-1210 leukemia, Walker muscular carcinosarcoma, and Lewis lung *in vivo* tumor systems. In addition, the fractions were evaluated for cytotoxicity using Eagle's 9 KB carcinoma of the nasopharynx in cell culture. Fractions A–C were inactive against all neoplasms and were not cytotoxic. Fraction D had marginal activity against the Lewis lung carcinoma, giving a T/C value[1] of 43% at 266 mg./kg. The monomethyl ester fumaric acid is inactive against the P-388 leukemia. It was also found to be noncytotoxic.

SUMMARY

The aqueous extract prepared from *T. minuta* L. aerial parts has shown reproducible activity against the Lewis lung carcinoma. A phytochemical investigation was initiated in an attempt to isolate and characterize the active antitumor principle(s). During the investigation, quercetagetrin, patuletrin, the monomethyl ester of fumaric acid, and syringic acid were isolated and identified. This is the first report on the occurrence of these four compounds in *T. minuta*. Only the ester was available in quantities sufficient for biological testing, and it was found to be noncytotoxic. Studies are in progress to isolate the active antitumor principle(s) from this plant.

Imidazolecarbohydrazides IV: Synthesis and Biological Evaluation

J. R. NULU* and JAY NEMATOLLAHI▲

Abstract □ A series of 1-methylimidazole-4,5-dicarboxylic acid hydrazides and a bicyclic compound imidazo[4,5-*d*]pyridazine were synthesized and their structures were elucidated. The compounds were subjected to a limited pharmacological evaluation (MAO inhibitory activity) and the results are reported.

Keyphrases □ 1-Methylimidazole-4,5-dicarboxylic acid hydrazides —synthesis, structure determination, screened for MAO inhibitory activity □ Imidazo[4,5-*d*]pyridazine—synthesis, structure determination, screened for MAO inhibitory activity □ Hydrazides, 1-methylimidazole-4,5-dicarboxylic acid—synthesis, structure determination, screened for MAO inhibitory activity □ MAO inhibitors, potential—synthesis and evaluation of 1-methylimidazole-4,5-dicarboxylic acid hydrazides and imidazo[4,5-*d*]pyridazine

The synthesis and certain biological properties of some imidazole-4(or 5)-mono- and 4,5-dicarboxylic acid esters, hydrazides, and hydrazones were reported previously (1, 2). The present paper reports the investigation of 1-methylimidazole-4,5-dicarboxylic acid derivatives and their bicyclic analogs.

The starting ester, dimethyl 1-methylimidazole-4,5-dicarboxylate (I), was synthesized by methods previously reported (1, 2). The reaction of I with hydrazine (II*a*) or methylhydrazine (II*b*), depending on the reaction conditions, gave the dihydrazide (III*a*) (1) or 1-methylimidazole-4,5-dicarboxylic acid bis(2-methylhydrazide) (III*b*), respectively, or their bicyclic analogs IV*a* (3) and 1,5-dimethyl-7-hydroxyimidazo[4,5-*d*]pyridazin-4-one (IV*b*), respectively. With phenylhydrazine (II*c*), only III*c* was obtained.

As depicted in Scheme I, some analogs of III were synthesized by sodium borohydride reduction of their respective hydrazones (4). In this study, the ethylidene derivative (VI) was found to be resistant to such reduction.

The reaction product of I and II*b* could possibly be IV*b*, IV*c*, or a mixture of the two. A relatively sharp melting point of the product, together with a single spot observed on a thin-layer chromatogram and the presence of only a single NMR peak for the CH_3 protons on the pyridazine, gave convincing evidence that the compound was not a mixture of the two isomers. The elucidation of the molecular structure of the compound was attempted by the following experimental procedure. Mixing stoichiometric quantities of an aqueous solution of silver nitrate and IV*a* gave a precipitate analogous to those reported (5) for purines on whose 6-position exists an OH or NH_2 with the 7 as pyridinic N, or on the 6-position a C=O with the 7 as pyrrolic NH. Separation of the precipitate by centrifugation, its dissolution in perchloric acid, and UV spectrophotometric analysis of both the dissolved precipitate and the supernate revealed a 1:1 silver–IV*a* chelate. Similar experiments on the bicyclic reaction product of I and II*b* did not produce any precipitate. Because the purine analog of IV*c* forms a water-insoluble silver chelate (5), the reaction product was assumed to be IV*b*.

The formation of IV*b* may possibly involve an intermediate half-ester half-hydrazide, 1-methylimidazole-4-carbomethoxy-5-(2-methylhydrazide), although it has not been isolated or identified. The phenyl analog of this compound, imidazole-4-carbomethoxy-5-(2-phenylhydrazide), however, has been shown (1) not to give an analogous bicyclic system. The possibility of III*b* being

the intermediate was excluded by recovering the compound intact after heating its butanolic solution for 24 hr.

EXPERIMENTAL[1]

1-Methylimidazole-4,5-dicarboxylic Acid Bis(2-methylhydrazide) (III*b*) and 1,5-Dimethyl-7-hydroxyimidazo[4,5-*d*]pyridazin-4-one (IV*b*)—To 2.0 g. (0.01 mole) of I was added 1.4 g. (0.03 mole) of methylhydrazine. The mixture was stirred at room temperature for 5 hr. The precipitated solid was washed with ether and then treated with a small amount of ethanol to give 1.5 g. (63%) of III*b*.

Heating of I and II*b* under reflux for 18 hr. gave 1.2 g. (62%) of IV*b*.

Compound III*c* was prepared under reaction conditions similar to those of IV*b*.

The preparation of the hydrazones and their respective hydrazides (Table I) are exemplified by the following methods described for V and VIII.

1-Methylimidazole-4,5-dicarboxylic Acid Bis(2-benzylidenehydrazide) (V) and 1-Methylimidazole-4,5-dicarboxylic Acid Bis(2-benzylhydrazide) (VIII)—Under nitrogen, a mixture of 1.9 g. (0.01 mole) of III*a* and 15 ml. of benzaldehyde was heated under reflux for 3 hr. The precipitated solid was washed with ether to give 2.9 g. (77%) of V.

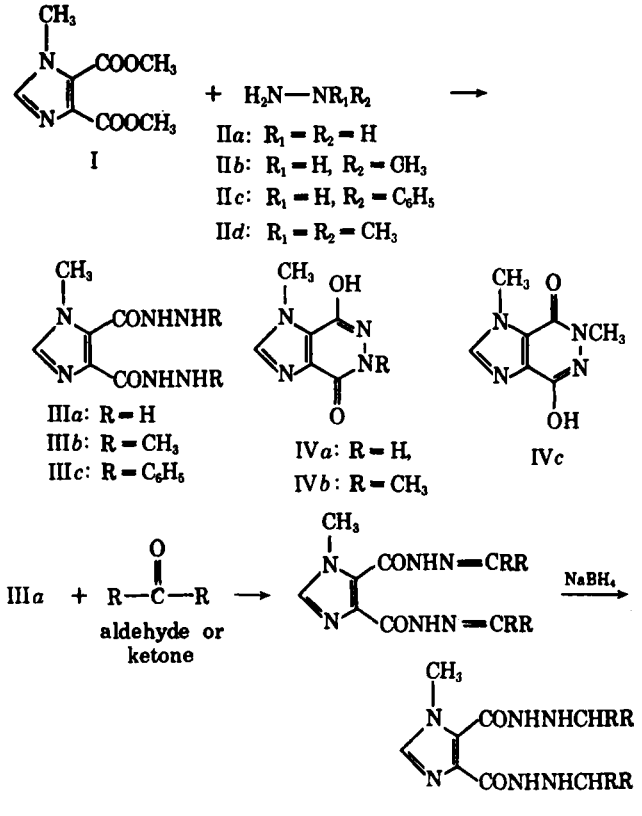
To a suspension of 1.85 g. (0.005 mole) of V in 50 ml. of water was added 0.8 g. (0.02 mole) of sodium borohydride. The mixture was heated under reflux on the steam bath for 1 hr. The solution was evaporated to 10 ml. and extracted twice with ether. The combined ether extracts was dried over sodium sulfate. After filtration, evaporation of solvent gave 1.4 g. (75%) of VIII.

Compound VI under such conditions could not be reduced.

DISCUSSION

The compounds listed in Table II were evaluated for their MAO inhibitory activity by three methods which were described previously (1, 2). The results, listed in Table II, indicate that 1-methylimidazole-4,5-dicarbohydrazides possess about the same level of activity as their previously reported analogs. A similar level of activity was also detected for the bicyclic analog, IV*b*.

A broad biological evaluation of the compounds for such functions as cardiovascular effect and antitubercular activity may be justified by considering the therapeutic use of hydralazine and isoniazid. Compound IV*b* may be conceived of as an analog of purine, a system of interest in tumor research.



Scheme I

[1] Melting points were determined in open capillary tubes in a Thomas-Hoover melting-point apparatus and are not corrected. All evaporations were made *in vacuo* with rotatory evaporators. The IR spectra were determined (KBr) with a Beckman IR-8 instrument, and NMR spectra were determined with a Varian A-60 spectrophotometer at ambient temperature (tetramethylsilane as a reference and deuterated dimethyl sulfoxide as a solvent). Elemental analyses were done by Schwarzkopf Microanalytical Laboratory, Woodside, N. Y. Crystallization solvents, melting points, and elemental analysis (C, H, N) values are listed in Table I.

Synthesis and Anticancer Activity of 5-(Propargyloxymethyl)-2-oxazolidinones

R. B. FUGITT and L. C. MARTINELLI[▲]

Abstract □ To determine the feasibility of producing a tissue-specific anticancer agent, a series of 2-oxazolidinones bearing an alkynoxymethyl side chain in the 5-position was prepared. These compounds were submitted to the National Cancer Institute for testing against L-1210 and/or P-388 tumor test systems. None of the compounds showed significant anticancer activity. The synthetic procedures and NMR spectral properties of the title compounds are described.

Keyphrases □ 5-(Propargyloxymethyl)-2-oxazolidinones—synthesis, screened for anticancer activity □ 2-Oxazolidinones, 5-(propargyloxymethyl)—synthesis, screened for anticancer activity □ Anticancer agents, potential—synthesis and screening of 5-(propargyloxymethyl)-2-oxazolidinones

Interest in carbamates bearing an acetylenic function developed from an interest in tissue- or organ-specific anticancer agents, particularly those specific for the CNS. The investigation of the title compounds stems, in part, from the work of Dillard *et al.* (1) who first demonstrated the oncolytic action of propargyl carbamates against plasma cell tumor X-5563 and the atypical myelogenous leukemia C-1498. Among the structure–activity relationships they observed was the necessity of the ethynyl moiety for significant oncolytic

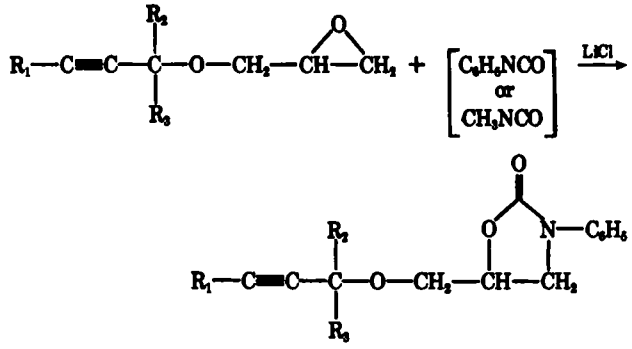
Among the structure–activity relationships they observed was the necessity of the ethynyl moiety for significant oncolytic



Scheme I—See Table I for R-group identification

activity. In addition, carbamates, especially ethynylmethyl carbamates, are known to be potent CNS depressants (2), thus indicating that they are readily transported across the blood–brain barrier. With the intent of screening new chemical entities with potential anticancer activity, the title compounds (Table I), bearing both an ethynyl and a carbamate function, were synthesized and subjected to anticancer screening.

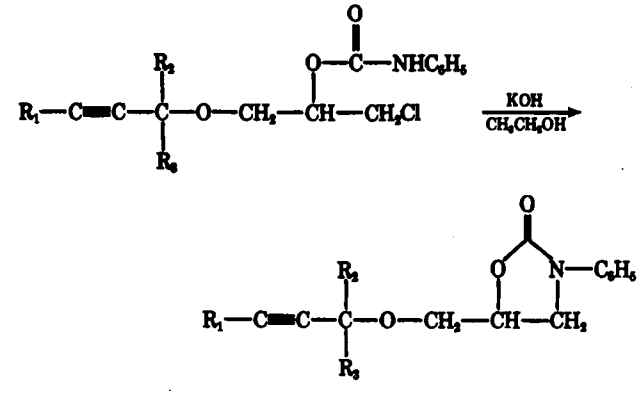
Additional impetus to study 2-oxazolidone ring compounds stems from observations that the potent anticancer agent 1,3-bis(2-chloroethyl)-1-nitrosourea decomposes in water to a Δ^2-oxazoline derivative (3). Similarly, the active *N*-acylethyleneimines readily rearrange to Δ^2-oxazolines (4).

The title compounds were synthesized by reported techniques, and their identification was achieved in part by comparison of NMR data with a compound with known ring stereochemistry. The six compounds were subjected to preliminary anticancer screening against L-1210 lymphoid leukemia and/or P-388 lymphocytic leukemia. Screening data are only available for I–IV; none showed significant activity in these systems.

CHEMISTRY

Compounds I–IV were synthesized (Scheme I) by lithium chloride-catalyzed condensation of the known epoxides (5) with phenylisocyanate or methylisocyanate in dry dimethylformamide at 100–150° (6). This method allows a high yield synthesis of *N*-alkyl- and *N*-aryl-2-oxazolidinones in one step from the epoxide. Compound II was also synthesized (Scheme II) by potassium hydroxide–ethanol cyclization (7) of the appropriate β-chloroethyl *N*-phenylcarbamate to provide a compound with known C-5 ring substitution.

Cyclization of the *N*-phenyl-β-chlorocarbamate ester resulted in the isolation of a small amount of a six-membered ring carbamate as a by-product, which arose from the isomeric γ-chlorohydrin formed in the synthesis of the starting β-chlorohydrins. Careful fractional



Scheme II—See Table I for R-group identification

distillation of the β-chlorohydrin prior to use eliminates this problem. The chlorohydrins were prepared from the reaction of the appropriate alcohol with epichlorohydrin (5).

The isocyanate–epoxide reaction is known to produce both C-4 and C-5 substitution products through breaking either the C_1—O or C_2—O epoxide bonds (8), although the C-5 isomer is generally the only product observed. From the limited study of Herweth *et al.* (6), only aryl-substituted epoxides led to the C-4 isomer regardless of the type of isocyanate (alkyl or aryl). The possibility existed, therefore, that the π-electron-rich ethynyl group may help direct C-4 isomer formation through π-interactions with the incoming isocyanate. That this did not occur is evident by comparison of the NMR data of II with the only products isolated from the isocyanate–epoxide reactions (I–IV).

The NMR spectral shift data (Table I) for H_A, H_B, and $H_{C,D}$ of I–IV are essentially identical with equivalent protons for II synthesized unambiguously. Further, these data are consistent with C-5 isomers reported in the literature (6). Compounds V and VI, the N—CH_3 analogs, are assigned as C-5 substitution since they exhibit proton NMR absorption consistent with the loss of anisotropic deshielding by a phenyl ring. The observation that the $\Delta\delta$ of H_A is larger than the $\Delta\delta$ of H_B when *N*-phenyl is replaced by *N*-methyl is not readily explainable, but it is consistent with similar findings by Herweth *et al.* (6).

BIOLOGICAL ASSAY[1]

Compounds I–IV were assayed against P-388 lymphocytic leukemia in BFD_1 mice, while only I was screened against L-1210 lymphoid leukemia (Table II). The compounds were administered at three dosages, 400, 200, and 100 mg./kg. i.p., every 4th day for three injections, and the percent increase in median survival time (percent test/control) was calculated at Day 30. Compound I was administered in hydroxypropylcellulose, while II–IV were administered in saline. The term "survivors" in Table II is a measure of toxicity and was determined at Day 5 after the first injection.

EXPERIMENTAL[2]

Melting points were obtained in open capillaries and are uncorrected. IR spectra[3] were obtained as neat oils between sodium chloride plates or in potassium bromide wafers for solids. All compounds, except III, exhibited acetylenic and carbonyl stretching frequencies at 2105–2290 and 1733–1740 $cm.^{-1}$, respectively. Compound III had no discernible acetylenic absorption but exhibited an acetylene C—H stretch at 3300 $cm.^{-1}$ as well as a carbonyl absorption at 1737 $cm.^{-1}$. All NMR spectra were obtained at 60 MHz. in deuteriochloroform containing 1% tetramethylsilane as internal standard.

1-(2-Butynyloxy)-3-chloro-2-propyl *N*-Phenylcarbamate—To a 250-ml. flask was added 25 g. (0.150 mole) of 1-(2-butynyloxy)-3-chloro-2-propanol prepared from the condensation of 2-butyn-1-ol and epichlorohydrin (5). Dried benzene (100 ml.) and 21.5 g. (0.180 mole) of freshly distilled phenylisocyanate were added and the reaction was stirred. Following a procedure similar to that of Loev and Kormendy (9), 1.5 ml. of trifluoroacetic acid was added; the reaction was topped with a calcium chloride tube and stirred for 4 hr. at room temperature. The reaction was cooled and filtered to remove diphenylurea and reduced to an oil by water aspiration. The oil was chromatographed on a 20 × 2-mm. alumina column using 1,2-dichloroethane, and the resulting oil was distilled *in vacuo* to give 22.4 g. (52%) of the desired product, b.p. 165–180° (0.1–0.2 mm.).

Anal.—Calc. for $C_{14}H_{16}ClNO_3$: C, 59.68; H, 5.72; Cl, 12.58; N, 4.97. Found: C, 59.74; H, 5.80; Cl, 12.74; N, 5.02.

The IR and NMR data were consistent with this structure. IR (neat): 3305 (N—H), 2220 and 2300 (C≡C), and 1625 (C=O) $cm.^{-1}$. NMR: 1.75 (t, 3), 3.72 (d, 4), 4.10 (d, 2), 4.30 (m, 1), 5.15 (m, 1), and 7.30 (m, 5) p.p.m.

[1] The screening was performed by Drug Research and Development, Chemotherapy, National Cancer Institute, National Institutes of Health, Bethesda, MD 20014

[2] Elemental analyses were performed by Atlantic Microlabs, Atlanta, Ga.

[3] Recorded on a Perkin-Elmer 237B spectrometer.

3-Phenyl-5-[(2-propynyloxy)methyl]-2-oxazolidinone (I)—From the procedure of Herweth *et al.* (6), a 100-ml. flask equipped with a calcium chloride tube, condenser, and dropping funnel was charged with 7 g. (0.063 mole) of 1,2-epoxy-3-propargyloxypropane, 25 ml. of dry dimethylformamide, and 0.5 g. of lithium chloride and the contents were warmed at 100°. A solution of 7.5 g. of freshly distilled phenylisocyanate in 7.5 ml. of dry dimethylformamide was added dropwise (less than 1 drop/sec.), and the reaction was warmed at 150° for 4 hr. The solvent was removed *in vacuo* (pot 120–130°), and the residue was diluted with 50 ml. of carbon tetrachloride and enough methylene chloride to ensure that the liquids were miscible; the lithium chloride was removed by filtration. Upon evaporation of solvent, 11.2 g. (83%) of I was isolated and recrystallized from ethanol, m.p. 83–86° [lit. (10) m.p. 80°].

Anal.—Calc. for $C_{13}H_{13}NO_3$: C, 67.52; H, 5.67; N, 6.06. Found: C, 67.42; H, 5.71; N, 6.06.

3-Phenyl-5-[(2-butynyloxy)methyl]-2-oxazolidinone (II)—*Procedure A: Potassium Hydroxide Method*—To a 50-ml. flask containing 12 g. (0.043 mole) of 1-(2-butynyloxy)-3-chloro-2-propyl *N*-phenylcarbamate and 35 ml. of 70% ethanol was added 29 g. (0.043 mole) of potassium hydroxide. The reaction was immediately warmed at 100° for 9 min. and then poured into 50 ml. of cold water, extracted with ether, and dried over magnesium sulfate. The ether was concentrated and the solution was cooled (5°), which afforded 5.8 g. (38%) of II. Recrystallization was from ethanol–water, m.p. 83–86°. Concentration of the mother liquor yielded 1.0 g. (7%) of a second compound, m.p. 62–65°, tentatively identified as 3-phenyl-5-(2-butynyloxy)-oxazin-2-one.

Procedure B: Epoxide–Isocyanate Method—The same procedure was followed as for I except that the oil bath was maintained at 145–150° throughout. The pot residue, after removal of dimethylformamide, was diluted with 40 ml. carbon tetrachloride; lithium chloride was removed by filtration. After concentrating to 25 ml. and cooling at 5°, 12.8 g. (85%) of II was isolated. The product was recrystallized from ethanol–water, m.p. 83–85°.

Anal.—Calc. for $C_{14}H_{15}NO_3$: C, 68.56; H, 6.16; N, 5.71. Found: C, 68.46; H, 6.23; N, 5.67.

3-Phenyl-5-{[(1-ethynylcyclohexyl)oxy]methyl}-2-oxazolidinone (III)—Following Procedure B for II, 6.1 g. (0.034 mole) of 2-{[(1-ethynylcyclohexyl)oxy]methyl}oxirane, 4.1 g. (0.034 mole) of freshly distilled phenylisocyanate, and 0.5 g. lithium chloride were reacted. Following workup in carbon tetrachloride and recrystallization from methanol, 7.3 g. of III was obtained (72%), m.p. 70–72°.

Anal.—Calc. for $C_{18}H_{21}NO_3$: C, 72.22; H, 7.07; N, 4.68. Found: C, 72.07; H, 7.12; N, 4.61.

3-Phenyl-5-{[(3-phenyl-2-propynyl)oxy]methyl}-2-oxazolidinone (IV)—Following Procedure B for II, 10 g. (0.053 mole) of 2-{[(3-phenyl-2-propynyl)oxy]methyl}oxirane, 6.55 g. (0.055 mole) of freshly distilled phenylisocyanate, and 0.4 g. of lithium chloride were reacted. Following workup and crystallization from ethanol, 12.5 g. of IV was isolated (77%), m.p. 70–73°.

Anal.—Calc. for $C_{19}H_{17}NO_3$: C, 74.25; H, 5.58; N, 4.56. Found: C, 74.37; H, 5.70; N, 4.52.

3-Methyl-5-[(2-propynyloxy)methyl]-2-oxazolidinone (V)—To a 250-ml. flask containing 20 g. (0.180 mole) of 1,2-epoxy-3-propargyloxypropane and 75 ml. dry dimethylformamide at 130° was added 1.0 g. lithium chloride, followed immediately by the slow addition (1 drop every 6–7 sec.) of a solution of 10.5 g. (0.184 mole) freshly distilled methylisocyanate in 18 ml. dry dimethylformamide. After 6 hr., dimethylformamide was removed (vacuum aspirator at 130°), the resulting oil was diluted with ethylene chlo-

Table II—Anticancer Activity

ride, and the lithium chloride was removed. After removal of the solvent, the oil was fractionally distilled to yield 22 g. (73%) of V, b.p. 122° (0.02 mm.).

Anal.—Calc. for $C_8H_{11}NO_3$: C, 56.80; H, 6.55; N, 8.27. Found: C, 56.61; H, 6.64; N, 8.21.

3-Methyl-5-[(2-butynyloxy)methyl]-2-oxazolidinone (VI)—A 50-ml. flask was equipped with a pressure-equalizing dropping funnel and a reflux condenser topped with a clamped rubber tube slit longitudinally for release of pressure. To this was added 4.2 g. (0.033 mole) of 2-[(2-butynyloxy)methyl]oxirane and 13 ml. of dry dimethylformamide. The solution was heated to 130° and 0.2 g. of lithium chloride was added, followed immediately by the slow addition (less than 1 drop every 6 sec.) of 2.0 g. (0.035 mole) of freshly distilled methylisocyanate in 3.5 ml. dry dimethylformamide. After 6 hr. at 130°, solvent was removed and the oil was diluted with methylene chloride; the lithium chloride was removed. The oil was distilled to give 4.3 g. of VI (70%), b.p. 110–125° (0.08 mm.).

Anal.—Calc. for $C_9H_{13}NO_3$: C, 59.00; H, 7.15; N, 7.64. Found: C, 58.81; H, 7.28; N, 7.57.

RESULTS AND DISCUSSION

The isocyanate–epoxide reaction provides high yield quantities of the title compounds and represents a method by which a variety of *N*-alkyl-2-oxazolidinones can be readily synthesized. Attempts to cyclize β-chloroethyl *N*-unsubstituted carbamates with several bases (potassium hydroxide–ethanol and sodium hydride–dimethylformamide) failed. Stronger bases are precluded because of the known ease of rearrangement of propargyl groups to allenes (11).

With the isocyanate–epoxide reaction, only C-5 substitution products were obtained; no C-4 products were isolated. Thus, the stereospecific nature of this reaction in the synthesis of the title compounds is apparently independent of π-electron interactions between isocyanate and acetylene π-electrons. From the work of Herweth *et al.* (6), such π-interactions might have been hypothesized for their isolation of C-4 as well as C-5 substitution products. That C-5 substitution appears exclusive in the present study is probably a result only of steric factors.

Compounds I–IV, the *N*-phenyl analogs, exhibited no anticancer activity against the L-1210 or P-388 tumor test systems employed. Based on reports preliminary to receiving testing data, the *N*-methyl Compounds V and VI are inactive as well. Activity is defined as percent T/C (test/control) of 125 or greater.

The lack of activity of the title compounds in the less sensitive L-1210 and P-388 tumor systems cannot be adequately explained at this time. The possibility exists that cyclic carbamates possess *in vivo* reactivities to nucleophiles significantly different from acyclic carbamates. Whether this or other physical–chemical and biological factors are important remains unanswered.

Metabolism of Aspirin in Rumen and Corpus Tissues of Rat Stomach during First Four Minutes after Administration

CLARENCE H. MORRIS[▲], JOHN E. CHRISTIAN, ROBERT R. LANDOLT, and WARREN G. HANSEN

Abstract □ TLC and liquid scintillation spectrometry were used to determine the identities and relative quantities of aspirin and its metabolites in the gastric juice, blood plasma, rumen (nonglandular portion), and corpus (glandular portion) of the rat stomach 4 min. after the oral administration of aspirin-7-^{14}C. It was found that aspirin and salicylic acid are the major components in the gastric juice, blood plasma, and rumen and corpus tissues. Trace levels of a compound with an R_f value corresponding to that of salicyluric acid was found in the fluids and tissues analyzed. No glucuronide conjugates of salicylic acid or polyhydroxy metabolites of aspirin were found. The level of salicylic acid was fourfold higher in the corpus tissue than in the rumen tissue.

Keyphrases □ Aspirin, radiolabeled—metabolism in rumen and corpus tissues, during first 4 min. after oral administration, rats, TLC and liquid scintillation spectrometric determination of metabolites □ Salicylic acid—determination as metabolite in rumen and corpus tissues of rat 4 min. after oral administration of radiolabeled aspirin □ Metabolism—radiolabeled aspirin, determination of metabolites in rat 4 min. after oral administration, rumen and corpus tissues

It is well known that gastric irritation leading to the production of lesions and occult bleeding occurs in laboratory animals and man following oral administration of salicylates (1, 2). Aspirin has been reported (3, 4) to produce gastric lesions in the corpus portion of the albino rat when administered orally at a level of 50 mg./kg. of body weight.

The production of gastric lesions following intravenous administration of salicylates was reported by Hurley and Crandall (5), Grossman *et al.* (6), and Morris (7), but the lesions were much less severe than those produced by oral administration.

Although systematic mechanisms have been proposed to explain the production of lesions, the present authors felt that the initial mechanism of lesion formation might be a localized chemical phenomenon since previous studies (3) had shown that some rats develop gastric lesions in the corpus (glandular) portion of the stomach within 5 min. after administration of aspirin. Lesions have not been produced in the rumen (nonglandular portion) under the same experimental conditions.

It, therefore, became of interest to identify and compare the relative quantities of aspirin and/or its metabolites in the rumen and corpus tissues of the rat shortly after administration of aspirin-7-^{14}C.

MATERIALS AND METHODS

Radiochemical purity of aspirin-7-^{14}C was established by TLC in conjunction with autoradiography and liquid scintillation spectrometry. The chemical identity and purity of standards of aspirin and its metabolites were established by melting point and TLC.

Four male albino laboratory rats[1], weighing between 100 and 200 g., were fasted for 12 hr. prior to the administration of aspirin-7-^{14}C but were allowed water *ad libitum* until the time of drug administration.

Drug Administration—To achieve the most rapid and uniform absorption, 0.1 mc. (9.3 mg.) of aspirin-7-^{14}C was administered orally as the sodium salt in 1.0 ml. of citrate buffer solution (pH 4.6).

Processing of Tissue—Two minutes after administration of the labeled aspirin, the rats were anesthesized with ether and the stomachs were removed. The stomachs were opened along the line of lesser curvature and the contents were collected in a small vial. Each stomach was stretched and pinned on a large rubber stopper, and the mucosal surface was rinsed with 100 ml. of 0.9% saline. Four minutes following administration, the stomachs were rapidly frozen with dry ice. The chest cavities of the rats were opened, and blood samples were obtained by cardiac puncture using syringes which had been previously swabbed with heparin[2]. The blood was placed in a centrifuge tube and centrifuged for 10 min. at 4600×g. While frozen, the rumen and corpus portions were separated. Each portion was minced and homogenized with 5 ml. of distilled water in a ground-glass tissue grinder, which was kept in an ice bath at 4° to inhibit enzymatic action and spontaneous hydrolysis of aspirin.

Identification of Metabolites—Following homogenization, the tissue samples were centrifuged at 4600×g for 15 min. Ten microliters of the aqueous supernate was spotted on thin-layer plates and analyzed for aspirin, salicylic acid, salicyluric acid, 2,3-dihydroxybenzoic acid, 2,5-dihydroxybenzoic acid, and 2,3,5-trihydroxybenzoic acid, utilizing the solvent systems described later. Ten-microliter samples of blood plasma and gastric juice were analyzed for these compounds in a similar manner. The remaining tissue was resuspended in the supernate, and the suspension was analyzed for the presence of salicyl acyl- and salicyl phenolic glucuronides using an extraction method described by Schachter (8) and Schachter and Manis (9), followed by TLC, autoradiography, and liquid scintillation spectrometry.

To determine the amount of spontaneous hydrolysis of the aspirin occurring during storage and analytical procedures, an aliquot of the dose solution was added to homogenized rumen and corpus tissue taken from four untreated animals. These samples were subsequently treated exactly as the experimental samples. An aliquot of the dose solution itself was also analyzed.

TLC—A stationary phase of standard thickness (250 μ) silica gel G mixed with fluorescent indicator on a thin aluminum backing was used for all thin-layer chromatographs[3]. The following solvent systems were used to identify aspirin and its metabolites in the gastric juice, blood plasma, and rumen and corpus tissues. Petroleum ether (boiling range 30–60°) and propionic acid (10:1 v/v) were used to separate aspirin and salicylic acid from each other and from the rest of the metabolites. A benzene, ether, glacial acetic acid, and methanol (120:60:18:1 v/v) system was used to separate salicyluric acid from the rest of the metabolites. A system of benzene, glacial acetic acid, and water (2:2:1 v/v) was used to separate the polyhydroxy metabolites from each other and from the rest of the metabolites. In all cases, unlabeled, authentic standards of the compounds were used to identify the labeled compounds found.

In the final stages of the work, two additional solvent systems were used to confirm the identities of aspirin and salicylic acid.

Table I—Mean Percent[a] and Ranges of Total Activity of Aspirin and Its Metabolites in Rat Tissues 4 min. after Administration of Aspirin-7-^{14}C

Tissue Analyzed	Aspirin		Salicylic Acid		Salicyluric Acid		Percentage of Total Radioactivity Identified, Mean
	Mean	Range	Mean	Range	Mean	Range	
Gastric juice	91.1	71.3–97.9	6.9	1.5–22.0	0.1	0.09–0.19	98.1
Blood plasma	65.1	60.3–73.9	18.8	0.0–31.6	11.5	3.4–19.6	95.4
Rumen tissue	91.8	87.8–94.0	6.6	0.0–10.5	0.6	0–1.19	99.0
Corpus tissue	74.0	64.7–88.2	25.4	11.3–35.0	0.5	0.0–1.59	99.9

[a] All percentages are averages taken from four animals.

These systems were hexane, glacial acetic acid, and chloroform (4:1:1 v/v) and carbon tetrachloride, ether, glacial acetic acid, and methanol (120:60:18:1 v/v).

After developing and drying the TLC plates, autoradiograms were made using no-screen medical X-ray film. Following exposure and development of the film, the R_f values of the standards (observed with UV radiation) were compared with the R_f values of the labeled compounds (observed by autoradiography). Subsequently, the areas corresponding to the R_f values of the labeled compounds, the origin, and the solvent front were removed and placed in counting vials, and the amount of radioactivity in each sample was determined by liquid scintillation spectrometry[4]. The internal method of standardization (10) was used to determine the disintegration rate of each sample. The scintillation solution consisted of 300 ml. xylene, 900 ml. dioxane, 900 ml. 2-ethoxylethanol[5], 21 g. diphenyloxazole, and 168 g. naphthalene.

RESULTS AND DISCUSSION

The results of the analyses for aspirin and its metabolites in the gastric juice, blood plasma, and rumen and corpus tissues of the rat stomachs are presented in Table I. The percentage activity reported represents the mean percentage activity calculated from individual percentage activities from four animals. Each individual percentage activity represents the percentage of the activity for the compound in question relative to the total amount of activity spotted on the thin-layer plate. No glucuronide conjugates of salicylic acid or polyhydroxy metabolites of aspirin were detected.

Trace amounts of a compound having the same R_f value as salicyluric acid were found in all samples examined for salicyluric acid, but it occurred as a significant percentage of total activity only in blood. The absolute amounts were so small (calculated to be approximately 10^{-11} g.) that further verification of identity was not warranted. In addition, very low levels of labeled but unidentified compounds were detected at the origin and solvent front in all systems studied.

The major components found in the gastric juice, blood plasma, and rumen and corpus tissues were aspirin and salicylic acid. The amounts of aspirin found (corrected for spontaneous hydrolysis), expressed as percentage of total radioactivity, were as follows: gastric juice, 91.1%; blood plasma, 65.9%; rumen, 92.1%; and corpus, 74.0%. Spontaneous hydrolysis of aspirin equaled 1.1% in the gastric juice and blood, 6% in the rumen tissue, and 8.4% in the corpus tissue. The amount of salicylic acid found (corrected for spontaneous hydrolysis of aspirin) was as follows: gastric juice, 6.9%; blood plasma, 18.8%; rumen, 6.6%; and corpus, 25.4%. The amount of salicylic acid found in the corpus tissue was fourfold higher than the amount found in the rumen tissue (25.4 *versus* 6.6%). Analysis of variance showed no significant difference between: (*a*) gastric juice and rumen tissue, (*b*) blood plasma and corpus tissue, and (*c*) animals, and it showed a significant difference between: (*a*) aspirin, salicylic acid, and salicyluric levels in all tissues, and (*b*) rumen and corpus tissue with respect to salicylic acid and aspirin levels ($p = 0.05$).

Since lesions occur only in corpus tissue under the conditions of this study, it is tempting to speculate that the higher levels of salicylic acid in that tissue may be related to lesion production. Historically, one undesirable side effect of sodium salicylate was gastric irritation, which was partly overcome by substitution on the phenolic hydroxyl group (11). It is possible to speculate that higher levels of esterase activity in corpus cells may account for the increased amounts of free salicylic acid in that tissue. The significance of this finding will be the object of future research.

Synthesis of Heptacosapeptide (AA_{111}–AA_{137}) of the γ-Chain of a Human Immunoglobulin (IgGl) Using *N-tert*-Butyloxycarbonyl-L-amino Acid Pentachlorophenyl Esters

BRIAN J. JOHNSON

Abstract □ The synthesis of the heptacosapeptide (AA_{111}–AA_{137}) of the γ-chain of a human immunoglobulin (IgGl) is described. The solid phase method was used, and coupling of each amino acid residue was achieved by use of the corresponding *N-tert*-butyloxycarbonyl-L-amino acid pentachlorophenyl ester.

Keyphrases □ Heptacosapeptide (AA_{111}–AA_{137}) of γ-chain of a human immunoglobulin—synthesis using *N-tert*-butyloxycarbonyl-L-amino acid pentachlorophenyl esters □ *N-tert*-Butyloxycarbonyl-L-amino acid pentachlorophenyl esters—used in the synthesis of heptacosapeptide (AA_{111}–AA_{137}) of the γ-chain of a human immunoglobulin □ Immunoglobulins, human—synthesis of the heptacosapeptide (AA_{111}–AA_{137}) of the γ-chain using *N-tert*-butyloxycarbonyl-L-amino acid pentachlorophenyl esters □ Peptides—synthesis of the heptacosapeptide (AA_{111}–AA_{137}) of the γ-chain of a human immunoglobulin (IgGl) using *N-tert*-butyloxycarbonyl-L-amino acid pentachlorophenyl esters

Recently the total primary structure of the human immunoglobulin IgGl Eu[1] was elucidated (4–14). The domain hypothesis (15) for immunoglobulins suggests that each region of the molecule containing disulfide linkage forms a compact domain, and that these areas are connected by a more extended peptide chain. The switch peptide, sequence AA_{111}–AA_{137}, of the γ-chain of this immunoglobulin is most probably one of these extended peptide regions bridging between two respective domains.

Some *N-tert*-butyloxycarbonyl-L-amino acid pentachlorophenyl esters were previously described (16), and they were shown to be useful intermediates for rapid peptide synthesis by the solution method (17) and also for the solid phase method of peptide synthesis (18).

This article reports the characterization of some new *N-tert*-butyloxycarbonyl-L-amino acid pentachlorophenyl esters and their application for the synthesis of the fragment AA_{111}–AA_{137} of the γ-chain of a human IgGl.

DISCUSSION

The *N-tert*-butyloxycarbonyl-L-amino acid pentachlorophenyl esters (Table I) were prepared from the corresponding free acids using the general procedure outlined in the *Experimental* section. These derivatives were used to synthesize a fragment of the γ-chain of a human IgGl comprised of 27 amino acids (I and II).

The fully protected, resin-bound peptide I was synthesized by the stepwise addition of the appropriate *N-tert*-butyloxycarbonyl-L-amino acid pentachlorophenyl ester to an insoluble polystyrene resin (19). The cycle for the addition of each amino acid residue consisted of the following steps: removal of the *N-tert*-butyloxycarbonyl protecting groups by treatment with excess anhydrous trifluoroacetic acid in methylene chloride, neutralization of the resulting salt with triethylamine in methylene chloride, and then double coupling the resulting free amino residue with three equivalents of the appropriate *N-tert*-butyloxycarbonyl-L-amino acid pentachlorophenyl ester in dimethylformamide for 4 hr., after which a further three equivalents of the same amino acid derivative was added and coupled for a further 4 hr. Where sterically hindered amino acid residues such as valine and leucine were attached to the resin, coupling times were increased to 12-hr. periods. At the end of the chain-lengthening sequence, the protected peptide was cleaved from its polymer support by liquid hydrogen fluoride (20, 21); all of the side-chain protecting groups were removed under these conditions. The peptide was purified by passage through two columns[2].

EXPERIMENTAL

General Procedure for Preparation of *N-tert*-Butyloxycarbonyl-L-Amino Acid Pentachlorophenyl Esters—The general procedure of preparation of these esters is illustrated by the preparation of *N-tert*-butyloxycarbonyl-β-benzyl-L-aspartic acid pentachlorophenyl ester. To a solution of 9.7 g. (30 mmoles) of *N-tert*-butyloxycarbonyl-β-benzyl-L-aspartic acid (22, 23) and 8 g. (30 mmoles) of pentachlorophenol in 100 ml. of methylene chloride, cooled to 0°, was added 6.8 g. (33 mmoles) of *N,N'*-dicyclohexylcarbodiimide. The mixture was stirred overnight at room temperature. The solid *N,N'*-dicyclohexylurea was filtered off, and the filtrate was evaporated to dryness under reduced pressure. The solid was dissolved in ethyl acetate and cooled, and a further crop of *N,N'*-dicyclohexylurea was removed by filtration. The filtrate was evaporated to dryness and the solid material was crystallized from methanol to yield the pentachlorophenyl activated ester, 13.0 g, 75%, m.p. 129–130°; $[\alpha]_D$ − 28.9° (c 2.6, dimethylformamide).

[a] BOC = *N-tert*-butyloxycarbonyl. [b] DMF = dimethylformamide.

1. Three washings with 20-ml. portions of methylene chloride.
2. Cleavage of the *tert*-butyloxycarbonyl group by the addition of 20 ml. of 20% trifluoroacetic acid in methylene chloride and shaking of the mixture for 30 min.
3. Six washings with 20-ml. portions of methylene chloride.
4. Neutralization of the trifluoroacetate salt with 15 ml. of a 10% solution of triethylamine in methylene chloride for 10 min.
5. Three washings with 20-ml. portions of methylene chloride.
6. Addition of three equivalents of *N-tert*-butyloxycarbonyl-amino acid pentachlorophenyl ester in 15 ml. of dimethylformamide–methylene chloride (1:1) and shaking for 4 hr., and then a further three equivalents of the same *N-tert*-butyloxycarbonyl-amino acid pentachlorophenyl ester in 15 ml. of dimethylformamide–methylene chloride (1:1) and shaking for a further 4 hr. Wherever *N-tert*-butyloxycarbonyl-L-valine pentachlorophenyl ester and *N-tert*-butyloxycarbonyl-L-leucine pentachlorophenyl ester were used, the coupling time of 12 hr. for each stage was used.
7. Three washings with 20 ml. of dimethylformamide.
8. Three washings with 20 ml. methylene chloride.

After 26 cycles, the resin was dried under vacuum to yield 3.3 g.

Gly-Leu-Val-Thr-Val-Ser-Ser-Ala-Ser-Thr-Lys-Gly-Pro-Ser-Val-Phe-Pro-Leu-Ala-Pro-Ser-Ser-Lys-Ser-Thr-Ser-Gly (II)—The above protected peptide resin was suspended in 30 ml. of redistilled anhydrous hydrogen fluoride containing 5 ml. of anisole. The resin was stirred for 1 hr. at 0°, after which the anhydrous hydrogen fluoride and anisole were removed under reduced pressure. The resin mixture was washed with two washes of 10 ml. of ethyl acetate. The resin was dried and the peptide was extracted into 50 ml. of 0.1 *M* acetic acid and lyophilized. The lyophilized crude peptide (0.4 g., 31%) was dissolved in 0.1 *M* acetic acid, placed on a column[3] (6.5 × 121 cm.), and eluted with pyridine–acetic acid–water solution, pH 8.0.

The lyophilized crude peptide was purified by chromatography on a column[4] (2.5 × 100 cm.) using pyridine–acetic acid–water solution, pH 6.1, as eluent. The major peak was collected and lyophilized to yield 103 mg. (8%, based on the starting substituted resin) of the free peptide. Amino acid analysis of an acid hydrolysate showed Ser, 7.8; Thr, 2.8; Gly, 3.1; Pro, 2.9; Val, 2.8; Leu, 2.0; Ala, 2.0; Phe, 0.9; and Lys, 2.0. The peptide II was found to be homogeneous by paper chromatography: R_f 0.67 (butanol–acetic acid–water–pyridine, 15:3:12:10); R_f 0.54 (pyridine–acetic acid–water, 5:3:1.5).

Subcellular Binding of Halothane-1-^{14}C in Mouse Liver and Brain

LEONARD C. HOWARD, Jr., DAVID R. BROWN, and DAVID A. BLAKE▲

Abstract □ The extent of binding of halothane-1-^{14}C to mouse liver and brain 24 hr. after injection of a subanesthetic dose was measured utilizing several techniques: (*a*) exhaustive dialysis with phosphate buffer, (*b*) solvent extraction with 0.25 *M* sucrose and toluene, (*c*) protein precipitation with trichloroacetic acid, and (*d*) soxhlet extraction with methanol and benzene. A substantial portion of the radioactivity was not removed by these procedures and thus was bound both in liver and brain, the liver containing a greater amount of bound radioactivity on both an absolute basis and a protein content basis. The liver microsomal fraction, subjected to exhaustive dialysis, contained a higher specific activity (disintegrations per minute per milligram protein) than the whole homogenate, 9000×*g* pellet, or cytosol. The combination of trichloroacetic acid precipitation and soxhlet extraction with methanol and benzene (1:1) removed virtually all radioactivity from the brain, whereas 13% of the initial radioactivity remained in the liver as tightly bound material. Thus, halothane or a metabolite is tightly and probably covalently bound to a protein or other high molecular weight component in mouse liver but not in the brain.

Keyphrases □ Halothane, radiolabeled—*toxicity*, subcellular binding in mouse liver and brain □ Toxicity, halothane—subcellular binding in mouse liver and brain, radiolabeled, type of bonding □ Hepatitis—subcellular binding of halothane-1-^{14}C to mouse liver and brain, type of bonding, distribution of radioactivity

Halothane (1,1,1-trifluoro-2-bromochloroethane) possesses two properties of the ideal anesthetic: it is potent and nonexplosive. However, fatal hepatic necrosis has been reported in a small portion of exposed human subjects (1–4). While the incidence of hepatitis after halothane reportedly represents no greater a risk than surgical anesthesia itself (5), it is nevertheless a well-established untoward reaction that deserves investigation. The recurrence of hepatitis in sensitized anesthetists after exposure to only traces of halothane (6, 7) and the overall low incidence which increases with multiple exposures (5) suggest that halothane-induced hepatic damage is the result of an allergic reaction.

If halothane hepatitis is caused by a sensitization reaction, then halothane or a metabolite must form a hapten of an antigen by binding covalently to a macromolecule (8). Nonvolatile metabolites of halothane have been found to persist in animal liver (9) as well as human urine (10, 11). The presence of high molecular weight metabolites of halothane in liver and urine (12) indicates that a metabolite of halothane may be associated with a macromolecule; however, no direct evidence exists as to whether these metabolites are, in fact, covalently bound. In support of this suggestion, other halogenated hydrocarbons, such as carbon tetrachloride (13) and bromobenzene (14), do form covalent bonds with endogenous substances. Therefore, the binding character of halothane-1-^{14}C *in vivo* in mice was investigated.

EXPERIMENTAL

Dosage and Tissue Preparation—Female Swiss Webster albino mice[1] (28–30 g.) were fasted for 24 hr., and 0.5 mg. of halothane-1-^{14}C in saline[2], containing 4 μc. of radioactivity was administered by intraperitoneal injection. Twenty-four hours later, the mice were sacrificed, the livers were perfused with cold 0.25 *M* sucrose, and both the livers and brains were removed and placed in ice-cold 0.25 *M* sucrose. Ten percent homogenates of these organs were prepared in cold 0.25 *M* sucrose, using a Potter–Elvehjem tissue grinder[3]. An aliquot of these homogenates was removed for analysis of bound radioactivity and protein, and the remainder was centrifuged at 9000×*g* (average) in a refrigerated centrifuge[4] for 20 min. The pellet was removed for analysis, and the supernate was recentrifuged at

Halothane (1,1,1-trifluoro-2-bromochloroethane) possesses two properties of the ideal anesthetic: it is potent and nonexplosive. However, fatal hepatic necrosis has been reported in a small portion of exposed human subjects (1–4). While the incidence of hepatitis after halothane reportedly represents no greater a risk than surgical anesthesia itself (5), it is nevertheless a well-established untoward reaction that deserves investigation. The recurrence of hepatitis in sensitized anesthetists after exposure to only traces of halothane (6, 7) and the overall low incidence which increases with multiple exposures (5) suggest that halothane-induced hepatic damage is the result of an allergic reaction.

If halothane hepatitis is caused by a sensitization reaction, then halothane or a metabolite must form a hapten of an antigen by binding covalently to a macromolecule (8). Nonvolatile metabolites of halothane have been found to persist in animal liver (9) as well as human urine (10, 11). The presence of high molecular weight metabolites of halothane in liver and urine (12) indicates that a metabolite of halothane may be associated with a macromolecule; however, no direct evidence exists as to whether these metabolites are, in fact, covalently bound. In support of this suggestion, other halogenated hydrocarbons, such as carbon tetrachloride (13) and bromobenzene (14), do form covalent bonds with endogenous substances. Therefore, the binding character of halothane-1-^{14}C *in vivo* in mice was investigated.

EXPERIMENTAL

Dosage and Tissue Preparation—Female Swiss Webster albino mice[1] (28–30 g.) were fasted for 24 hr., and 0.5 mg. of halothane-1-^{14}C in saline[2], containing 4 μc. of radioactivity was administered by intraperitoneal injection. Twenty-four hours later, the mice were sacrificed, the livers were perfused with cold 0.25 *M* sucrose, and both the livers and brains were removed and placed in ice-cold 0.25 *M* sucrose. Ten percent homogenates of these organs were prepared in cold 0.25 *M* sucrose, using a Potter–Elvehjem tissue grinder[3]. An aliquot of these homogenates was removed for analysis of bound radioactivity and protein, and the remainder was centrifuged at 9000×*g* (average) in a refrigerated centrifuge[4] for 20 min. The pellet was removed for analysis, and the supernate was recentrifuged at

78,480×g (average) in an ultracentrifuge[5] for 160 min. to prepare microsomes and cytosol, which were also analyzed for bound radioactivity and protein.

Exhaustive Dialysis—The livers and brains from six mice were combined and separated into the fractions as previously described. Each fraction was dialyzed in a visking tubing[6] against 4000 volumes of 0.01 *M* phosphate buffer (pH 7.2), which flowed continuously for 18 hr. at 4°[7]. Protein and radioactivity contents were determined both before and after dialysis. Protein was determined using the Lowry *et al.* (15) method with bovine serum albumin as the standard. The radioactivity was measured in a liquid scintillation spectrometer[8], and disintegrations per minute were calculated using toluene-^{14}C as an internal standard.

Washing, Extraction, and Centrifugation—The 9000×g pellet and microsomal fractions were separated from the 9000×g supernate and cytosol, respectively, resuspended three times in an equivalent volume of cold 0.25 *M* sucrose, and recentrifuged to remove residual water-soluble radioactivity. The washed 9000×g and microsomal pellets were then suspended in 10 times their volume of toluene, shaken manually, and recentrifuged to extract soluble nonpolar radioactivity.

Soxhlet Extraction—Protein was precipitated by the addition of an equal volume of 1 *M* trichloroacetic acid to a homogenate and removed by centrifugation at 2000 r.p.m. for 10 min. in a refrigerated centrifuge[9]. The denatured protein was washed three times with an aqueous 5% trichloroacetic acid solution and recentrifuged. An aliquot of the washed protein precipitate was taken for the determination of bound radioactivity. The remaining protein precipitate was placed in a thimble and extracted with methanol–benzene (1:1) for 24 hr.[10] in a microsoxhlet apparatus[11]. The final extracted protein was solubilized[12] and then analyzed for radioactivity.

RESULTS AND DISCUSSION

If halothane or a metabolite binds covalently with a hepatic macromolecule *in vivo*, then a portion of the liver radioactivity would not be dialyzable. To test this hypothesis, halothane-1-^{14}C was administered to mice. Then the brains and livers were removed, homogenized, fractionated, and subjected to exhaustive dialysis. The amount of nondialyzable radioactivity was determined. The results of this experiment (Figs. 1 and 2) indicate that a significant amount of nondialyzable radioactivity remains after 24 hr. in all liver fractions. Trifluoroacetate, a known metabolite of halothane (16, 17) probably constitutes most of the dialyzable fraction. The distribution of halothane-1-^{14}C-derived radioactivity in the liver was shown to predominate in the microsomal fraction, which had the highest amount of protein-associated counts. These results show that binding occurs in the liver, the location of halothane metabolism (18), and suggest that a metabolite, possibly formed in the endoplasmic reticulum, is the moiety bound.

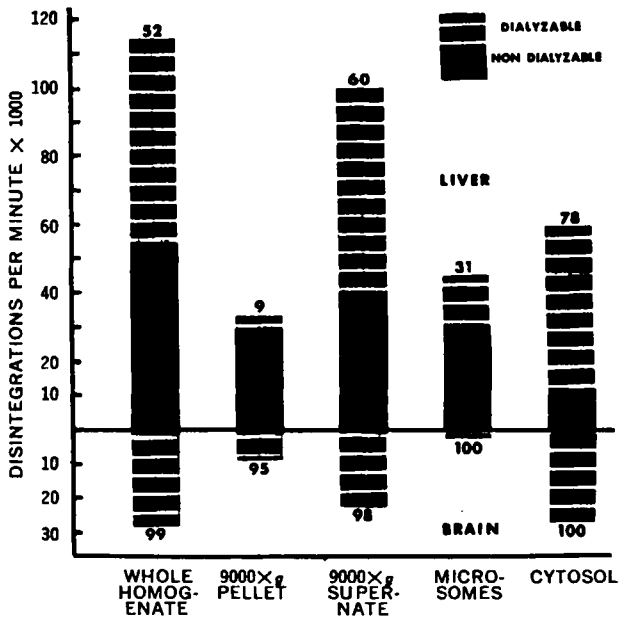

Figure 1—*Relationship between dialyzable and nondialyzable radioactivity in liver and brain subcellular fractions pooled from six mice pretreated with 0.5 mg. of halothane-1-^{14}C 24 hr. before sacrifice. (Numbers represent percentage of initial radioactivity that was dialyzable.)*

It is possible that either nonpolar halothane or a lipid-soluble metabolite is not removed by exhaustive dialysis against phosphate buffer. To test this alternative, the microsomal fraction was washed three times with 0.25 *M* sucrose and extracted with 10 volumes of toluene to remove lipid. This procedure removed 60% of the radioactivity from the microsomes, while only 31% was removed by dialysis. These results suggest that while halothane or a metabolite may be sequestered in lipid, at least 40% is bound to other tissue components. The data would also support the possibility that a portion of the radioactivity was not dialyzable against an aqueous buffer, because it was unmetabolized halothane. However, this is unlikely since dialysis did remove virtually all of the radioactivity from the brain, where small amounts of unchanged halothane would also be expected to reside under the conditions of the experiment. A more likely explanation is that part of the binding occurs on lipoprotein which, while not dialyzable, is nevertheless soluble in toluene.

To measure only protein-bound radioactivity, the liver and brain homogenates were treated with trichloroacetic acid followed by exhaustive extraction with solvent. Preliminary results of this trichloroacetic acid–soxhlet method showed that maximal extraction of radioactivity occurred at 24 hr., using a solvent system of equal amounts of methanol and benzene. Therefore, these conditions were used in all extractions. The results (Table I) show that 25.3% of the liver and 3.4% of the brain initial radioactivity were precipitated by trichloroacetic acid. The soxhlet technique extracted an additional 12.2% from the trichloroacetic acid precipitate of liver, leaving 13.1% of the initial radioactivity as tightly bound material. In contrast, soxhlet extraction of trichloroacetic acid precipitates from brain removed virtually all of the radioactivity in this tissue. The liver-to-brain ratio of radioactivity remaining after trichloroacetic acid precipitation increased from 7.4 to 21.8 after soxhlet extraction. This 22-fold higher amount of nonextractable radioactivity in the liver relative to the brain demonstrates that factors other than the initial concentration of halothane in a tissue determine the extent of binding.

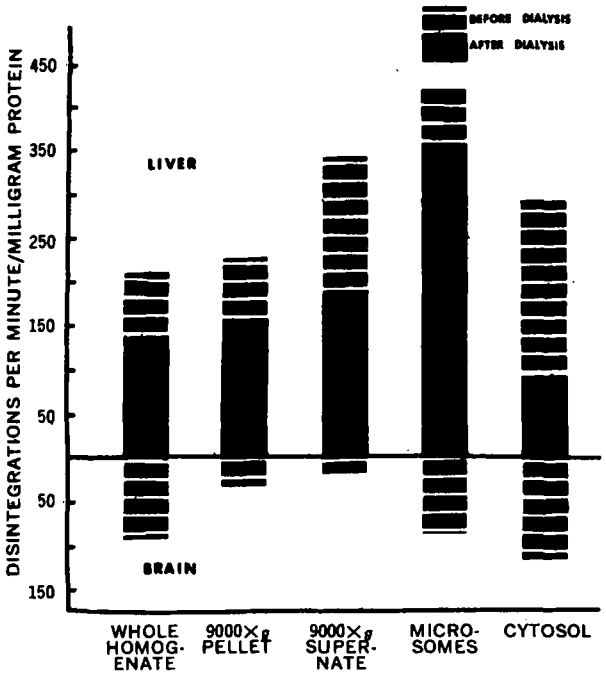

Figure 2—*Effect of dialysis on the specific activity (disintegrations per minute per milligram protein) of pooled liver and brain subcellular fractions from six mice pretreated with 0.5 mg. of halothane-1-^{14}C 24 hr. before sacrifice.*

Since exhaustive dialysis and centrifugal washing do not distinguish between reversible and irreversible binding, the method of solvent (soxhlet) extraction was employed. A similar technique has been used to demonstrate the covalent binding of bromobenzene in the liver (14). The trichloroacetic acid–soxhlet method extracted more halothane-derived radioactivity from whole homogenates of liver than either dialysis or washing, indicating that some of the radioactivity remaining after the use of the latter methods was possibly due to reversibly bound metabolites or that the labeled material may have been covalently bound to lipoprotein. Although trichloroacetic acid precipitation and solvent extraction will remove all of the radioactivity except that which is very tightly bound, it in itself does not constitute a completely rigorous proof of covalent binding. Therefore, protein digestion and the identification of amino acid-bound activity are currently being investigated.

If one proposes a hapten–antigen model for the hepatotoxicity of halothane, then the initial component of this hypothesis would require the covalent attachment of a small molecular weight moiety to some endogenous macromolecule. The altered molecule thus produced could elicit a delayed hypersensitivity *via* sensitized lymphocytes. The appearance of high levels of bound radioactivity in the membraneous fractions of the liver (*i.e.*, 9000×*g* pellet and microsomes) and the association of irreversibly and probably covalently bound radioactivity with protein in the whole liver homogenates subjected to soxhlet extraction are consistent with this suggestion that the altered macromolecule is a membrane protein. Furthermore, the protein-bound radioactivity found in the cytosol of the liver could possibly be the basis for transferral of antigenic material to sites of antibody formation.

From the results of other investigators (9, 10, 12, 17, 18), it would appear that halothane undergoes similar metabolic pathways in humans, mice, and rats. The finding of covalently bound radioactivity in hepatic tissue is consistent with the sensitivity theory and would also explain the low incidence of halothane-induced hepatitis in humans and the relative failure of investigators to reproduce hepatic injury in animals. Variability in both the immunologic and metabolic responses between and among various species may further explain these findings, and it is also possible that the binding phenomenon itself may be highly variable.

Qualitative Method for Dantrolene and a Related Metabolite in Urine

JOHN D. CONKLIN▲ and R. J. SOBERS

Abstract □ A qualitative method is described for the determination of dantrolene, a new skeletal muscle relaxant, and a related nonreduced metabolite in human urine. The method consists of the direct extraction of the drug and the metabolite from urine into nitromethane. Addition of a hyamine hydroxide solution to the solvent extract from urines containing the drug and the metabolite results in a yellow color which is linearly related to the amount of drug and metabolite present. A yellow color is not apparent when the alkaline solution is added to solvent extracts from control urine. The method is specific for dantrolene plus the nonreduced metabolite in the presence of a reduced metabolite. Data obtained from urine specimens, collected from humans receiving sodium dantrolene and analyzed by the qualitative method, are also presented.

Keyphrases □ Dantrolene and metabolite—qualitative colorimetric determination in urine □ Colorimetry—qualitative determination of dantrolene and metabolite in urine

Sodium dantrolene[1], 1-{[5-(*p*-nitrophenyl)furfurylidene]amino}hydantoin sodium hydrate, is a new skeletal muscle relaxant (1–3). By utilizing a combination of solvent extractions and chromatography followed by fluorometric measurement, dantrolene is quantitatively determined in biological specimens (4). There still is need, however, for a qualitative method which the clinical laboratory can readily perform. This report describes a simple and rapid colorimetric method for dantrolene and a related nonreduced metabolite, designated as Metabolite A, in human urine.

EXPERIMENTAL

Reagents and Instrument—The reagents used included: crystalline dantrolene[2]; ammonium sulfate[3], special enzyme grade; *N,N*-dimethylformamide[4], reagent grade; nitromethane[5], practical grade; methanol[6], analytical reagent grade; and hyamine hydroxide[7], 1 *M* in methanol. The 1 *M* hyamine solution (2 ml.) is diluted to 25 ml. with absolute methanol to obtain a 0.08 *M* solution.

A spectrophotometer[8] was used to measure absorbances.

Procedure—To 2 ml. of urine in a tube, add 1 ml. of water and then 3 ml. of saturated ammonium sulfate solution and mix thoroughly. Add 5 ml. of nitromethane, mix the tube contents vigorously for 1 min., and centrifuge at 2000 r.p.m. for 10 min. Transfer 3 ml. of the solvent extract (top layer) to a test tube. Then add 5 drops of 0.08 *M* hyamine hydroxide solution and mix the contents.

In the qualitative test, the color of the extract from the unknown sample is immediately compared with the color of the corresponding extract from a control sample against a white background. Under these conditions, extracts from urine specimens containing dantrolene and Metabolite A exhibit a yellow color which is linearly related to the amount of drug and metabolite present. Control urine extracts do not exhibit any apparent yellow color when the hyamine reagent is added.

Table I—Determinations of Dantrolene and Metabolite A Standards by the Nitromethane–Hyamine Method

Sample, mcg./ml.	Absorbance[a], 400 nm. Dantrolene Water	Dantrolene Urine	Metabolite A Water	Metabolite A Urine
Control	0.009	0.033	0.006	0.037
2.5	0.079	0.083	0.078	0.077
5.0	0.157	0.162	0.154	0.158
15.0	0.478	0.483	0.464	0.469
25.0	0.780	0.799	0.759	0.765

[a] Mean based on three samples. Absorbances for standards are control corrected.

If an estimate of the drug concentration is desired, the solvent extract is then subjected to spectrophotometric measurement at 400 nm. within 1 min. after addition of the hyamine reagent. Pure nitromethane is used to set the instrument to zero absorbance. The absorbance of the control sample is subtracted from the absorbance of the unknown sample, and the estimated drug and metabolite present are calculated from dantrolene standards subjected to the method. The results are expressed as dantrolene equivalents. A dantrolene standard with a concentration of 25 mcg./ml. exhibits an absorbance of about 0.800. Dilutions are necessary when a nitromethane extract from a sample subjected to the procedure exhibits an absorbance greater than 0.800 after addition of the hyamine reagent. If this occurs, some of the remaining nitromethane extract, not reacted with the hyamine reagent, is diluted with pure nitromethane and then the hyamine reagent is added.

In preparing standard solutions, 50 mg. of crystalline dantrolene is dissolved in 50 ml. of dimethylformamide. Ten milliliters of this solution is placed in a 100-ml. volumetric flask, 40 ml. of dimethylformamide is added, and the solution is diluted to volume with water to obtain a drug concentration of 100 mcg./ml. This solution is then diluted with water to obtain the required drug concentrations. Standards[2] of Metabolite A and acetylated dantrolene[9] are prepared in an identical manner.

Urine reference standards are prepared with 2 ml. of urine, 1 ml. of standard solution, and 3 ml. of saturated ammonium sulfate solution. Aqueous standards are prepared in an identical manner except that 2 ml. of water is substituted for the 2 ml. of urine. Water or the human urine used to prepare the reference standards serves as a control.

RESULTS

The results presented in Table I show that both dantrolene and Metabolite A are susceptible to the nitromethane–hyamine procedure. Standard curves for each compound are linear from 2.5 to 25.0 mcg./ml. Drug concentrations as low as 2.5 mcg./ml. (5 mcg./tube) are visually identified by a distinct yellow color. Agreement is apparent between aqueous and human urine reference standards for both dantrolene and Metabolite A (Table I). Average recoveries of added dantrolene and Metabolite A from human urine were 102.9 ± 1.6 and 100.8 ± 1.6%, respectively, based on aqueous standards. Acetylated dantrolene, another metabolite, did not exhibit appreciable absorbance when subjected to the nitromethane–hyamine procedure.

Urine specimens collected from healthy humans who had received sodium dantrolene as an encapsulated formulation orally were subjected to the nitromethane–hyamine method. Nitromethane

[9] 1-{[5-(*p*-Acetamidophenyl)furfurylidene]amino} hydantoin.

Table II—Determinations of Urine Specimens from Humans Administered Sodium Dantrolene by the Nitromethane–Hyamine Method[a]

Subject	Absorbance[b], 400 nm.	Concentration[c], mcg./ml.
3	0.098 (0.062)	3.06
6	0.149 (0.034)	4.65
2	0.719 (0.013)	22.47
5	0.745 (0.015)	23.28
11	0.541 (0.032)	16.90

[a] An encapsulated sodium dantrolene formulation was administered orally as a single dose at 100 mg. to Subjects 3 and 6 and at 100 mg. q.i.d. to Subjects 2, 5, and 11. Urine specimens were collected from 0–24 hr., pooled, and frozen. A control urine specimen was collected just before drug administration. [b] Control corrected; figure in parentheses represents the control urine absorbance. [c] Estimated drug concentration for 0–24 hr., expressed as dantrolene equivalents, represents dantrolene plus Metabolite A.

extracts from each of the specimens, collected after drug administration, exhibited a visual yellow color following the addition of the hyamine reagent (Table II). Under these conditions, a yellow color was not apparent with extracts from corresponding control urines, collected before drug administration.

The dantrolene–hyamine complex in nitromethane exhibits an absorbance maximum near 400 nm., while the corresponding Metabolite A–hyamine complex displays a maximum near 395 nm. When subjected to the nitromethane–hyamine procedure, the human urines collected after the administration of sodium dantrolene yielded an absorbance maximum from 380 to 385 nm.

An estimate of the drug and metabolite concentration present in the urine specimens was obtained by spectrophotometric measurement (Table II). These results are expressed as dantrolene equivalents, based on dantrolene standards, and represent dantrolene plus Metabolite A.

DISCUSSION

At present, two of the major dantrolene-related metabolites recovered from human urine after the administration of sodium dantrolene are reduced acetylated dantrolene and a nonreduced metabolite designated as A (5). The amount of each of these metabolites excreted in urine is usually much greater than the corresponding amount of dantrolene (5). It is assumed that dantrolene plus Metabolite A is primarily responsible for the yellow color observed when urine specimens collected from humans receiving sodium dantrolene are analyzed by the nitromethane–hyamine procedure, since standards of acetylated dantrolene do not exhibit an appreciable absorbance when subjected to the qualitative method. A partial explanation for this specificity is that acetylated dantrolene does not contain the nitro group on the benzene ring which is present in both dantrolene and Metabolite A.

Dansyl Derivatives of Δ^9- and Δ^8-Tetrahydrocannabinols

Keyphrases □ Dansyl derivatives of Δ^9- and Δ^8-tetrahydrocannabinols—synthesis, physical and chemical properties □ Tetrahydrocannabinols—*synthesis of dansyl derivatives*, physical and chemical properties

Sir:

The use of dansyl chloride (5-dimethylamino-1-naphthalenesulfonyl chloride, I) in the fluorometric determination of amines and phenols is well documented (1). Dansylated cannabinol-related compounds were recently derived from blood, urine, and saliva samples following hashish administration (2). As a prerequisite for the development of suitable methodology for the assay of compounds and metabolites derived from *Cannabis sativa*, a series of dansyl derivatives of several cannabinoid compounds was prepared in micromolar quantities and their TLC properties were reported (3). The preparation of larger quantities of dansyl-Δ^9-tetrahydrocannabinol (II) and dansyl-Δ^8-tetrahydrocannabinol (III) was accomplished to determine the physical and chemical properties of these derivatives.

The reaction of Δ^9- or Δ^8-tetrahydrocannabinol and excess dansyl chloride was performed in acetone–water solution saturated with sodium carbonate at 40° for 2 hr. After excess dansyl chloride was hydrolyzed by treatment with base, the reaction mixture was extracted with ethyl acetate. Compounds II and III were isolated as thick oils. Crystallization could only be induced by prolonged storage at −5° in hexane. Recrystallization from hexane or heptane yielded crystalline solids which provided microanalytical values within acceptable limits and the correct molecular weight by mass spectrometry. The physical and spectral characteristics of Compounds II and III are summarized in Tables I and II.

The reaction of I would be expected to occur on the phenolic group of tetrahydrocannabinol. Examples are known with reactions similar to dansylation where the substituent does not add onto the phenolic oxygen but

Dansyl Derivatives of Δ^9- and Δ^8-Tetrahydrocannabinols

Keyphrases □ Dansyl derivatives of Δ^9- and Δ^8-tetrahydrocannabinols—synthesis, physical and chemical properties □ Tetrahydrocannabinols—*synthesis of dansyl derivatives*, physical and chemical properties

Sir:

The use of dansyl chloride (5-dimethylamino-1-naphthalenesulfonyl chloride, I) in the fluorometric determination of amines and phenols is well documented (1). Dansylated cannabinol-related compounds were recently derived from blood, urine, and saliva samples following hashish administration (2). As a prerequisite for the development of suitable methodology for the assay of compounds and metabolites derived from *Cannabis sativa*, a series of dansyl derivatives of several cannabinoid compounds was prepared in micromolar quantities and their TLC properties were reported (3). The preparation of larger quantities of dansyl-Δ^9-tetrahydrocannabinol (II) and dansyl-Δ^8-tetrahydrocannabinol (III) was accomplished to determine the physical and chemical properties of these derivatives.

The reaction of Δ^9- or Δ^8-tetrahydrocannabinol and excess dansyl chloride was performed in acetone–water solution saturated with sodium carbonate at 40° for 2 hr. After excess dansyl chloride was hydrolyzed by treatment with base, the reaction mixture was extracted with ethyl acetate. Compounds II and III were isolated as thick oils. Crystallization could only be induced by prolonged storage at −5° in hexane. Recrystallization from hexane or heptane yielded crystalline solids which provided microanalytical values within acceptable limits and the correct molecular weight by mass spectrometry. The physical and spectral characteristics of Compounds II and III are summarized in Tables I and II.

The reaction of I would be expected to occur on the phenolic group of tetrahydrocannabinol. Examples are known with reactions similar to dansylation where the substituent does not add onto the phenolic oxygen but

Table I—Physical and Spectral Characteristics of Dansyl-Δ^9- and Dansyl-Δ^8-tetrahydrocannabinols (II and III)

	II	III
Appearance	Greenish-yellow crystals	Greenish-yellow crystals
Melting point (uncorrected)	81–84°	105–107°
λ_{max} in ethanol	345 nm. (ε 4100) 283 s (4590) 253 (15,860)	345 nm. (ε 3780) 283 s (3880) 253 (14,800) 215 s (46,000)
λ_{max} excitation	350 nm.	350 nm.
λ_{max} emission	530 nm.	530 nm.

is substituted into the nucleophilic 2-position of the aromatic ring (4, 5). On NMR analysis in deuteriochloroform, the dansylation products of Δ^9- or Δ^8-tetrahydrocannabinol exhibit two doublets, each integrating for one proton, in the aromatic region (II, δ = 6.45 p.p.m., 6.22; III, δ = 6.50 p.p.m., 6.27) with a coupling constant of 1.5–2.0 Hz. These signals fit an *AB* system characteristic of *meta*-coupled aromatic protons. The more downfield proton corresponds to the 4-position proton and the other to the 2-position proton. On this basis, II and III are proposed to be *O*-dansyl and not C-dansyl compounds. The absence of any exchangeable protons upon the addition of D_2O provides further evidence to support the proposed structure.

Dansylated compounds were reported (1) to decompose when allowed to remain on silica gel for prolonged periods. In our experience, if pure II was left on a silica gel thin-layer plate for over 4 hr. in a dry state, the original greenish-yellow fluorescence of the spot took on a dull-orange color. Scraping and rechromatographing this spot gave at least two additional spots. This observation suggests that II undergoes significant degradation under the test conditions. The literature further documents examples of instability of dansylated phenols to UV exposure (6). Irradiation of Compounds II and III on a silica gel plate with 350- or 254-nm. UV light caused changes in TLC properties after only 10 min.

Solutions of II and III in ethanol slowly decompose regardless of storage conditions. After storage at room temperature and exposure to laboratory light, changes in color and in the UV absorption spectrum were apparent after 1 week. Refrigeration delayed these changes for several weeks. However, storage of the crystals in screw-capped vials under nitrogen, in the dark, in a desiccator produced no observable changes in TLC properties in more than 3 months.

Mechanism of Phenobarbital Degradation

Keyphrases □ Phenobarbital—mechanism of degradation, products identified □ Barbiturate degradation—mechanism of ring cleavage, phenobarbital and products

Sir:

In a recent paper, Garrett *et al.* (1) further elucidated the kinetics of hydrolysis of several important barbiturates. In their studies, they discovered the rather surprising fact that diethylmalonuric acid (V) (Scheme I) in basic solution may cyclize to form the parent-substituted barbituric acid, barbital (IV). Previous workers (2, 3) assumed that the hydrolysis of the parent barbiturate to the corresponding malonuric acid was irreversible, and various degradation schemes were predicated on that assumption. Hegarty and Bruice (4) also reported a similar reaction in the cyclization of 2-ureidobenzoic acid.

We have now repeated the work relative to diethylmalonuric acid and verified by mass spectrometry that the cyclization product of diethylmalonuric acid in basic solution is barbital. The reversibility of the hydrolysis of the barbituric acid nucleus is an important discovery and may have interesting biological ramifications.

In discussing the reversibility of this reaction, Garrett *et al.* (1) challenged the mechanism of phenobarbital degradation proposed by Tishler *et al.* (3). They put forward a rather tortuous argument to explain the ex-

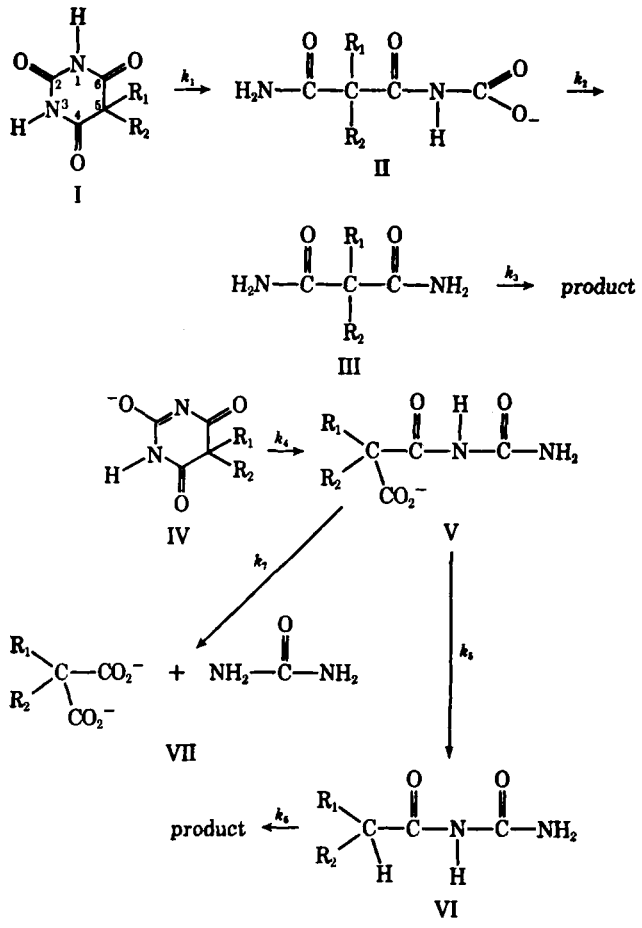
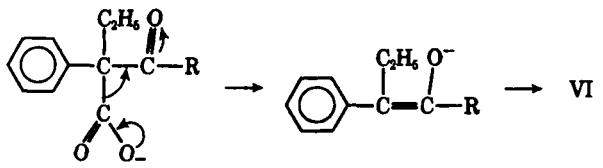


Scheme I—Degradative pathway of barbituric acid derivatives (barbital: R_1, R_2 = ethyl; phenobarbital: R_1 = ethyl, R_2 = phenyl)

perimental results of Tishler and coworkers. However, their argument depends on the reversibility of the phenylmalonuric acid formation in a manner analogous to diethylmalonuric acid. In the paper where Fretwurst (5) reported recovery of 50% of degraded barbital as the diethylmalonuric acid, he also reported finding no corresponding malonuric acid under several different conditions with phenobarbital. Several other barbiturates, substituted such that the malonuric acid derived from them contains a group that can conjugate with the ureide carbonyl in the enol intermediate postulated for the decarboxylation mechanism (Scheme II), likewise were devoid of isolatable substituted malonuric acid. If the mechanism proposed by Hegarty and Bruice (4) for the cyclization of 2-ureidobenzoic acid is correct, different malonuric acids should cyclize at about the same rate (in basic solution) since the mechanism depends upon the nucleophilicity of the terminal amino group, which would be only minimally affected by different substituents. It would, therefore, appear that substitution of one of the ethyl groups of barbital by the phenyl group results in labilization of malonuric acid, such that decarboxylation occurs at a much higher rate than in the barbital product, with little change in the cyclization rate, making the step from phenobarbital to phenylethylmalonuric acid essentially irreversible, as assumed by Tishler *et al.* (3).

Moreover, Fretwurst (5), when using two equivalents of sodium hydroxide for each equivalent of phenobarbital, identified 73% of the reaction product as



Scheme II—Postulated mechanism for decarboxylation of disubstituted malonuric acid

malonic acid (VII) instead of isolating the substituted acetylurea (VI) as the primary product, apparently indicating that the hydrolysis to malonic acid at higher base concentrations proceeds at a more rapid rate than the parallel decarboxylation reaction.

The known facts relative to barbiturate degradation would fit a scheme in which the unionized barbiturate can be cleaved at the one–two position, leading to production of the bisamide (III), or at the one–six (three–four) position, leading to the ureide (VI); the ionized barbiturate would cleave only at the one–six (three–four) position, leading to the ureide (or malonic acid) exclusively. For example, in the paper by Tishler *et al.*, (3) the equation describing the ureide pathway would be:

$$f = \frac{k_4K_a + k_u[H^+]}{k_d[K_a] + k_1[H^+]} \qquad \text{(Eq. 1)}$$

assuming that k_1, mentioned in the previous paper (3), is the sum of the rate constant relating production of the ureide, k_u, and the rate constant relative to the rate of production of the bisamide, k_d, from undissociated phenobarbital (I). In the 8.2–9.5 pH range studied by the authors, the K_a (10^{-7}–10^{-8}) of phenobarbital would be much greater than the hydrogen-ion concentration, and one could assume with Garrett *et al.* (1) that the ureide pathway for the unionized barbiturate is severely hampered through steric hindrance by the presence of the phenyl group at the five position; thus, the product k_4K_a would be much greater than $k_u[H^+]$, and the results found by Tishler *et al.* (3) are explained. On the other hand, the results also reported by Garrett *et al.* (1) relative to the hydrolysis of barbital at pH 6.15, where the ureide represents 84% of hydrolyzed barbital, is also explicable in allowing the nonsterically hindered hydroxide-ion attack at the one–six or three–four position. It is certainly clear that more work is needed on the hydrolysis of barbiturates, particularly on the degradation beyond the initial cleavage of the barbituric acid itself.

Antitumor Agents V: Effect of Epoxidation on Cytotoxicity of Helenalin-Related Derivatives

Keyphrases ☐ Helenalin derivatives—epoxidation, effect on cytotoxicity ☐ Epoxidation of helenalin derivatives—effect on cytotoxicity ☐ Cytotoxicity, helenalin derivatives—effect of epoxidation on activity ☐ Structure–activity relationships—helenalin derivatives, epoxidation and cytotoxicity

Sir:

In connection with our study of the structure–activity relationships among helenalin (I)-related sesquiterpene lactones for cytotoxic or antitumor activity (1–3), we wish to report a preliminary account of the effect of epoxidation on cytotoxicity of helenalin-related derivatives.

The epoxy function is a structural feature commonly found in many naturally occurring sesquiterpene lactones. It is well known that certain classes of synthetic compounds (4), as well as naturally occurring substances, owe their antitumor or cytotoxic activity to the introduction of the diepoxide or triepoxide functionality; *e.g.*, the cyclohexane diepoxide, crotepoxide (5); the sesquiterpene dilactone diepoxide, mikanolide (6, 7); and the diterpene triepoxides, triptolide and tripdiolide (8). With this in mind, it has been inferred that one important factor governing the cytotoxicity of the sesquiterpene lactones could be due to the introduction of the epoxy group. The epoxy group might act as a second alkylating function in addition to the essential alkylating center, the α-methylene-γ-lactone moiety (1, 9, 10). However, it was suggested (6) that cytotoxicity appears to be independent of the presence or absence of an epoxy group, although this conclusion was based upon only a small number of examples.

We felt that the role of the epoxide function with respect to the effect upon cytotoxicity should be further

Antitumor Agents V: Effect of Epoxidation on Cytotoxicity of Helenalin-Related Derivatives

Keyphrases ☐ Helenalin derivatives—epoxidation, effect on cytotoxicity ☐ Epoxidation of helenalin derivatives—effect on cytotoxicity ☐ Cytotoxicity, helenalin derivatives—effect of epoxidation on activity ☐ Structure–activity relationships—helenalin derivatives, epoxidation and cytotoxicity

Sir:

In connection with our study of the structure–activity relationships among helenalin (I)-related sesquiterpene lactones for cytotoxic or antitumor activity (1–3), we wish to report a preliminary account of the effect of epoxidation on cytotoxicity of helenalin-related derivatives.

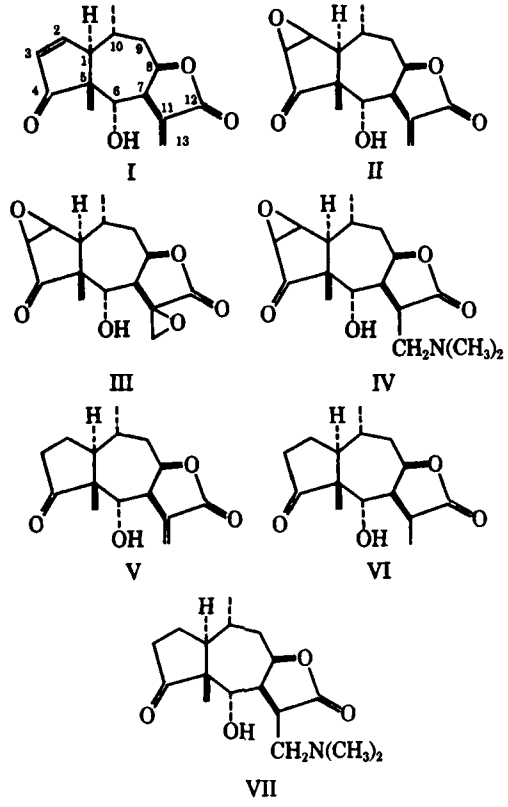
The epoxy function is a structural feature commonly found in many naturally occurring sesquiterpene lactones. It is well known that certain classes of synthetic compounds (4), as well as naturally occurring substances, owe their antitumor or cytotoxic activity to the introduction of the diepoxide or triepoxide functionality; *e.g.*, the cyclohexane diepoxide, crotepoxide (5); the sesquiterpene dilactone diepoxide, mikanolide (6, 7); and the diterpene triepoxides, triptolide and tripdiolide (8). With this in mind, it has been inferred that one important factor governing the cytotoxicity of the sesquiterpene lactones could be due to the introduction of the epoxy group. The epoxy group might act as a second alkylating function in addition to the essential alkylating center, the α-methylene-γ-lactone moiety (1, 9, 10). However, it was suggested (6) that cytotoxicity appears to be independent of the presence or absence of an epoxy group, although this conclusion was based upon only a small number of examples.

We felt that the role of the epoxide function with respect to the effect upon cytotoxicity should be further

Table I—Cytotoxicity of Helenalin-Related Derivatives

Number	Compound	Reference	ED_{50}, mcg./ml. (H.Ep.-2)
I	Helenalin	1–3	0.10
II	2,3-Epoxyhelenalin	—[a]	0.11
III	2,3,11,13-Diepoxyhelenalin	—[a]	0.50
IV	2,3-Epoxyhelenalin dimethylamine adduct	—[a]	1.36
V	2,3-Dihydrohelenalin	2	3.84
VI	2,3,11,13-Tetrahydrohelenalin	2	>40
VII	2,3-Dihydrohelenalin dimethylamine adduct	2	6.04

[a] K. H. Lee, S. H. Kim, H. Furukawa, C. Piantadosi, and E. S. Huang, unpublished data.



clarified. Therefore, the epoxidation of helenalin was undertaken. 2,3-Epoxyhelenalin (II, m.p. 217° dec.), 2,3,11,13-diepoxyhelenalin (III, m.p. 234–236°), and the dimethylamine adduct of 2,3-epoxyhelenalin (IV, m.p. 194–195°) were synthesized[1] and screened for their cytotoxicity against the growth of tissue culture cells originating from human epidermoid carcinoma of larynx (H.Ep.-2) according to a rapid microtiter method (11).

Comparison of the ED_{50} values for the cytotoxicity of the compounds listed in Table I disclosed that both the 2–3 double bond of Compound I and the 2–3 epoxide of Compound II gave equally effective cytotoxicity. The corresponding saturated compound (V) gave a 35-fold decrease in activity. Significant cytotoxicity could also be maintained when the two alkylating centers, such as the O=C—C=CH_2 system in the ketone and the lactone of helenalin, were masked by the epoxy moiety, although the diepoxide (III) was 5 times less active in comparison with helenalin (I). However, the absence of the diepoxy functionality in Compound III resulted in more than an 80-fold diminution in cytotoxicity (compare Compounds III and VI). Similar results were seen in the case of the dimethylamine adduct of 2,3-epoxyhelenalin (IV). As the epxoy group was removed, the activity was decreased (compare Compounds IV and VII). Moreover, a comparison of the activities of Compound II to Compounds I and III further indicated that the α-epoxyketonic moiety played a more important role than the α-epoxy-γ-lactonic moiety in the contribution and maintenance of the high level of cytotoxicity.

Commencement of Basket Rotation Time as Variable in Official Dissolution Test

Keyphrases ☐ Dissolution, tablets—basket rotation time as variable in compendial dissolution test ☐ Basket rotation time—variable in compendial dissolution testing of tablets

Sir:

The dissolution characteristics of many dosage forms are now being determined by using the procedures described in either USP XVIII or NF XIII (1, 2). NF Method I and the procedure described in the USP are based on the use of a basket–stirrer assembly. This method, although official, has been criticized by a number of researchers[1] (3, 4) who found that variable results occur because of vibrational effects within the apparatus, clogging of the 40-mesh screen, and poor stirring characteristics of the assembly. During an investigation of the dissolution characteristics of several brands of chlorpromazine hydrochloride tablets, we observed another possible variable which should be considered when using this apparatus.

The compendia state that the dosage form should be placed in the basket, immersed in the dissolution medium to a point where the bottom of the basket is 2.0 cm. from the bottom of the dissolution vessel, and rotated at the speed specified in the monograph. This procedure can be varied ("Modified USP XVIII Method" in Table I) by placing the tablet in the basket, rotating the basket at the speed specified, and then immersing the rotating basket to the required depth in the dissolution medium.

Dissolution values (Table I) for one brand of chlorpromazine hydrochloride tablets were obtained by using the USP XVIII procedure and the modification of it just described. The dissolution medium was simulated gastric fluid USP (without enzyme), the total volume of medium was 900 ml., and the basket was rotated at 50 r.p.m.

The tablets were purported to contain 25.0 mg. of active ingredient. Ten tablets were assayed individually by using the procedure described in USP XVIII. Values ranged from 24.60 to 25.75 mg./tablet and indicated that there was little variability with respect to drug content.

Table I shows that drastically different results are obtained by a seemingly minor modification in the USP procedure. For example, $T_{60\%}$ values change from 23.4 to 39.3 min. but, at the same time, the modified USP method yields more reproducible results (that is, the standard deviation values are, in general, less than those reported in column 2 of Table I).

The reason for the variation in results is not at once evident but appears to be related to the mesh size of the basket (40 mesh). Studies with a 10-mesh basket yielded relatively the same values by both methods, but the values were much less than those shown in Table I. For example, the $T_{60\%}$ value for this product was ap-

[1] R. H. Blythe and W. J. Mader, "Report of the USP–NF Joint Panel on Physiological Availability," personal communication, 1969.

clarified. Therefore, the epoxidation of helenalin was undertaken. 2,3-Epoxyhelenalin (II, m.p. 217° dec.), 2,3,11,13-diepoxyhelenalin (III, m.p. 234–236°), and the dimethylamine adduct of 2,3-epoxyhelenalin (IV, m.p. 194–195°) were synthesized[1] and screened for their cytotoxicity against the growth of tissue culture cells originating from human epidermoid carcinoma of larynx (H.Ep.-2) according to a rapid microtiter method (11).

Comparison of the ED_{50} values for the cytotoxicity of the compounds listed in Table I disclosed that both the 2–3 double bond of Compound I and the 2–3 epoxide of Compound II gave equally effective cytotoxicity. The corresponding saturated compound (V) gave a 35-fold decrease in activity. Significant cytotoxicity could also be maintained when the two alkylating centers, such as the O=C—C=CH_2 system in the ketone and the lactone of helenalin, were masked by the epoxy moiety, although the diepoxide (III) was 5 times less active in comparison with helenalin (I). However, the absence of the diepoxy functionality in Compound III resulted in more than an 80-fold diminution in cytotoxicity (compare Compounds III and VI). Similar results were seen in the case of the dimethylamine adduct of 2,3-epoxyhelenalin (IV). As the epxoy group was removed, the activity was decreased (compare Compounds IV and VII). Moreover, a comparison of the activities of Compound II to Compounds I and III further indicated that the α-epoxyketonic moiety played a more important role than the α-epoxy-γ-lactonic moiety in the contribution and maintenance of the high level of cytotoxicity.

Table I—Dissolution Values for Chlorpromazine Hydrochloride Tablets

T Value[a]	USP XVIII Method	Modified USP XVIII Method
$T_{30\%}$	4.5 ± 1.3	6.7 ± 2.2
$T_{40\%}$	12.5 ± 4.4	20.5 ± 2.3
$T_{60\%}$	23.4 ± 7.6	39.3 ± 1.8
$T_{80\%}$	35.8 ± 10.3	60.6 ± 2.7

[a] Each T value (min.) is the mean of 10 determinations ± SD.

proximately 9 min. when a 10-mesh basket was used. Furthermore, variable results were not obtained when other brands of chlorpromazine hydrochloride tablets were tested or, if observed, the degree of variability was much less than that shown in Table I. This would appear to indicate that the inherent characteristics of the tablets tested led, in part, to the type of variability reported here.

The "correct" dissolution conditions are always difficult to establish, particularly in the absence of *in vivo* data. It is important, therefore, to standardize a procedure carefully in order to evaluate accurately various lots of the same drug product. From the results reported here, it appears that the time at which the rotation of the basket is commenced is important and that any variation from a standardized approach may yield variable results.

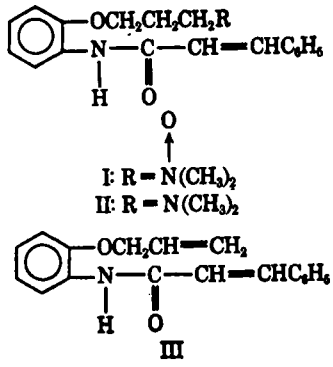
Identification of 2′-[3-(Dimethylamino)-propoxy]cinnamanilide *N*′-Oxide by Mass Spectral Thermolysis

Keyphrases □ 2′-[3-(Dimethylamino)propoxy]cinnamanilide *N*′-oxide—identified using mass spectral thermolysis □ *N*-Oxides—identification of 2′-[3-(dimethylamino)propoxy]cinnamanilide *N*′-oxide using mass spectral thermolysis □ Mass spectral thermolysis—identification, *N*′-oxide of 2′-[3-(dimethylamino)propoxy]cinnamanilide

Sir:

The occurrence of *N*-oxides as natural products or as metabolites of pharmacologically active compounds



III

was reviewed previously (1). The only mass spectral studies of *N*-oxides have been those of aromatic *N*-oxides that usually exhibit the M^+-16 ion, instead of the M^+, as the highest mass ion (2). Mass spectrometry was used to elucidate the structures of some thiopropyldimethylamino-*N*-oxide metabolites (3). In this report, these observations are extended to the thermolysis of 2′-[3-(dimethylamino)propoxy]cinnamanilide *N*′-oxide (I).

Since volatilization of the *N*-oxide base, I (mol. wt. 340), occurs very near its thermolysis point, the spectra obtained at temperatures below 150° were extremely weak and would not normally suffice to establish the structure of metabolites in the presence of the usual artifacts. Generally, the similarity in the mass spectra[1] of *N*-oxides and of free amines would make it difficult to assign structures to *N*-oxide metabolites. However, variation of the ion-source temperature does permit differentiation of amines and their *N*-oxides. At 155° or higher, I showed no M^+, and the M^+-16 ion, though still present, was diminished in intensity relative to the *m/e* 279 ion (Table I). The composition of the *m/e* 279 (M^+-61) ion corresponds to the olefin, III, formed by the Cope elimination of an *N*-oxide (5).

The *N*-oxide hydrochloride, I-HCl, shows the M^+-16 ion, the *m/e* 58 ion, and a temperature-dependent ion at *m/e* 279. At 185°, fragment ions of I-HCl are present at M^+-18 and M^+-30 (the former being a dehydration product) but are absent at higher temperatures. At temperatures >185°, the *m/e* 279 ion is more intense. However, the persistence of the M^+-16 ion, coupled with the increase in intensity of the *m/e* 58 ion, demonstrates that the thermolysis of I-HCl yields more II (mol. wt. 324) than does the thermolysis of I.

Differential thermal and thermal gravimetric analyses[2] also show the difference in the thermolysis of the hydrochloride and the free base of the *N*-oxide. The hydrochloride, I-HCl, melts in two exothermal steps at 186 and 191°, with a total loss of 7% of its weight. Since the loss of oxygen requires a weight loss of 4.3%, and the Cope elimination product requires a weight loss of 12%, the intermediate value for weight loss demonstrates that a mixed-product thermolysis can occur and substantiates the mass spectral results, which show that various thermolytic products were formed. But the free base of the *N*-oxide, I, showed an endotherm at

REVIEWS

Pharmacology of the Endocrine System and Related Drugs: Progesterone, Progestational Drugs and Antifertility Agents, Volume II. Section Editor, M. TAUSK. Pergamon Press, Inc., Maxwell House, Fairview Park, Elmsford, NY 10523, 1972. xiv + 538 pp. 16 × 24 cm. Price $36.00.

This second volume of section 48 of the International Encyclopedia of Pharmacology and Therapeutics is composed of 11 chapters by eight eminent contributors. It has accomplished, very completely, in a rather limited amount of space, what it was supposed to do—namely, provide a thorough review of the synthetic progestational drugs that will serve the purpose of a wide variety of basic and applied scientists.

The first part of the text deals with synthetic progestational agents in humans and animals, highlighting their pharmacology, metabolism, and therapeutic applications. The latter part is confined to the antifertility aspects of estrogens, progestational compounds, combinations of both, and their side effects. In addition, there is a concluding summary chapter that not only covers material in both volumes, but also includes some recent information that has come about during the 5 years this volume was in preparation.

Outstanding features of this book include separate subject and author indexes, as well as complete reference sources for this area of pharmacology. The buyer should be cautioned that, in order to really have at hand all the necessary facts for the subject under discussion, the initial volume must also be purchased. Most of the material presented is done so in as readable a manner as can be accomplished in this kind of undertaking and, for the most part, the clarity is better than most other reviews.

This book will undoubtedly be added to all medical libraries throughout the world, and it should find use among not only pharmacologists and endocrinologists, but also obstetricians, gynecologists, and steroidal research groups interested in the actions, mechanisms, and uses of the myriad of compounds described.

Pharmaceutical Applications of Thin-Layer and Paper Chromatography. Edited by KAREL MACEK. American Elsevier, 52 Vanderbilt Ave., New York, NY 10017, 1972. xvi + 742 pp. 16 × 24.5 cm. Price $78.50.

Macek and twelve cocontributors approached the enormous literature of TLC and paper chromatography (cumulatively called "flat-bed" as the lines of demarcation have dimmed in recent years) with a single objective: to produce a volume uniquely useful to the pharmaceutical milieu. This objective is a reasonable one and long overdue. They have succeeded through diligent coverage of the chosen field and unyielding exclusion of related information from activities in agriculture, dyes, synthetic organic chemistry, and biochemistry.

Rich discussions of technique and interpretation are given so that this volume is no mere catalog of mobilities and references. Their inclusion of both paper and thin-layer data and exclusion of data not of direct pharmaceutical interest have steered the volume reasonably clear of that great and obvious danger, overlap with existing compilations. Moreover, this freshness of effort is aided by the simple fact that more recent literature is included, that is to say reasonably thorough coverage through 1970 with some 1971 work.

Twenty-one chapters, individually authored, divide the mass of information into realistic compartments with only minor discontinuity or overlap. The heart of the volume resides in 10 chapters covering pharmaceutical compounds by class: synthetic organics, steroids, glycosides, saponins, peptide and protein hormones (which suffers slightly from the exclusion of another "flat-bed" technique, electrophoresis), alkaloids, vitamins, antibiotics, plant extracts, and formulation components. One strength of this volume lies in the inclusion of isolation and sample preparation procedures within the context of the individual chapters. Each chapter is well organized and the literature coverage is excellent throughout.

General techniques, choices of systems, and quantitative aspects of each flat-bed method are reviewed in two chapters which are both critical and informative. There is a good chapter on radioisotopic methods. Two chapters are devoted to the interfacing of flat-bed methods with spectroscopic and other chromatographic methods—precisely the areas of greatest recent and future growth. Other chapters deal with qualitative analysis (with schemes), documentation, and detection reagents. A chapter on applications in drug metabolism is included, but this is disappointing when viewed against the current importance of this area in pharmaceutical research. Two insignificant chapters, on laboratory design and "tasks," could have been woven into the stronger fabric of the introductory chapters.

Three indexes are given, so that the reader may retrieve specific information by compound, author, or subject; all are thorough and readily readable. Literature references for each chapter are given by author rather than number, and these are adequately distinguished within the text. The work appears essentially free of typographical errors.

Consistent with a work intended for utility, it is written and edited in a clear, concise fashion. Tabulations of mobilities, systems, and visualizations are extremely clear and easily followed. The figures and diagrams are well executed. The paper, printing, and binding are first rate which, when amplified by the limited production inherent in this area, result in a remarkably costly volume. Few individuals could add it to their personal shelves. This premium price may indeed detract from the stated objective of a uniquely useful volume by placing it out of the reach of many potential users. It is, however, strongly recommended as a library or institutional acquisition and should be available to groups of working pharmaceutical analysts where it will be a major reference for years to come.

REVIEWS

Pharmacology of the Endocrine System and Related Drugs: Progesterone, Progestational Drugs and Antifertility Agents, Volume II. Section Editor, M. TAUSK. Pergamon Press, Inc., Maxwell House, Fairview Park, Elmsford, NY 10523, 1972. xiv + 538 pp. 16 × 24 cm. Price $36.00.

This second volume of section 48 of the International Encyclopedia of Pharmacology and Therapeutics is composed of 11 chapters by eight eminent contributors. It has accomplished, very completely, in a rather limited amount of space, what it was supposed to do—namely, provide a thorough review of the synthetic progestational drugs that will serve the purpose of a wide variety of basic and applied scientists.

The first part of the text deals with synthetic progestational agents in humans and animals, highlighting their pharmacology, metabolism, and therapeutic applications. The latter part is confined to the antifertility aspects of estrogens, progestational compounds, combinations of both, and their side effects. In addition, there is a concluding summary chapter that not only covers material in both volumes, but also includes some recent information that has come about during the 5 years this volume was in preparation.

Outstanding features of this book include separate subject and author indexes, as well as complete reference sources for this area of pharmacology. The buyer should be cautioned that, in order to really have at hand all the necessary facts for the subject under discussion, the initial volume must also be purchased. Most of the material presented is done so in as readable a manner as can be accomplished in this kind of undertaking and, for the most part, the clarity is better than most other reviews.

This book will undoubtedly be added to all medical libraries throughout the world, and it should find use among not only pharmacologists and endocrinologists, but also obstetricians, gynecologists, and steroidal research groups interested in the actions, mechanisms, and uses of the myriad of compounds described.

Pharmaceutical Applications of Thin-Layer and Paper Chromatography. Edited by KAREL MACEK. American Elsevier, 52 Vanderbilt Ave., New York, NY 10017, 1972. xvi + 742 pp. 16 × 24.5 cm. Price $78.50.

Macek and twelve cocontributors approached the enormous literature of TLC and paper chromatography (cumulatively called "flat-bed" as the lines of demarcation have dimmed in recent years) with a single objective: to produce a volume uniquely useful to the pharmaceutical milieu. This objective is a reasonable one and long overdue. They have succeeded through diligent coverage of the chosen field and unyielding exclusion of related information from activities in agriculture, dyes, synthetic organic chemistry, and biochemistry.

Rich discussions of technique and interpretation are given so that this volume is no mere catalog of mobilities and references. Their inclusion of both paper and thin-layer data and exclusion of data not of direct pharmaceutical interest have steered the volume reasonably clear of that great and obvious danger, overlap with existing compilations. Moreover, this freshness of effort is aided by the simple fact that more recent literature is included, that is to say reasonably thorough coverage through 1970 with some 1971 work.

Twenty-one chapters, individually authored, divide the mass of information into realistic compartments with only minor discontinuity or overlap. The heart of the volume resides in 10 chapters covering pharmaceutical compounds by class: synthetic organics, steroids, glycosides, saponins, peptide and protein hormones (which suffers slightly from the exclusion of another "flat-bed" technique, electrophoresis), alkaloids, vitamins, antibiotics, plant extracts, and formulation components. One strength of this volume lies in the inclusion of isolation and sample preparation procedures within the context of the individual chapters. Each chapter is well organized and the literature coverage is excellent throughout.

General techniques, choices of systems, and quantitative aspects of each flat-bed method are reviewed in two chapters which are both critical and informative. There is a good chapter on radioisotopic methods. Two chapters are devoted to the interfacing of flat-bed methods with spectroscopic and other chromatographic methods—precisely the areas of greatest recent and future growth. Other chapters deal with qualitative analysis (with schemes), documentation, and detection reagents. A chapter on applications in drug metabolism is included, but this is disappointing when viewed against the current importance of this area in pharmaceutical research. Two insignificant chapters, on laboratory design and "tasks," could have been woven into the stronger fabric of the introductory chapters.

Three indexes are given, so that the reader may retrieve specific information by compound, author, or subject; all are thorough and readily readable. Literature references for each chapter are given by author rather than number, and these are adequately distinguished within the text. The work appears essentially free of typographical errors.

‡*Editor's note:* Part II of this article will appear in the August 1973 issue of the *Journal of Pharmaceutical Sciences.*

This review of the literature represents a comprehensive cross section of the research and development effort in various selected disciplines of pharmaceutical sciences. As in past years, the scope of this endeavor has been limited to a review of the area of pharmaceutics because annual reviews of the literature related to other areas of pharmaceutical sciences are published elsewhere. This is the 11th annual survey of the series (1–10). To compile it, numerous journals, periodicals, and selected sections of *Chemical Abstracts* were abstracted.

The review was prepared to provide a convenient method for pharmaceutical scientists to review the literature of the past year and to supply a source of references to articles of preferred interest. To maintain continuity, the well-accepted format of last year's review was retained.

GENERAL PHARMACY

A comprehensive review of the biosynthesis, chemistry, stability, analytical methods, metabolism, and biology of the prostaglandins was presented by Oesterling *et al.* (11). Other reviews appearing over the past year in the general area of pharmacy concerned formula-

tion of aspirin (12), use of polymers for pharmaceutical applications (13), boron compounds of pharmaceutical interest (14), application of silicones in pharmacy (15), use of silicates in the pharmaceutical area (16), and pharmaceutical properties of dimethyl sulfoxide (17). Statistical data were presented on the results of quality control of raw materials in the Brazilian pharmaceutical industry between 1940 and 1968 (18). The extent of drug product recalls occurring over an 18-month period and the types of product quality defects and their significance were discussed (19). Examples for each type of product quality defect were cited. A review was presented on the chemical and physical incompatibilities in drug solutions, emulsions, suspensions, salves, and capsules and their effects within the biological system (20). As an example, streptomycin in combination with anionic compounds, such as sodium alginate, exhibited greater antimicrobial activity than that observed for the sulfate derivative.

Preservatives—In a study relating cetrimonium bromide (cetyltrimethylammonium bromide) concentrations with the ζ-potential of the bacterial cell wall, this agent completely inhibited the growth of *Streptococcus faecalis* at a concentration producing only a 10–30% decrease in the absolute value of the ζ-potential (21). These results seem to indicate that the primary site of attack of this compound is probably not the cell wall. During studies on the antimicrobial efficacy of 4-hydroxybenzoic acid esters, a direct relationship between the lipid–water partition coefficient and antimicrobial activity was indicated (22). Introduction of a hydroxy or oxo group into the alkyl ester chain increased water solubility, but it decreased antimicrobial activity. Likewise, it was shown in a study of a series of homologous aliphatic amines that inhibition increased with increasing alkyl chain length and the maximum was reached at C_{12}–C_{15} (23). The poor inhibitory effect of the longer chain molecules was thought due to micelle formation, with concomitant lowering of the solubility. In determining the antibacterial activity in a series of quaternary ammonium compounds, it was found that the length of the side chain was less determinant in the case of Gram-negative bacteria (24). This was attributed to the differences in the cell wall lipid concentration between Gram-negative and Gram-positive bacteria.

Pseudomonas aeruginosa cells grown in the presence of phenylethanol were more sensitive to the action of benzalkonium chloride, chlorhexidine, and phenylmercuric nitrate than cells grown in nutrient broth alone (25). This suggested the use of phenylethanol as a co-preservative when using these other agents. Bradshaw *et al.* (26) were able to predict the degree of inhibition of cetylpyridinium chloride in combination with a nonionic surfactant on microbial cells at higher concentrations. However, at lower concentrations of bactericide, other factors, such as changes in cell wall permeability, made this prediction less possible. It was also determined that polysorbate 80 antagonized the activity of fenticlor against exponential phase cultures of *Staphylococcus aureus*, *Proteus vulgaris*, and *Escherichia coli* (27). In the same study, it was demonstrated that phenylethanol enhanced activity against similar cultures.

The effects of glycerol and propylene glycol on microbiological contamination of some oil-in-water emulsion ointment bases were determined (28). While glycerol stimulated the growth of molds and yeasts with the simultaneous decrease of bacteria, propylene glycol gave microbial purity. However, in another study with preservation of oil-in-water emulsions, it was found that propylene glycol caused apparent partial antagonism of potassium sorbate in these systems (29). Sterilization of contaminating bacteria by solutions of phenylmercuric nitrate and thimerosal was delayed or prevented by addition of edetate (EDTA) or sodium thiosulfate, but metabisulfite reduced the sterilization times of both these agents at acid pH (30). The antibacterial activity of sodium metabisulfite appeared to be due to an interaction with bacterial DNA.

Methods for the rapid screening of preservatives for pharmaceutical and cosmetic preparations, based on instrumental monitoring of indexes of cell development that occur early in the growth cycle and that are susceptible to preservative agents, were reviewed (31). In another review, the relative sensitizing potentials of parabens, sorbic acid, phenolics, formaldehyde, mercurials, quaternary ammonium compounds, betaines, dimethoxane, and dihydroacidic acid were discussed because they are used in cosmetic emulsions and dermatological preparations (32). Combinations of benzalkonium chloride, chlorhexidine, phenylmercuric nitrate, chlorocresol, and chlorobutanol with phenylethanol were consistently effective in preserving ophthalmic solutions (33). Polymyxin and benzyl alcohol were also found to be suitable preservatives for ophthalmic drops (34). However, the use of an antibiotic as a preservative was regarded as unadvantageous.

The safety of intravenously administered benzyl alcohol and paraben preservatives was ascertained (35). The higher antibacterial activity of benzyl alcohol, shown in challenge tests, plus its comparable tolerances to parabens favor the use of benzyl alcohol as a preservative. A study was made of eight substituted phenolic preservative solutions in 2% polysorbate 80 (36). These results showed less sorption into polyethylene than from aqueous solutions, but the micellized systems were not adequately preserved. Several common preservatives that are absorbed by filter paper, rubber stoppers, and inorganic adjuvants or that react with organic macromolecular compounds were discussed (37). Preservatives preferred or considered not suitable for different pharmaceutical preparations were also listed.

Other articles of interest related to the subject of preservatives are listed in Table I.

Flavor, Aroma, and Color—Additions to the list of Generally Regarded As Safe (GRAS) substances made in 1970–1971 and their maximum use levels were tabulated (52). The concept of "toxicological insignificance" was explained, and data on total daily per capita intake of flavoring substances were presented. A review of the classification of the components of taste, methodology, choice of flavor, control, and stability of taste-masking drugs was presented (53). It was pointed out that flavoring of a drug includes two processes: the masking of the disagreeable taste and aromatization (54). Prescriptions for flavoring were given using sac-

charin, chocolate, vanilla, caramel, orange essence, and raisin juice in different combinations. The flavor chemist's greater reliance on the results of instrumental techniques, the faster development of new aromatics from laboratory curiosities to accepted standard items, and the increasing number of new materials and methods determine today's trend in flavors (55). Hofmann (56) reviewed and discussed the several theories explaining the relation between sweetness and chemical structure. A study of several stereoselectively sweet amino acids molecules led to a prediction of the presence and approximate location of a third structural feature, relative to the currently postulated A–H/B features in the glucophore (57). A relationship between the polarizability parameter and sweetness level in a series of substituted nitroanilines led to the hypothesis that this third binding site may be involved in dispersion bonding with an appropriate receptor feature.

An encyclopedic evaluation of the literature in the perfumery materials field was continued by Bedoukian (58) in his 28th annual review. It was pointed out that modern perfumery is no longer a question of merely adding a harmonious blend of materials in proper concentrations (59). It involves chemical interactions, research, packaging, testing, and fragrance selection, coupled with the application of perfumes to a wider range of products. It was urged that fragrance materials be examined in their use environment (60). Since it has been demonstrated that fragrance materials associate with protein, factors that influence efficacious perfumery of protein materials can be considered in a new way. Encapsulation of fragrance material was postulated as a means for overcoming difficult problems (61). A water-soluble capsule would protect the fragrance up to the time of use.

In studying odor sensations arising from the 1,2,4-triaxial arrangement of the substituents in a decalin ring system, it was determined that the position of an oxygen function within the triaxial system moves the odor sensation in the direction of different but distinct qualities (62). On the other hand, the surroundings of the center triggering the odor, as well as the chemical nature of the oxygen substituent, seemed to be of minor importance. In discussions concerning the relationships observed between odor and molecular structure, it was stated that small differences in structure can create changes in potency in some cases, changes in quality in others, and changes in both quality and potency in still others (63, 64).

Stability—The stability of neutral regular insulin was compared to conventional acid regular insulin (65). The increased stability of the former warrants its consideration as a pharmaceutical form of soluble regular insulin and as a replacement for the conventional acidic form. Seydel and Voigt (66, 67) conducted extensive studies on the stability of amino acid solutions. Stability results on individual amino acids and on combinations of amino acids alone and with various preservatives were reported. The stability of amino acids in aqueous solutions of casein hydrolysate stored at various temperatures was examined (68). Only glutamine and cysteine were rapidly degraded in this system. In a further study, these same workers determined that lyophilization significantly enhanced stability of the amino acids (69). Macromolecules such as bovine serum albumin and macrocyclon effectively enhanced the stability of aromatic nitrogen mustards, including chlorambucil, while not necessarily altering the antitumor activity of these compounds when given concurrently (70).

The causes of coloring of sulfonamide suspensions with prolonged action were investigated (71, 72). It was determined that with the proper use of antioxidants, adjustment of pH, and nitrogen flushing, coloring could be eliminated. In a study on the thermal degradation of sulfonylureas, results indicated that dissociation rather than solvolysis was the most likely mechanism by which sulfonylureas undergo breakdown in alcohols and water (73). Procaine hydrochloride was successfully stabilized by the addition of methylidene, glycerin, and propylene glycol (74). The mechanism postulated for protection was a pseudochelating action. It was shown that dipyrone degradation was not subject to pH in the 4.8–8.8 range and that the probable mechanism of degradation was oxidation (75). It was suggested that improved stability could be obtained by flushing the headspace with an inert atmosphere and by incorporating a suitable antioxidant.

A stabilized phenylephrine hydrochloride nasal drop formulation was described which contained methylparaben, propylparaben, and sodium bisulfite with a pH adjustment of 5–6 (76). The decomposition of aspirin (acetylsalicylic acid) and possibilities for its stabilization in a solid dosage form were discussed and reviewed (77). During an investigation of the decomposition of physostigmine salicylate during thermal sterilization, it was determined that the quantity of decomposition in ampuls depends on the quantity of oxygen present in the solution (78). The replacement of

oxygen with nitrogen decreased the decomposition threefold. Boric acid had no effect on oxidative changes of lanolin, while glycero-boric acid was very effective in this respect (79). The protective efficiency for the stabilization of oxygen-sensitive systems using gas permeation was determined by measuring the relative deaeration produced by this technique *versus* current methods for reducing dissolved oxygen concentrations in liquid systems (80). In terms of deaeration efficiency, gas permeators ranked second only to the addition of antioxidant materials in the drug system, but they did have the advantage of eliminating the addition of chemicals in the dosage form which might produce adverse reactions.

In a discussion of the advantages of preservation of medicinal solutions by freezing, emphasis was placed on the proper choice of adjuvants and construction of the containers used (81). A method was described for the rapid determination of color stability in tablet formulations (82). Data obtained in the phenometer in 24 hr., as well as results from exposure in a light cabinet for 28 days, facilitated the comparative evaluation. Rapid testing for the stability of BCG vaccine by accelerated heat testing was accomplished, along with rapid viability testing by assaying for the adenosine triphosphate content of the vaccine (83). The viability determined by adenosine triphosphate analysis correlated well with the viable count as determined by culturing. Stability programs for determining chemical and physical stability and the analytical implications were reviewed by Rehm (84). Other workers warned against too heavy a reliance on accelerated stability testing (85). As an example, they cited the case of 500-mg. ascorbic acid tablets that had strong color degradation apparent although they were chemically unchanged.

Other papers of interest related to the topic of stability are listed in Table II.

Stability Kinetics—Drug and drug system stability predictions based on kinetics of degradative reactions and Arrhenius-type relationships were reviewed by several authors. These included both isothermal and nonisothermal methods (131–135). However, one group of workers pointed out that stability based on accelerated temperature studies may lead to erroneous results because mechanisms of degradation may change at higher temperature (136). While using procaine, meperidine, homatropine, and scopolamine as examples, the hydrolytic behavior of esters in aqueous solutions was discussed (137). Such factors as the effects of pH, solvents, ionic strength, acid and base catalysis, and steric hindrance were included. Dexamethasone 21-phosphate in aqueous solution was shown to be susceptible to a reversible bisulfite addition, which was a

second-order reaction in which sulfite ion and monoanionic dexamethasone 21-phosphate were the major participants (138). The decomposition of aspirin in polyethylene glycols was shown to be a pseudo-first-order reaction (139). Different molecular weights of polyethylene glycol had no effect upon the reaction rate, which was demonstrated to be due to transesterification. In alkaline media the 2-, 3-, and 4-monohexanoates of lincomycin rapidly isomerized, each entering into facile equilibrium with the other two, accompanied by hydrolysis of each species to lincomycin. By using a digital computer and a nonlinear estimation program, Oesterling and Metzler (140) were able to estimate simultaneously the four isomerization rate constants and the three hydrolysis rate constants.

It was demonstrated that the methanesulfonic acid derivative of sulfisoxazole undergoes successively reversible hydrolysis in aqueous solution (141). The pH profiles of the logarithm of apparent hydrolysis and reverse reaction rates and those of equilibrium constants were obtained, and the effects of ionization of the derivatives and hydrolysates were explained by mathematical equations. The decomposition of a series of benzoic acid derivatives in the solid state was studied (142). It was found that for decomposition to take place below the melting point, the σ value must be less than -0.35. The decomposition then follows Bawn-type kinetics. C-21-Dideuteriohydrocortisone was shown to be more stable than hydrocortisone under oxidative conditions (143). A possible explanation for this enhanced stability was that the reaction path for these degradations involved a rate-determining enolization in the C-17-dihydroxyacetone side chain. The pharmaceutical stability of a solution of potassium canrenoate was shown to be a function of the solubility of the lactone canrenone at equilibrium and the pH-dependent thermodynamic equilibrium of the reversible lactonization and hydrolysis processes. Garrett and Hermann (144) predicted the minimum pH values for various mixed solvent solutions that would maintain unprecipitating potassium canrenoate solutions for desired injectable concentrations of the drug. The hydrolytic decomposition of intrazole obeyed first-order kinetics and was subject to both acid and base catalysis (145). The pH of maximum stability of this compound under buffer-free conditions was 3.20. The kinetics of hydrolysis of the carbamoyl group in salicylanilide *N*-methylcarbamate and 4-biphenylyl *N*-methylcarbamate showed that the reaction was first order with respect to both hydroxide ion and carbamate (146). At 37°, the hydroxide ion-catalyzed hydrolysis of the former to yield salicylanilide proceeded at a rate over 200 times that for the hydrolysis of the latter, which produced 4-biphenylol. During a study of the kinetics of dextrose degradation during autoclaving, the reaction was shown to exhibit an induction period with respect to 5-hydroxymethylfurfural production, which was due to the formation of an intermediate compound (147). A reaction mechanism was proposed that appeared consistent with experimental measurements.

In studies aimed at predicting shelflife stability of arabinosylcytosine in aqueous solutions, Notari *et al.* (148) determined that the loss of substrate in the pH 0–6 region was accompanied by formation of an intermediate which reacts further to yield arabinosyluracil. In alkaline solutions the loss of arabinosylcytosine was about 10 times more rapid than in acid and was most likely due to hydrolysis of the pyrimidine ring, since no arabinosyluracil UV absorption spectra were detected. Other workers (149) confirmed by UV spectrophotometry and TLC that cytosine and cytidine deaminate to uracil and uridine, respectively, at all pH values. These products slowly degrade further in strongly alkaline solutions. Differences in the intermediates formed in the degradation of chlorothiazide in alkaline medium and acidic medium were investigated, using a molecular orbital method to understand the hydrolysis mechanism (150). The hydrolysis pathway was explained by the electronegativity of the atoms involved in the postulated activated complex, 3-hydroxyhydrochlorothiazide. Depending upon the reaction conditions, two pathways of cleavage of butalbital were described (151): (*a*) through 1,6-ring opening to the malonuric acid, and (*b*) *via* 1,2-cleavage of the barbiturate producing the diamide. In following the hydrolysis of certain 5-aminodibenzo-[*a*,*d*]cycloheptanes, it was determined that degradation is characterized by cleavage of a carbon–nitrogen bond at the 5-position of the fused ring system (152). The process was shown to proceed possibly by a carbonium-ion intermediate or its equivalent. The hydrolytic rate of degradation of sodium sulfacetamide in aqueous solution was shown to be minimal at pH 8–8.5 (153). Hydrolysis of methyl hippurate under the influence of α-chymotrypsin and some aliphatic alcohols was investigated (154). Methanol, ethanol, *n*-propanol, *n*-butanol, and *n*-pentanol were found to inhibit the rate of hydrolysis.

Other papers related to the topic of stability kinetics are listed in Table III.

Antibiotic Stability—In comparing the relative stabilities of hetacillin and ampicillin solutions, Schwartz and Hayton (169) found rates of degradation inconsistent with what should be expected. An explanation of this inconsistency was offered by adopting a model reaction scheme that incorporated the concentration

dependence of both the ampicillin degradation and the hetacillin–ampicillin equilibrium. Ionic strength up to 0.5 did not affect the chemical stability of potassium penicillin G unless one of the ions contributing to ionic strength was also catalytic (170). A study to elucidate, by *in vitro* kinetic analysis, the role of cupric [Cu (II)] ions through complexation with an amino acid was undertaken (171). A mechanism was postulated that involved the rapid formation of a ternary penicillin–Cu (II)–glycine complex followed by a rate-limiting hydroxyl-ion attack. It was demonstrated that the nature of the penicillin side chain, particularly the stereospecificity, played a significant role in the stability of penicillin toward β-lactamase (172). In another study, the rate constants for the penicillinase hydrolysis of a series of phenoxymethyl penicillins substituted on the benzene ring by methyl, ethyl, chloro, bromo, formyl, nitro, or cyano were correlated with the Hammett σ-constants (173).

In studying the compatibility and stability of disodium carbenicillin in combination with other drugs and large volume parenteral solutions, Zost and Yanchick (174) reported this antibiotic to be degraded rapidly when mixed with a combination of multiple B vitamins and vitamin C (ascorbic acid). The decomposition rates of a series of semisynthetic penicillins were measured in aqueous solutions at pH 4–9 (175). Methicillin was the most labile, ampicillin and oxacillin were of intermediate stability, and cloxacillin was the most stable. Chemical evaluation of the degradation of solid tetracycline dodecylsulfamate at various temperatures indicated a pseudo-first-order reaction (176). Predictions of shelflife using Arrhenius mathematics indicated a probable shelflife of 2600 days at 25°. These results were confirmed by actual data.

In studies dealing with the stability of antibiotics in frozen systems, Larsen (177, 178) demonstrated that the rate of degradation of these drugs is dependent on buffers, absolute temperature, antibiotic concentration, and rate of freezing. Other workers reported that sodium cephalothin and cephaloridine may be stabilized for short periods by freezing (179). Hamycin was shown to exhibit its maximum stability in aqueous solutions at pH 8 (180). The influence of honey on the stability of monomycin, neomycin, streptomycin, tetracycline, oxytetracycline, and chlortetracycline was reported (181). The microbiologically determined stability of dermostatin in 12 selected ointment bases at 37° was investigated, and maximum stability was exhibited in anhydrous bases as compared with those containing water (182). The stabilities of penicillin G, tetracycline, neomycin, and chloramphenicol were determined in bentonite glycerogels (183). Additions of sorbitan monopalmitate, polysorbate 80, sorbitan monolaurate, and sodium lauryl sulfate had drastic effects on reducing degradation rates.

Other references relating to antibiotic stability can be found in Table IV.

Vitamin Stability—The effects of metal complexing agents on the stability of injectable ascorbic acid solutions were investigated (194). The optimum concentration of these agents on the stability of the drug depended on the amount of heavy metal ions in the solution. The pH–log rate profile of the rate of disappearance of ascorbic acid from an aqueous solution under aerobic conditions was determined at 67° in the pH 3.52–7.22 range and exhibited a maximum near the pKa of ascorbic acid (195). Other workers (196) reported that maximum stability of ascorbic acid solutions could be achieved by the addition of sodium thiosulfate and edetate (ETDA) after passing carbon dioxide through the solution. Microencapsulation of ascorbic acid increased its stability during storage both in the powder form and as tablets (197). Best results were achieved with cetyl alcohol as the coating agent, and the process was carried out by fluidization. An investigation of the stability of vitamin A palmitate in selected ointment bases indicated that lanolin accelerated the decomposition of this vitamin (198). The synergistic effect of the antioxidants butylated hydroxytoluene and butylated hydroxyanisole was demonstrated on the stability of vitamin A acetate in soybean oil (199). An extensive review on the oxidation of vitamin A was also presented (200).

The effects of common additives on the stability of injectable solutions of vitamin B_1 were evaluated (201). The most important factor for solution stability was shown to be the quality of the thiamine hydrochloride used. The stability of supersaturated solutions of thiamine chloride and thiamine bromide at 7 and 20° depended on the degree of supercooling (202). The addition of ethanol affected the rate of crystallization at nucleation centers, resulting from its influence on surface tension and activation energy. The stability of

multivitamin granules containing thiamine disulfide, sodium riboflavin 5′-phosphate, pyridoxine hydrochloride, niacinamide, cyanocobalamin, and calcium pantothenate was studied using accelerated tests (203). Granulation with ethanol and 5% polyvinylpyrrolidone was the recommended method of manufacture. The stability of pyridoxal 5-phosphate was determined in the presence of its degradation products and other substances with which it is commonly associated (204). It was found that the only additives increasing the degradation rate were riboflavin and cyanocobalamin.

Additional references on vitamin stability are listed in Table V.

PHARMACEUTICAL TECHNOLOGY

Recent advances in the pharmaceutical industry as they relate to pharmaceutical technology were reviewed by several authors (211–213). Use of computers in electronic data processing in the pharmaceutical technology areas was also reviewed (214, 215). The historical background, basic principles, and applications of lyophilization to pharmaceuticals were discussed (216). As an alternative to freeze drying for removal of ethanol from plasma proteins, vacuum distillation was offered (217). Both capital and operating costs were less than for freeze drying. Cookson and Morgan (218) compared the various methods for deionized water bed sterilization and recommended 0.25% formaldehyde solution, primarily because of the lower price as compared to other available agents. The various factors affecting antacid efficiency, including micromeritic properties, method of preparation, and effect of dosage form were reported (219–221). The suspension was considered the best dosage form since it has reasonable neutralizing capacity, the fastest rate for acid neutralization, and the longest sustained action within the desirable pH range. The influence of setting temperature on the organization of gelatin gels was studied (222). The gel structure and its behavior depend mainly on the first formed bonds, and a setting at a few degrees below the melting temperature promotes high rigidities. The physical and chemical properties of pharmaceutical gelatin were reviewed, with emphasis on alkaline or acid treatment and source of raw material (223). The principles and uses of microencapsulation of drugs was reviewed by Bakan and Sloan (224). Ultrasonic cleaning was reviewed from both a technological viewpoint (225) and as it can be used in the pharmaceutical industry (226).

Additional references on pharmaceutical technology are listed in Table VI.

Parenterals—Jennings (244) pointed out some problem areas in the manufacturing and administration of parenterals, including the need of a total concept of sterility, the potential hazard of particulate matter, the addition of other drugs to large-volume parenterals prior to their administration, and packaging designs for large-volume parenterals. Modes of administration, solubility, stability, and incompatibility with other drugs and their adverse effects were tabulated for 19 commonly used antibiotics including the tetracycline and penicillin derivatives (245). Procedures for the manufacture of parenteral suspensions were reviewed,

with emphasis on the characteristics inherent to this dosage form not shared with other pharmaceutical suspensions (246). Perrin *et al.* (247) proposed that highly protein-bound excipients, which compete with drugs for binding sites, be added to lower the dose of drugs necessary to produce a given pharmacological response and, hence, to lower the toxicity and cost of parenteral dosage forms. Polyethylene glycol, when used as a solvent for intravenous injections of water-soluble agents, showed a relatively low toxicity (248). This solubilizing agent did not induce hemoglobinurea as was observed with glycerol, dimethyl sulfoxide, or dimethylformamide when used as solvents. The technology involved in preparing fluorocarbon emulsions as blood substitutes was reported (249). Five formulations of fat emulsions used in parenteral nutrition were reviewed as to their use in clinical medicine, absorption, and adverse effects (250). Riebe and Oesterling (251) outlined the procedures involved in the successful development of an injectable form of clindamycin. Problems encountered in the formulation of clindamycin 2-phosphate as a suitable parenteral dosage form were described.

Particulate matter in parenteral glass containers was significantly reduced by washing with either hydrofluoric acid or ammonium bifluoride solution (252). This method of washing also improved the chemical resistance of Type I glass containers to a degree equivalent to that of a good sulfur dioxide treatment. Minute crystals occurring in solutions packaged in multiple-dose vials and sealed with butyl stoppers were shown, by electron probe microanalysis, to be complexes containing zinc and calcium (253). These metal ions were believed to have originated as surface contaminants of the butyl stopper, and a procedure for washing the

stoppers to remove this contamination was described. Methods for testing of silicone coatings on ampuls and vials for injectable solutions were reported (254). Ampuls treated with a 1.5 or 2% aqueous silicone emulsion showed fewer defects of coating than those treated with a 0.5 or 1% emulsion. Hall (255) elucidated the potential problem areas in the manufacture of single-dose ophthalmic products. These included the chemicals used, the packaging materials, the water used, personnel, plant facilities, and control procedures. Use of methylcellulose and hydroxyethyl cellulose, polyvinylpyrrolidone, benzalkonium chloride, cetrimide, and thimerosal were evaluated for use in contact lens solutions (256). Tabulated data were presented to facilitate the selection of suitable combinations of these chemicals with respect to viscosity, film-forming properties, hydration, stability of solutions, and protection against microbial contamination. Ophthalmic solutions prepared with 2% aqueous polyvinyl alcohol were shown to be superior to solutions prepared with water alone (257). No side effects of polyvinyl alcohol were noticed when these solutions were administered to 30 patients with corneal lesions.

Reconstituted antibiotic intravenous products prepared by a number of companies were surveyed for foreign particulate matter (258). The results indicated a variation among companies as to the amount of particulate matter found in their products. Other workers noted that asbestos was found in approximately one-third of the samples from two sets of 17 widely used parenteral drugs (259). McGinn (260) reported that much of the nonviable particulate matter found in parenteral solutions packaged in glass vials originated from the packing material used in shipping the empty vials. He suggested that using a type of plastic film wrapping for these empty containers would reduce appreciably the rejects due to this source of particulate matter. However, all parameters involved in the manufacturing process of injectable fluids were investigated and shown to play an important role in contamination by particles (261). Summaries of the activities of a committee appointed by the Pharmaceutical Manufacturers Association (PMA) to explore the methodology for determination of particulate matter in large-volume parenterals was reported (262). A comparison of results obtained from visual inspection, Coulter counter measurements, microscopic examination, and counting of particles collected on membrane filters was made to evaluate the visual method commonly used to control the cleanliness of parenteral solutions (263). It was concluded that visual inspection data obtained during the manufacturing process must be controlled by the laboratory afterward.

Sterility—Boucher (284) reviewed the various physical and chemical methods of sterilization. He concluded that synergistic sterilization, the use of combinations of chemical and physical methods, is on its way to making a profound impact not only in the pharmaceutical field but also in chemical, food, and decontamination industries. The current status of biological indicators was discussed, and plans for future studies were outlined (285). One investigator (286) reported significant differences found among five commercial biological indicators with regard to bacterial count and performance as measured by survival and kill in 10 autoclaves at 121°. He called for further work in the improvement and standardization of these indicators.

The use of cellulase in membrane sterility testing of solutions containing carboxymethylcellulose was discussed (287). An empirical filtration rate test was developed for determining cellulase activity. A group of compounds which rapidly inactivate certain antibiotics and thus facilitate sterility testing of the antibiotic solution was reported (288). The factors necessary to consider in establishing a successful ethylene oxide sterilization cycle were discussed (289). As an example, these factors were applied in the sterilization of a production lot of plastic disposable syringes in paper wrappers. Two compounds, 2-chloroethanol (290) and chloroacetaldehyde (291), which have been associated with residual ethylene oxide in sterilized material were subjected to biological testing. Ethylene oxide sterilization was shown to have no effect on the microbiological activity of streptomycin sulfate, dihydrostreptomycin sulfate, neomycin sulfate, and paromomycin sulfate (292). A slight increase in the color of streptomycin sulfate and dihydrostreptomycin sulfate was noted.

Relative humidities of at least 50% were essential for the sterilization of spore-contaminated materials using formaldehyde (293). The history and an extensive review of the use of radiation methods for the sterilization of drugs were presented (294). Also reviewed was

the method of sterilization of air and gases used in the pharmaceutical industry (295). A survey was conducted by the Food and Drug Administration to obtain a profile of the microbial load in all antimicrobial ophthalmic ointments manufactured in the United States (296). Of the 82 batches of ointments from 27 manufacturers that were tested, 16 showed contamination. Pyrogen-free solutions of 5% glucose were obtained by sterilizing at 121–124° for only 12 min. (297). Unsterilized glucose solutions were shown to be pyrogenic by injection of 10-ml. portions into rabbits, resulting in temperature rises of 0.7–1.3°. The Limulus test method for pyrogen testing was compared with the USP XVIII pyrogen test on a variety of commercial parenteral preparations (298, 299). The correlation was excellent, providing proper allowance was made for the greater sensitivity of the Limulus method.

Tablets and Capsules—Cooper and Rees (311) presented an excellent review of the literature from 1969 to 1971, including all phases of tableting research and technology. A comprehensive review article covering the various factors affecting tablet disintegration was presented by Lowenthal (312). Several other areas dealing with the general topic of tableting technology were reviewed (313–315). The other numerous publications dealing with pharmaceutical technology of tablets and capsules have been subdivided into the following classifications to facilitate a search of the literature: comminution, mixing, granulation, and drying; powder characteristics; compression; effect of excipients; and tablet coating. For a thorough review, consideration of the entire section is advised since there is an obvious overlap in the subject matter of the subclassifications.

Comminution, Mixing, Granulation, and Drying—Size reduction of drug compounds by a method involving phase conversion was reviewed (316). The rate of decrease of the mean molecular weight and molecular weight distribution of polyvinylpyrrolidone powders as affected by ball milling in nitrogen, air, and oxygen was investigated (317). The influence of the ball milling atmosphere on the probability of the polyvinylpyrrolidone molecule breakdown in a unit time and the molecular size distribution of the polymers formed by the breakdown in a unit time were discussed. The problems involved in mixing and mixing mechanisms of particulate systems were reviewed (318, 319). Mixing properties of barium sulfate, lactose, spray-dried lactose, magnesium oxide, and basic magnesium carbonate were investigated (320). The effects of the specific volume of the powders, time of mixing, and type of mixing equipment used were studied. Mixing of potato starch and sodium bicarbonate under a very high dilution ratio (2500–100,000) was studied using a radioactive tracer technique (321). The results of this study demonstrated that the state of fully random mixing does not depend on the particle-size characteristics of the diluent. However, other workers using radioactive tracer techniques determined that mixing efficiency was very dependent on the particle size of the diluent (322, 323). The dependence of the degree of mixing and the time of mixing on the speed of rotation and quantity of powder to be mixed in solid–solid mixing was investigated for industrial applications (324). To obtain the same results with scale-up of the mixing equipment, consideration must be given not only to the geometric and dynamic similarities but also to the ratio between size of sample and size of batch in both pilot and largescale equipment.

Calcium phosphate requires more granulating fluid to produce a cohesive mass during wet granulation than other tablet diluents, such as lactose or starch (325). It was postulated that the intraparticulate porosity is such in calcium phosphate that at low moisture contents the liquid becomes located within the particles, thus preventing the formation of pendular liquid bridges between adjacent particles. Lactose granules were prepared by massing and screening, using water as a binder, and the effects of initial particle size, size distribution, and binder concentration on the physical properties of the granules were studied (326). Increasing the mean initial particle size decreased the amount of binder necessary to form granules and also decreased their strength, porosity, flow, and packing at equivalent moisture contents; narrowing the size distribution increased granule porosity but decreased strength even further. Granulations made by the spheronization method showed an improved granulation flow rate and narrow particle-size distribution as compared to a conventionally processed wet granulation (327). Other testing of this same method indicated that plate rotational speed was of great importance in establishing the geometric form of final granules but that dwell time did not have an appreciable effect (328).

The optimum parameters for granulation on laboratory scale and pilot plant equipment were investigated for a fluidized-bed spray granulation process (329). An increase in the amount of binding agent increased mechanical strength and decreased wear loss, while an increase in flow rate of fluidizing air and a decrease in feeding rate of the granulating fluid resulted in a particle-size decrease. Davies and Gloor (330) reported that the physical properties of fluidized-bed granulations were strongly influenced by the binder and the binder concentration. An increase in the binder concentration increased the adhesiveness, yielding less friable granules of a greater average size. Other workers obtained fundamental information on the relationship between

the amount of a binder and several characteristics indicating granulating state and properties of the granules formed (331).

A mixture formed by heating rosin and glycerol was found to be a satisfactory anhydrous binder for the granulation of tablet preparations (332). The surfaces of granules formed by the spray drying of aqueous slurries of salicylic acid and sodium salicylate with both gum arabic and polyvinylpyrrolidone were found to contain no holes or craters as compared to slurries spray dried with other binders such as gelatin, polyvinyl alcohol, carboxymethylcellulose, methylcellulose, tragacanth, and sodium alginate (333, 334). Sodium warfarin tablets prepared by a wet granulation method were unsatisfactory as to content uniformity due to the migration of the drug substance during the drying period (335). By using a TLC method, additives were selected which demonstrated inhibition of the migration of the drug substance. The use of ultrasonics for drying pharmaceutical granulations was discussed (336). It was reported that drying time was approximately one-sixtieth that of rack drying (337).

Additional references on comminution, mixing, granulation, and drying are listed in Table IX.

Powder Characteristics—Reviews of the physical–chemical methods of characterizing powder surfaces were presented (350, 351). Both Hiestand (352) and Pilpel (353) discussed various methods for obtaining meaningful physical data for cohesive pharmaceutical powders. The problem of solid dosage forms containing small amounts of active ingredients was treated statistically (354). Equations which included particle-size distribution were derived for the calculation of theoretical coefficients of variation of drug content for solid dosage forms. Particle size of materials had very little influence on compressed tablet properties with substances having weak particle-to-particle bonding, but it had rather considerable influence with particles having strong interactions (355).

A simple test to determine the proportion of micronized drug that can be used to prepare satisfactory mixes for tableting was reported (356). The test consisted of measuring the angle of repose of a micronized powder–coarse particle mixture as a function of the concentration of micronized material. Particle densities, packing changes, and sieving properties of five commercially available samples of magnesium stearate were investigated (357). The significance of sample variation in relation to pharmaceutical processing was discussed. Description and evaluation of various testing methods for determining powder flow and powder cohesiveness were the subjects of several papers (358–360). Results of a study investigating mechanical properties of dry powders over a range of temperatures resulted in a postulation that, under the influence of pressure, melting can occur at the points of contact between particles at temperatures below their conventional melting points (361). This hypothesis accounts for the formation of solid bonds which contribute to the strength and hardness of pharmaceutical tablets. The role of moisture in compaction of particulate material was studied (362). It was determined that moisture decreases the compact strength by reducing the strength of interparticulate bonds. The effect of moisture on tensile strength of bulk solids was determined (363, 364). At a constant state of packing, the tensile strength was shown to increase as moisture content rose. This was attributed to an increase in number and dimension of liquid pendular bonds.

Additional articles relative to powder characteristics are listed in Table X.

Compression—In a series of papers reporting studies of compression of powder-like materials, Bessho *et al.* (392–394) discussed, on a theoretical basis, stress distribution, density distribution, and energy involved. The ability to convert the load at which a tablet fails in tension under diametrical compression into a tensile strength was extended to deep concave tablets (395). It was demonstrated that sucrose tablets with an upper beveled edge capped at high applied forces unlike those tablets prepared with a flat upper face (396). This was thought due to high radial forces in the beveled top at the end of the compression cycle resulting in breakdown of interparticulate bonds formed during compression. Newton and Rowley (397) suggested that compaction force or pressure does not completely characterize the formation of a tablet. They offered the concept of force–time measurements as a possible solution. An instrumented punch and dye set was used to determine the force–displacement curve during compression of sodium chloride, boric acid, asagran, vitamin yeast powder mix, ibuprofen granulation, and acetaminophen (paracetamol) granulation (398). Although all of the materials behaved elastically following compaction, only sodium chloride was approximately linearly elastic.

A system designed to simulate the double-acting compression effect of rotary tableting presses was described (399). The double-acting compression was achieved by a controlled downward movement of the dye at a slower rate than the simultaneous downward movement of the upper punch. A 16-station high speed rotary tableting machine was fitted with pressure rolls containing piezoelectric transducers in the axles (400). The compaction force exerted at each tablet compression event produced an electrical pulse which could be fed to

an integrated-circuit pulse-discriminating unit. An extensive review by Cavaco (401) was presented on the various aspects of tablet production by direct compaction and included physical factors influencing the cohesion of solid particles, their behavior during compression, improvement of the agglomeration by solid adjuvants, and the final characteristics of tablets. Reviews on the compression of powders (402) and the physical phenomena in tablet compression were also presented (403).

Other articles concerning compression are listed in Table XI.

Effect of Excipients—The effect of various starches such as corn, potato, rice, arrowroot, and a compressible starch on the rate of dissolution of salicylic acid tablets was investigated (415). In all instances, the dissolution of the drug was fastest from tablets containing compressible starch, whereas the rank order of the dissolution times of the other starch formulations depended on the dissolution test method used. In a

study to determine the effect of intra- and extragranular maize starch on the disintegration of compressed tablets, intragranular starch resulted in the recovery of finer particles than when extragranular starch was used, but the disintegration time was longer with intragranular starch (416). Lowenthal (417) determined that starch grains were deformed by pressure and did not regain their original shape nor swell significantly when moistened. He concluded that the regaining of the shape of starch grains is apparently not the mechanism of action as a tablet disintegrant.

The effect of compression force on tablets containing sodium carboxymethylcellulose of two different molecular weights was measured (418). The lower molecular weight material resulted in tablets having larger specific surface area. An investigation of their disintegration properties showed that both cation-exchange resin and alginic acid were more efficient than calcium sodium alginate, sodium carboxymethylcellulose, and starch (corn) (419). Other studies determined that calcium sodium alginate compared favorably with alginic acid and starch when evaluated as tablet disintegrants (420). By using additives such as ethylcellulose, glyceryl monostearate, and sorbitol, it was possible to regulate the absorption levels for achieving a therapeutic effect with sulfosalicylic acid–polyvinyl chloride tablets (421). Tablets containing microencapsulated ferrous fumarate demonstrated that microencapsulation increased the dissolution of iron in gastric juice and reduced local irritation by preventing contact between the salt crystals and the gastric mucosa (422). Javaid and Cadwallader (423) studied 11 different compounds representing various classes of buffering agents with respect to their effect on dissolution of aspirin from tablet formulations. In general, carbon dioxide-producing agents such as sodium bicarbonate, magnesium carbonate, and calcium carbonate gave more rapid dissolution than the readily water-soluble buffering agents.

Magnesium stearate and sodium stearyl fumarate were compared as tablet lubricants in an antacid formulation and judged by punch force, distintegration time, and *in vitro* availability (424). By the three testing parameters used, sodium stearyl fumarate was superior. In another study, the pressure remaining immediately after compression was used as a measure of the lubrica-

ting effect (425). By this measurement, both lubricants were shown to be equal. It was reported that magnesium lauryl sulfate possessed the lubricating properties of magnesium stearate but not its waterproofing liability (426). Factors affecting the direct compression of tablets using microcrystalline cellulose were reviewed (427). Twenty-four formulations of placebo tablets made from eight excipients for direct compression and three disintegrants were evaluated under various conditions of relative humidity (428). The data were evaluated statistically so that the formulations could be given a relative ranking on the basis of maximum hardness, minimum change in disintegration time, minimum moisture uptake, and minimum change in volume. Jones (429) reviewed the growing evidence indicating that formulation of the capsule fill is the rate-determining step in disintegration and dissolution.

References to additional literature on effect of excipients are listed in Table XII.

Tablet Coating—Several different films cast from solutions of ethylcellulose or polyamide resin were plasticized with varying concentrations of cetyl (hexadecyl) alcohol or butyl (tributyl) citrate (451). The permeability coefficient of ethylcellulose films was substantially greater than that of films consisting of polyamide resin, and it was also noted that the permeability coefficient was dependent upon the plasticizer used as well as its concentration. Two formulations were developed using polyvinylpyrrolidone for film coating of tablets by the pan-coating method (452). The addition of ethylcellulose and shellac eliminated the tackiness sometimes associated with polyvinylpyrrolidone due to the hygroscopicity of the film formed but did not alter disintegration or dissolution rates of the tablets. An apparatus for placing a film coat on individual tablets for film evaluation was described (453). Talc and

magnesium stearate were evaluated as adjuvants in enteric-coated tablets (454). Incorporation of talc was more satisfactory in providing favorable enteric coatings and served to preserve or augment the hardness of the tablets.

Additional references on tablet coating are listed in Table XIII.

Suspensions—Thickening agents for formulation of suspensions, emulsions, and gels of pharmaceutical interest were reviewed (465). Hiestand (466) developed the probable mechanism for the control of floc structure by polymeric materials from the theory of polymer stabilization of disperse systems. Although quantitative predictions were difficult to make, the curdled look after flocculation suggested that inadequate polymeric material was present and, therefore, the average coordination number was too high. On the other hand, settling to produce a very thick, noncaking sediment was probably due to excessive protection by suspending agents. Several agents were investigated for their stabilizing properties on griseofulvin suspensions (467). Among polyvinyl alcohol, polyvinylpyrrolidone, polysorbate 80, sodium carboxymethylcellulose, dry milk, and kaolin, polyvinyl alcohol was superior.

A graphical method was described for determining the effects of concentration and particle size on the sedimentation of suspensions; this method was based on traditional formulas describing the motion of particles in a liquid under the action of gravity (468). In the determination of yield values of hectorite gels, advantages of the falling sphere method over the cone-plate viscometer were discussed (469). Studies on the effects of particle charge of barium sulfate preparations indicated that charge alone contributes little to stability and cannot explain adherence of barium sulfate to mucosal linings (470). A microscopic electrophoretic method was used to study dilute aqueous barium sulfate suspensions (471). The isoelectric point for barium sulfate was reported at pH 4.2, and the ζ-potential varied from 140 mv. at pH 1 to -120 mv. at pH 10. The problem of pH measurements in suspensions was investigated (472). In the suspensions studied, the Wiegner–Pallmann suspension effect played a role which, however, was not identical with the pH-disturbing effect due to anomalous diffusion potentials.

Two types of mechanisms of particle adhesion to glass containers were found (473) by examining the adhesion

of chloramphenicol treated with benzalkonium chloride: (*a*) simple adhesion without mutual affinity or interaction and (*b*) adhesion with affinity. The ζ-potential of chloramphenicol crystals and glass powder was determined, and its influence on the adhesion and adsorption was discussed. In similar studies, but using prednisone, Runkel and Palagyi (474) determined that maximum adsorption of particles to glass containers occurred at a concentration of benzalkonium chloride that was just sufficient to neutralize the inherent negative charge of the prednisone particles. When the average particle diameter of the prednisone was increased to 50 μ, adsorption was negligible and drainage characteristics were excellent. A review of the physical and chemical characteristics of suspensions, including free energy of particles, humectation, flotation, crystal growth, sedimentation, rheology, and flocculation, as well as their pharmaceutical formulation, was presented (475).

Additional references on the subject of suspensions are listed in Table XIV.

Emulsions—Several reviews on the effects of processing and manufacturing procedures on the physical properties of emulsions were presented (484–486). The methods used in the evaluation of the physical properties and stability of emulsions were also reviewed (487, 488). Sherman (489) stated that accelerated aging tests at high and low temperatures and under centrifuge conditions are not suitable for predicting stability of emulsions. He reported that the measurement of the electrophoretic mobility better relates to the stability of oil-in-water emulsions at room temperature and at 40°. The effect of ultrasonic power on a mineral oil–surfactant–water emulsion system was reported (490). An optimum amount of energy was required to produce the best emulsion, but the effects of the hydrophilic–lipophilic balance (HLB) and surfactant parameters appeared to be more important in the emulsions studied. The time dependence of the droplet size distribution and the phase-inversion occurrence times were determined as functions of volume ratios, emulsifier concentration, and impeller speed for mixing water and carbon tetrachloride containing polysorbate 60 in a baffled, stirred tank (491). Phase inversion, which was very sensitive to emulsifier concentration, occurred even during stirring and the final specific interfacial area was independent of the emulsifier concentration.

An emulsion formulation suitable for freeze drying and reconstitution was described (492). Mannitol, urea, and glycine were used as supportive agents. In studying emulsifying agents, it was demonstrated that the critical

HLB numbers increased approximately linearly with the decrease of the logarithm of the oil phase dielectric constant (493). Pharmaceutical and chemical problems involved in the choice of an emulsifier for cosmetic formulations including anionic, amphoteric, cationic, and nonionic surfactants were discussed (494). Mathematical expressions for the HLB, minimum volume of emulsifier for oil-in-water and water-in-oil emulsions, and stability of the emulsions were developed. It was suggested that the optimum stability of oil-in-water emulsions stabilized by 1:1 molar ratios of sorbitan esters (Spans) and polysorbates (Tweens) is due to association between the emulsifier molecules adsorbed at the oil–water interface (495). The various analytical procedures for determining HLB values of emulsifiers do not account for interaction between emulsifiers and the aqueous and oil phases. It was, therefore, suggested that phase-inversion temperature determinations may provide more meaningful values (496), and a programmed viscometric technique was described for determining phase-inversion temperatures (497). With surfactant mixtures of polyoxyethylene ethers of fatty alcohols (Brij 92 and Brij 96), the phase-inversion temperature

was found to rise in approximately linear fashion as the HLB increased toward the optimum value.

The stability of mineral oil (Nujol) emulsions emulsified with sodium lauryl sulfate could be increased by adding lauryl alcohol (498). Speculation attributed the increase in stability to adsorption of lauryl alcohol at the interface not occupied by adsorbed sodium lauryl sulfate. Other workers concluded that combinations of emulsifying agents, as opposed to single emulsifying agents, produce more stable emulsions (499). The structure of oil-in-water emulsions stabilized by binary surfactant mixtures was represented schematically according to the oriented wedge theory (500). The stability of oil-in-water emulsions of paraffinic oils stabilized by sodium lauryl sulfate and sodium cetyl sulfate was shown to increase with increasing chain length of the paraffin (501). It was suggested that long-chain paraffin molecules are strongly held at the interface by association with alkyl sulfate molecules, thus increasing the coherence of the interfacial film. Starch treated with 4–5% glycerol monostearate formed a stable cream emulsion and was shown to be an effective emulsifier for cosmetic creams with a high water content (502).

Other references pertinent to emulsions are listed in Table XV.

Ointments and Creams—Particle dispersion as measured by the electron microscope was determined for salicylic acid in white petrolatum and polyethylene ointment bases and for a base of calcium soap and mineral oil (532). The rheological properties, as well as the consistency of the polyethylene base, were optimal and gave the best release of medication. The pharmacology, physical chemistry, and clinical actions of polyethylene glycol-based ointments containing hydrocortisone, antibiotics, iodine, potassium iodide, boric acid, sulfur, and coal tar were reviewed (533). Other reviews stressed the importance of selecting the correct vehicle for assuring greatest effectiveness of a drug applied to the skin (534, 535). Release of citric acid from ointments prepared with petrolatum or hardened soybean oil was enhanced by the addition of 1–7.5% egg lecithin (536). Phosphatidylcholine was considered to be the essential factor responsible for this effect. Ointment bases containing surfactants gave better release of salicylic acid, chloramphenicol, and tetracycline than bases without them (537). The HLB values of the surfactant incorporated into the ointment base influenced the release pattern, but the variation did not fit any general pattern and differed for different bases and drugs. When comparing hydrophilic and hydrophobic bases, it was shown that sulfathiazole and potassium iodide revealed higher release coefficients from hydrophilic bases (538).

The effect of some physicochemical properties of palmseed oil on the liberation of drugs from the vehicle was investigated, and it was found that release was more rapid and greater from palmseed oil of higher iodine numbers and also from bases that were mixtures of small-chain fatty acids (539). The release of citric acid was determined *in vitro* from ointment bases composed of white petrolatum and various natural oils and fats (540). Accelerated release was observed solely after addition of palmseed oil, and the rate of release was directly proportional to the content of palmseed oil in the base. Twelve protective creams containing silicone oil were evaluated by conductometric determination of diffusion rates for sulfuric acid and sodium hydroxide (541). The higher the diffusion rate, the lower was the protective capacity of the preparation. The technology for an anti-inflammatory ointment base for gums and oral mucosa was described (542). The penetration of crystalline particles of cosmetic and pharmaceutical formulations into the horny layer of human skin was evaluated by microscopic evaluation of stripped films of the stratum corneum in polarized light (543). Penetration was judged to be dependent on particle shape and solubility in the constituents of the horny skin layer rather than on particle size. A greater diffusion of methylene blue was obtained from an ambiphilic emulsion ointment on an agar base than from either lipophilic or hydrophilic emulsions, indicating the superior drug dispersal qualities of the ambiphilic systems (544).

Barry and Grace (545) investigated the rheological parameters operative during application of topical preparations to the skin. The information derived was used to develop a method for instrumentally determining rheological conditions in routine industrial control procedures and a spreadability screening test for application during innovative work prior to field trials. A review was presented on the use of creams in pharmaceuticals and cosmetics with examples of formulations and industrial manufacturing techniques (546). Polli *et al.* (547) described a laboratory investigation conducted to evaluate the use of conventional sterilizing techniques during manufacture of sterile topical dosage forms. Methods determined suitable for the sterilization

Suppositories—For lipophilic bases, the homogeneity of suspensions of active agents in the bases, the rheological behavior at 37–40°, the viscosity at 40°, and the thixotropic index could be used as criteria for determining the suitability of these bases for use in suppositories (567). The index of emulsionability, the maximum percentage of water that a suppository mass may contain as a stable emulsion, was determined by the uniformity of color given to the mass by Sudan II (568). Good emulsifying power was correlated with higher dehydration tendencies. The addition of sorbitan esters (Spans) or sorbitan ester–polysorbate (Span–Tween) mixtures to suppositories containing aminopyrine (amidopyrine) decreased their disintegration time and thus accelerated the release of the active ingredient (569). Approximately twice as much sodium iodide was absorbed in rats from rectal suppositories prepared with polyethylene glycol, Witepsol S, or Witepsol E as from those prepared with cocoa butter (570). Absorption was measured by ^{131}I activity in the thyroid.

Addition of monoglycerides to suppository bases did not improve the passage of drugs through a membrane (571). As the amount of monoglycerides in the base increased, the amount of liberated drug decreased. Triglycerides gave the opposite effect. In studies on Shay butter, it was determined that the addition of 20% hard paraffin or 15% white beeswax was necessary for use in suppositories (572). Gelatin and methylcellulose used in 2 and 0.75% concentrations, respectively, were more suitable than 1% sodium alginate, 2% polyvinylpyrrolidone, or 4% yeast in the manufacture of suppositories by freeze drying (573). The choice of active ingredients present in the suppositories and their concentrations strongly affected the lyophilization properties of the base compounds. Therefore, the appropriate base must be chosen to correspond with the desired active ingredient.

Additional references on suppositories can be found in Table XVII.

Aerosols—Several aspects of aerosols were reviewed, including the development of pharmaceutical aerosols (580), the pharmaceutical uses of aerosols (581), aerosol drug therapy (582), solvent propellants (583), and technical problems of powder aerosols and aerosol propellants (584). The series of events, including product development, leading to the marketing of a new aerosol product was traced through the eyes of a cosmetic chemist (585). Sciarra *et al.* (586) investigated the possible formulation of various epinephrine salts such as malate, maleate, and fumarate for inclusion in aerosol dosage forms. The results of solubility studies of these salts in propellants indicated that the formulation of epinephrine salts as an aerosol dosage form must be accomplished through use of a cosolvent or by formulating a dispersed system. A stable aqueous suspension of a mixture of thymol, peppermint oil, and eucalyptus oil was described for application as an aerosol (587). The use of nitrogen at 6 atmospheres as the propellant gave aerosol particles of 40–50 μ in diameter. The particle-size distributions of four hair-spray formulations were measured as a function of the propellant composition (588). The mass median diameters of the sprays were found to decrease with increasing pressure of the aerosol.

A method was described for determining comparatively the proportion of the emitted dose of an aerosol formulation that penetrated a system of wet-lined tubes and arrived at a filter (589). Clinical work with bronchodilators showed that this method permitted comparisons between different formulations of the same dose of the same drug. By using a conifuge, measurements were made of the particle-size distribution of aerosols generated by three types of nebulizers intended for therapeutic use (590). After converting the size distribution to a mass distribution, the deposition of different fractions in the human respiratory tract could be predicted. The critical variables that control the movement of aerosol particles were found to be the size and density of the individual particles, their initial velocity, and the velocity of the surrounding air (591). These may be adjusted, within limits, to promote the desired deposition of the particles or to prevent an unwanted deposition.

Timed Release—A listing of recognized types of timed-release dosage forms included: barrier coating, imbedding in a slowly eroding matrix, imbedding in a plastic matrix, repeat action through layering in tablets, mixture with ion-exchange resins, imbedding in a hydrophilic matrix, epoxy resin beads, soft gelatin retard capsules, and drug complexing (592). Methods of prolonging the action of antibiotics and some other drugs by altering molecular structure so as to decrease solubility and by using coatings or capsules to delay absorption were discussed and evaluated (593). Hollister (594) suggested that although oral timed-release medications delay or slow absorption of drugs, the advantages are often slight or, at times, disadvantageous. The oral antidiabetic buformin (butylbiguanide), which has a normal half-life of approximately 2 hr., was formulated in a timed-release form for which serum concentration remained almost constant for approximately 7 hr. (595). Timed-release tablets of the insoluble matrix type containing 15 mg. phenylpropanolamine hydrochloride (norephedrine chloride) and an antihistaminic were evaluated (596). *In vivo* and *in vitro* drug release showed good agreement with all tablets except one formulation in which the *in vitro* dissolution rate depended on the pH of the dissolution medium.

Surface areas and transverse surfaces of fracture from timed-release tablets manufactured by the imbedding principle were investigated (597). Pressure-dependent differences in the texture of tablets influenced the drug release rate. Granulations for tablets with prolonged action were prepared containing lauric, palmitic, and stearic acid as adjuvants, applied by coating (598). The release rate *in vitro* decreased with the increasing molecular weight of the acids. A method for preparing timed-release calcium chloride tablets in which this ingredient was suspended in a melt of cetyl alcohol, hydrogenated cottonseed oil, and stearic acid was described (599). The release rate of sodium salicylate from timed-release tablets was measured as a function of the amount of magnesium stearate in the tablet (600). Large amounts of this agent blocked the release of the active substance, while too small amounts caused a rapid disintegration of the tablets. The possible use of biodegradable polymers impregnated with the drug for timed-release preparations was discussed in terms of diffusion and permeability theories (601).

Intravenous administration of sodium barbiturates formulated in a soybean oil emulsion showed prolonged-action effects (602). It was postulated that this effect was caused by the oil droplet acting as a depot, releasing the drug to blood and brain capillaries by direct contact, and, therefore, serving as a bridge between the circulation system and the blood–brain barrier. A parenteral suspension of microspheroids consisting of microcrystals of drug surrounded by a totally enclosing semipermeable protective shell was suggested as a prolonged-action intravenous dosage form (603). Release of drugs from the circulating microspheroids markedly prolonged the apparent biological half-life of the drug quinacrine hydrochloride. The alginic acid salt of pilocarpine, when administered as an ophthalmic disk in the cul-de-sac of the eye, provided a significantly greater miotic response than was obtained from pilocarpine solutions (604). This observation suggested that the use of solid ophthalmic dosages in the treatment of glaucoma may be more effective and require less frequent drug administration to produce a prolonged physiological effect.

Cosmetics—Microbiological contamination of cosmetic products continues to be a subject of great concern to the cosmetic industry. To facilitate a literature search relevant to this critical problem, the subject of cosmetics has been divided into the following subclassifications: microbiological contamination of cosmetics, and aspects of formulation and technology of cosmetics.

Microbiological Contamination of Cosmetics—Although contamination by Gram-negative organisms, particularly those of the pseudomonas group, is still a problem, the cosmetic industry continues to show a concerted effort to improve the quality of its products (615). Three years ago, 61 of 250 samples examined were contaminated; last year, only eight of 223 examined were reported contaminated. A review of the microbiological control of nonsterile products and raw materials was presented (616). A listing of essential oils, *e.g.*, orange and thyme oils, active against *Bacterium coli*, *Bacterium typhi*, *Corynebacterium diphtheriae*, *S. aureus*, *Streptococcus pyogenes*, and meningococcus was given (617), and other therapeutic properties of these oils were presented.

The inhibitory effect of ethanol and propylene glycol against three strains of *P. aeruginosa* was investigated in the presence and absence of 0.1% potassium sorbate (618). Results suggested that ethanol concentrations of 5% or more may exert a preservative action and that 10% propylene glycol is also suitable. The effect was augmented by addition of potassium sorbate at pH 6–7. Bruch (619) enumerated the common contaminating organisms present in nonsterile products and listed those that are most dangerous to certain types of products. The organisms of clinical significance in pharmaceutical and cosmetic preparations are "free living" types of Gram-negative bacilli and belong to the klebsiella, enterobacter, serratia, pseudomonas, and flavobacterium groups (620). Many of them have a remarkable ability to survive and even to multiply in the presence of commonly used disinfectant and bacteriostatic agents. The potential hazard to consumers from use of eye-area cosmetics contaminated with *P. aeruginosa* was evaluated (621). Experimental results suggested that corneal destruction resulted from the organism's elaboration of a collagenolytic enzyme, which may be activated *in vivo* during the infective process. A full discussion of the importance of monitoring the chemical and microbiological quality of the water used in cosmetics was presented (622).

Aspects of Formulation and Technology of Cosmetics—In suntan preparations containing a commonly used screening agent, oil-based vehicles gave better sunburn protection to human skin than oil-in-water emulsion vehicles (623). However, it was also reported that oil-in-water emulsions were superior in promoting tanning. Data were presented to indicate that substantive proteins, protein hydrolysates, may be useful moisturizing agents in skin-care products (624). Polyamino acids may have an immediate effect on the skin and/or hair, but polypeptides must be changed by enzymatic and acylatic processes to form polyamino acids (625). These processes of change often failed or were delayed, especially with unhealthy skin or hair, but polyamino acids always produced the desired results. Stratum

corneum, in the form of excised callus, was immersed in distilled water, organic solvents, and aqueous solutions of detergents, humectants, and soaps for different lengths of time (626). Weight increases were compared in an effort to determine the factors influencing the water content of skin and the conservation of this water. Although the chemical pyrrolidonecarboxylic acid has been known for many years, only recently was it reported that pyrrolidonecarboxylic acid, especially in salt form, was a naturally occurring moisturizing agent in the skin (627).

Idson (628) reviewed the factors that caused skin to retain or lose moisture, such as relative humidity, hygroscopic materials normally present in the skin, and water-binding mechanisms in the stratum corneum. In a discussion on humectants *versus* moisturizers, humectants were defined as components of cosmetic products that prevent water or moisture loss from the preparation and moisturizers as active additives which restore moisture to the stratum corneum (629).

Titanium dioxide was colored to increase its applicability in cosmetic preparations by reducing a synthetic vat dye to its leuco base followed by the addition of sufficient powdered titanium dioxide at 80° under carbon dioxide (630). Electron microscopy and X-ray analysis showed that a thin, well-adhering layer of the dye coated the particles. Tests to determine the safety of cosmetic products for infants were described. It was concluded that more attention should be paid to developing products best suited for the skin of particular age groups (631). Bell (632) predicted that, due to improvements in enzyme technology, the addition of these agents to cosmetic formulations will open a new field in the near future. Squalene was cited as a natural cosmetic raw material which could be incorporated into preparations to act as an emollient, humectant, and lubricant (633). The interrelations between moisture regulators and lipids of the dermal surface were discussed, and widely used test methods were described (634). Several formulas for modern cosmetic preparations using moisturizing factors were given.

Common ingredients used in emollient preparations and their contribution to emolliency, elegance, *etc.*, were reviewed (635). Properties of white mineral oils and their application to cosmetic preparations, differences between paraffinic and naphthenic oils, and the requirements of official compendia for these oils were discussed (636). The physical and chemical properties of various grades of white mineral oil used in cosmetic formulations were compared (637). Systems for thickening liquids using Carbopol and no alkali were described (638). The use of Carbopol as a thickening agent depended on having polyethoxy or polyhydroxy liquids present, in which case the thickening is based on hydrogen bonding. Courtney (639) presented an interesting review on the history, formulation, structure, and future of gels in cosmetics and toiletry products. Experimental results suggested that water affects the mechanical properties of single fibers of hair, and these in turn strongly influence the set-holding characteristics of hair tresses (640). The binding of water appeared to be a site binding process; *i.e.*, interactions occurred in stoichiometric ratios between the water molecules and the various hydrophilic groups of the protein (carboxylic, amino, and peptide groups) and were governed by the mass action law.

Packaging—The factors that should be taken into consideration when designing a "childproof" package were discussed (667). The mechanism, functioning, filling, performance, precision and constancy of dosage, compatibility with valve and solution, safety, and application of metering valves were described and discussed (668). The uses of polyethylene, polyvinyl chloride, polystyrene, and blends of these plastics and the effects of processing on their suitability for packaging of cosmetic emulsions were outlined (669). Evaluation methods for plastics that are to be in contact with medicinal preparations were described (670, 671). It was stressed that approval of a formulation is only valid for the product–plastic combination (672). Polypropylene containers were shown to be satisfactory for storing aqueous solutions containing common phenolic preservatives (673). Sorbic acid solutions in the same containers deteriorated rapidly. In evaluating disposable rubber closures for bulk irrigating solutions, it was ascertained that the amount of total extractives from the closures was influenced by the total mass of the closure as well as its surface area (674). Based on the UV absorption decrease of aqueous solutions in the presence of various plastics, the effect on the stability of local

anesthetics in the presence of polyamides 6 and 12 and high pressure polyethylene of low crystallinity was determined (675). Polypropylene, polyvinyl chloride, polystyrene, and polycarbonate had no influence.

The biological activity and toxicity of stabilized amyl nitrate were not affected by long storage when cellular polyurethane vial closures were used (676). Effervescent granules were stored in various containers for 6 months and evaluated for carbon dioxide loss (677). Aluminum foil (2 mm.) provided the best protection for this type of product. Guidelines were presented covering the selection of syringes in process controls and procedures for prepackaging parenteral drug products in hospital pharmacies (678). The shattering of sterile vacuum-sealed fluid bottles during removal of the cap was reported (679). Apparently this can occur when the cap is removed quickly with the bottle in an inverted or partially inverted position due to a "water hammer" effect. Instructions were presented to the practicing pharmacist for the packaging of nitroglycerin tablets for preventing loss of potency during storage (680). The use of varnished aluminum tubes for packaging of ophthalmic ointments partly resolved the problem of metallic particles (681). The manufacturing process of these tubes for ointments was reviewed briefly, and the different methods used in testing were described. Leakage tests, currently in general use, for flame-sealed ampuls were demonstrated to be inadequate for determining whether passages to the outside exist in finished ampuls (682). Those containing these passageways may or may not pass existing leakage tests, depending upon the severity of the test.

Table XX contains additional references in the area of packaging.

Equipment—A European cylindrical shredder was described, and its performance was evaluated for wet and dry granulations (698). It was shown to be comparable to the Fitzpatrick mill for normally wet granulations but superior when the material was overly wetted.

The principle of sieving pharmaceutical materials by gyratory vibration was reviewed and compared with the efficiency of standard vibratory methods (699). For powder mixtures containing low concentrations of active materials, the Erweka planetary mixer, with a fixed vat, was shown to be superior to the Erweka cubical mixer in the rapidity with which homogeneity was obtained (700). The speed of dispersion of the active principle throughout the excipient was greater in the cubical mixer, but the latter was unable to reduce the agglomeration of particles. Methods for testing the friability, disintegration time, and dissolution behavior of tablets using the E-70 apparatus were reviewed, and the details of testing, the prescribed limits of disintegration times, and the performance of the test were emphasized (701).

Shah (702) reviewed the nondrying applications of spray drying including stabilization, blending, use for reaction mixtures, timed-release formulations, and waste disposal with the production of useful by-products. The design of a continuous manufacturing process for an oil-in-water cosmetic cream was described (703). In arriving at a final process design and selection of equipment, emphasis was placed upon the determination of the basic chemistry responsible for the stability and characteristic consistency of the product and the determination of the relative importance of process and ingredient variations. The fundamental microbiological aspects of modern cleaning and sterilizing equipment were discussed (704). Beard (705) discussed the variables such as speed, changeover time, and product shape and how these considerations govern the choice of tablet-counting equipment. A prototype irradiation module was built and successfully tested (706). This unit could be adapted to packaging lines for the sterilization of packages and materials prior to filling at normal line speeds.

Additional references on equipment can be found in Table XXI.

PHYSICAL PHARMACY

Methods of preparation of three polymorphs, two solvates, and an amorphous modification of sulfameter (sulphamethoxydiazine) were described (713). The interconversion of these forms under various conditions of heating, suspension in water, and grinding, as well as dissolution behavior, was studied. Thermal analysis of sulfanilamide polymorphs indicated that the α-, β-, and δ-forms are transformed to the γ-form prior to melting (714). The phase-transition temperatures and heats of transition was as follows: α-form, 108°, 358 cal./

mole; β-form, 131–141°, 347 cal./mole; and δ-form, 108°, 386 cal./mole. Shefter *et al.* (715) used X-ray crystallographic methods to determine the structures of sulfadimethoxine, sulfadoxine, and sulfisoxazole. The molecules had similar conformations about their sulfonamide linkage but had markedly different orientations of their respective heterocyclic rings relative to the sulfanilamide portion of the molecule. In a study of polymorphism in sulfonamides, it was postulated that electron-withdrawing and electron-donating groups at the *N'*-position influenced the strength of the hydrogen bonds that form and, hence, the tendency of these compounds to exhibit more than one crystalline form (716). In some cases, however, minor alterations in structure resulted in disproportionate changes in the compactness of the crystal lattice, and this fact made it difficult to develop broad generalizations applicable to large groups of compounds.

The controversy over polymorphism in aspirin continued. Schwartzman (717) attributed apparent polymorphism to different crystal habits caused by different solvents used for crystallization, and dissimilar melting points to poor transfer of heat caused by the larger crystal size or to possible crystal defects. Other workers attributed the apparent polymorphism to salicylic acid impurities present in the aspirin samples tested (718). On the other hand, Borka (719) presented evidence for the existence of two polymorphic forms of aspirin. Solution phase transformation of the metastable Form II into the stable Form I was cited as further evidence for the existence of Form II.

The properties of liquid crystals were studied by spectroscopic or electromagnetic methods such as X-ray, IR, UV, NMR, double-refraction, and dielectric constant (720). The expansion coefficient and surface tension were also measured to obtain thermodynamic information. Phase transitions in mixtures of mesomorphic cholesteryl esters were studied by visual thermal microscopy (721). Binary mixtures of saturated cholesteryl esters showed transitions from the solid phase to the mesomorphic phase at temperatures that were depressed well below the phase-transition temperatures of either pure compound. The phase-transition temperatures in the solid, liquid crystal, and isotropic liquid states of four cholesteryl esters were determined by polarization microscopy, differential thermal analysis, and measurement of the dielectric constant and dielectric loss (722). Data on transition temperatures obtained from these various methods were generally in good agreement with each other and were found to be useful for mesophase identification.

Dissolution rates of drugs in solid dispersions in polyethylene glycol 4000 were investigated, but no differences in dissolution rates were shown in drugs that were not soluble in polyethylene glycol 4000 (723). In cases where drugs were soluble in polyethylene glycol 4000, an increase in dissolution rate was noted. Surpuriya and Higuchi (724) studied the kinetics of cholesterol and desmosterol transfer from aqueous sodium lauryl sulfate solutions and from sodium taurocholate–lecithin solutions into hexadecane and vice versa by means of the multiparticulate dispersion technique. The results were discussed in terms of an interface-controlled mechanism being operative, involving solute–micelle complex or free solute in the rate-determining step.

The diffusion of ephedrine, sulfathiazole, chloramphenicol, acetaminophen (paracetemol), isoniazid, and amphetamine in solutions of polysorbate 40, polysorbate 80, and polyethylene glycol 1000 monocetyl ether (Cetomacrogol 1000) was studied (725). With the exception of isoniazid, the observed diffusion coefficients, corrected for resistance to flow, depended upon the surfactant used and both the drug and surfactant concentrations. An extensive investigation of the kinetic and thermodynamic aspects of the transfer of sulfonamides through immiscible phases was reported (726). Included was a postulated activated complex for the interphase transfer of these compounds. A linear relationship with unit slope was found between the logarithm of the intrinsic partition coefficient of *p*-alkyl pyridines and the logarithm of the extraction constants of the corresponding ion-pairs of the protonated base chlorides, as determined in chloroform–water and octanol–water systems (727). Because of methylene increments occurring distantly from the polar portion of the molecule, their influence upon the oil–water partition coefficient would be expected to be the same for the free base and ion-pair. Yalkowsky *et al.* (728) suggested that change in crystal structure as a function of chain length in alkyl *p*-aminobenzoates is somewhat analogous to micelle formation within a homologous series. The lower members of a surfactant series exist only as monomers whose properties are primarily determined by the polar group; but as the chain length is increased, the increasing amphiphilic character provides for orientation of the molecules into a particular structure, the micelle. Further increases in chain length serve to increase the stability of these structures relative to the monomeric state.

By using diffuse reflectance spectroscopy, the interaction between dextroamphetamine sulfate and spray-dried lactose and dextrose in solid–solid mixtures was studied (729). Two new absorption maxima were observed in the reflectance spectra of heated samples and were attributed to the chemisorption of the amine molecules on the surface of the sugars. In preformulation studies of a lyophilized product, melting-point–composition diagrams were constructed and percent melt values at room temperature were calculated (730). Final product physical appearance correlated well with calculated percent melt as ascertained by controlled lyophilizations. The characteristic differences between one gel and another were reviewed and traced to the variations of framework flexibility, number and nature of cross-links, attractions and repulsions between framework elements, and interactions with solvents (731). Theoretical calculations based on the Debye–Hückel theory indicated that for weak monoprotic bases that do not involve a hydroxyl group, a stoichiometric pKa determined at any ionic strength would be no different from the thermodynamic pKa (732). The pKa's of two local anesthetic amines determined at several ionic concentrations supported this theory. Terada (733) described a method for determining true partition coefficients for amphoteric acids by determining the

apparent partition coefficients as a function of pH. The values obtained for *p*-aminobenzoic acid, sulfonamide, and sulfameter (sulfamonomethoxine) agreed well with the results of others.

One of the most potentially successful approaches to drug design is the attempt to place correlations between changes in molecular structure with changes in biological activity on a quantitative and predictive level (734). While qualitative efforts were made in this area by chemists and pharmacologists for over 100 years, more recent progress illustrates the potential of regression analysis, molecular orbital calculations, and parameterization using various physicochemical measurements. A review was presented dealing with basic areas of molecular orbital theory important in interpreting drug activity (735). Peradejordi *et al.* (736) investigated the relations existing between electronic structure and base strength of benzacridines and their amino derivatives using semi-empirical molecular orbital calculations. Their results indicated that the energy to protonate a nitrogen derivative of a conjugated hydrocarbon may be divided into the terms ΔE_ρ and ΔE_π for changes in localized and delocalized energies, respectively, an energy for solvation, and a term for steric hindrance to protonation.

Additional references relating to physical pharmacy are listed in Table XXII.

Dissolution—Dissolution times of some commercially available tablets of sulfamethizole were measured using four different methods, but no correlations of predictive value were obtained between dissolution and absorption parameters (770). The stationary-basket method discriminated best between formulations and was the most useful for quality control purposes. A new approach was described for increasing the dissolution rate of relatively insoluble powders (771). It was based on the concept of increasing the surface available for contact with dissolution media and was accomplished by equilibration of the drug in an organic solvent on an insoluble excipient with an extensive surface area (*e.g.*, fumed silicon dioxide). An increased rate of release from these minuscular drug delivery systems was observed in all instances, and it was suggested that a decrease in particle size was a major factor in improving the dissolution rates (772).

To minimize effects of differences in particle-surface areas which occurred from experiment to experiment and during each individual experiment, Higuchi *et al.* (773) employed a "concentration jump" technique during the determination of dissolution rates in solvents containing complexing agents. The results demonstrated the importance of the magnitudes of both the diffusion coefficient of the complexing component in the solvent and of the stability constant of the complex on dissolution kinetics. *In vitro* studies on the dissolution rate of cholesterol monohydrate crystals in micellar bile acid solutions showed that the addition of lecithin decreased the dissolution rate, even though lecithin increased the equilibrium solubility of cholesterol in these systems (774). The reduction in rates caused by lecithin was attributed to a large crystal–solution interfacial barrier.

The total solubility of benzoic acid in aqueous solutions of polysorbate 80 was shown to increase linearly as the concentration of the surfactant was increased (775). Since the concentration of polysorbate 80 was increased with a limited increase in viscosity of the micellar solution, the dissolution of benzoic acid was increased to a maximum rate, but further increases in the concentration of polysorbate 80 decreased the dissolution medium. Utilizing *in vitro* studies, Tawashi and Piccolo (776) demonstrated that very low concentrations of FD&C Blue No. 1 significantly reduced the dissolution rate of sulfathiazole crystals in 0.04 *M* sodium cholate solutions. These results were confirmed by *in vivo* absorption studies in man. The intrinsic dissolution rates of the monohydrochloride, dihydrochloride, and disulfate salts of an experimental antihypertensive were studied (777). Although there were significant differences in the dissolution rates of these salts, comparative hypotensive activity in anesthetized dogs showed that the three salts did not differ from each other.

Although the dissolution rate of powdered aspirin (acetylsalicylic acid) is inversely proportional to crystal size, the opposite was found true in tablets (778). This was shown to be due to the agglomeration of the fine particles, but this effect could be hindered by appropriate adjuvants. Under stirred and sink conditions, the dissolution of benzoic acid in aqueous solutions of polysorbate 80 was shown to occur in accord with the diffusion layer model (779). The micellar diffusion coefficient was decreased as the quantity of solubilized species in solution was increased, presumably due to changes in the size and weight of the solubilized species. Particles dissolving in a dissolution medium initially decrease in linear dimension while the number of particles remains unaltered. However, at a particular point in time, the smallest particle disappears and, from that point on, the number of particles decreases (780). These phenomena were simulated on a digital computer, and the agglomerate dissolution pattern under sink conditions was shown to follow a cube-root law.

The effect of low concentrations of an *n*-alkyl polyoxyethylene surfactant on the dissolution of hydrocortisone was investigated (781). It was shown that the plot of the dissolution rate constant *versus* the surfactant concentration exhibited a pronounced maxima at the region of the critical micelle concentration (CMC). Rates of dissolution of salicylic acid were determined at constant pH in the absence of buffer salts by using a pH-stat (782). The dissolution rate increased with increasing pH up to a maximum of pH 4. Wadke and Reier (783) described a method whereby transition temperatures and other thermodynamic parameters associated with the transitions of chloramphenicol palmitate form B, anhydrous ampicillin, and theophylline to chloramphenicol palmitate form A, ampicillin trihydrate, and theophylline monohydrate, respectively, were determined from intrinsic dissolution rates. In a series of papers, Kildsig and coworkers (784–787) investigated some parameters involved in the dissolution mechanism including concentration gradients, surface tension of solids, solid–liquid interface energies, and effective interfacial concentrations. The release of a mixture of two acidic drugs (benzoic and salicylic acids) and a mixture of two amphoteric drugs (sulfadiazine and sulfapyridine) from an inert matrix into different buffers was investigated using the physical model approach (788–790). Equations were derived describing the diffusional behavior and interactions of the various species under different conditions. The *in vitro* release of four progesterone-type steroids from a silicone polymer was studied by Roseman (791) and was found to be dependent upon the molecular structure of the steroid. Since the diffusion coefficients of the steroids were of the same magnitude, the diversity in release patterns was mainly attributed to the difference in the polymer solubilities of the steroids.

A flow visualization technique was used to compare flow patterns in several kinds of dissolution apparatus in wide use (792). The technique readily revealed the undesirable characteristics and provided a rational basis for judging an empirically developed dissolution apparatus. The shape of the dissolution flask, which is not clearly defined in USP XVIII and NF XIII, can significantly affect dissolution patterns (793). Formulators should be aware that these differences exist, and it was recommended that there be more definitive specifications for the dissolution vessel in the compendia. Tingstad *et al.* (794) described a modified, continuous flow column-type dissolution apparatus using commercially available components. Specific advantages of the flow method, especially for sublingual tablets, were cited. Dissolution studies were carried out on commercially available dosage forms of 300-mg. lithium carbonate tablets and capsules (795). Log-probability analysis of the data showed significant differences in the dissolution of the two dosage forms. The usefulness of a

rotating compartmentalized disk for dissolution rate determinations was demonstrated by the ease with which it discriminated between experimental capsule formulations and commercially available chlordiazepoxide hydrochloride capsules (796). An automatic multiple-channel apparatus for dissolution rate studies under sink conditions was developed, and an economical and reliable system for transmitting the experimental data to a remote computer was described (797).

Table XXIII lists additional references on dissolution.

Solubility–Solubilization Phenomena—Both Mukerjee (831) and Nelson (832) presented interesting discussions on the theoretical aspects of applying the Kelvin equation to the solubility of solids. Both refuted the concept that the effect of particle size on solubility is due to entropy changes alone. Methyl and propyl gallates were solubilized in aqueous solutions of surfactants which were polyoxyethylene ethers of cetyl alcohol, but ethyl gallate could not be solubilized in the same manner because it formed a gel-like product with the surfactants (833). The amount of the gel-like product formed was proportional to surfactant concentration and was greater when a larger number of polyoxyethylene ether units was present in the surfactant molecule. Solubility studies showed that testosterone was solubilized by glycocholate below the apparent binary CMC, although the solubilizing capacity was quite low (834). The complex association between testosterone and glycocholate suggested mixed micelle formation. Solubilities of phenobarbital, salicylic acid, and caffeine in a mixture of 12 kinds of solubilizing agents and water were measured, and the relationship between solubility and dielectric constant was examined (835). In a solvent system of water and solubilizing agents containing only a hydrophilic group, a plot of dielectric constant *versus* the logarithm of solubility, expressed as molar fraction, gave a straight line; for solubilizing solvents containing both hydrophobic and hydrophilic groups, the same plot gave one flexion in the straight line, indicating that these solubilizing agents undergo association at a specific concentration.

The solubilities of sulfadiazine, sulfisomidine, and sulfadimethoxine in several normal alcohols were determined over a limited temperature range (836). The entropy of solution was used for interpreting the results, which showed that in most cases the entropy quantity increased with decreasing solubility for any particular solute. To understand better the solubility behavior of nonelectrolytes in binary polar solvents, an equation for predicting solubility was presented and appeared to be applicable to many systems (837). Kramer and Flynn (838) examined the solubilities of two polysubstituted 1,3-dioxolanes, containing a 4-(2′-piperidyl) substituent, as a function of pH, temperature, and solvent composition. Mathematical equations describing the total solubility at any arbitrary pH in terms of the independent solubilities of the hydrochloride and free base species and the dissociation constants of the salt were derived and fitted to the data with good results. The method of sample preparation markedly influenced the rate of dissolution and attainment of supersaturated states of cholesterol in lecithin–bile salt systems (839).

The equilibrium solubility of cholesterol studied as a function of its physical state in a model bile system was almost half that of the previously accepted values. The authors suggested that slow attainment of the equilibrium state may have acted to bias previous studies.

Other papers of interest in the area of solubility–solubilization phenomena can be found in Table XXIV.

Spectrofluorometric Determination of Substituted Dihydroisoquinolines and Tertiary Tetrahydroisoquinolines as Their Isoquinolinium Derivatives

J. ARTHUR F. de SILVA▲, NORMAN STROJNY, and NANCY MUNNO

Abstract □ A spectrofluorometric method was developed for the determination of a substituted dihydro- and a tertiary tetrahydroisoquinoline in biological fluids based on a chemical and/or photochemical oxidation reaction to produce the isoquinolinium derivatives which fluoresce strongly in acidic media. This principle was used for the development of assays of these compounds in blood and urine with sensitivity limits in the submicrogram range. TLC was used to establish the specificity of the assays for the intact drugs and their biotransformation products. The method was applied to the determination of blood levels and the urinary excretion of these compounds administered in the dog and in man. Both compounds were found to be rapidly absorbed and extensively metabolized by both species.

Keyphrases □ 3,4-Dihydro-1-isoquinoline acetamide—determination of blood levels and urinary excretion in dogs and man, spectrofluorometric assay developed □ 8-Methoxy-2-methyl-1,2,3,4-tetrahydroisoquinoline—determination of blood levels and urinary excretion in dogs and man, spectrofluorometric assay developed □ Isoquinoline derivatives—spectrofluorometric assay in blood and urine □ Blood levels—3,4-dihydro-1-isoquinoline acetamide and 8-methoxy-2-methyl-1,2,3,4-tetrahydroisoquinoline, dogs, man □ Excretion, urinary—3,4-dihydro-1-isoquinoline acetamide and 8-methoxy-2-methyl-1,2,3,4-tetrahydroisoquinoline, dogs, man □ Spectrophotofluorometry—analysis, dihydro- and tetrahydroisoquinoline derivatives in blood and urine

The chemistry of the isoquinoline alkaloids has been extensively investigated (1-3) and has led to the synthesis of a large number of chemical derivatives of widely different pharmacological properties (4) such as analgesic (5), antiviral (6-9), and antihypertensive (10, 11) activities. This report describes the spectrofluorometric determination of two new members of this class of compounds, one showing antiviral activity and the other antihypertensive activity. 3,4-Dihydro-1-isoquinoline acetamide hydrochloride (I-HCl)[1] was synthesized by Creighton *et al.* (12) (Scheme I and Table I) and was shown to have antiviral activity (13–15). 8-Methoxy-2-methyl-1,2,3,4-tetrahydroisoquinoline hydrochloride (II-HCl) was synthesized by Schenker *et al.* (16) (Tables I and II) and was clinically evaluated as a hypotensive agent (17).

Tertiary tetrahydroisoquinolines can be readily oxidized to their 3,4-dihydroisoquinoline derivatives, which exhibit UV absorption and fluorescence in acidic media (18). This oxidative reaction was first described by Knabe (18) for the oxidation of tertiary amines using mercuric acetate in ethylenediaminetetraacetic acid. He also found it to be a useful general reaction applicable to a variety of tertiary tetrahydroisoquinolines. Knabe's method was modified by Schwartz and Rieder (19), who omitted ethylenediaminetetraacetic acid and used mercuric acetate in acetic acid and 0.1 *N* H_2SO_4. This modification, which was reported to give more quantitative and reproducible yields of the oxidation products, was used for the determination of emetine and dehydroemetine in biological fluids (19) and for the determination of methopholine and its metabolites in man and in the rabbit (20).

The chemical oxidation step usually introduces only one double bond in the 1,2-position of the tetrahydroisoquinoline ring to form the 3,4-dihydroisoquinoline derivatives. This report describes a photochemical oxidation which introduces a second double bond in the 3,4-position of the dihydroisoquinoline to form the fully aromatized isoquinolinium derivatives (21, 22) (Table II), which are highly fluorescent in acidic media. This photochemical oxidation was used to develop sensitive assays for the quantitation of I and II in blood and urine.

EXPERIMENTAL

Determination of 3,4-Dihydro-1-isoquinoline Acetamide Hydrochloride (I-HCl) and 1-Isoquinoline Acetamide (I-A) in Blood and Urine

Reference Standards—I-HCl, mol. wt. 224.69, m.p. 195–197° dec.

Stock Solution—Weigh out 11.940 mg. of I-HCl equivalent to 10.000 mg. of free base, transfer into a 100-ml. volumetric actinic flask, and dissolve in 100 ml. of methanol. This stock solution contains 100-mcg. equivalents of free base/ml.

Working Solution—Dilute 1.0 ml. of the stock solution to 10 ml. with methanol. This solution contains 10.0-mcg. equivalents of free base/ml., suitable aliquots of which are used as internal standards added to blood for the determination of percent recovery.

Standard Solution of I-A—1-Isoquinoline acetamide, mol. wt. 186.21, m.p. 204.5–205° dec.

Stock and Working Solutions—Weigh out 10.000 mg. of I-A and follow the procedure exactly as described for I-HCl.

External Standard of I—The determination of percent recovery from blood of added internal standards requires the use of a standard curve of I in 30% trichloroacetic acid exposed to UV light under similar conditions as the internal standard.

Weigh out 11.940 mg. of I-HCl equivalent to 10.000 mg. of free base, transfer into a 100-ml. volumetric actinic flask, and dis-

[1] The Roman numerals refer to the free base of the compound; the salts of a given compound are indicated by the appropriate abbreviations.

Table I—Chemical Names and Physical Properties of Compounds Referred to in Scheme I and Table II

Compound	Chemical Name	Molecular Weight	Melting Point	Reference Synthesis
I-HCl	3,4-Dihydro-1-isoquinolineacetamide hydrochloride	224.69	195–197° dec.	12
I-A	1-Isoquinolineacetamide	186.21 (B)[a]	204–205° dec.	—[b]
II-HCl	8-Methoxy-2-methyl-1,2,3,4-tetrahydroisoquinoline hydrochloride	213.70	215–216°	16, 21
III-HCl	8-Methoxy-1,2,3,4-tetrahydroisoquinoline hydrochloride	199.68	261–262.5°	16, 21
IV-HCl	2-Methyl-1,2,3,4-tetrahydro-8-isoquinolinol hydrochloride	199.71 163.21 (B)	243–244° 173–174.5° (B)	16 21
V-HCl	1,2,3,4-Tetrahydro-8-isoquinolinol hydrochloride	185.68 149.18 (B)	271–272° 181–181.5° (B)	16 21
II-A-HI	8-Methoxy-2-methyl-3,4-dihydroisoquinolinium iodide	303.15	182–182.5° dec.	21
III-A-HCl	8-Methoxy-3,4-dihydroisoquinoline hydrochloride	197.70	175–175.5°	21
IV-A	2-Methyl-3,4-dihydro-8-isoquinolinol	162.18	—	N.S.[c]

solve in a minimal amount of water. Add 0.6 ml. of 0.1 *N* NaOH to liberate the free base[2], which is insoluble in aqueous media, resulting in a turbid solution. Add 25 ml. of 30% trichloroacetic acid solution to dissolve the free base. Make to volume with 30% trichloroacetic acid solution. This stock solution of I contains 10 mg. free base/100 ml. or 100 mcg./ml.

Make serial dilutions of this stock solution in 30% trichloroacetic acid to give standard solutions containing 0.125, 0.25, 0.50, 1.0, and 2.0 mcg. of free base/ml. to be used in making an external standard curve.

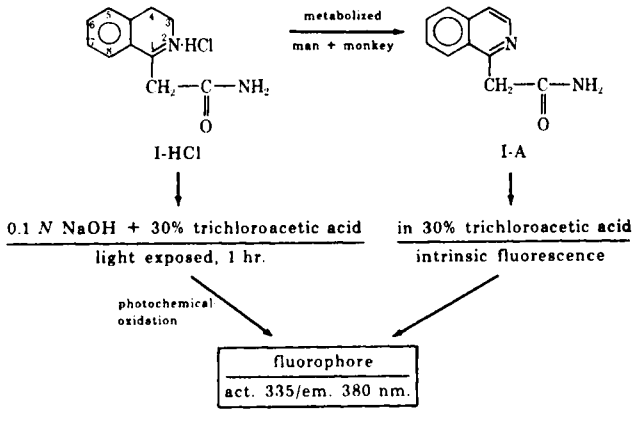
External Standards of I-A—Dissolve 10.000 mg. of compound in 100 ml. of 30% trichloroacetic acid. Make serial dilutions of this solution in 30% trichloroacetic acid to give standard solutions containing 0.125, 0.25, 0.50, 1.0, and 2.0 mcg./ml. Use these solutions to prepare an external standard curve of I-A (described later).

Reagents—The following were used: ether[3] (peroxide free), 1.0 *M* pH 9.0 borate–potassium carbonate–potassium chloride buffer solution (23), 30% trichloroacetic acid in distilled water, 5 *N* NaOH in distilled water, 1 *N* HCl in distilled water[4], and 0.1% bromthymol blue indicator in 50% alcohol.

Procedure for Blood and Urine—To 1.0 ml. of blood in a 50-ml. centrifuge tube, add 5 ml. of pH 9.0 buffer and 15 ml. of ether. Stopper the tube and shake for 15 min. on a reciprocating shaker. Along with the samples, run a 1-ml. specimen of control blood (taken prior to medication) and duplicate 1-ml. specimens of control blood containing 1.0 mcg. of both I-HCl and I-A (0.1 ml. of each working solution) added as internal standards.

To 1.0 ml. of urine, add 4 ml. of 2 *N* NaOH and 15 ml. of ether and extract as described for blood. Along with the samples, run 1.0 ml. of control urine and duplicate 1.0-ml. specimens of control urine containing 1.0 mcg. of both I-HCl and I-A added as internal standards.

Centrifuge all samples for 10 min. at 2000 r.p.m., preferably at 0–4° in a refrigerated centrifuge; then transfer the ether layer



Scheme I—Postulated chemical reactions of I and its biotransformation to I-A

[2] This procedure is necessary because only the free base (I) dissolved in 30% trichloroacetic acid gives an optimal, photochemically produced yield of I-A. When I-HCl was dissolved directly in 30% trichloroacetic acid and irradiated, it gave only 25% of the fluorescence yield as that produced by I.

[3] Mallinckrodt anhydrous analytical reagent grade diethylether from a freshly opened can may be used for up to 4 days after opening.

[4] Acculate.

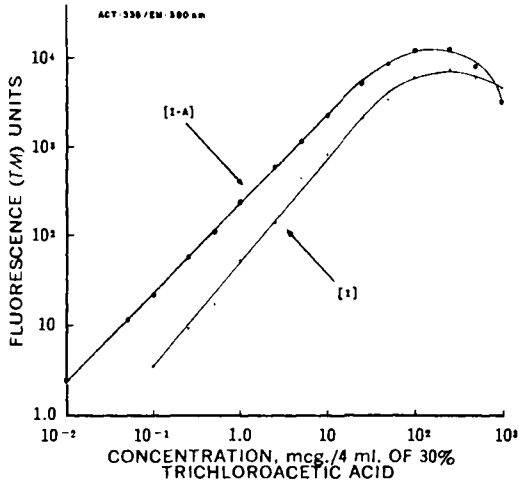


Figure 1—*Linear dynamic range of fluorescence* versus *concentration of I and I-A in 30% trichloroacetic acid.*

quantitatively into another 50-ml. centrifuge tube and evaporate to dryness. Repeat the extraction of each specimen with another 15-ml. portion of ether, combine the ether extracts, and evaporate to dryness.

Each residue is then dissolved in 100 μl. of methanol, which is transferred quantitatively onto a 20 × 20-cm. silica gel G/F_{254} thin-layer chromatoplate[6]. The chromatogram is developed in ethyl acetate–methanol–concentrated ammonium hydroxide (95:4:2), ascending for 12 cm. The intact drug (I, R_f 0.6) and the metabolite (I-A, R_f 0.3) are detected by their intrinsic blue-green fluorescence under shortwave UV light and are identified by reference to the R_f values of authentic standards run alongside the sample extracts. The areas on the plate corresponding to I and I-A are scraped off immediately after development[6] and transferred into separate 15-ml. centrifuge tubes. Both I and I-A are eluted from the silica gel with 4 ml. of 30% trichloroacetic acid by slurring vigorously on a high-speed mixer[7] for 60 sec. After centrifugation of the silica gel, the clear supernates are transferred into a fresh set of 15-ml. centrifuge tubes. At this point in the assay, a series of external standards of I and I-A in 30% trichloroacetic acid are prepared by transferring 4-ml. aliquots of each standard solution into separate 15-ml. centrifuge tubes. The external standards and biological specimens containing I *only* are then stoppered and exposed for 60 min. to high intensity light from a lamp[8] contained in an aluminum foil-lined box. The samples are placed in a single row 30.48 cm. (12 in.) away from the light source to standardize the photochemical formation of the fluorophore prior to fluorometric analysis. The intrinsic fluorescence of I-A in the external and internal standards and of the metabolite in the biological specimen is measured directly *without* prior light exposure.

Fluorometric Analysis—Read the fluorescence (TM)[9] of all the solutions in a 1-cm. path cell at 380 nm., activating at 335 nm. and using 4 ml. of irradiated 30% trichloroacetic acid as the reagent blank.

Plot external standard curves for I and I-A of the respective fluorescence units corrected for blank *versus* concentration of standard (micrograms per milliliter) (Fig. 1), from which the recovery of the internal standards of I-HCl and I-A added to blood or urine can be determined.

The fluorescence readings of the biological samples are corrected for control blood or urine blank readings, while that of the external standards of I and I-A are corrected for reagent blank (30% trichloroacetic acid) readings. The concentration of each compound in the unknown is determined by direct comparison to the fluorescence reading of the respective internal standard. The percent recovery of the added internal standards of I-HCl and I-A may be determined by direct comparison to the fluorescence reading of the respective external standards.

Calculations—*Determination of I and I-A in Blood and Urine*—

$$\frac{TM_{380} \text{ of unknown}}{TM_{380} \text{ of internal standard}} \times \frac{\text{concentration of internal standard (1.0 mcg. I or I-A)}}{\text{ml. sample assayed}} = \text{mcg. I and I-A/ml. blood or urine} \quad \text{(Eq. 1)}$$

Determination of Percent Recovery of I and I-A—

$$\frac{[TM/\text{mcg./ml.}] \text{ internal standard}}{[TM/\text{mcg./ml.}] \text{ external standard}} \times 100 = \text{percent recovery} \quad \text{(Eq. 2)}$$

The percent recovery of internal standards should be determined routinely as a check on analytical precision and reproducibility.

Determination of 8-Methoxy-2-methyl-1,2,3,4-tetrahydroisoquinoline Hydrochloride (II-HCl) and Its Metabolites in Blood and Urine

Reference Standards—II-HCl, mol. wt. 213.70, m.p. 213–214°.

Stock Solution—Weigh out 12.10 mg. of II-HCl equivalent to 10.00 mg. of free base, transfer into a 10-ml. volumetric actinic flask, and make to volume in absolute ethanol. This stock solution contains 1 mg. of II/ml.

Working Solution—Make two serial 1:10 dilutions of the stock solution with ethanol to yield a working solution containing 10 mcg./ml. Suitable aliquots of this solution are used as internal standards added to blood for the determination of percent recovery.

External Standard of II—The determination of percent recovery from blood of added internal standards requires the use of a standard curve of II in 0.1 N H_2SO_4, oxidized in mercuric acetate–acetic acid and exposed to light under the same conditions as the internal standards.

Weigh out 12.100 mg. of II-HCl equivalent to 10.000 mg. of free base, transfer into a 10-ml. volumetric actinic flask, and dissolve in a minimal amount of water (1–1.5 ml.). Add 0.6 ml. of 0.1 N NaOH to liberate the free base, which is insoluble in aqueous media, resulting in a turbid solution. Add 5 ml. of 0.1 N H_2SO_4 solution to dissolve the free base, and make to volume with 0.1 N H_2SO_4 solution. This stock solution contains 1.0-mg. equivalent of II/ml. Make serial dilutions of this solution with 0.1 N H_2SO_4 to give standard solutions containing 0.125-, 0.25-, 0.50-, 1.0-, and 2.0-mcg. equivalents of II/ml. to be used in making a standard curve (Fig 2.).

Reagents—The following were used: ether[3] (peroxide free), 0.1 N H_2SO_4 in distilled water, and 1.0 and 0.1 N NaOH solutions in distilled water. For mercuric acetate reagent (pH 6.0), dissolve 32.4 g. of sodium acetate (anhydrous), 1.0 g. mercuric acetate, and 3 ml. of glacial acetic acid/100 ml. of distilled water. This solution must be made fresh every 2–3 days due to precipitation and crystallization of the salt. For 1.0 M phosphate buffer (pH 5.5), dissolve 138.01 g. of $NaH_2PO_4 \cdot H_2O$ in distilled water and make to 1 l. Titrate to pH 5.5 with 1.0 N NaOH, and mix well by inversion.

An enzyme preparation[10] containing 100,000 units of glucuronidase and 50,000 units of sulfatase/ml. is available commercially.

Procedure—*Extraction of Blood and Urine*—To 1.0 ml. of blood or 4.0 ml. of urine in a 50-ml. centrifuge tube, add 4 ml. of 1.0 N NaOH solution and 15 ml. of ether. Stopper the tubes and shake for 15 min. on a reciprocating shaker. Along with the samples, run a 1-ml. specimen of control blood or 4 ml. of control urine (taken prior to medication) and duplicate 1-ml. specimens of control blood

[6] Brinkmann F_{254}.

[6] Compounds I and I-A are unstable to atmospheric oxidation and light exposure, especially on a thin-layer chromatoplate. Both compounds undergo extensive oxidation on exposure to the atmosphere and also when irradiated on the TLC plate by a Pyro-Lux R-57 lamp. Therefore, immediately following TLC separation of the biological extracts, the silica gel areas corresponding to I and I-A must be scraped off, eluted, and processed for fluorometric analysis as described.

[7] Vortex Super-Mix.

[8] Pyro-Lux R-57, Luxor Corp., N. Y.

[9] (TM) = transmittance (T) × meter multiplier factor (M). All fluorescence measurements were made in a Farrand spectrofluorometer equipped with a xenon arc energy source and an RCA IP-28 photomultiplier. The 10-nm. slit arrangement was used in all four positions. The monochromators were corrected for the fundamental mercury lines, but the fluorescence measurements were not corrected for energy and other instrumental artifacts. The instrument sensitivity was adjusted for maximum energy for each day, using a Pyrex reference rod and a standard solution of the compound to be analyzed.

[10] Glusulase, Endo Laboratories, Inc., Garden City, N. Y.

or 4-ml. specimens of control urine containing 0.50 mcg. II (50 μl. of the working solution evaporated to dryness under nitrogen).

Centrifuge all samples for 10 min. at 2000 r.p.m., preferably in a refrigerated centrifuge at 0–5°, and transfer the ether phase quantitatively into another 50-ml. centrifuge tube. Repeat the extraction with a second 10-ml. portion of ether, centrifuge, and combine the ether extracts. The whole blood specimen is discarded at this point, but the urine specimen is saved for further analysis of the conjugated metabolites.

Assay in Blood—The combined ether extracts of blood are back-extracted with 2 ml. of 0.1 *N* H_2SO_4 by shaking for 15 min. Centrifuge at 2000 r.p.m. at room temperature for 5 min., and aspirate off the supernatant ether layer.

The sulfuric acid extract is backwashed with two 10-ml. portions of ether by shaking for 5 min. each, centrifuging, and aspirating off the ether layer. To the ether-washed sulfuric acid extract, add 2 ml. of mercuric acetate reagent and place in a boiling water bath. Allow 5 min. for equilibration to expel all residual ether from the acid.

At this stage in the assay, pipet 2-ml. aliquots of each standard solution of the external standards of II into 15-ml. centrifuge tubes, add 2 ml. of the mercuric acetate reagent into each tube, and process these samples through the rest of the procedure along with the biological extracts. Stopper the tubes tightly (seal with a drop of distilled water), and allow the chemical oxidation step to proceed for 30 min. in a boiling water bath (100°). Then cool the samples to room temperature, wipe the tubes dry prior to irradiation, and expose all samples including the external standards of II directly to high intensity light from a lamp[8] contained in an aluminum foil-lined box. The samples must be arranged in a single row in a suitable rack and placed 30.48 cm. (12 in.) from the light source. Expose for 15 min. to complete the photochemical oxidation reaction for optimal fluorophore formation. The fluorescence of each sample is read in a 1-cm. path quartz cell at 458 nm., activating at 370 nm., within 1 hr. after light exposure. The concentrations in the unknowns are calculated by direct comparison to the corrected fluorescence of the internal standards:

$$\frac{TM_{458} \text{ of unknown}}{TM_{458} \text{ of internal standard}} \times \frac{\text{concentration of internal standard (0.5 mcg.)}}{\text{ml. sample assayed}} = \text{mcg. II/ml. blood} \qquad \text{(Eq. 3)}$$

Assay in Urine—The initial ether extract of the urine contains unconjugated metabolites in addition to the parent compound. To assay for conjugated metabolites, the ether-extracted urine specimen is transferred into a 50-ml. erlenmeyer flask, titrated potentiometrically to pH 5.5 with 2 *N* HCl, and buffered with 5 ml. of 1.0 *M* phosphate buffer (pH 5.5). The enzyme preparation is added to a final concentration of 1% (v/v), and the flask is stoppered loosely with cotton and incubated at 37° for 2 hr. in a Dubnoff incubation shaker with mild reciprocation. After incubation, the samples are cooled to room temperature, transferred into 50-ml. centrifuge tubes, and extracted at pH 5.5 with 2 × 15-ml. portions of ether to remove the deconjugated weakly acidic phenolic metabolites. The urine specimen is then made strongly alkaline (pH 14) with sufficient 10 *N* NaOH and is reextracted with 2 × 15-ml. portions of ether to remove the deconjugated basic metabolites.

The three separate ether extracts of urine are evaporated to dryness, and the residues are dissolved in 100 μl. of methanol and transferred quantitatively onto separate 20 × 20-cm. silica gel G/F thin-layer chromatoplates[5]. The TLC plates are developed in a vapor-saturated chamber containing ethyl acetate–methanol–ammonium hydroxide (90:10:1) until the solvent front has ascended 12–15 cm. The plates are air dried after development, sprayed with 0.1 *N* H_2SO_4 followed by the mercuric acetate–acetic acid reagent, and then heated for 10 min. in an oven at 100°. The parent drug (II) is located as a highly fluorescent (blue-green) spot (R_f 0.4–0.5) by reference to the R_f of an authentic standard of 1.0 mcg. of II run alongside the sample extracts. All drug-related components fluoresce with characteristically different colors when viewed under longwave UV light, especially the polar metabolites seen at the origin and slightly above it.

The major urinary metabolites, the *N*-desmethyl analog (III, R_f 0.10), the *O*-desmethyl analog (IV, R_f 0.20), and the tetrahydro-8-isoquinolinol analog (V, R_f 0.08) can be readily identified by the very distinctive colors of the fluorophores formed on the TLC plate after the initial oxidative spray treatment and by comparison with the R_f values of authentic standards run alongside the sample extracts.

Scrape the silica gel from the fluorescent areas on the plate corresponding to II into 15-ml. conical centrifuge tubes, add 3 ml. of 0.1 *N* H_2SO_4, and slurry on a supermixer[7] for 1 min. to dissolve the compound in the acid phase. Wash the acid phase with 5 ml. of ether by slurring on the supermixer for 1 min., centrifuge, and then remove the ether layer by aspiration. If the acid phase does not appear clear (water white) when viewed against the light, repeat the ether wash. Transfer a 2-ml. aliquot of the ether-washed sulfuric acid solution into another 15-ml. centrifuge tube, taking care not to disturb the silica gel at the bottom of the 15-ml. tube. Proceed as described for blood to complete the chemical and photochemical oxidation process for fluorophore formation and quantitate fluorometrically as described for blood.

Determination of Percent Recovery of II from Blood and Urine—The recovery of internal standards of II may be determined by comparison of the corrected fluorescence of the internal standard against that of an external standard as described earlier for I.

RESULTS AND DISCUSSION

Tertiary tetrahydroisoquinolines are basic compounds and are extracted into polar solvents such as ether or ethyl acetate at a pH greater than 9.0. Compounds I-HCl and II-HCl were quantitatively extracted from blood or urine into ether at pH 9.0 or above as their respective free bases and back-extracted into dilute acid (0.1 *N* H_2SO_4 or HCl). This property was used as an effective "cleanup" step prior to quantitation. Both compounds have sufficient UV absorbance in dilute acids for quantitation with sensitivity in the microgram range. However, much higher sensitivity is achieved by fluorometric determination of these compounds as their isoquinolinium derivatives.

Compound I-HCl—Studies on the *in vitro* metabolism of I-HCl by Schwartz and Taylor[11], using the 9000 × *g* microsomal fraction of liver from phenobarbital-pretreated rats, indicated a moderate conversion of I to a fluorescent metabolite. This metabolite was isolated and characterized by mass and UV spectrometry as having a structure compatible with 1-isoquinoline acetamide (I-A). An authentic reference sample was synthesized by Schenker[12] and was used to confirm the identity of the metabolite by TLC migration (R_f) values. Further metabolic studies on orally administered I in the monkey showed that the major component in the blood was not the intact drug but was a metabolite (I-A) whose fluorescent properties were similar to that of photochemically oxidized I dissolved in 30% trichloroacetic acid. Authentic I-A was also used as a reference standard in the studies on elucidating the chemical nature of the fluorophore of I.

Characterization of Fluorophore of I—The characterization of the chemical nature of the photochemically produced fluorophore of I was undertaken using UV absorption spectra, activation–emission spectra, TLC, and differential pulse polarographic techniques. It was noted initially that I-HCl dissolved in 0.1 *N* HCl or in 30% trichloroacetic acid exhibited weak intrinsic fluorescence at 380 nm., activating at 335 nm. The fluorescence yield was greatly increased by irradiating I-HCl in the high intensity light from a lamp[8]. The fluorescence yield after irradiation in 30% trichloroacetic acid was about 20 times greater than that produced in 0.1 *N* HCl. The free base I dissolved directly in 30% trichloroacetic acid after irradiation produced 2.7 times the fluorescence yield of I-HCl dissolved in the same medium. This indicated that I is more amenable to photochemical oxidation than is I-HCl.

It was also noted that I-A in 0.1 *N* HCl or 30% trichloroacetic acid exhibited strong intrinsic fluorescence at 380 nm., activating at 335 nm., and that the fluorescence yield in 30% trichloroacetic acid was about four times greater than that in 0.1 *N* HCl. These observations indicated that 30% trichloroacetic acid was the medium of choice for effecting the optimal photochemical conversion of I to its fluorophore and also for measuring the optimal fluorescence yield. The fact that the activation–emission spectral characteristics

[11] M. A. Schwartz and M. K. Taylor, Hoffmann-La Roche, Inc., Nutley, N. J., unpublished data on file, 1967.

[12] F. E. Schenker, Department of Chemical Research, Hoffmann-La Roche Inc., Nutley, N. J., unpublished data, 1967.

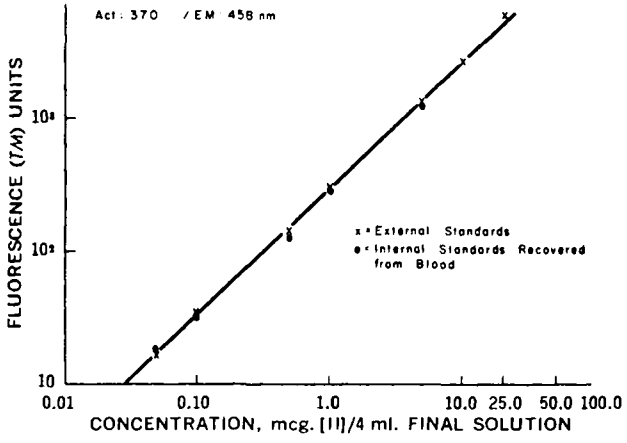

Figure 2—*Linear dynamic range of fluorescence* versus *concentration of external standards and blood-recovered internal standards of II after chemical and photochemical oxidation to their isoquinolinium derivatives.*

of I-A and the photochemically produced fluorophore of I in 30% trichloroacetic acid were identical indicated that I was oxidized (dehydrogenated) to produce I-A (Scheme I). The ratio of the fluorescence yields for equivalent (microgram) amounts of the two compounds (Fig. 1) indicated a conversion efficiency of about 20–25% at low concentrations of I (0.1–1.0 mcg./4 ml.), which increased to about 40–45% at higher concentrations (5–15 mcg./4 ml.). Although the photochemical conversion of I to I-A is not quantitative, it is sufficiently reproducible and linear to be analytically usable.

Further characterization of the fluorophore I-A was effected by a comparison of the UV absorption spectra of I, I-A, and the fluorophore produced by the photochemical oxidation of I. The UV absorption spectra of the two compounds in 0.1 *N* HCl (Fig. 3) show a single absorption maximum for I at 282 nm. (A/mcg./ml. = 0.052), whereas I-A has two absorption maxima, an intense one at 228 nm. (A/mcg./ml. = 0.260) and a weak one at 335 nm. which also corresponds to the wavelength of activation for fluorescence measurements. The reaction products of photochemically oxidized I were extracted into ether (after making the medium strongly alkaline with sodium hydroxide) and back-extracted into 0.1 *N* HCl, and its UV spectrum was determined. The UV spectrum indicated that the major peak of I at 282 nm. had decreased significantly, and absorption maxima at 228 and 335 nm. similar to those of I-A were observed. The reaction products were also analyzed by two-dimensional TLC (Fig. 4), which indicated that the major reaction product had the same R_f as I-A and also exhibited strong intrinsic fluorescence under longwave UV light when the plate was sprayed with 30% trichloroacetic acid. In addition to some unconverted parent compound, a second minor component migrating lower than I-A was also seen. This component showed weak intrinsic fluorescence in 30% trichloroacetic acid and was also present in

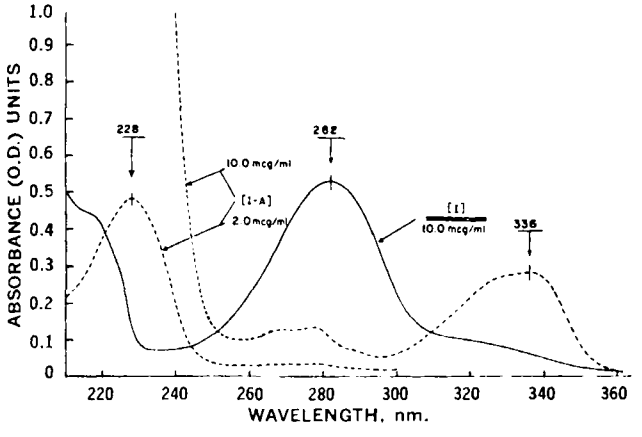

Figure 3—*UV absorption spectra of I and I-A in 0.1* N *HCl.*

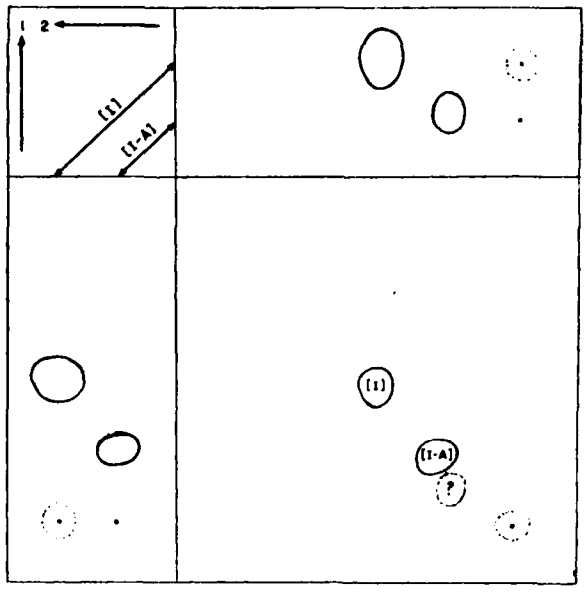

Figure 4—*Two-dimensional TLC of the photochemical oxidation products of I in 30% trichloroacetic acid. Key: 1, ethyl acetate–methanol–ammonium hydroxide (95:4:2); and 2, ethyl acetate–chloroform–ethanol (40:40:20).*

trace amounts when I-A dissolved in 30% trichloroacetic acid was irradiated for over 60 min. It appears to be a breakdown product of I-A produced by prolonged irradiation.

Electrochemical studies on the conversion of I to I-A, using differential pulse polarographic analysis (24), revealed that I-HCl gave a distinct peak at −0.700 v. *versus* standard calomel electrode (SCE) in 1.0 *N* HCl; this was attributed to the reduction of the azomethine (>C=N–) bond (25-27) in the isoquinoline ring. The peak also showed a characteristic pH shift to more negative potential with decreasing acidity from −0.700 v. *versus* SCE in 1.0 *N* HCl to −0.750 v. *versus* SCE in 0.1 *N* HCl and −0.990 v. *versus* SCE in pH 7.0 (1.0 *M* KCl/0.1 *M* PO_4) buffer solution, respectively (Fig. 5*a*). The isoquinolinium derivative (I-A), on the other hand, gave no reduction waves in any of the above media. Similar loss of electrochemical activity was reported for quinoline and isoquinoline in aqueous supporting electrolytes when compared with either nonaqueous or mixed electrolytes (28, 29) and was attributed to the adsorption of the electroinactive substance on the electrode surface. However, I-A gives a well-defined polarographic peak at −1.90 v. *versus* SCE in 95% dimethylformamide–5% water, which is about three times the height as that obtained with an equivalent concentration of I-HCl [E_p (peak potential) = −2.19 v. *versus* SCE) in the same supporting electrolyte. The E_p value for I-A is in close agreement with that reported for isoquinoline (−1.84 v. *versus* SCE) in the same electrolyte (30). Analogous electrochemical activity was noted with the products of the photochemical oxidation of I in 30% trichloroacetic acid.

These experiments demonstrated that I irradiated in 30% trichloroacetic acid, was photochemically oxidized (dehydrogenated) to 1-isoquinoline acetamide (I-A), the major fluorophore produced in this reaction.

Recovery of I and I-A—The direct assay procedure for I gave an overall recovery of 86 ± 5.0% (Table III). Since the TLC separa-

Table III—Overall Recovery Data on I-HCl, I-A, and II-HCl from Blood and Urine

Compound	Blood		Urine	
	Direct Analysis	With TLC	Direct Analysis	With TLC
	Overall Percent Recovery			
I-HCl	86 ± 5.0	63 ± 4.0	≃61	45 ± 6.0
I-A	≃57	41 ± 3.0	≃55	37 ± 5.0
II-HCl	89 ± 5.0	≃60	≃55	33 ± 5.0

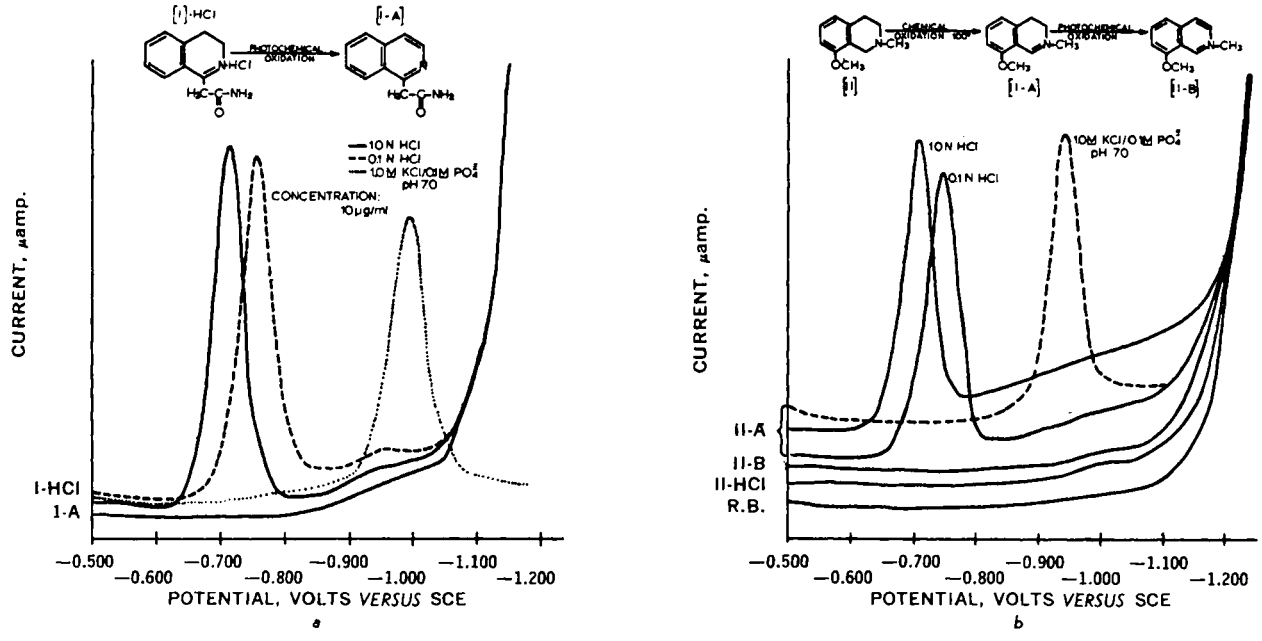

Figure 5—(a) *Differential pulse polarograms of I-HCl and I-A.* (b) *Differential pulse polarograms of II-HCl and the products of chemical oxidation (II-A) and the combined chemical and photochemical oxidations (II-B).*

tion step is essential to ensure the specificity of the assay for the intact drug (I) and its metabolite (I-A) in both blood and urine, the overall recovery of both compounds was determined after inclusion of the TLC separation step. The overall recovery from blood of I was 63 ± 4.0%, while that of I-A was 41 ± 3.0%. The overall recoveries of I and I-A from urine were 45 ± 6.0 and 37 ± 5.0%, respectively. The sensitivity limits of the assay were of the order of 0.25–0.50 mcg. I and 0.25 mcg. I-A/ml. of blood and 0.75–1.00 mcg. I and 0.50 mcg. I-A/ml. of urine, respectively.

Compound II-HCl—Compound II-HCl is a weak base (pKa = 8.2), and it is quantitatively extracted as its free base into ether from alkalinized blood or urine and is back-extracted into 0.1 *N* H_2SO_4 or 0.1 *N* HCl. The compound exhibits UV maxima at 272 and 278 nm. of about equal intensity (*A*/mcg./ml. = 0.077). Following chemical oxidation in the mercuric acetate–acetic acid–sulfuric acid mixture, a significant hypsochromic shift of the UV maxima was observed together with a significant hyperchromic effect. The UV absorption maxima shifted to 264 and 267 nm., indicative of aromatization, and the absorbance at either wavelength (*A*/mcg./ml. = 0.184) also increased twofold over that seen at 272 and 278 nm. Irradiation for 15 min. with UV light[8] produced no further shifts in the UV maxima. The absorbance, however, showed a further increase to 3.5 times that of the parent compound.

The reaction products of the chemical oxidation step and the combined chemical–photochemical oxidation process were also examined by differential pulse polarography in the same aqueous supporting electrolytes as were used for I-HCl. The polarograms shown in Fig. 5*b* indicate that the parent compound (II-HCl) has no intrinsic electrochemical activity. The product of chemical oxidation, II-A, showed peaks typical of a 3,4-dihydroisoquinoline and were almost superimposable on those shown by I-HCl (Fig. 5*a*). However, the isoquinolinium derivative (II-B) formed by the combined chemical and photochemical oxidation reaction showed no activity as did I-A. Attempts to study these reactions in 95% dimethylformamide–5% water were unsuccessful due to trace amounts of coextracted impurities from the reaction medium which interfered with the peaks in the potential region of from −1.80 to −2.00 v. *versus* SCE.

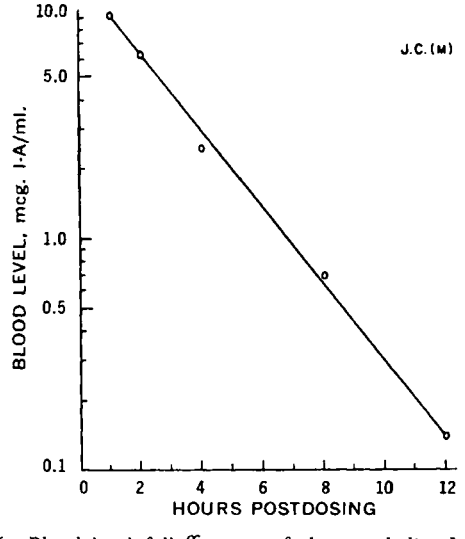

Figure 6—*Blood level falloff curve of the metabolite I-A in man following a single, 1000-mg. oral dose of I-HCl.*

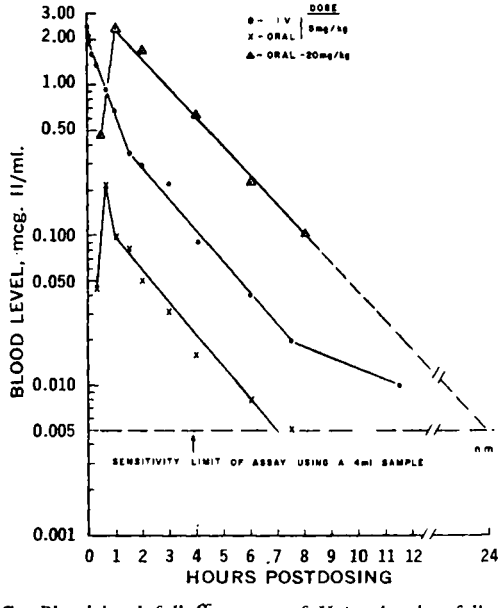

Figure 7—*Blood level falloff curves of II in the dog following intravenous and oral administration.*

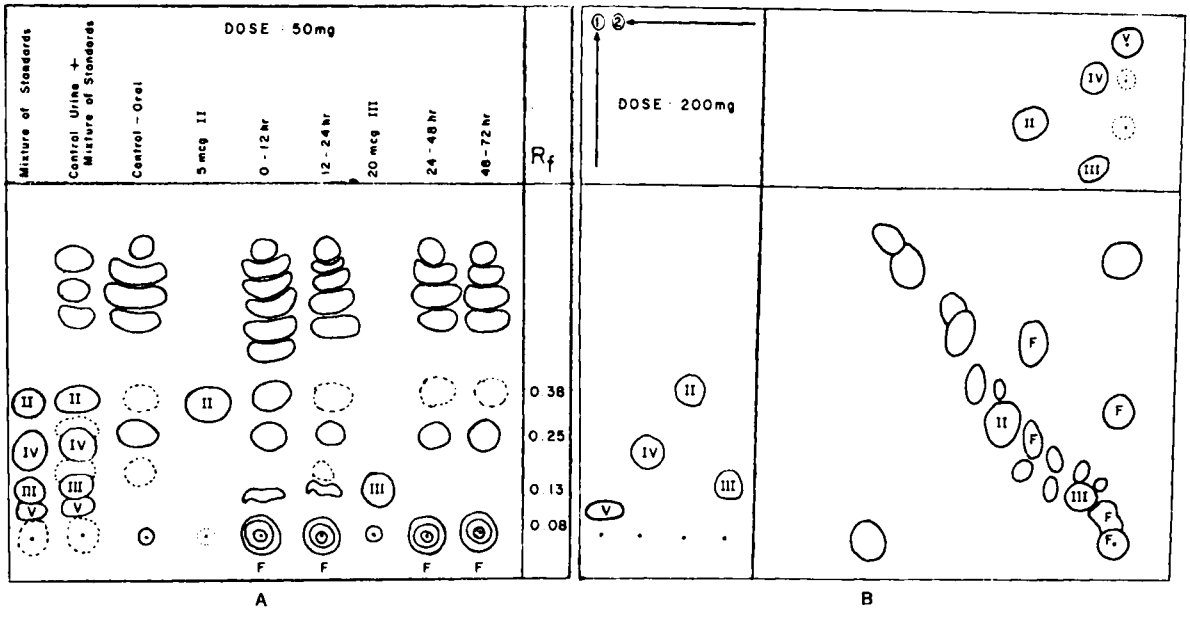

Figure 8 *Thin-layer chromatograms of the direct ether extracts of urine (made strongly alkaline, pH 14) from a dog following oral administration of II. F = fluorescent metabolites. Key: A, developed in one dimension; solvent system of ethyl acetate–methanol–ammonium hydroxide (90:10:1); B, developed in two dimensions; solvent system of (1) ethyl acetate–methanol ammonium hydroxide (90:10:1) or (2) benzene–methanol–glacial acetic acid (90:10:1).*

Polarographic and spectrophotometric studies on the analogous chemical reduction products by partial hydrogenation of isoquinoline to 3,4-dihydroisoquinoline and of 3,4-dihydropapaverine to papaverine also were reported (31) and showed similar stepwise changes in electrochemical activity.

Further characterization of the reaction products of II following either chemical oxidation or the combined chemical–photochemical oxidation reaction was obtained using TLC. The reaction products were extracted at alkaline pH into ether, analyzed by one-dimensional TLC in ethyl acetate–methanol ammonium hydroxide (90:10:1), and examined under longwave UV light. Under both sets of conditions, two fluorescent spots were present, one at the origin and the other close to the solvent front (R_f 0.90), in addition to some residual II (R_f 0.50). The fluorescence of the two spots was of about equal intensity following only chemical oxidation, whereas the fluorescence of the lower spot increased several fold in intensity following the combined oxidation procedure. The two fluorescent spots were eluted into 0.1 *N* H_2SO_4 and scanned for their spectral characteristics. The two compounds had identical UV absorption and activation–emission spectra, indicating that these reaction products are a mixture of fluorophores whose "total" fluorescence in solution is apparently reproducible and analytically acceptable.

Similar reactions were observed with the other tetrahydroisoquinoline analogs (III, IV, and V) shown in Table II. However, the fluorescence yield decreased markedly with the removal of the methyl group in either or both positions of II. Thus, the fully aromatized isoquinoline derivatives of II showed the highest fluorescence (at 370/458 nm.), the fluorescence yield being over 25 times greater than that of the *N*-desmethyl analog (III) at the same wavelengths. Of the two phenolic analogs, the isoquinoline derivative of the *O*-desmethyl analog (IV) exhibited about 2.5 times more fluorescence (at 425/525 nm.) than III (at 370/458 nm.), while the *N*- and *O*-desmethyl analog (V) had the weakest fluorescence (at 425/525 nm.) of them all. Thus, the fluorophores produced by equiv-

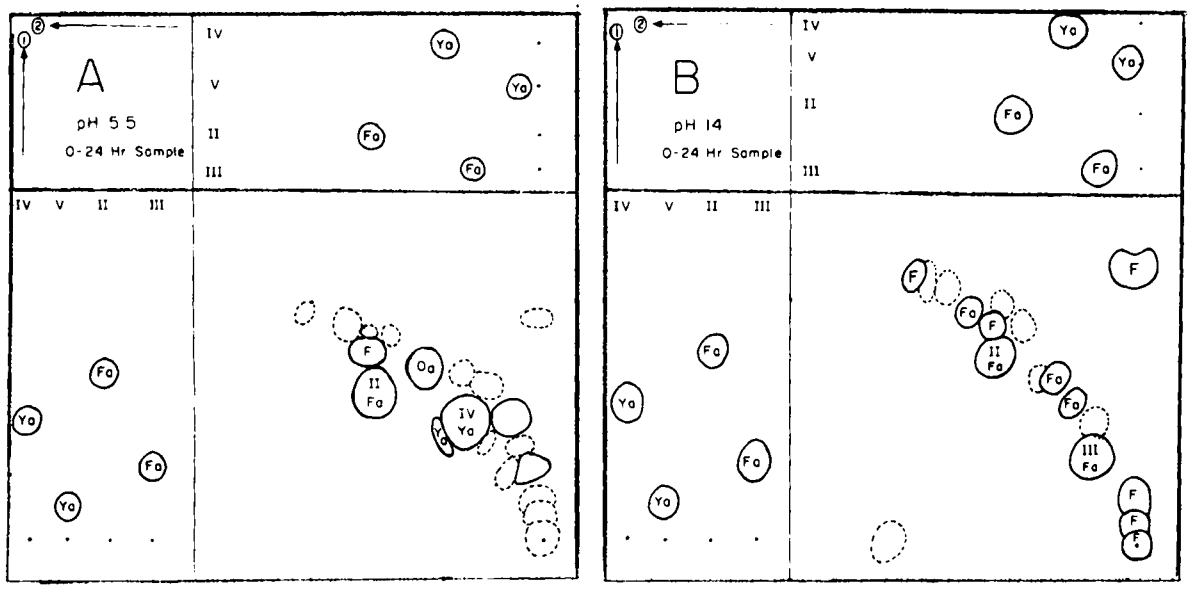

Figure 9 *Two-dimensional thin-layer chromatograms of ether extracts of dog urine after enzyme incubation following oral administration of a 20-mg./kg. dose of II. Key: solvent system: 1, ethyl acetate–methanol–ammonium hydroxide (90:10:1); and 2, benzene–methanol–glacial acetic acid (90:10:1). F = fluorescent before and after oxidation, Fa = fluorescent only after oxidation, Ya = yellow colored only after oxidation, and Oa = orange colored only after oxidation. A = acidic pH 5.5 extract, and B = basic pH 14 extract.*

alent (microgram) amounts of the respective tetrahydroisoquinolines (read at their respective wavelengths of maximum activation–emission) arranged in decreasing order of fluorescence emission are II > IV > III > V. These studies showed that in the overall oxidation process the first step (chemical oxidation) introduces a double bond in the 1,2-position of the tetrahydroisoquinoline ring while the second step (photochemical oxidation) introduces a second double bond in the 3,4-position to produce the fully aromatized isoquinolinium derivative (Table II). These derivatives exhibit high UV absorption and fluorescence in acidic media due to the increase in the aromaticity in the molecule.

Recovery of II from Blood and Urine—Recovery experiments with II from blood and urine indicated that the overall recovery from blood using the direct assay procedure was 89 ± 5.0% (Table III) while that from urine, which included the TLC separation step, was significantly lower (33 ± 5.0%).

The sensitivity limits of the assay for blood and urine are of the order of 0.05–0.10 mcg. II/ml. and can be extended to 0.005 mcg./ml. of blood using a 4-ml. specimen. The linear range of fluorescence *versus* concentration of oxidized II as external standards and as internal standards recovered from blood is of the order of 0.05–25.0 mcg. II/4 ml. of final solution (Fig. 2).

Application of Methods to Biological Specimens—*Compound I-HCl: Blood Levels in Man following a Single 1000-mg. Oral Dose*—A pilot blood level study was performed with one volunteer who was administered a single dose of 1000 mg. of I-HCl orally. Whole blood, oxalated, was drawn at 0, 1, 2, 4, 8, 12, 24, 48, 72, and 96 hr. after administration and was analyzed. No measurable levels of the intact drug (I) were seen at any time point. Measurable levels of a metabolite I-A were seen; however, the peak blood level of 9.0 mcg./ml. at 1 hr. declined rapidly within 12 hr., with an apparent half-life of about 2 hr. After 12 hr. the metabolite levels were no longer measurable (Fig. 6). The data indicate rapid absorption of I-HCl and rapid biotransformation to I-A.

Specificity of Assay for I and Characterization of Blood Metabolite I-A in Man and Monkey—Blood ether extracts from man and monkey following oral administration of I-HCl were analyzed by one-dimensional TLC in ethyl acetate–methanol–concentrated ammonium hydroxide (95:4:2). The chromatoplate did not show the presence of any intact drug (I, R_f 0.60). The major component was a metabolite seen in both man and monkey blood whose R_f 0.28 was identical with that of authentic I-A chromatographed alongside the sample extracts. This TLC step, which is also used in the assay, ensures its specificity for I and I-A. The metabolite and compound I-A, when cochromatographed, ran as one spot having the same R_f as the reference standard, indicating that the two compounds were identical. Thus, I-A was identified as the major ether-extractable metabolite of I-HCl in the blood of man and in the monkey. On-going studies[13] on the metabolism of I-HCl in man and in the dog also indicate extensive metabolism, resulting in several polar metabolites present in blood and urine which can be analyzed by selective solvent extraction and TLC separation

Compound II-HCl—Blood levels in the dog were determined in one animal following the administration of a 5-mg./kg. (total 50-mg.) dose of II-HCl by intravenous and oral routes and in another animal following a single oral 20-mg./kg. (total 200-mg.) dose. The blood level falloff curves are shown in Fig. 7. Following the 5-mg./kg. i.v. dose, a biphasic falloff pattern in the blood levels of II was seen, with the α-component (distribution phase) showing a rapid apparent half-life of 40 min., while the β-component (elimination phase) showed an apparent half-life of 1.4 hr.

Following oral administration of the 5-mg./kg. (50-mg.) dose, the blood levels of II appeared to reach a peak level (0.22 mcg./ml.) at 40 min. followed by a progressive decline, with an apparent half-life of 1.5 hr. between 1.0 and 7.5 hr. The blood level falloff data determined following a single 20-mg./kg. (200-mg.) oral dose indicated a peak blood II level of 2.33 mcg./ml. 1 hr. after dosing, which declined to nonmeasurable levels in 24 hr., again with an apparent half-life of 1.5 hr.

The recovery of the intact drug into ether from dog urine made alkaline (pH 14) was very low. After the 5-mg./kg. i.v. dose, only 1.5% of the drug was recovered in the 0–24-hr. period; following the 5- and 20-mg./kg. oral doses, only 0.21 and 3.9% of the respective administered doses were recovered in the same excretion period. Again, TLC of the direct ether extracts of urine (Figs. 8A and 8B) indicated the presence of the intact drug, the *N*-desmethyl analog (III), and several highly fluorescent, incompletely resolved compounds near the origin.

The 0–24-hr. urine sample from the dog dosed with 20 mg./kg. following enzyme incubation at pH 5.5 was extracted at pH 5.5 and 14 and analyzed by two-dimensional TLC. The chromatogram of the pH 5.5 ether extract (Fig. 9A) indicated the presence of the parent drug (II), the phenolic analog (IV), and three unidentified acidic metabolites. The pH 14 ether extract (Fig. 9B) indicated the presence of II, the *N*-desmethyl analog (III), and at least eight other discernible basic metabolites which were strongly fluorescent either intrinsically or after oxidation with mercuric acetate–acetic acid. The basic metabolites showed a typical blue-green isoquinoline-like fluorescence similar to that of oxidized II, whereas the acidic phenolic metabolites IV and V showed characteristic yellow- or orange-colored fluorescence after oxidation.

The highly fluorescent metabolites seen at the origin of the TLC plate were those present in the most significant amounts, as indicated by the intrinsic fluorescence obtained upon their elution from silica gel into 4 ml. of 0.1 *N* H_2SO_4 and measurement of the fluorescence at the same wavelengths as for oxidized II. Based on the assumption that the specific intrinsic fluorescence of these metabolites is approximately the same as that of oxidized II, the total amount of the fluorescent metabolites recovered from the chromatoplate represents about 37% of the dose. The intact drug (II) recovered from both acidic and basic extracts accounted for about 8% of the administered dose. These fluorescent metabolites appear to be chemically similar to the isoquinoline derivatives of II (oxidized) but have yet to be characterized. The percent of the dose recovered as the acidic phenolic metabolites also appears to be considerable. It is conservatively estimated that more than 50% of a given dose can be accounted for in the urine over a 24-hr. excretion period, indicating rapid and extensive biotransformation of the drug.

Blood levels of II were determined in man (17) during the clinical evaluation of the drug, when doses ranging from 50 to 300 mg. were administered orally. Peak blood II levels were seen 1–2 hr. after dosing, followed by a rapid decline in blood levels over the next 10 hr. The urinary excretion data indicated extensive biotransformation of the drug with less than 1% of the orally administered dose recovered in the 0–24-hr. period (17).

Specificity of the Assay—The blood level assay is apparently specific for the intact drug (II) after single doses in the dog, since only the intact drug was seen in the blood ether extracts analyzed by TLC. Chronic administration to dogs at high doses (20 mg./kg.), however, showed the presence of trace amounts of III and another unidentified fluorescent metabolite[14]. This would necessitate the use of TLC to establish the specificity of the assay in blood for II and its metabolites. In the direct assay in blood, small amounts of III would not seriously interfere with the assay values for II because of the 25-fold difference in the fluorescence intensities of the isoquinolinium derivatives of II over III. However, the highly fluorescent isoquinoline-like metabolites seen in urine, if present in blood following chronic administration, would have to be separated by TLC prior to the determination of II.

The urine assay requires the use of the TLC separation step to resolve the parent drug (II) from the many metabolites present, especially the highly fluorescent isoquinoline-like metabolites which have similar fluorescence properties as that of oxidized II.

CONCLUSION

The chemical oxidation of tertiary tetrahydroisoquinolines is a useful general reaction for converting these compounds to their 3,4-dihydroisoquinoline derivatives (18–20). These derivatives can be further oxidized by photochemical oxidation by exposure to UV radiation in acidic media to yield the fully aromatized isoquinolinium derivatives, which are highly fluorescent and amenable to sensitive quantitation in the nanogram range. Both principles have been effectively used in developing assays for the spectrofluorometric quantitation of these types of compounds in biological fluids. Photochemical methods are useful on the microscale for

Serum Protein Binding of Erythromycin, Lincomycin, and Clindamycin

R. C. GORDON, C. REGAMEY, and W. M. M. KIRBY▲

Abstract □ Serum protein binding determinations for erythromycin, lincomycin, and clindamycin utilizing ultrafiltration of serum containing antibiotic in a concentration of 5 mcg./ml. and tube dilution techniques revealed a high degree of binding: erythromycin base, 73%; erythromycin propionate, 93%; lincomycin, 72%; and clindamycin, 94%.

Keyphrases □ Erythromycin and erythromycin propionate—serum protein binding □ Lincomycin—serum protein binding □ Clindamycin—serum protein binding □ Antibiotics—serum protein binding of erythromycin, lincomycin, and clindamycin □ Serum protein binding—erythromycin, lincomycin, and clindamycin

Serum protein binding of antibiotics is of potential clinical significance since bound antibiotic has been found to have no antibacterial activity and it is probable that the level of free antibiotic in the tissues is no greater than the peak level in the blood (1). The extent of protein binding of erythromycin, lincomycin, and

derivatization reactions and are also used extensively in organic synthesis (32), especially in the preparation of isoquinoline alkaloids (33).

clindamycin has been variously reported in the literature as low (2–4) to high (5–7). The present study was carried out to help delineate the protein binding characteristics of these three antibiotics using a variety of methods.

EXPERIMENTAL

Three techniques were used to study binding of these antibiotics by human serum proteins to compare the results obtained and to investigate possible causes of variation in the results reported by other workers. The antibiotic standard powders used in these studies were: erythromycin base[1], erythromycin propionate[1], ^{14}C-erythromycin[1], lincomycin[2], and clindamycin hydrochloride[2].

Ultrafiltration Method—The precise method and equipment reported by Bennett and Kirby (8) was used in these protein binding determinations involving vacuum ultrafiltration of pooled human serum from healthy volunteers containing antibiotic added in a concentration of approximately 5 mcg./ml. For these studies, a single layer of cellophane membrane[3], previously sterilized by rinsing with 90% ethanol, was utilized. All experiments were performed in a manner simulating *in vivo* conditions in that the initial serum pH was adjusted to the physiological range by bubbling of carbon dioxide, and all experiments were carried out in a 37° incubator. Ultrafiltration required less than 45 min. in every case, and post-filtration pH determinations revealed that the pH remained in the physiological range throughout the tests.

A serum sample, corresponding to 100% serum because of concentration during filtration, was obtained for antibiotic assay at the midpoint of filtration. The principle and mathematics of this were explained in the original article (8). Antibiotic concentrations in the midpoint sample and in the ultrafiltrate sample were assayed by an agar well method (9) using *Bacillus subtilus* (ATCC 6633) as the test organism for erythromycin and *Sarcina lutea* (FDA, PCI 1001) for lincomycin and clindamycin. The percent binding by 100% human serum was calculated by dividing the difference between the midpoint serum and filtrate antibiotic concentrations by the serum antibiotic concentration and multiplying by 100. Modifications of this same formula were used throughout this study for determination of protein binding. Impermeability of the membrane to unbound antibiotic as a possible cause of apparent protein binding was investigated by ultrafiltration of buffered saline solutions of the drugs.

Tube Dilution Method—A good correlation between protein binding and decrease in antibacterial activity has been observed by a number of workers (10, 11). For the present studies the minimum inhibitory concentration in tryptose phosphate broth was compared to that obtained in a series of tubes containing a fixed concentration of serum (25, 75, 90, or 100%) and small increments of antibiotic (0.02 mcg./ml.), with a range from 0.005 to 2.0 mcg./ml.

132,130.0	31,445.0	76.2			
129,948.0	26,440.0	79.6			
		73.5			

The test organism was a group A beta hemolytic streptococcus (clinical isolate), and hemolysis of human group O red blood cells was used as the bacteriostatic end-point. Minimal bactericidal concentrations were determined by subculture to antibiotic-free agar to establish an end-point where the hemolytic end-point was not clear cut. Percent binding was determined by dividing the difference between the minimum inhibitory concentration in serum and in tryptose phosphate broth by the minimum inhibitory concentration in serum and multiplying by 100.

Radioactive Assay Method—As an additional check on the accuracy of protein binding results, and as another way to study the possibility of membrane trapping of free antibiotic, a series of experiments was performed using labeled erythromycin. The ultrafiltration technique was modified so that counting of disintegrations per minute rather than bioassay was used to determine antibiotic concentrations. Experiments were also carried out using the centrifuge[4] cone technique, which is an ultrafiltration method using centrifugation rather than suction to effect separation of protein bound from free antibiotic. With this method, 5 ml. of serum containing the labeled antibiotic (5 mcg./ml.) was placed in a commercially prepared porous cone lined with an inner synthetic membrane and centrifuged at $100 \times g$ for 20 min. at 37°, yielding 1 ml. of protein-free filtrate. The antibiotic used in this series of experiments was ^{14}C-labeled erythromycin[5] at a specific activity of 9.45 μc./mg. All specimens were counted[6] for 20 min. in a liquid scintillation spectrometer[7] using appropriate internal standards. The concentration of erythromycin in the serum was compared with that in the filtrate or centrifugate by counting as already described, and the percent binding was calculated by dividing the difference between the counts per minute in serum and centrifugate or filtrate

by the number of counts per minute in the serum and multiplying by 100.

Impermeability of the membranes to free antibiotic as a possible cause of high protein binding values was also studied by ultrafiltration and centrifugation of buffered saline solutions rather than serum. Possible membrane trapping was also checked in another way: the membranes used in two of the experiments with serum were carefully removed from the chambers, rinsed lightly with distilled water, and, after air drying, were burned to release carbon dioxide in a sample oxidizer[8]; radioactivity representing erythromycin adherent to the membrane was then counted.

RESULTS

Using the ultrafiltration method with 100% serum and bioassay of the specimens, binding of the four antibiotics was found to be as follows: erythromycin base, 73.4%; erythromycin propionate, 92.6%; lincomycin, 71.9%; and clindamycin, 93.6% (Tables I and II). Ultrafiltration of buffered saline solutions of the antibiotics revealed that less than 10% was trapped by the cellophane membrane, *i.e.*, did not pass through into the filtrate.

These ultrafiltration results correlated well with binding as determined by measurements of the decrease in antibacterial activity in serum by the tube dilution technique (Table III). With the use of small increments of antibiotic (0.02 mcg./ml.) from one tube to the next and bactericidal end-points, particularly for the higher serum concentrations, there was good agreement of serum binding figures obtained with the two methods.

Table IV summarizes the results of protein binding studies using ^{14}C-labeled erythromycin base. In these experiments, the mean binding of erythromycin by the ultrafiltration method was 73.5%, very close to the 73.4% observed with bioassay. Filtration of buffered saline solutions of the drug demonstrated little evidence of membrane trapping (retention <4%), again a result similar to that reported with bioassay of the specimens. Studies of membrane trapping carried out by burning the membrane after ultrafiltration of serum and counting the labeled carbon dioxide released showed that only 0.05 mcg. or less of the erythromycin was retained by the membrane. Centrifugation studies, performed with the cone technique as an alternative method of checking protein binding of ^{14}C-erythromycin, yielded a binding figure of 67.7%. With centrifugation of buffered saline solutions of the labeled antibiotic, 11.7% of the radioactivity was present in the cone.

DISCUSSION

The low degree of serum protein binding commonly attributed to erythromycin (2), lincomycin (3), and clindamycin (4) has been based chiefly upon tube dilution studies demonstrating little or no increase in minimum inhibiting concentration in serum as compared with broth. However, these measurements are subject to a large error when twofold dilutions are used and when the concentration of serum employed, often 50%, is far below that occurring in the blood. Other technical factors that may cause erroneous binding determinations include use of very high concentrations of antibiotic, far above those seen under *in vivo* circumstances, or the use of serum of different species which has been found to give binding results different for some drugs from those of human serum (1). A widely quoted ultrafiltration study said to demonstrate 18% binding of erythromycin by human serum was actually done with serum protein fractions rather than whole serum (12). A lincomycin dialysis study using 50% horse serum demonstrated no evidence of binding, while a similar study showing 20% binding did not specify the concentration of antibiotic used (3).

Recently reported high degrees of binding of erythromycin and erythromycin estolate carried out at antibiotic concentrations in the range usually found in patients and using the ultrafiltration technique revealed binding values of 81.4 and ≥95.7%, respectively (13). Other recent studies have also shown quite high binding figures for lincomycin (80–90%) (6) and clindamycin (83%) (7).

The presently reported studies, carried out in conjunction with the various controls described earlier, also indicate a high degree of serum protein binding for erythromycin and erythromycin propionate, which is the free base of erythromycin estolate. The difference in binding noted for the two erythromycins is apparently not solely due to the difference in molecular weights, since the percent binding for erythromycin base (mol. wt. 733.92) is about 20% less than that of erythromycin propionate (mol. wt. 789.96), while there is only a 7% difference in their molecular weights.

Pharmacological Evaluation of Medicinal Plants from Western Samoa

T. R. NORTON▲, M. L. BRISTOL, G. W. READ, O. A. BUSHNELL, M. KASHIWAGI, C. M. OKINAGA, and C. S. ODA

Abstract □ A total of 110 plant parts from 34 different species of medicinal and toxic plants was collected for pharmacological testing in or near the Lefaga District on the island of Upolu in Western Samoa. Voucher specimens of all species were also made. From the 110 plant parts, 211 different extracts were prepared and evaluated for antiviral, antibacterial, and anti-Ehrlich ascites tumor properties and for effects on blood pressure, heart rate, respiration, electrocardiogram, electroencephalogram, and gastric motility. Twelve extracts were effective *in vitro* as antibacterial agents and six inhibited Ehrlich ascites tumor growth in mice. Ninety-one extracts showed hypotensive properties, 31 for more than 30 min.

Keyphrases □ Medicinal plants—pharmacological evaluation of 34 species from Western Samoa □ Antiviral activity—34 plants from Western Samoa screened □ Antitumor activity—34 plants from Western Samoa screened □ Antibacterial activity—34 plants from Western Samoa screened □ Antihypertensive activity—34 plants from Western Samoa screened

As part of a broad program of ethnobotanical and pharmacological studies of medicinal plants and other biota from the Pacific basin, medicinal and poisonous plants of Western Samoa were collected for pharmacological and chemical evaluation. The ethnobotanical phase was centered in Lefaga District on the island of Upolu. The flora was studied intensively, and a large collection of herbarium specimens was obtained. Ethnobotanical data concerning the names, usage, and special significance of most of the woody and some of the herbaceous flora were gathered for native and introduced plants. This information, which included a large body of medicinal lore, was gathered from many people in Lefaga District. No prominent practitioner of native medicine was located in the District, so the data obtained on medicinal plants are not those of one outstanding individual but rather reflect that body of information widely known to many Samoans. Extensive botanical collections were also made in the interior of Savaii island and to a lesser extent at many coastal points on both islands. Whenever possible, ethnobotanical data were gathered at the same time from local people.

The 34 plants chosen for inclusion in the pharmacological studies are native or naturalized species, many of which also occur on adjacent island groups. Most are of therapeutic or toxicological interest to the Samoans today and many are noted in the literature concerning Samoa. Three plants, *Ochrosia oppositifolia*, *Barringtonia samoensis*, and *Terminalia samoensis*, were included because of their close botanical relationship to plants known for their physiological activity. Herbarium voucher specimens were made for all the plants studied[1]. The plant materials analyzed were air dried in Samoa in a large rack of screen trays heated gently by kerosene lanterns. The material was sealed in polyethylene for air shipment to Honolulu, Hawaii.

A direct evaluation under clinical conditions of the use of the plants by the local Samoans was not attempted. However, it was felt that the probability of physiological and chemotherapeutic effects might be greater with plants selected by the local people for medicinal use than with plants selected at random. Whether this is so remains a moot point. No checks were carried out for possible potentiation corresponding to use of several plants in a given local remedy.

Each plant part from Western Samoa was powdered and extracted with methylene chloride and then 60% ethanol. In this manner, the extraction method gave two extracts, the methylene chloride extract containing the relatively nonpolar constituents and the aqueous ethanolic extracts containing the more polar constituents. All extracts were examined for antiviral, antitumor, and antibacterial activity as well as for systemic effects in the rat.

EXPERIMENTAL

Extraction—The dried plants received by air from Western Samoa were powdered in a Wiley mill. About 100–300 g. of the powdered sample was suspended in 5–10 times its weight of methylene chloride, the amount of solvent necessary to impart fluidity to the mixture. In a few cases, chloroform was used instead of methylene chloride. After standing for about 24 hr., the mixture was filtered and the marc was washed several times with additional chlorinated solvent. The combined filtrate was evaporated to dryness at room temperature, and the residue was mixed with approximately 300 ml. of 95% ethanol. This mixture was then evaporated at ≦50° to a volume (in milliliters) equal to one-tenth of the weight (in grams) of the original sample; it was then diluted with nine volumes of water to give a 10% ethanolic emulsion, called the "methylene chloride extract."

The marc was air dried at room temperature and then suspended in 5–10 times its weight of 60% ethanol, the amount of solvent necessary to impart fluidity to the mixture. After standing for 24 hr., the mixture was filtered and the marc was washed several times with additional 60% ethanol. The combined filtrates were evaporated at ≦50° to a volume equal (in milliliters) to the original weight (in grams) of the plant sample. The resulting extract was called the "aqueous ethanol extract."

All extracts were stored frozen and thawed just before use.

Columbia SK Virus—Five-week-old Swiss-Webster mice were inoculated intraperitoneally with Columbia SK virus (brain adapted) of LD_{70-90} titer (1). The infected controls were in groups of 20 and the treated mice were in groups of 10 for each drug. Two hours after the virus inoculation, 0.1 ml. of the extract was inoculated subcutaneously. All extracts were first checked for acute toxicity at 0.1 ml. If toxic at this level, dilutions were made to achieve the maximum nontoxic dose. This latter dose was injected subcutaneously for a total of 4 days (eight doses). The mice were observed for another 5 days after termination of the treatment. The T/C listed in Table I is the percent mortality of the treated mice divided by the percent mortality of the controls, multiplied by 100. When enough sample was available, experiments that gave T/C values below 75 were rerun for confirmation.

Ehrlich Ascites Tumor—Five-week-old Swiss-Webster mice were injected intraperitoneally with 5×10^5 Ehrlich ascites tumor cells. The experiments were carried out as previously reported (2). One-tenth milliliter of extract was checked for acute toxicity. If 0.1 ml. of extract was acutely toxic, dilutions of the extract were made to determine a maximum nontoxic dose. Intraperitoneal injections of the maximum nontoxic dose to groups of five mice were started 24 hr. after Ehrlich ascites tumor cell inoculation and were continued twice daily for 10 days. The mice were observed daily for 30 days after Ehrlich ascites tumor inoculation. Groups of 10 diseased controls always died by the 21st day, with a mean survival

time of about 17 days. A drug was considered active if there were any survivors at 30 days.

Systemic Effects—Wistar-derived (MW-3) male rats (300–500 g.) were anesthetized with sodium pentobarbital[2] (50 mg./kg.) and connected to an eight-channel polygraph[3]. The following parameters were recorded: electrocardiogram (lead I), electroencephalogram (parietal skin leads), heart rate (tachograph driven by the output of the electrocardiogram channel), arterial and intragastric pressures (liquid pressure transducers[4] connected by cannulas to a femoral artery, and the stomach, *via* the esophagus, respectively), respiration (low pressure air transducer[5] connected to the trachea by a cannula), and respiratory rate (tachograph driven by the output of the respiration channel). Sodium heparin[6] (10 mg./kg.), the extracts, and drugs were given intravenously through a cannula inserted into a femoral vein.

In those cases where the extracts depressed the blood pressure, preliminary studies on the characteristics for the hypotensive action were begun. These consisted of testing the extract by other routes (oral and/or intraperitoneal) against the antihistamine diphenhydramine hydrochloride[7] (10 mg./kg.), challenging with epinephrine bitartrate[8] (3 mg./kg.), and boiling the extract for 5 min. prior to injection.

Inhibition of Bacterial Growth—The qualitative evaluation for antibacterial activity of the extracts was conducted using a modification of the small tube method of Catalfomo and Schultz (3). Cultures of mycobacteria and nocardia were maintained on Bushnell's poi agar, while all other bacteria were maintained on Bacto stock culture agar. The mycobacteria and nocardia were inoculated into Bacto dubos broth and allowed to grow for approximately 2 weeks at 37°. All other organisms were inoculated into BBL trypticase soy broth and incubated at 37° for approximatey 24 hr. These suspensions were used as the inocula for testing.

Each extract was centrifuged at approximately $30,000 \times g$ for 20 min. The supernate was then passed through a filter unit[9] equipped with a 0.45-μ filter[10] to obtain a sterile extract. Two drops of the sterile extract was added to 0.5 ml. of the desired melted medium at 45° in 17 × 60-mm. screw-capped vials. The vials were then allowed to cool in a slanted position. The mycobacteria and nocardia were grown in Bacto dubos agar, while all others were grown in BBL trypticase soy agar. After cooling, 1 drop of the liquid culture of the test bacterium was added to each vial. Aseptic technique was used throughout. The test vials were incubated at 37° for up to 2 weeks or until the control had grown. To determine growth, cultures were examined with a binocular dissecting microscope. All extracts that showed no growth were retested for confirmation of activity. In the retests, the pH of the extract was also adjusted to 7.0 to detect any effect of pH change. The organisms employed were: F21, *Mycobacterium smegmatis;* F47, *M. kansasii,* F61, *M. avium;* F284, *M. kansasii;* F808, *M.* sp., Battey type; F1224, *Nocardia* sp.; H37Ra, *M. tuberculosis;* P27, *M.* sp., scotochromogen; P39, *M.* sp., Battey type; R11, *M.* sp., from dairy; T3, *M.* sp., from patient; T122, *M.* sp., from bovine feces; OH9BA, *Escherichia coli,* pathogenic serotype; *Pseudomonas aeruginosa*[11]; *Salmonella typhimurium*[11], *Shigella flexneri*[11]; *Staphylococcus aureus,* penicillin resistant[11]; and *Streptococcus pyogenes*[11].

RESULTS AND DISCUSSION

The results of the pharmacological tests are shown in Table I. None of the 211 extracts showed any significant inhibition of Columbia SK virus. However, 12 extracts showed inhibition of bacterial growth *in vitro* and six inhibited Ehrlich ascites tumor growth in mice. Ninety-one of the 211 extracts caused hypotensive effects; some were quite potent, lowering the blood pressure by as much as 70%, with the effects lasting for several hours. Four of the extracts produced a general systemic toxicity.

Because some species produced more than one active extract (probably because the active agent was present in more than one tissue of the plant), it is more meaningful to speak in terms of the number of species yielding active extracts. On this basis, 19 of the 34 species tested contained hypotensive substances worthy of further study (produced hypotension for more than 30 min.).

There were no clear cut correlations between local medicinal use and the pharmacological results reported here. A report of the ethnobotanical study will be made later.

ACKNOWLEDGMENTS AND ADDRESSES

Received October 30, 1972, from the *Department of Pharmacology, University of Hawaii, Leahi Hospital, Honolulu, HI 96816*

Accepted for publication January 16, 1973.

Supported by Public Health Service Research Grant GM-15198 from the National Institute of General Medical Sciences.

The authors thank Dr. W. C. Cutting for his encouragement and advice in undertaking this study. The ethnobotanical study could not have been made without the generous cooperation of the Government of Western Samoa. The Hon. Tuaopepe Taula Tame graciously permitted the use of his fine residence in the village of Savaia during the entire year 1968. The authors are particularly grateful to the village High Chiefs Fui Tauaivalo and Leapai Vaa and to the Rev. Alama. In the village, as throughout the islands, the very generous hospitality of the Samoan people was enjoyed. From the literature on Samoa, Josephine Bristol has painstakingly extracted a great volume of ethnobotanical lore, some of which has aided the evaluations. The authors also acknowledge the technical assistance with the extraction of plant material by Caroline Devine, Ge-gun Youn, and Janice Aoki.

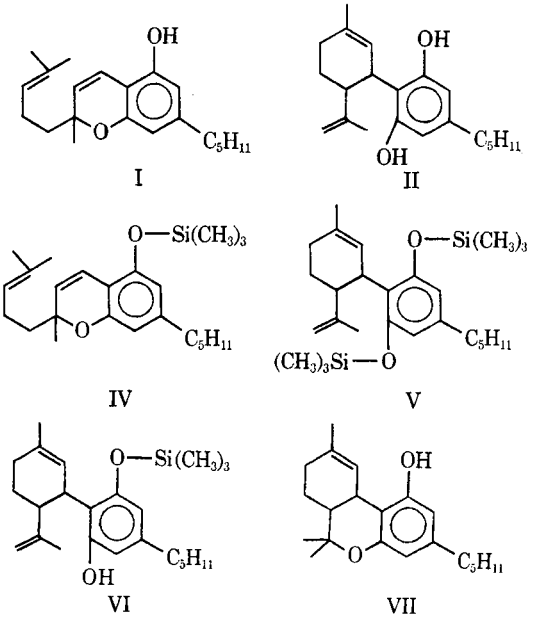
Constituents of *Cannabis sativa* L. III: Clear and Discrete Separation of Cannabidiol and Cannabichromene

CARLTON E. TURNER▲ and KATHY W. HADLEY

Abstract □ Synthetic cannabidiol and cannabichromene were discretely separated by GLC using their trimethylsilyl ether derivatives. The mono and disilylated derivatives of cannabidiol were identified. This procedure was utilized in the analysis of *Cannabis sativa* L.

Keyphrases □ *Cannabis sativa* L. constituents—separation of synthetic cannabidiol and cannabichromene using trimethylsilyl ether derivatives □ Cannabidiol—GLC separation from cannabichromene □ Cannabichromene—GLC separation from cannabidiol □ GLC—separation, cannabidiol and cannabichromene

Gaoni and Mechoulam (1) reported the separation of cannabichromene and cannabidiol by conventional GC techniques. However, this separation was based on retention times having only a 5-sec. time differentiation. With the identification of the propyl homologs by Vollner *et al.* (2), Gill *et al.* (3), and Merkus (4), there exists the possibility that, when used alone, GC analysis of cannabis constituents could lead to erroneous interpretations. Moreover, Vree *et al.* (5) showed that the propyl homolog of cannabinol, cannabivarin, was often found under the peak of a gas chromatogram normally attributed to cannabidiol or cannabichromene. These investigators were using hashish samples from Brazil and Lebanon; however, Fetterman and Turner (6) and Turner and Hadley (7) found propyl homologs in aerial parts of freshly harvested Indian *Cannabis sativa* L. grown in Mississippi. Additionally, they observed that cannabichromene was often reported as cannabidiol when GC was used as the only method for analysis (7). Accurate identification could, however, be obtained by using TLC and GC combined with a high-resolution mass spectrometer. The questioned validity of using only GC for the analysis of cannabidiol, cannabichromene, and cannabivarin prompted this investigation.



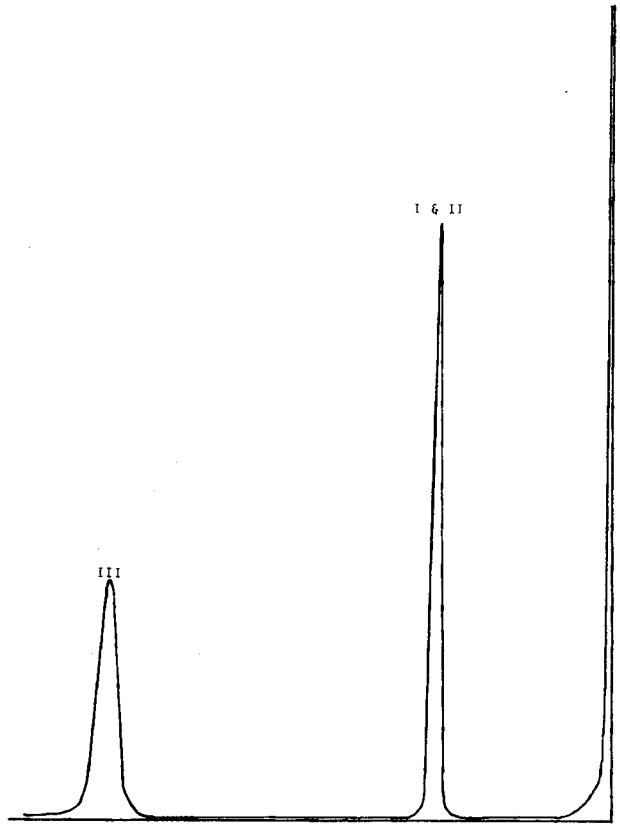


Figure 1—*Gas chromatogram of unsilylated cannabichromene (I), cannabidiol (II), and 4-androstene-3,17-dione, the internal standard (III).*

METHODS[1]

GC Analysis—Analyses were performed using gas chromatographs[2] equipped with hydrogen flame-ionization detectors and operated isothermally at 210°. The inlet temperature was 240° and the detector temperature was 260°. Glass columns [0.6-cm. (0.25-in.) o.d., 2-mm. i.d., × 2.4 m. (8 ft.)] were packed with 2% OV-17[3] on 100–120-mesh Chromosorb WHP. Nitrogen was used as the carrier gas at a flow rate of 10–16 ml./min., depending upon the instrument used.

[1] Authentic synthetic samples of cannabidiol and cannabichromene were obtained from the National Institute of Mental Health (NIMH). Relative retention times reported are relative to the internal standard 4-androstene-3,17-dione.

[2] Beckman GC-45 and GC 72-5.

[3] High purity polar phenyl methyl silicone of approximately 30,000 mol. wt. Packed by Beckman Instruments Co.

Table I—GC Relative Retention Times of Cannabinoids

Cannabinoid	Relative Retention Time
Cannabidiol bis(trimethylsilyl) ether	0.11
Cannabichromene trimethylsilyl ether	0.17
Cannabidiol mono(trimethylsilyl) ether	0.18
(−)-Δ^9-*trans*-Tetrahydrocannabinol trimethylsilyl ether	0.22
Cannabidiolic acid trimethylsilyl ester–bis(ether)	0.28
Cannabichromene	0.34
Cannabidiol	0.34
(−)-Δ^9-*trans*-Tetrahydrocannabinolic acid trimethylsilyl ester–ether	0.64
4-Androstene-3,17-dione	1.00

Silylation of Synthetic Cannabinoids—Five milligrams each of cannabidiol and cannabichromene was added to 0.2 ml. of anhydrous pyridine contained in a 50-ml. round-bottom single-neck flask. The pyridine solution was then subjected to continuous vibration from an ultrasonic vibrator until the cannabinoids were in solution. Then 0.3 mg. of the internal standard was added *via* a 10:1 pyridine–steroid solution. At this point, 0.4 ml. of *N,O*-bis(trimethylsilyl)-trifluoroacetamide with 1% trimethylchlorosilane[4] was added. The resulting reaction mixture was heated, using a heating mantle, for approximately 10 min. at 80°. Then 0.1 μl. of the reaction mixture was injected into the gas chromatograph.

Silylation of Plant Extract—A 1-g. sample was extracted with 40 ml. of spectrograde chloroform. The resulting solution was refrigerated at 6° and shaken at 10-min. intervals for 1 hr. The plant material then was removed by filtration, and the mother liquor was concentrated *in vacuo* at ambient temperature to a greenish paste void of solvent.

Anhydrous pyridine, 0.5 ml., was added, followed by continuous vibration from an ultrasonic vibrator until all resin was in solution. At this point, 0.5 ml. of *N,O*-bis(trimethylsilyl)-trifluoroacetamide[4] with 1% trimethylchlorosilane was added. The resulting reaction mixture was then processed as described previously for the silylation of synthetic cannabinoids. Unsilylated plant samples of *C. sativa* L. were analyzed according to the literature procedure (7).

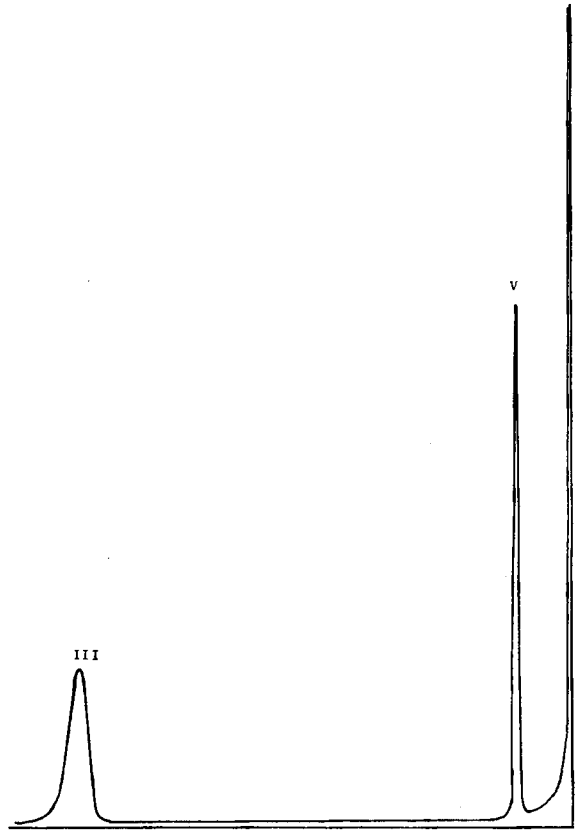

Figure 3—*Gas chromatogram of bis(trimethylsilyl) ether of cannabidiol (V).*

RESULTS AND DISCUSSION

The structures of natural and synthetic cannabichromene (I) and cannabidiol (II) are well known (1). Individual analysis of each of these cannabinoids is carried out routinely; however, when a sample contains both cannabidiol and cannabichromene (Fig. 1), no clean separation is obtained. This presents many problems to the researcher trying to ascertain if the sample contains a mixture of the two or is a pure sample of either. Claussen *et al.* (8) used the trimethylsilyl ether–ester derivatives to separate the free phenols from the carboxylic acid derivatives of some cannabinoids. Fetterman *et al.* (9) used a similar procedure to analyze for (−)-Δ^9-*trans*-tetrahydrocannabinolic acid. Claussen *et al.* (8) were unable to identify many peaks in the chromatogram obtained, whereas Fetterman *et al.* (9) used fresh marijuana having a very high concentration of (−)-Δ^9-*trans*-tetrahydrocannabinolic acid (approximately 90–97%) and a very small content of (−)-Δ^9-*trans*-tetrahydrocannabinol. Additionally, Davis *et al.* (10) described a silylated extract of cannabis. These three procedures are excellent but do not approach the problem of separating cannabidiol and cannabichromene as their free phenols.

A clean separation has been obtained by using the trimethylsilyl ethers of synthetic and natural cannabichromene and cannabidiol. Figure 1 is a chromatogram of equal parts (2 mg.) of synthetic cannabichromene and cannabidiol, analyzed as described under the *GC Analysis* section. The relative retention time of both compounds when compared to the internal standard 4-androstene-3,17-dione (III) is 0.34. Figure 2 is a chromatogram of the trimethylsilyl ether of synthetic cannabichromene (IV) having a relative retention time of 0.17, and Fig. 3 is a chromatogram of the bis(trimethylsilyl) ether of cannabidiol (V) having a relative retention time of 0.11.

Several factors affect the efficiency of silylation. The most common is incorrect handling of the sample. No solvents having an

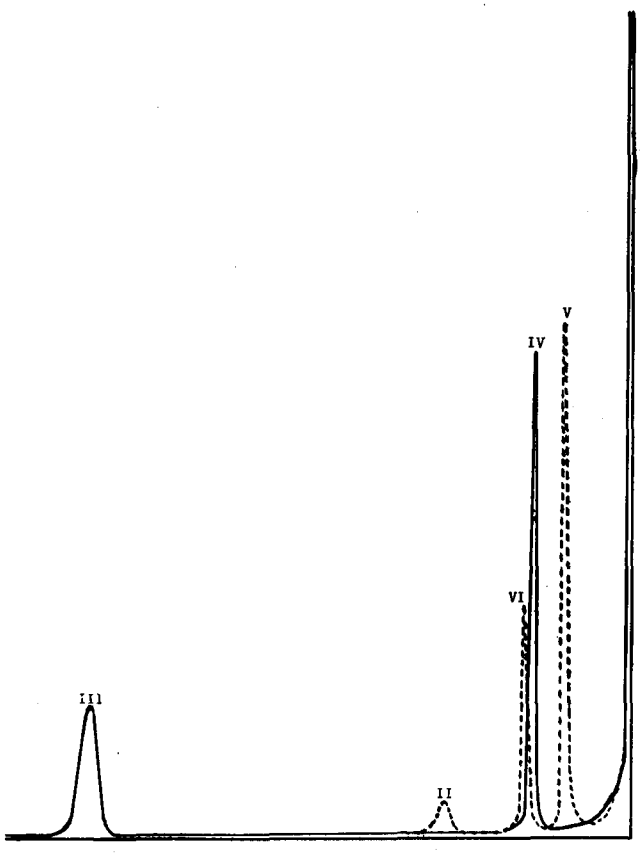

Figure 4—*Overlay of incompletely silylated cannabidiol and silylated cannabichromene, showing cannabidiol (II), mono(trimethylsilyl) ether of cannabidiol (VI), trimethylsilyl ether of cannabichromene (IV), and bis(trimethylsilyl) ether of cannabidiol (V). Key: ——, silylated synthetic cannabichromene; and - - -, products of incompletely silylated synthetic cannabidiol.*

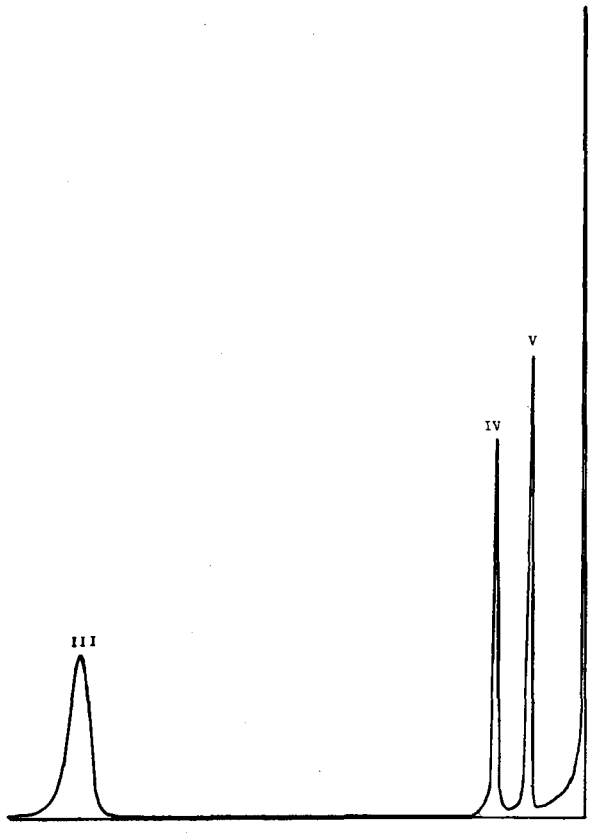

Figure 5—*Chromatogram of the trimethylsilyl ether of cannabichromene (IV) and the bis(trimethylsilyl) ether of cannabidiol (V).*

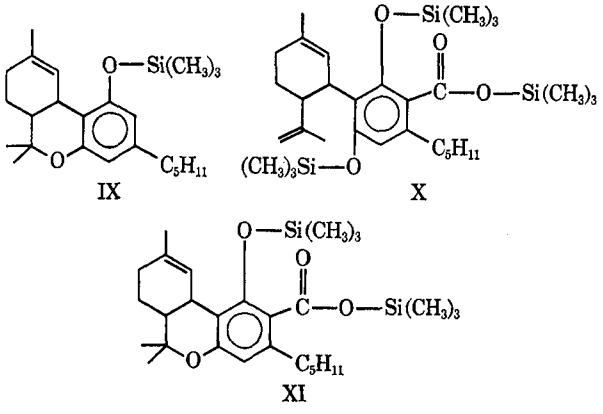
easily ionizable proton should be used. The silylation should be carried out with freshly obtained anhydrous solvents or solvents stored over drying agents such as molecular sieves.

Incomplete silylation can also be caused by an insufficient reaction time, too weak a silylating reagent, and/or an insufficient amount of silylating solution. For best results, an excess of the silylating solution should be added. Figure 4 is an overlay of an insufficient amount of a silylating solution being added to an equal weight of cannabidiol and cannabichromene. The solid line represents the trimethylsilyl ether of cannabichromene (IV), and the broken line represents silylated products of cannabidiol and free cannabidiol. The peak labeled II is unsilylated cannabidiol. The peak labeled VI is the mono(trimethylsilyl) ether of cannabidiol, and the peak labeled V is the bis(trimethylsilyl) ether of cannabidiol.

With the addition of a sufficient amount of the silylating solution, II and VI disappear. Synthetic cannabichromene and cannabidiol



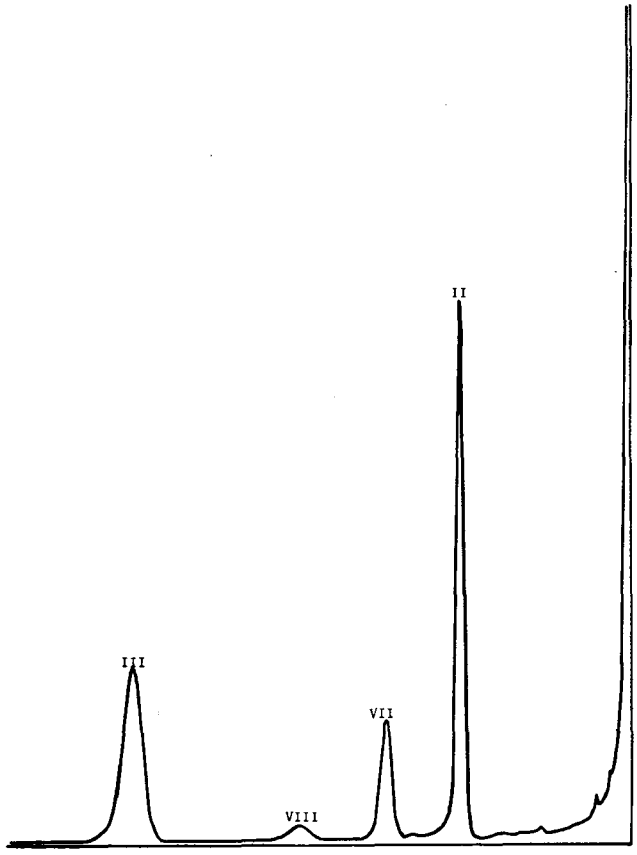


Figure 6—*Chromatogram of unsilylated Turkish (TU-A) C. sativa L., showing cannabidiol (II), (—)-Δ⁹-trans-tetrahydrocannabinol (VII), and unknown constituent (VIII).*

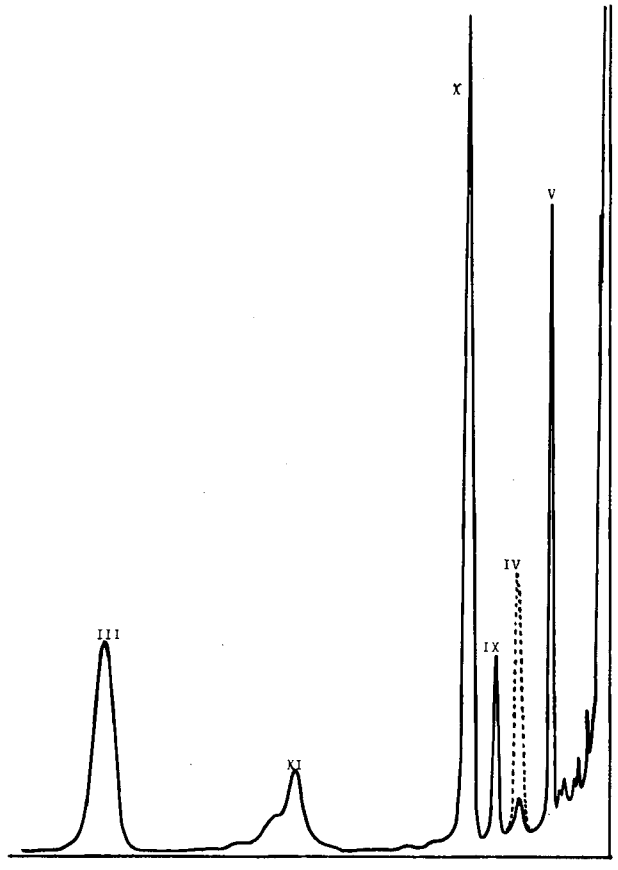

Figure 7—*Overlay of silylated synthetic cannabichromene and Turkish (TU-A) C. sativa L., showing bis(trimethylsilyl) ether of cannabidiol (V), trimethylsilyl ether of cannabichromene (IV), trimethylsilyl ether of (—)-Δ⁹-trans-tetrahydrocannabinol (IX), trimethylsilyl ester–bis(ether) of cannabidiolic acid (X), and trimethylsilyl ester–ether of (—)-Δ⁹-trans-tetrahydrocannabinolic acid (XI). Key: ——, silylated Turkish variant; and - - -, silylated Turkish variant plus synthetic cannabichromene.*

can be discretely separated when a slight excess of silylating solution is used (Fig. 5). Care must be taken, however, to ensure complete silylation since the mono(trimethylsilyl) ether of cannabidiol (Fig. 4) has a relative retention time of 0.18, very near that of the cannabichromene trimethylsilyl ether at 0.17 (Table I).

To illustrate the versatility and application of this procedure, a sample of Turkish *C. sativa* L. was analyzed (Fig. 6). Regular cannabis analysis decarboxylates cannabinoid acids to their free phenol. Thus, cannabidiol (II) and (−)-Δ⁹-*trans*-tetrahydrocannabinol (VII), along with an unknown constituent (VIII), are shown in Fig. 6. The unknown constituent is under further investigation at this time. Without close observation, VIII would normally be called cannabinol. However, cannabinol has a relative retention time of 0.63, whereas VIII is located at 0.67. Both cannabinol and VIII occur in some plant samples, particularly Mexican. Usually VIII appears as a shoulder immediately after cannabinol.

Silylated cannabinoids from a Turkish variant of *C. sativa* L. are shown in Fig. 7. The bis(trimethylsilyl) ether of cannabidiol is V. Peak IV is the trimethylsilyl ether of cannabichromene. The broken line represents a cannabichromene-enriched plant sample. Peak IX is the trimethylsilyl ether of (−)-Δ⁹-*trans*-tetrahydrocannabinol, and X is the trimethylsilyl ester–bis(ether) of cannabidiolic acid. The trimethylsilyl ester–ether of (−)-Δ⁹-*trans*-tetrahydrocannabinolic acid (XI) is followed by a shoulder of an unknown component.

Thus, trimethylsilyl derivatives of cannabinoids can be used to differentiate if a plant sample of *C. sativa* L. contains cannabidiol, cannabichromene, or a mixture of the two. However, caution must be observed to ensure complete silylation, and/or the absence of the internal standard will lead to erroneous results.

SUMMARY

Synthetic cannabidiol and cannabichromene are separated as their trimethylsilyl ethers. The mono(trimethlysilyl) ether of cannabidiol is identified. The procedure described is applicable to samples of *C. sativa* L. plant material when the defined conditions are observed. Therefore, it is possible to determine qualitatively, using GC, if a sample of cannabis contains cannabichromene, cannabidiol, or a mixture of the two.

Kinetics and Mechanisms of Action of Drugs on Microorganisms XVI: Effect of Oleandomycin and Its Combinations with Tetracycline, Chloramphenicol, Erythromycin, Lincomycin, and 1′-Demethyl-4′-depropyl-4′-(R and S)-*n*-pentylclindamycin on Microbial Generation of *Escherichia coli*

CHONG MIN WON and EDWARD R. GARRETT▲

Abstract □ The steady-state generation of *Escherichia coli* culture is inhibited by oleandomycin to a new initial steady state with a new generation rate constant, k_{app}, which is linearly related to drug concentrations in the low concentration range. At higher concentrations, a saturation model is implied in which drug molecules bind to a limited number of receptor sites and the k_{app} asymptotically approaches zero with infinite concentration. Oleandomycin demonstrates another subsequent action in that cell division is inhibited and the oleandomycin-affected cells show increased size with generation rates that are less than the initial effect. The antimicrobial activity of oleandomycin decreases with the nutrient concentrations of Medium 3 USP or casamino acid–glucose–buffer salt medium (Anton's medium), probably because of the binding of drug molecules to the proteins and casamino acids in the broth media. The activity of the drug increases with the pH of the media. This is consistent with the postulate that only the unprotonated fraction of the drug concentration contributes to the activity. Combinations of oleandomycin or erythromycin with tetracycline are synergistic while those with chloramphenicol, erythromycin, or lincomycin are indifferent. These phenomena are evidenced by the decreased or invariant k_{app} values of *a priori* equipotent concentrations.

Keyphrases □ Antimicrobial activity—effect of oleandomycin and combinations with other antibiotics on *Escherichia coli* generation, kinetics □ Oleandomycin and combinations with other antibiotics—effect on *Escherichia coli* generation, kinetics □ *Escherichia coli* generation—effect of subinhibitory oleandomycin and combinations with other antibiotics, kinetics □ Antibiotics—effect of oleandomycin and combinations with other antibiotics on *Escherichia coli* generation, kinetics

Oleandomycin (1) is a medium-spectrum antibiotic with an antibacterial spectrum similar to that of erythromycin and other macrolides (1, 2). Its action is predominantly bacteriostatic (3) and, like other macrolide antibiotics, it inhibits the binding of radioactive chloramphenicol to bacterial ribosomes *in vitro* (4), which suggests that the antibiotic also acts on the 50S ribosomal subunit. Oleandomycin, like erythromycin and lincomycin, shows the same differential effect as chloramphenicol on proline, lysine, and phenylalanine incorporation in cell-free systems (5). This implies that its action in protein synthesis may be at the same site as chloramphenicol.

Oleandomycin has been extensively used as a 1:2 mixture with tetracycline, and synergism has been claimed for this combination (6–8). However, this opinion has been denied by others (9–13).

The effects of drugs can be quantified and insight into their mechanisms of action can be gained by monitoring the generation rate of microorganisms in the presence of varied subinhibitory concentrations (14). This paper presents the quantitative kinetic expressions for microbial generation when inhibited by oleandomycin as functions of drug concentrations, inoculum size, pH, and compositions of the nutrient media. Microbial kinetics have served as a proper tool for the appropriate classification of the actions of drug combinations (14). This paper also presents studies on the evaluation of drug combinations containing oleandomycin.

EXPERIMENTAL

Organism—Replicate slants of *Escherichia coli* (ATCC 12407) were used in all experiments. The slants were prepared from a single colony and were stored in a refrigerator at 4°.

Culture Media—Bacto Antibiotic Medium 3[1] was rehydrated to Medium 3 USP according to the specifications of the manufacturer. The media were filtered and autoclaved as described previously (14). The pH of the media was 7.05 ± 0.05 with the exception of those used to study the antimicrobial activity as a function of pH. To obtain media with a pH in the range of 6.30–7.55, various amounts of concentrated hydrochloric acid or sodium hydroxide solutions were added aseptically to the culture media. To study the effects of various components of culture medium, Anton's medium (15), which had 10% acid-hydrolyzed casein (Bacto Casamino Acids[1]) in Davis's medium, was also used.

Antibiotics—The references to concentrations of oleandomycin phosphate[2] (775 mcg. base eq. mg.$^{-1}$) throughout this paper refer to this phosphate salt. Samples of tetracycline hydrochloride USP[3], lincomycin hydrochloride[3] (895 μg. base eq. mg.$^{-1}$), 1′-demethyl-4′-depropyl-4′-(R and S)-*n*-pentylclindamycin hydrochloride[3,4] (I) (pure), erythromycin lactobionate[5] (670 μg. base eq. mg.$^{-1}$), and chloramphenicol[6] (purity grade) were also used.

Inoculation and Generation—An aliquot (5 ml.) of culture medium was inoculated from a fresh slant, and the culture was allowed to generate for 15 hr. at 37.5° in an incubator. A sample of 0.5 ml. was then diluted into 49.5 ml. broth. The generation of the culture was followed up to 2×10^7 *E. coli*/ml. This culture was then finally diluted 100-fold into a bulk amount of broth. The inoculated broth, contained in a flask fitted with 49.5-ml. delivery head, was then shaken and kept in an incubator at 37.5° for 15 min. Aliquots (49.5 ml.) of the inoculated broth were then aseptically transferred into replicate 125-ml., loosely capped conical flasks. The cultures were maintained at 37.5 ± 0.01° in a 189.27-l. (50-gal.) constant-temperature water bath with constant shaking. All pipets and media used for the dilutions of the cultures were prewarmed to prevent temperature shocks on the organisms.

Total Count Method—Samples of 1.00 or 0.50 ml. were withdrawn at 25-min. intervals and diluted into an appropriate amount (24 or 49 ml.) of diluent in such a way that the obtained counts were less than 100,000 counts/50 μl. on the Coulter counter[7], which was

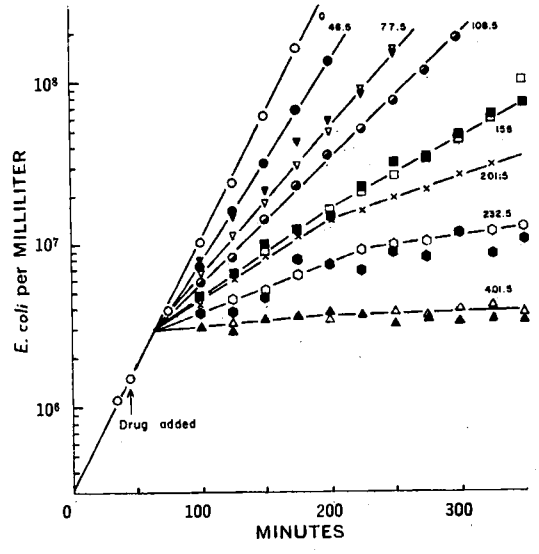

Figure 1—*Typical generation curves of* E. coli *in Medium 3 USP at pH 7.05 and 37.5° in the absence and presence of various concentrations of oleandomycin phosphate, obtained by total (○●▽○□×○△) and viable (▼■○▲) counts. The curves are labeled according to the oleandomycin phosphate concentration in micrograms per milliliter.*

equipped with a 30-μ orifice. The coincidence corrections for the counter were made by programming in a calculator[8] in accordance with the coincidence correction chart supplied in the manufacturer's manual. The diluent used was a filtered[9] aqueous solution of 0.85% NaCl and 1% formaldehyde. The total counts were also corrected for the background count of the particular batch of medium used, diluted in the same way as the sample. The average background counts were normally 400/50 μl. Semilogarithmic plots of *E. coli* per milliliter total counts against time for various oleandomycin phosphate concentrations in Medium 3 USP are given in Fig. 1.

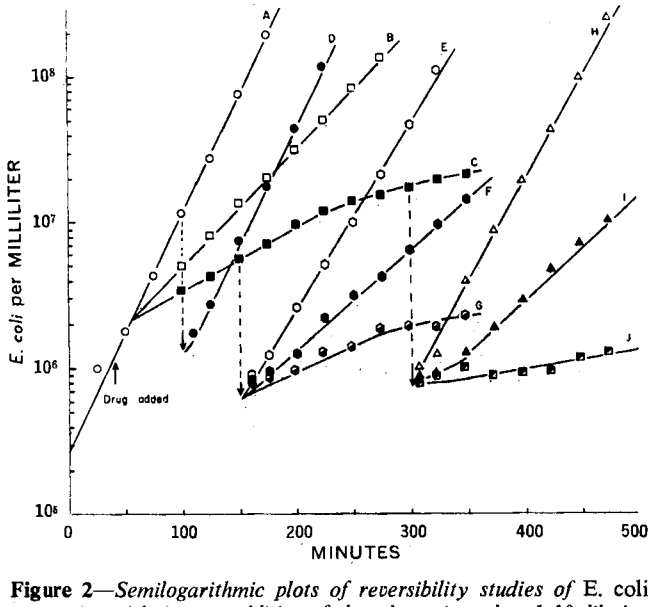

Figure 2—*Semilogarithmic plots of reversibility studies of* E. coli *generation with time on addition of oleandomycin and on 1:10 dilution of culture with broth. Curve A is drug-free culture. Curves B and C are after addition of oleandomycin phosphate to achieve final concentrations of 101 and 202 mcg./ml., respectively. Curve D is after 1:10 dilution of curve A culture. Curves E, F, and G and curves H, I, and J are after 1:10 dilution of curve C at 150 and 300 min., respectively, with broth containing oleandomycin. Curves E and H, curves F and I, and curves G and J had final concentrations of 21, 101, and 202 mcg./ml. oleandomycin phosphate, respectively.*

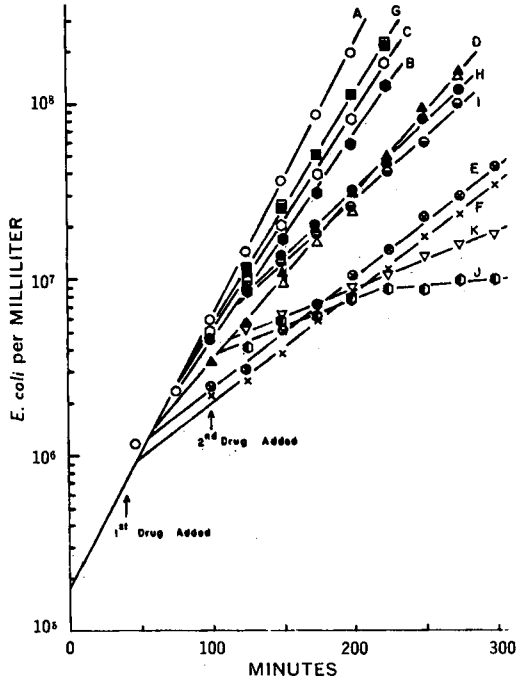

Figure 3—*Effects of order of addition of equipotent oleandomycin and tetracycline on generation rates of* E. coli *in Medium 3 USP at 37.5°. Curve A is for the generation of* E. coli *in the absence of drug. Curves B and C are for the generation in the presence of 38 mcg./ml. oleandomycin phosphate and 0.034 mcg./ml. tetracycline, respectively. Curve G is when equipotent tetracycline is added (■) to the oleandomycin-affected culture or oleandomycin is added (□) to the tetracycline-affected culture so that the final concentrations are equipotent with those of curves B and C. Curve D is for the generation in the presence of 86 mcg./ml. oleandomycin phosphate (△) or 0.076 mcg./ml. tetracycline (▲). Curves H and I are when equipotent tetracycline is added to the oleandomycin-affected culture and equipotent oleandomycin is added to the tetracycline-affected culture, respectively, so that the final concentrations are equipotent with that of curve D. Curves E and F are for the generation in the presence of 152 mcg./ml. oleandomycin phosphate and 0.15 mcg./ml. tetracycline, respectively. Curves J and K are when equipotent tetracycline is added to the oleandomycin-affected culture and equipotent oleandomycin is added to the tetracycline-affected culture, respectively, so that the final concentrations are equipotent with those of curves E and F.*

Viable Count Method—Samples of 0.50 ml. were withdrawn from the cultures and appropriately diluted into sterilized 0.85% saline solution in accordance with a preplanned dilution scheme so that 60–80 colonies per plate would result. From these dilutions, aliquots of 1.00 ml. were pipeted onto each of three replicate agar plates. The plates were incubated for 48 hr. at 37.5° and the colonies were counted on a colony counter[10]. Semilogarithmic plots of *E. coli* per milliliter viable counts for various oleandomycin phosphate concentrations in Medium 3 USP are given in Fig. 1.

Cell Size Analyses—The size-frequency distributions of the cells of *E. coli* in the absence or presence of oleandomycin were studied using the Coulter counter[7] in conjunction with a Channelyzer[11] and plotter[11]. The instruments were calibrated with polyvinyl toluene latex beads of 3.49 mean diameter. Two replicate 49.5-ml. samples of culture generating in logarithmic phase were treated with oleandomycin phosphate solution to give final concentrations of 31 and 77.5 mcg./ml. Samples were taken every 30 min., and size distributions as well as total counts were obtained. A culture generated in the absence of the drug was studied as a control.

Effect of Antibiotic Concentrations on Generation Rates—Fresh solutions of the respective antibiotics were aseptically prepared for

[8] Wang 700.
[9] Millipore 0.45-μ HA.

[10] Model C-110, New Brunswick Scientific Co., New Brunswick, N. J.
[11] Coulter Electronics Inc., Hialiah, Fla.

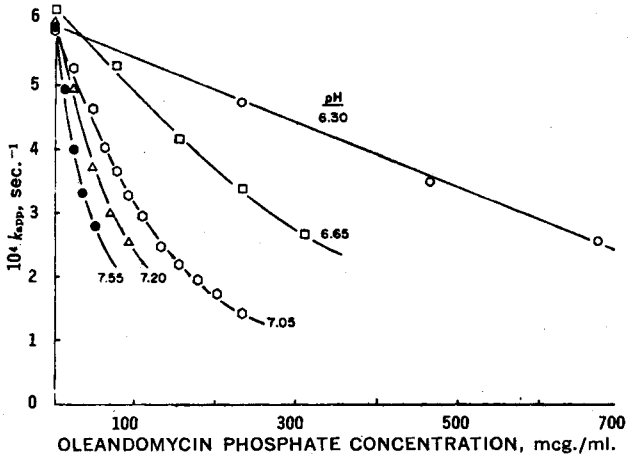

Figure 4—*Dependence of the apparent first-order generation rate constant,* k_{app}, *for* E. coli *in Medium 3 USP on oleandomycin phosphate concentration at various pH values at 37.5°.*

each experiment. They were sufficiently diluted so that aliquots of 0.50 ml. added to the 49.5-ml. culture volumes yielded the desired oleandomycin phosphate concentrations. The drug solutions were added to the cultures generating at 37.5° in the logarithmic phase at predetermined organism concentrations. Samples were withdrawn every 25 min. and counted by the Coulter counter. One culture without drug was studied in each experiment to obtain a control generation rate constant.

Effect of Inoculum Size on Drug-Affected Generation Rates—An aliquot of a culture in logarithmic phase containing 2×10^7 *E. coli*/ml. was diluted 1000-fold into a bulk amount of broth. The inoculated bulk broth was then shaken and kept in an incubator at 37.5° for 15 min. Aliquots (49.5 ml.) of the inoculated broth were aseptically transferred into one control and three sets of five replicate flasks. The drug solutions were added to each set when the organism concentrations in the control flask reached 1.8×10^6, 1.8×10^6, and 1.1×10^7/ml.

Effect of Broth Variations on Drug-Affected Generation Rates—Various strengths of Medium 3 USP and Anton's medium were prepared so that the concentrations of broth ingredients were normal, halved, and doubled. The ingredients of Anton's medium were varied in several ways to study the effects of each ingredient on the drug-affected generation rates. The ingredients studied were phosphates, magnesium sulfate, and casamino acids.

Effect of pH on Drug-Affected Generation Rates—The preparation of Medium 3 USP with different pH values was described previously (14), and the drug-affected generation rates were studied by the total count method.

Reversibility of Drug Action at 37.5°—An aliquot (5.0 ml.) of a drug-free culture generating in the logarithmic phase (curve A in Fig. 2) was added to 49.5 ml. of fresh broth so that the organism population was diluted 11-fold (curve D). Two flasks with 49.5 ml. broth were treated with 0.5 ml. drug solutions to achieve final concentrations of 101 (curve B) and 202 mcg./ml. (curve C). When the drug-affected culture of curve C was in a steady-state generation, an aliquot (5.0 ml.) of the culture was added to 49.5 ml. of fresh medium (curve E). At the same time, aliquots (5.0 ml.) of the culture of curve C were added to 50 ml. volume broth which contained enough drug solution so that the drug concentrations were restored to 101 (curve F) and 202 (curve G) mcg./ml. Similar dilutions were made after the drug-affected culture of curve C had deviated from the semilogarithmic linearity. They were made with fresh medium (curve H) and to broth containing enough drug solution to reestablish final concentrations of 101 (curve I) and 202 (curve J) mcg./ml.

Effect of Equipotent Combinations of Oleandomycin with Other Antibiotics—Equipotent mixtures of 100, 90, 80, 60, 50, 40, 20, 10, and 0% of oleandomycin and the residual percentage of tetracycline, chloramphenicol, erythromycin, lincomycin, or I were prepared. Aliquots (0.50 or 1.00 ml.) of the equipotent mixtures of drug solutions were added to replicate 49.5-ml. volumes of culture generating in logarithmic phase in Medium 3 USP. Samples were withdrawn every 25 min., and the bacterial cells were counted by the total

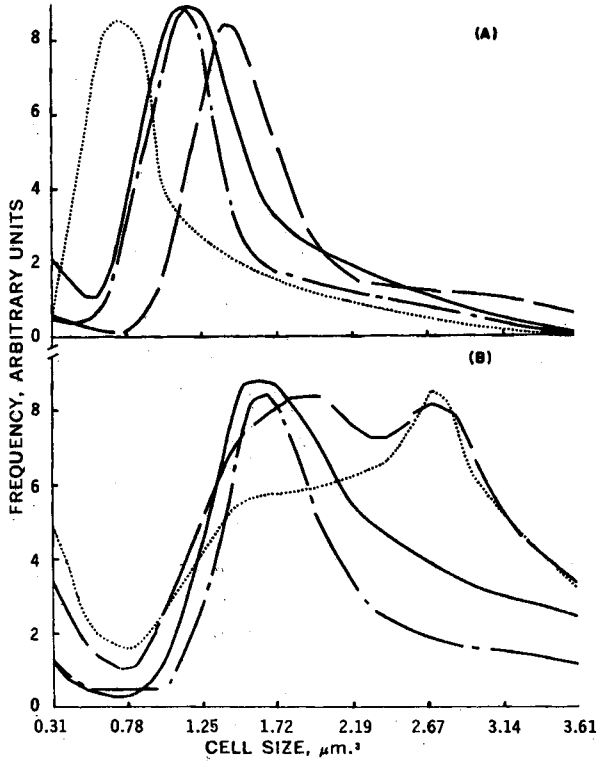

Figure 5—*(A) Size-frequency distribution of the control organisms of* E. coli *in Medium 3 USP 30–140 (——) and 170–200 (- - -) min. after inoculation and of generating organism treated with 132 mcg./ml. oleandomycin phosphate 75–230 (— —) and 260–350 (— - —) min. after the time of inoculation (see Fig. 1). (B) Size-frequency distribution of organisms treated with 233 mcg./ml. oleandomycin phosphate 75–230 (— - —), 260 (——), 290–320 (— —), and 350 (- - -) min. after the time of inoculation (see Fig. 1).*

count method. The combination studies of oleandomycin with tetracycline were repeated in Anton's medium with 0.01 and 0.1% $MgSO_4 \cdot 7H_2O$. They were also repeated in Anton's medium with the normal concentration of nutrients and with half the normal concentration.

Effect of Order of Addition of Oleandomycin–Tetracycline Combinations on Microbial Generation—Replicate 49.5-ml. volumes of a culture containing 7×10^5 *E. coli*/ml. generating in the logarithmic phase (curve A in Fig. 3) were treated with 1.0 ml. of either oleandomycin or equipotent tetracycline solution to give three different concentrations in the final Medium 3 USP media: 152 mcg./ml. oleandomycin phosphate (curve E) or 0.15 mcg./ml. tetracycline (curve F), 86 mcg./ml. oleandomycin phosphate (curve D) or 0.076 mcg./ml. tetracycline (curve D), and 38 mcg./ml. oleandomycin phosphate (curve B) or 0.034 mcg./ml. tetracycline (curve C). The cultures to which 0.5 ml. of the above tetracycline solutions had been added were treated with 0.5 ml. of the oleandomycin solutions 60 min. after the first drug addition at three different dose levels so that the mixtures and the solutions of either drug alone were equipotent *a priori*. Similarly, 0.5-ml. amounts of tetracycline were added to the cultures to which oleandomycin had been added initially.

RESULTS

In the logarithmic generation phase, the bacterial generation rate, dN/dt, is proportional to the number, N, of organisms per unit volume, so that:

$$\log N = (k_{app}/2.303)t + \log N_0 \qquad \text{(Eq. 1)}$$

where N_0 is the number of organisms per unit volume at some zero time when the new steady-state generation is achieved, and the k_{app} determined from the slopes of appropriate plots is the apparent first-order generation rate constant. The addition of graded concentrations of oleandomycin to the culture decreases the generation

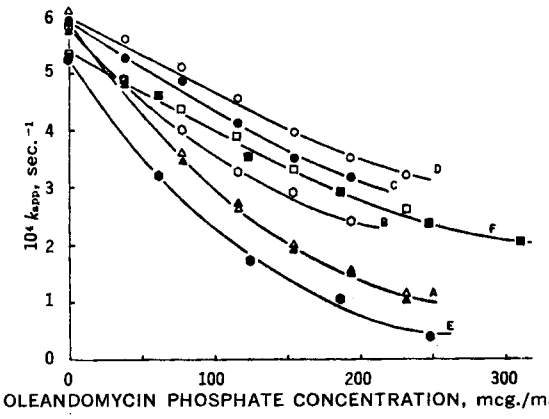

Figure 6—*Dependence of the apparent first-order generation rate constant,* k_{app}, *for* E. coli *on oleandomycin phosphate concentrations at various nutrient concentrations of Medium 3 USP (A, B, C, and D) and of Anton's medium [E and F (■)] and at various phosphate concentrations in Anton's medium [F (■) and F (□)]. The curves, the multiples of the stated concentrations, and the* 10^6 k_A*'s are: A (▲), 0.5, 3.2; A (△), 1.0, 3.2; B, 1.3, 2.3; C, 1.6, 1.5; D, 2.0, 1.3; E, 0.5, 3.4; F (■), 1.0, 1.3; and F (□), 0.5, 1.3.*

rate as a function of antibiotic concentrations, and the semilogarithmic plots of cell numbers against time show a linear relation with slopes that decrease with increasing drug concentrations (Fig. 1). Plots of the determined k_{app} values against various drug concentrations, A, of oleandomycin are given in Fig. 4. At the lower drug concentrations, the plot conforms to the expression:

$$k_{app} = k_0 - k_A A \qquad \text{(Eq. 2)}$$

where k_0 is the generation rate constant in the absence of drug and k_A is defined as the inhibitory constant.

Since the numbers of viable and total cells are coincident (Fig. 1), no kill or death of microorganisms occurs up to the highest drug concentration studied and the use of total counts to determine the generation rates of organism affected by subinhibitory concentrations of oleandomycin is justified. Prolonged contact of microorganisms to higher drug concentrations made the cells grow in size (Fig. 5) and appeared to be related to the deviation from the semilogarithmic linearity of the initial drug-affected steady state. The k_{app} values used were calculated from this initial steady state.

Culture Broth Variations—The concentrations of nutrients in the culture media, both Medium 3 USP and Anton's medium (Fig. 6), have significant effect on the drug-affected generation rate constants. There were no significant differences in drug-affected generation rate constants when the concentrations of phosphates were varied

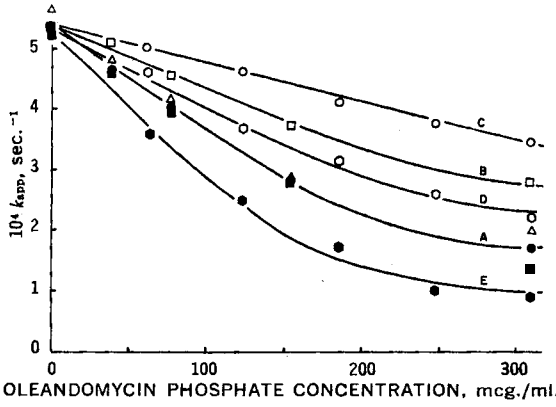

Figure 7—*Dependence of the apparent first-order generation rate constant,* k_{app}, *for* E. coli *on oleandomycin phosphate at various magnesium salt (A and B) and casamino acid (C, D, and E) concentrations in Anton's medium. The curves, the percent* $MgSO_4 \cdot 7H_2O$ *concentrations or multiples of the stated casamino acid concentrations, and the* 10^6 k_A*'s are: A (■), 0.001, 2.2; A (●), 0.005, 2.2; A (▲), 0.02, 2.2; B, 0.1, 1.1; C, 2.0, 0.65; D, 1.0, 1.4; and E, 0.5, 2.5.*

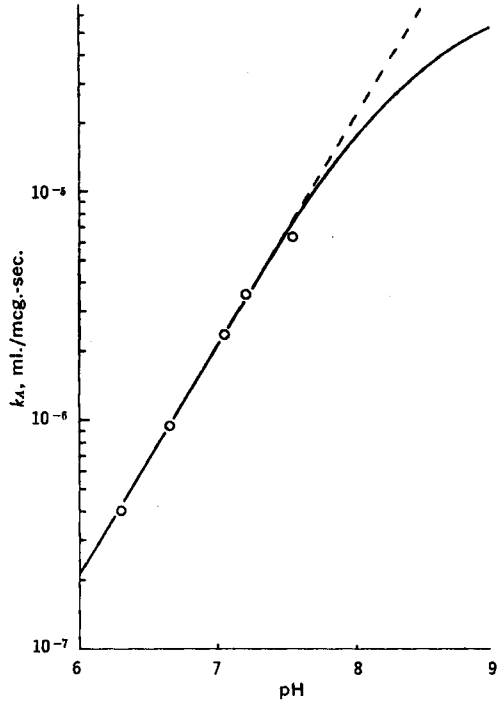

Figure 8—*Dependence of the logarithm of the inhibitory constant,* k_A, *for the action of oleandomycin phosphate on* E. coli *in Medium 3 USP at 37.5° on the pH value. The points are experimental values and the solid line is the theoretical value calculated on the basis that only the unprotonated fraction of the drug concentration contributes to the activity.*

(Fig. 6). Magnesium ion had a minor antagonistic effect only when its concentration was 10 times greater than its normal concentration in Anton's medium (Fig. 7). However, there were significant differences in k_{app} values at the same drug concentrations when the concentrations of casamino acids in Anton's medium were varied; the generation rate constants decreased with increasing nutrient strengths (Fig. 7). The drug may be bound to the casamino acids of Anton's medium and to the proteins in Medium 3 USP to decrease the amount of drug available for antibacterial activity.

Effect of Inoculum Size on Drug-Affected Generation Rates—The apparent generation rate constants were obtained at various concentrations of oleandomycin over almost a 100-fold range in inoculum size at the time of drug addition and were not significantly different. Thus, it cannot be concluded that the drug is metabolized by the organisms, adsorbed to the cells, or inactivated by excretory substances which may be functions of organism population.

Effect of pH on Drug-Affected Generation Rates—The apparent generation rate constants, k_{app}, obtained in broth at pH values 6.30–7.55 in the absence and presence of graded oleandomycin concentrations are plotted in Fig. 4. The drug-free generation rate constants were not significantly affected, but the drug-affected generation rate constants decreased markedly with increasing pH at comparable drug concentrations. The logarithms of the inhibitory constants, k_A, obtained from the slopes of the initial linear portion of plots similar to Fig. 1 appear to be a linear function of the pH of the medium in the range studied (Fig. 8).

Reversibility of Drug Action (Fig. 2)—The culture attained a new steady-state generation 20–25 min. after the drug addition to the culture generation in logarithmic phase. The reasonably short lag time would predict a reversibility of the action of oleandomycin within short time intervals. The steady-state generation affected by 202 mcg./ml. oleandomycin phosphate (curve C) reverted to a new steady state when diluted 11-fold (curve E), and the new steady state was as readily achieved as the drug-free culture (curve A to curve D). There were no significant differences between magnitudes of rate constants obtained from the generation (curve B) attained directly by addition of drug solution to the culture to give a final concentration of 101 mcg./ml. and that attained by diluting the culture of curve C into fresh medium containing enough drug

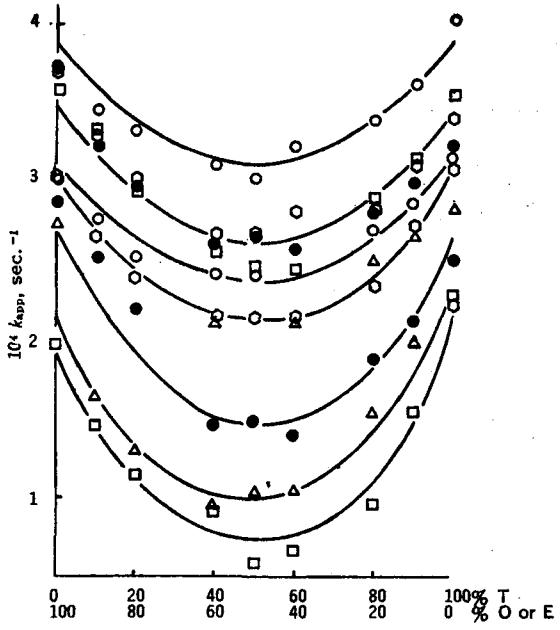

Figure 9—*Effect of varied oleandomycin (O) and tetracycline (T) fractions of* a priori *equipotent combinations at various potency levels in Medium 3 USP (□) and in Anton's medium with a normal concentration of nutrients, 0.01% $MgSO_4 \cdot 7H_2O$ (○), with half the normal concentration (△), and with a normal concentration except for 0.1% $MgSO_4 \cdot 7H_2O$ (○). The effect of varied erythromycin (E) and tetracycline fractions in Anton's medium (●) at 37.5° is also shown.*

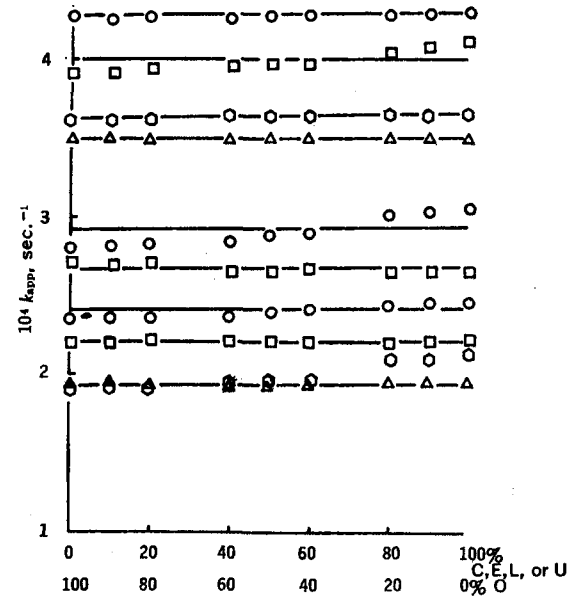

Figure 10—*Effect of varied fractions of oleandomycin with chloramphenicol [C (○)], erythromycin [E (○)], lincomycin, [L (□)], and I [U (△)] in* a priori *equipotent combinations at various potency levels on the apparent generation rate constant of* E. coli *in Medium 3 USP at pH 7.05 and 37.5°.*

solution to give the same final drug concentration (curve F). The dilution of curve C to the restored drug concentration (curve G) had no significant effect on the magnitude of the generation rate constant nor on the fact that the prolonged contact enlarges the cell size. Similarly, the 11-fold dilution of the culture of oversized cells (later portions of curve C) into fresh medium containing halved (curve I) or restored (curve J) concentrations of the drug produced new steady-state generations with predictable rate constants after longer lag periods.

Effect of Equipotent Mixtures of Oleandomycin and Other Antibiotics—The generation rate constants, k_{app}, of cultures affected by equipotent combinations of oleandomycin and tetracycline, erythromycin, lincomycin hydrochloride, chloramphenicol, or I in Medium 3 USP are given in Fig. 9. The mixtures contained 0–100% oleandomycin and the residual percentage of an equipotent amount of the other antibiotic. The mixtures were prepared so as to be *a priori* equipotent in their combined action at two or three different potency levels. The mixtures of oleandomycin and tetracycline exhibited increased activity, as indicated by lower k_{app} values than the equipotent antibiotic used alone. This unequivocally demonstrates synergism (14) between oleandomycin and tetracycline in their combined action against the generation of *E. coli*. The synergism was also observed in Anton's medium with a normal concentration (0.01%) and with a higher concentration (0.1%) of $MgSO_4 \cdot 7H_2O$. It was observed also with half the normal concentration of ingredients (Fig. 9). A similar synergism was observed with the antibiotic pair erythromycin and tetracycline (Fig. 9). However, the null slopes of plots of the k_{app} values for all of the other *a priori* equipotent mixtures demonstrate the lack of any antagonism or synergism in the subinhibitory concentration range (Fig. 10).

Effect of Order of Addition of Oleandomycin and Tetracycline in Combination on Microbial Generation—There were no significant differences between the generation inhibitions produced by the action of 152 mcg./ml. oleandomycin phosphate (curve E in Fig. 3) or 0.15 mcg./ml. tetracycline (curve F), between the inhibitions by 86 mcg./ml. oleandomycin phosphate or 0.076 mcg./ml. tetracycline (curve D), and between the inhibitions by 38 mcg./ml. oleandomycin phosphate (curve B) or 0.034 mcg./ml. tetracycline (curve C).

The addition of either 19 mcg./ml. oleandomycin phosphate (curve G) to the 0.017-mcg./ml. tetracycline-affected culture 60 min. after the first drug addition or 0.017 mcg./ml. tetracycline to the 19-mcg./ml. oleandomycin phosphate-affected culture did not inhibit the generation rate any more than the equipotent amounts of either drug alone did (curves B and C). The combined action is indifferent at the lowest dose level studied.

The addition of either 43 mcg./ml. oleandomycin phosphate (curve I) to the 0.038-mcg./ml. tetracycline-affected culture or 0.038 mcg./ml. tetracycline (curve H) to the 43-mcg./ml. oleandomycin phosphate-affected culture inhibited the generation rate more than did the equipotent amounts of either drug alone (curve D). This demonstrates that the combined action of oleandomycin with tetracycline is synergistic at higher dose levels. This pattern of response was likewise observed for combinations of 76 mcg./ml. oleandomycin phosphate with equipotent concentrations of 0.075 mcg./ml. of tetracycline, since the slopes of curve K and initial portions of curve J are lower than those of curves E and F. In both cases the sequence of addition of the antibiotics produced no significant effects on the synergistic action, since the slopes of curve I and curve K and those of curve H and the initial portions of curve J are the same, respectively.

DISCUSSION

The coincidence of viable and total counts in the subinhibitory range ($\leq$600 mcg./ml.) of oleandomycin phosphate-affected generation (Fig. 1) confirms that the action of oleandomycin is primarily bacteriostatic (3). The drug-affected generation rate constants, k_{app}, are not a linear function of oleandomycin phosphate concentration throughout the entire concentration range (Fig. 4). The shape of the curve indicates the presence of some saturable process in which drug molecules at the high concentrations bind to a limited number of receptor sites (14).

The fact that no significant changes in apparent generation rate constants were observed in the control culture when the concentrations of nutrients in Medium 3 USP or Anton's medium were varied (Fig. 6) implies that the differences in the oleandomycin-affected generation rate contants with different concentrations of Medium 3 USP and Anton's medium can be attributed to the reversible binding of oleandomycin molecules to both protein ingredients of Medium 3 USP and casamino acids in Anton's medium (Fig. 7).

The extent of generation inhibition by oleandomycin increases as the pH of the media increases (Figs. 4 and 8). Since oleandomycin has a pKa of 8.5 (16), the unprotonated fraction of the total drug concentration might be the only effective inhibitory species,

since the relative concentration of the unprotonated species increases as pH increases. The inhibitory constant k_A should be a function of the unprotonated fraction f of oleandomycin in accordance with the equation (14):

$$k_A = k_A^* f = k_A^* \left(\frac{K_a}{K_a + [H^+]}\right) \qquad \text{(Eq. 3)}$$

where k_A^* is the intrinsic inhibitory constant of the unprotonated species. The semilogarithmic plot of k_A against pH is given in Fig. 8. The intrinsic inhibitory constant k_A^* is calculated from the intercept of the plot when $[H^+] \gg K_a$; $k_A^* = 6.96 \times 10^{-5}$ ml./mcg.-sec., from which the antibacterial activity at any pH value can be estimated using Eq. 3.

At doses higher than 200 mcg./ml. of oleandomycin phosphate, a definite change in cell size distribution (Fig. 4) occurs subsequent to the inhibition of microbial generation by the drug. This results in the observed two phases of action (Fig. 1). This phenomenon was not observed with erythromycin-affected generation (17).

Both macrolides, oleandomycin and erythromycin, are synergistic in combined action with tetracycline against microbial generation (Fig. 9). Synergism of antimicrobial activity observed with a combination of two drugs (14) may be assigned to: (*a*) the allosteric modification of the receptor site of one drug by the other so that the affinity of the former increases, (*b*) sequential blocking (18) in which each drug acts on separate rate-determining steps in the sequential metabolic pathway (14) and both drugs show a saturable mechanism of binding to receptor sites, (*c*) the increase in transport to the biophase of one drug by another, and/or (*d*) the fact that one drug effectively eliminates or negates a compound or species in the nutrient media that normally acts as the inhibitor of the action of the other.

The first possible explanation is the most speculative. The second possible explanation cannot be readily reconciled with the linear dependence of k_{app} on tetracycline concentrations which demonstrates a nonsaturable process for the action that results from tetracycline binding to its receptor sites. On the basis of the similarity of structures and postulated equivalent modes of action of the macrolides, erythromycin and oleandomycin, the speculation that combinations of erythromycin and tetracycline would be also synergistic in their action was confirmed (Fig. 9).

The additivity effects for combinations of oleandomycin with chloramphenicol, erythromycin, lincomycin, or I (Fig. 10) may be expected since all of these antibiotics bind to the 50S ribosomal subunit and presumably act on a similar rate-determining step in protein biosynthesis. However, it does appear anomalous that oleandomycin is not antagonistic in combination with both lincomycin and I whereas erythromycin is antagonistic with but one (I) of the two.

The third possible explanation might lead to the demonstration of a significant variation in the degree of synergism with a change in the sequence of addition of oleandomycin and tetracycline; *i.e.*, a greater synergism may result if the antibiotic that increases the transport of the other is added first. However, there was no significant difference in the extent of synergism with a change in the sequence of addition (Fig. 3).

The fourth possible explanation is not valid with respect to inhibition by magnesium salt concentration (Fig. 9) since the degree of synergism is independent of this concentration. Thus, the explanation given for the synergistic action of novobiocin–tetracycline combinations (unpublished data) that the removal of significant amounts of magnesium ion by tetracycline chelation increased the antibacterial effect of novobiocin at low magnesium-ion concentrations is not applicable here. The demonstration of the same extent of synergism in half the normal concentration of nutrient media (Fig. 9) rejects the possibility of negation of the inhibitory action of another constituent of the media by one antibiotic of the combination.

The probable mode of action of the macrolides is on translocation (19) rather than on peptidyl transfer. Combinations of tetracycline with antibiotics such as the lincosaminides and chloramphenicol, which are presumed to act in such a manner (19), show no synergism. Thus, it is reasonable to project that these two different mechanisms of action may be manifested in combinations with tetracycline by the presence or absence of the synergism observed in these studies. It is also implied that the action of a macrolide is enhanced by tetracycline or, conversely, possibly by one increasing the affinity of the other to its respective receptor site or by one increasing the permeability of the other through the cell wall.

Michaelis–Menten Kinetic Parameters of Renal Tubular Secretion of *para*-Alkylated Mandelic Acids and Their Use in Revealing Possible Chemical Characteristics around Receptor Site of Secretion Carrier in Rats

JANARDAN B. NAGWEKAR▲, PRAVIN M. PATEL, and MOIZ A. KHAMBATI

Abstract □ From the determination of the Michaelis–Menten kinetic parameters (V_m and K_m) of renal tubular secretion of D-(−)-*p*-*n*-propylmandelic acid (V) and D-(−)-*p*-isopropylmandelic acid (VI) in rats, it is shown that these compounds involve the same renal tubular carrier for their secretion but the affinity of V for the carrier is approximately twice that of VI. By considering these parameters as well as the structural variations of V and VI, together with those of other homologs of D-(−)-mandelic acid (I) studied previously, inferences have been drawn regarding the chemical nature around the possible cationic receptor site of the carrier for renal tubular secretion of organic anions in rats. The utilization of the model compounds of a homologous series of I in studying the influence of alkyl groups present in the organic anions on the pharmacokinetic parameters, particularly the volume of distribution, is discussed.

Keyphrases □ Renal tubular secretion—Michaelis–Menten kinetic parameters, *para*-alkylated mandelic acids used to determine chemical nature of secretion carrier receptor site environment, rats □ Michaelis–Menten kinetic parameters—renal tubular secretion, *para*-alkylated mandelic acids used to study chemical environment of cationic receptor sites of the carrier, influence of alkyl groups, volume of distribution, rats □ Receptor sites, renal tubular secretion carrier—Michaelis–Menten kinetic parameters, *para*-alkylated mandelic acids, influence of alkyl groups, rats □ Secretion, renal tubular, rats—*para*-alkylated mandelic acids used to study chemical environment of carrier receptor site, Michaelis–Menten kinetic parameters, influence of alkyl groups, volume of distribution □ Pharmacokinetic parameters, Michaelis–Menten—renal tubular secretion of *para*-alkylated mandelic acids, use in revealing possible chemical characteristics around the receptor site of secretion carrier, rats

The Michaelis–Menten kinetic parameters (V_m and K_m) of renal tubular secretion determined in rats for D-(−)-mandelic acid (I), tropic acid (II), D(−)-*p*-methylmandelic acid (III), and D-(−)-*p*-ethylmandelic acid (IV) were reported (1, 2) recently. The analysis of these parameters indicated that these compounds are secreted in rats by involving a common carrier and that the affinity of III for the carrier is similar to that of I but that the affinity of IV or II is almost twice that of I. The data obtained in these studies in terms of V_m and K_m were further utilized to distinguish certain chemical structural features of a possible renal tubular carrier responsible for the secretion of these compounds.

Another interesting inference drawn from previous studies (1, 2) in rats was that the apparent volume of distribution (V_d) of the *para*-alkylated mandelic acids (III and IV) is approximately half of that of I, the parent compound.

Since these compounds are neither bound to plasma proteins, metabolized, nor reabsorbed from the renal tubules, in addition to being recovered completely in the urine of rats in the unchanged form, it became possible to determine the effect of introducing alkyl groups in the *para*-position of I on the V_d, initial glomerular filtration rates, and renal tubular secretion rates of these compounds in rats. Noticing such dramatic effects of *para*-alkylation of I on the pharmacokinetic parameters of the compounds, it was considered of great interest to study in rats the effect on these parameters of substituting propyl ($CH_3CH_2CH_2$—) and isopropyl [—$CH(CH_3)_2$] groups in the *para*-position of I.

Therefore, the purpose of the present study was to determine the relative magnitudes of the V_d and the Michaelis–Menten kinetic parameters of renal tubular secretion of D-(−)-*p*-*n*-propylmandelic acid (V) and D-(−)-*p*-isopropylmandelic acid (VI) from the urinary excretion kinetic studies in rats. These data will also be utilized in ascertaining certain inferences drawn from previous studies regarding the topography of the renal tubular secretion carrier receptor around its cationic site(s) which is (are) considered to form primary sites of attachment of the compounds used in the study.

EXPERIMENTAL

Materials—The following were used: D-(−)-mandelic acid, m.p. 132–133°, $[\alpha]_D^{25}$ −154°; D-(−)-*p*-*n*-propylmandelic acid, m.p. 124–125°, $[\alpha]_D^{25}$ −142°, obtained by resolving from the racemic acid synthesized by the method of Reibsomer *et al.* (3); D-(−)-*p*-isopropylmandelic acid, m.p. 159–160°, $[\alpha]_D^{25}$ −129°, obtained by resolving from the racemic acid synthesized by adapting the method of Carson *et al.* (4) for the synthesis of I; and DL-tropic acid, m.p. 117–120°.

Apparatus and Analytical Procedure—The equipment and the GC procedure used for quantitative determination of I and its homologs appearing in the urine of rats were the same as described previously (1). The procedures for specific rotation determination, pH measurements, dissociation constant determination, partition coefficient determination, protein binding determination, and absolute configuration determination of the compounds were also described previously (1). The absolute configuration of the compounds found was D.

Methodology—The procedure followed for preparing the rats and for urine collection following intravenous administration of the compounds was the same as described previously (1). Approximately 65 Sprague–Dawley male rats, weighing 170–220 g., were used repeatedly. Of the 65 rats, 30 were used in the urinary excretion studies involving VI and the rest were used in the urinary excretion studies involving V. The aqueous solutions of sodium salt of each compound used for intravenous administration were made isotonic, and the volumes of intravenous injections varied from 1 to 2 ml. The urinary excretion kinetics of V were studied over the dosage range of 72–258 μmoles/kg. (3–10 mg./rat) and that of VI were studied over the dosage of 129–387 μmoles/kg. (5–15 mg./rat). The reason for using lower doses of V is explained later.

To determine the initial glomerular filtration rates of V at the dosage levels of 72–132 μmoles/kg., the appropriate dose of the substrate compound (V) and the 3012-μmoles/kg. dose of II as an inhibitor, both as their sodium salts contained in 2 ml., were injected intravenously to the rat.

Table I—Overall Urinary Recovery of the Compounds in the Unchanged Form

Compound	Number of Rat Studied	Dose per Rat, mg.	Recovery, mg.
DL-V	3	10	6.1–6.6
DL-VI	3	10	6.5–6.8
V	3	10	9.9–10.0
VI	6	5	4.6–4.9

To determine the nature of inhibition of the renal tubular secretion of VI by II, the urinary excretion kinetic studies of VI at the intravenous dosage levels of 206, 257, and 387 μmoles/kg. in the presence of a 1355-μmoles/kg. dose of II were carried out. Both VI and II were administered as their sodium salts and were contained in the same intravenous solution.

In studies where the apparent initial glomerular filtration rates of VI and I were simultaneously determined in the same rat in the presence of 3012 μmoles/kg. of II as the inhibitor of secretion of these compounds, the equimolar doses of VI and I were used. Three different doses of these compounds were employed: 180, 258, and 387 μmoles/kg.

RESULTS AND DISCUSSION

Selection of Optical Isomers of Compounds—The selection of V and VI for the present study was based on the following ideal properties possessed by the compounds.

1. From the overall urinary recovery (Table I) of the administered intravenous doses of racemic *p*-propylmandelic acid, racemic *p*-isopropylmandelic acid, V, and VI, it becomes clear that only with the levorotatory isomers of the compounds is virtually 100% of the given doses recovered in the unchanged form. The poor recovery of the compounds (unchanged) following administration of the racemic form was due to metabolism of the dextrorotatory form of the compounds, as found previously for other homologs of I (1, 2). In view of the objectives of the study, quantitative recovery of V and VI was considered to be ideal.

2. The pKa value reported for VI is 3.64 (5) and that determined for V is 3.7. Therefore, these compounds are expected to remain in the ionized form in the biological fluids.

3. The partition coefficients ($C_{organic}/C_{buffer}$) determined for these compounds according to the procedure previously described (2) were zero, which lead to the reasonable assumption that the reabsorption of the compounds in the renal tubules is negligible, if any.

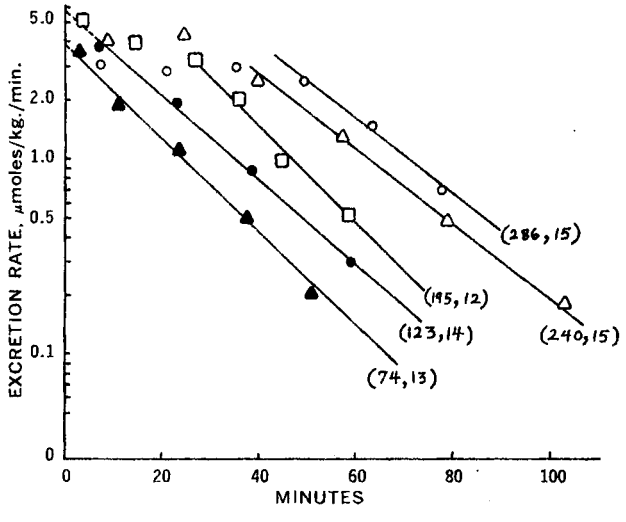

Figure 1—*Plots of log urinary excretion rate* versus *time for V following intravenous administration of various doses to rats. (The numbers in parentheses refer to intravenous dose in micromoles per kilogram and the biological half-life of the compound, respectively. At doses of 240 and 286 μmoles/kg., the biological half-life refers to the data obtained after 30 min., as explained in the text.)*

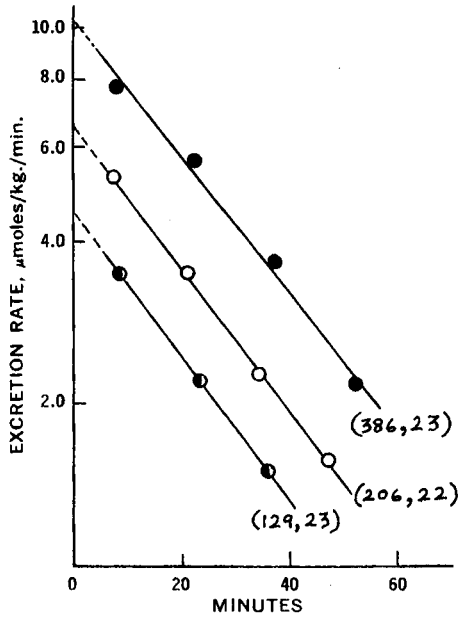

Figure 2—*Apparent first-order urinary excretion of VI following intravenous administration of various intravenous doses to rats. (The numbers in parentheses refer to the intravenous dose in micromoles per kilogram and the biological half-life of the compound, respectively.)*

4. From the equilibrium dialysis studies, it was noticed that at the equilibrium concentrations of 0.152–0.255 mg./4 ml. of V in the plasma, about 3.7–5.2% of the compound was bound. For practical purposes, this extent of binding was considered negligible. The binding of VI to plasma proteins was found to be negligible.

Urinary Excretion Kinetics of V and VI—As can be seen from the data presented in Fig. 1, two different patterns of urinary excretion of V in rats become evident. At the intravenous doses of 72–143 μmoles/kg. studied, the excretion of V occurred by an apparent first-order process and the kinetic model for the compound was indeed describable as the one-compartment open model. Since the administered dose of the compound is recovered entirely in the urine in the unchanged form, the urinary excretion data were treated according to the following equation:

$$\log \Delta Ae/\Delta t = \log kA_0 - kt/2.303 \qquad \text{(Eq. 1)}$$

where $\Delta Ae/\Delta t$ is the rate of excretion of the compound at time t, which is the midpoint of the urine collection interval; A_0 is the amount of the compound in the body at zero time, k is the apparent first-order rate constant for excretion of the compound, and kA_0 is the apparent initial excretion rate of the compound at a given intravenous dose. The rate constant k was obtained from the slope ($-k/2.303$), and the initial excretion rate was obtained from the intercept of the straight line obtained upon plotting log $\Delta Ae/\Delta t$ *versus* t. The straight line in each case was obtained by the method of least squares. The rate constant k is designated as the rate constant of urinary excretion because the administered doses of the compound are recovered entirely in the urine in the unchanged form (1). The biological half-life of Compound V was calculated from $0.693/k$. The average biological half-life of the compound determined from 23 studies over the intravenous dosage range of 72–143 μmoles/kg. was 13 min.

However, when the studies were carried out at the intravenous dosage levels of 195–294 μmoles/kg., the excretion of Compound V in almost all of the 11 studies was found to take place by an apparent first-order process (with the biological half-life of about 12 min.), but generally after 30 min. During the initial 30 min., the excretion rate of the compound declined so gradually that the rates appeared to be almost constant (Fig. 1). Although it may be expected that, since V is secreted by the renal tubules of rats as shown later, the biological half-life of the compound would tend to increase with the increase in the dose due to increasing saturation of the secretory process, such an extremely gradual decline in the excretion rate noted during the initial period cannot be accounted for

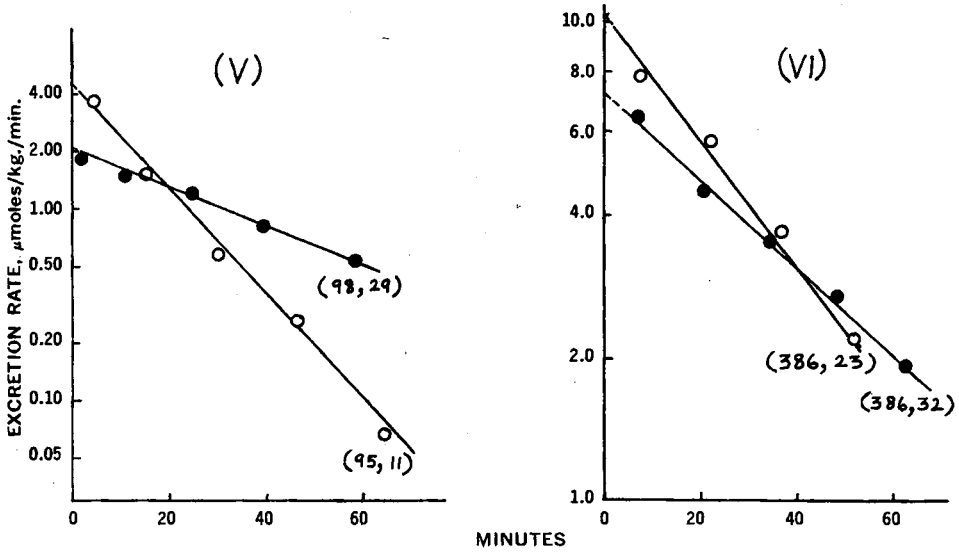

Figure 3—*Apparent first-order urinary excretion of V and VI in the absence* (○) *and in the presence* (●) *of a simultaneously administered 3020-μmoles/kg. i.v. dose of II. (The numbers in parentheses refer to the intravenous dose in micromoles per kilogram of the respective compound and its biological half-life, respectively.)*

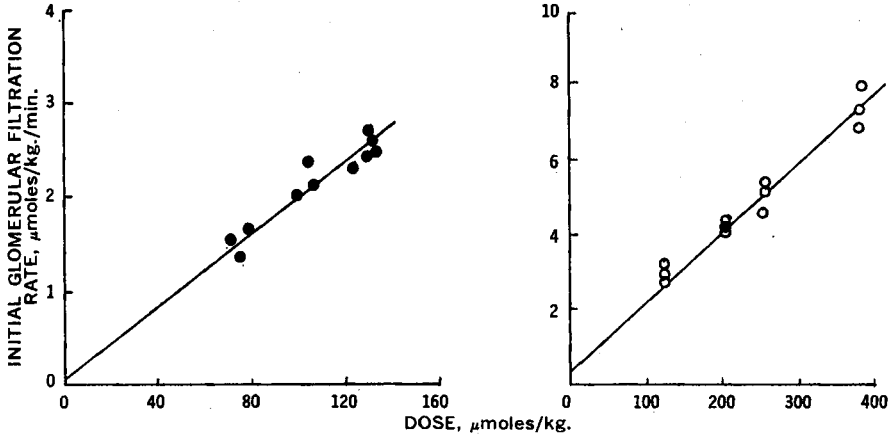

Figure 4—*Relationship between the apparent initial glomerular filtration rates and the intravenous doses for V* (●) *and VI* (○).

on this basis. The reason for this belief is that even IV, which has almost the same V_d and affinity for the renal tubular secretion carrier in rats, did not show such a saturation effect, as evidenced by the constancy of its biological half-life even up to a 885-μmoles/kg. i.v. dose (2). The reason for this phenomenon has been investigated and will be reported separately.

The facts that VI is excreted by an apparent first-order process and that its excretion is describable by the one-compartment open model become evident from the data presented in Fig. 2. The average biological half-life determined for the compound is 23 min.

Determination of Apparent Initial Glomerular Filtration Rates and Apparent Renal Tubular Secretion Rates—In previous studies (2), II was shown to inhibit competitively the renal tubular secretion of the homologs of I in rats. Therefore, II was used to inhibit the tubular secretion of 129–387-μmoles/kg. doses of VI or 72–132-μmoles/kg. doses of V. The preliminary studies indicated that the apparent initial excretion rates obtained for the compounds at these doses were the same in the presence of a 3012- or a 4500-μmoles/kg. i.v. dose of II, indicating that the dose of 3012 μmoles/kg. of II was adequate to inhibit the secretion of the compounds. Therefore, in each study, a 3012-μmoles/kg. dose of II (inhibitor), along with an appropriate dose of each compound, was administered to the rat intravenously. Both the substrate compound and the inhibitor were administered as their sodium salts contained in a 2.5-ml. isotonic solution. The overall urinary recovery of the doses of the substrate compounds in these studies was found to be quantitative and, as evidenced from the typical studies presented in Fig. 3, the excretion of the substrate compounds in the presence of II occurred by an apparent first-order process. The apparent initial excretion rates obtained in these studies were plotted against the corresponding doses of the compounds (Fig. 4). As shown in this figure, the least-squares straight lines obtained for the data almost passed through the origin, indicating that the apparent initial excretion rates determined in these studies represent the apparent initial glomerular filtration rates of the compounds at the corresponding intravenous doses.

The apparent initial secretion rates were computed by subtracting the initial glomerular filtration rates from the apparent initial excretion rates at the corresponding intravenous doses of each compound. The glomerular filtration rates used in the computation of the apparent initial secretion rates were, however, those obtained from the representative plots (Fig. 4) corrected to pass through the origin.

The composite plots of apparent initial excretion rates, initial glomerular filtration rates, and initial secretion rates *versus* intravenous doses of the compounds are shown in Figs. 5 and 6.

Determination of Michaelis–Menten Kinetic Parameters for Renal Tubular Secretion—As previously demonstrated (1, 2), the data regarding the initial secretion rates (V) and the intravenous doses (D) were treated according to the Lineweaver–Burk equation:

$$1/V = K_m/V_mD + 1/V_m \qquad \text{(Eq. 2)}$$

and the values of the apparent maximum initial secretion rate (V_m) and the intravenous dose (K_m) required to produce 1/2 V_m were calculated from the straight-line (least-squares) plot obtained for each compound upon plotting $1/V$ *versus* $1/D$ (Fig. 7). The respective

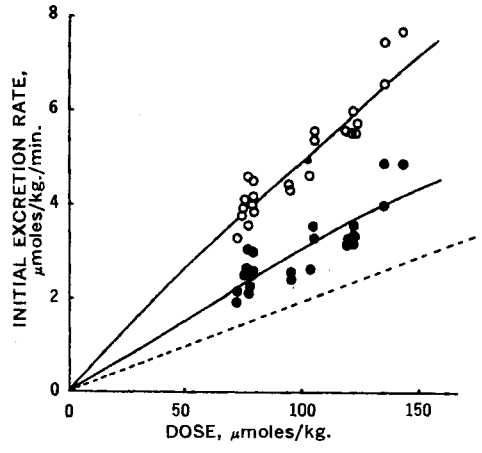

Figure 5—*Apparent initial excretion rates* (○), *initial glomerular filtration rates* (- - -), *and initial secretion rates* (●) *obtained for V following the intravenous administration of appropriate doses to rats.*

values of V_m for these compounds were calculated from the intercepts on the y-axis, and those of K_m were calculated from the slopes of the straight lines. The values of V_m and K_m are listed in Table II, along with those for I, II, III, and IV for comparison.

Although no claim can be made that the values of V_m and K_m (Table II) obtained from four different studies are precise enough to allow a distinction with respect to the precise affinity of the various compounds for the common carrier, it is reasonable to conclude that all of these compounds are secreted by the same renal tubular secretion carrier. As additional support to this conclusion, studies were carried out to show that II competitively inhibits the secretion of VI in rats. From the apparent initial excretion rates determined for VI (206–287 μmoles/kg.) in the presence of simultaneously administered 1355-μmoles/kg. i.v. doses of II, the apparent initial secretion rates were determined by subtraction from their apparent initial glomerular filtration rates at the corresponding doses. The plot of $1/V$ *versus* $1/D$ obtained for the studies is shown in Fig. 7. The apparent common y-intercept noted in this figure indicates that II competitively inhibits the secretion of VI.

Simultaneous Determination of Apparent Initial Glomerular Filtration Rates of VI and I in the Same Rats—In the present studies, it is noted that at the equimolar doses the apparent glomerular filtration rates of VI are similar (but not identical) to that of V, which in turn appear to be similar to that of III or IV reported previously (2). Randinitis *et al.* (1) showed that at the equimolar

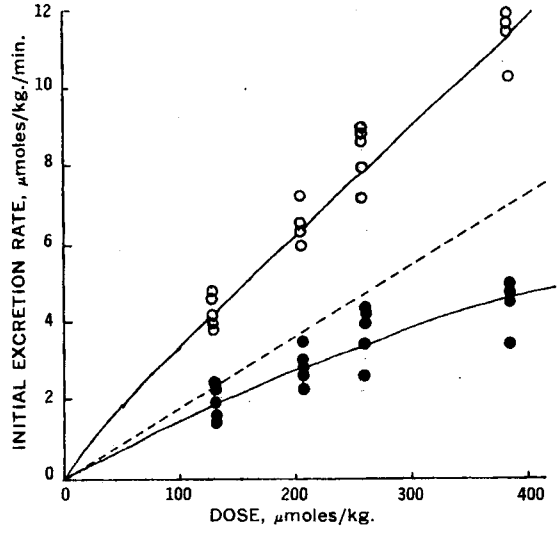

Figure 6—*Apparent initial excretion rates* (○), *initial glomerular filtration rates* (- - -), *and initial secretion rates* (●) *obtained for VI following intravenous administration of appropriate doses to rats.*

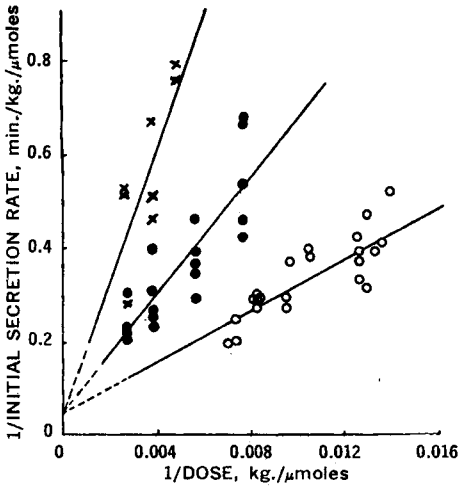

Figure 7—*Lineweaver–Burk plots of the reciprocal of intravenous doses* versus *the reciprocal of apparent initial secretion rates for V* (○) *and VI* (●) *in the absence of II and for VI* (×) *in the presence of a simultaneously administered 1355-μmoles/kg. i.v. dose of II (inhibitor).*

doses the initial glomerular filtration rates of I and its homologs obtained by introducing methylene groups in the side chain (*i.e.*, II, 4-hydroxy-4-phenylbutanoic acid, phenyllactic acid, and benzyllactic acid) are also similar. The inference (2) that the V_d in rats for III or IV is approximately half of that for I or II was based on the comparison of the apparent initial glomerular filtration rates reported in these two separate studies.

To substantiate further that the V_d of the homologs of I obtained by introducing methylene groups in the side chain is almost twice the V_d of the homologs of I obtained by *para*-alkylation, the initial glomerular filtration rates of VI and I (each representing the respective group of the homologs) were determined in the same rats by simultaneously administering the appropriate equimolar intravenous doses (180, 258, or 387 μmoles/kg.) in the presence of a 3012-μmoles/kg. dose of II. Typical data are presented in Fig. 8, and the data regarding the apparent initial glomerular filtration rates against the doses of the compounds are presented in Fig. 9. It is evident from these data that the V_d of I is almost 1.7 times greater than the V_d of VI.

Possible Interpretation of Michaelis–Menten Kinetic Parameter Data to Elucidate the Chemical Features around the Receptor Site(s) of the Renal Tubular Secretion Carrier—Since I and its various homologs (pKa 3.4–3.7) exist in the blood (pH 7.4) in ionized form, it has been tacitly assumed that the primary interaction between these compounds and the renal tubular secretion carrier present in the tubular membrane occurs through electrostatic forces. The anions of these acids are supposed to interact with the cationic receptor site(s) of the carrier.

From examination of the data in Table II, it is noted that, among the *para*-alkylated homologs of I, the affinity of V is about twice that of VI, III, and I. Although a large hydrophobic group is present, namely the isopropyl group in a VI molecule, the affinity of the molecule for the secretion "carrier" is not different from that of I or III. Therefore, it may be instinctively deduced that, among the

Table II—Michaelis–Menten Kinetic Parameters of Renal Tubular Secretion of I and Its Homologs in Rats

Compound	Apparent V_m, μmoles/kg./min.	Apparent K_m, μmoles/kg.
I[a]	18.5	11,100
II[a]	20.8	5,200
III[b]	21.6	10,200
IV[b]	18.5	4,900
V	19.6	5,640
VI	17.7	11,200

[a] Values for these compounds were obtained from *Reference 1*. [b] Values for these compounds were obtained from *Reference 2*.

para-alkylated homologs of I, the length of the hydrophobic group attached in the *para*-position in the phenyl group of I determines the extent of hydrophobic interaction of the compounds with the carrier. But it is further noted that the affinity of V for the carrier is almost the same as that of IV, indicating that the length of the alkyl group in the *para*-position of the homolog molecule alone does not determine the affinity of the molecule for the carrier.

From previous studies (1) in rats involving I and its homologs [obtained by introducing methylene group(s) in the side chain of I], the possible chemical structural characteristics distinguished were that the hydrophobic region around the cationic site of the carrier molecule probably does not extend uninterruptedly beyond the hydrophobic region represented by two carbon atoms (possibly two methylene groups) and, following such hydrophobic region, there is a polar group present. This interpretation to envision the chemical nature of the receptor of the carrier was also supported by the analysis of Michaelis–Menten kinetic parameter data obtained for the *para*-alkylated homologs of I, namely, III and IV (2). Since the *para*-substitution of an ethyl group, but not that of methyl (2), resulted in increasing the affinity of the resulting molecule, as evidenced by the K_m values, it was further suggested (2) that the increased affinity of IV for the carrier is due to the additional interaction of its end methyl group with the hydrophobic portion that should be present next to the polar group of the carrier molecule.

Although it is not known exactly what component of the renal tubular membrane constitutes the carrier for the organic anions, proteins and/or phospholipid(s) have been suggested as the carrier (6, 7). Without being specific about the exact chemical entity of the membrane that is responsible for the transmembrane transport, it seems reasonable to assume that the chemical component of the membrane that serves as the carrier for the organic anions should have cationic groups. Therefore, it is believed that, because of their suitable physicochemical properties, I and its homologs used in past and present studies can serve as probes to reveal the chemical nature of the renal tubular carrier around its cationic receptor site(s). In the present study, the *para*-substitution of the *n*-propyl group in I did not result in further increase in the affinity of the resulting molecule (*i.e.*, V) for the carrier than that of IV. Owing to the additional methylene group, if the affinity of V for the carrier were to be higher than that of IV, hydrophobic interaction was expected to occur between the additional methylene (or methyl) group of V and the complementary hydrophobic group of the receptor site of the carrier. The lack of such increase in the affinity of V for the carrier may be interpreted to suggest that the end methyl group of V comes in contact not with a nonpolar group but possibly with a polar group. Thus, this study serves to distinguish a further structural characteristic of the carrier by indicating that the hydrophobic group suggested to be present next to the polar group of the carrier from the studies of (IV) (2) is probably represented by one carbon atom (possibly a methylene group), and next to this group there is present probably a polar group.

Pharmacokinetic Significance—To induce a biologial effect, it is well recognized that the drug should be present in effective concentration at the site of action and interact with the receptors in some appropriate manner. It is further recognized that there is a relationship between the physicochemical properties of the drug and its biological activity (8), because the attainment of effective concentration of the drug at the receptors is a function of several rate processes the drug is simultaneously subjected to in the body. These rate processes include the rate of access of the drug to, and the rate of disappearance of the drug from, its site of action, the rate of metabolism, the rate of glomerular filtration and renal tubular secretion, and the extent of binding of drug to plasma proteins. These processes depend on the physicochemical properties of the drug and, therefore, often rather complicated structure–activity relations are found even for compounds of a homologous series (8). It is generally believed that the introduction of hydrophobic groups in a given drug molecule tends to increase its lipid solubility, giving rise to its increased permeability into the tissue. Unfortunately, however, it does not become possible in the case of a majority of drugs to evaluate this specific effect of a hydrophobic group on the tissue permeability of the drug, since the presence of the same hydrophobic group in the drug molecule may simultaneously result in changes in its rate of metabolism, rate of excretion, and/or extent of binding to plasma proteins and thus complicate such evaluation of a single pharmacokinetic factor.

However, it is reasonable to expect that the fewer above-mentioned pharmacokinetic processes the drug is subjected to in the body the greater is the opportunity for success in correlating the effect of systematic introduction of the hydrophobic group in a drug molecule on a given pharmacokinetic process or parameter. It is in this context that I and its homologs (1, 2) are considered as the model compounds because these compounds (organic anions) are neither metabolized, bound to plasma proteins, nor reabsorbed in the renal tubules of rats. Consequently, it is possible to determine the effect of alkyl groups on the V_d, glomerular filtration rates, and renal tubular secretion rates. It is not meant to imply that the introduction of methyl or methylene groups in an organic molecule will always bring about such changes in the pharmacokinetic parameters, regardless of the nature of the organic compound. Such generalization cannot be made from the limited studies discussed here. Nevertheless, the striking effects observed of *para*-alkylation of I on the V_d, glomerular filtration rates, and tubular secretion rates are indicative of the possibility that further studies with suitable compounds would eventually provide definite insight as to the effects of alkyl substitution in the organic anions on their pharmacokinetic parameters.

The introduction of hydrophobic groups in a drug molecule is generally believed to tend to increase the lipid (tissue) solubility of the compound, consequently resulting in its increase in the V_d. But the effect of introducing alkyl groups in the *para*-position of the organic anions in the present homologous series was found to be just the opposite. The V_d of the *para*-alkylated homologs of I decreased while that of II remained practically unchanged (1), as compared to the V_d of the parent compound, I. This illustrates the influence of the position of the alkyl group in the compound on its V_d in the body.

Chronic Isoproterenol Treatment of Neonatal Rats

GERDA I. KLINGMAN▲ and GENIE McKAY

Abstract □ The chronic subcutaneous administration of isoproterenol to neonatal and young male and female rats resulted in statistically significant reductions of the norepinephrine concentrations of the heart and submaxillary and parotid glands and increased concentrations in the stellate ganglion. However, the total norepinephrine content of these tissues was not affected. The epinephrine levels of these tissues were not significantly different from controls except for an increased total content in the submaxillary glands. Chronic treatment did not alter the norepinephrine levels of the brain, superior cervical ganglion, adrenal glands, vas deferens, uterus, spleen, kidneys, lungs, and small intestine. Growth of neonatal rats was retarded. The wet weights of the submaxillary and parotid glands were significantly greater, while the spleen, uterus, adrenal glands, and stellate ganglion weighed less in isoproterenol-treated than in control rats. The wet weights of other peripheral tissues were not affected. The ratios of the tissue weight to the body weight were significantly increased for the heart and submaxillary and parotid glands and decreased for the uterus. The first dose of isoproterenol produced hypothermia in mature rats but hyperthermia in newborn rats. Sparse hair growth in neonatal rats and hair loss in weanling rats were also observed during chronic treatment.

Keyphrases □ Isoproterenol, chronic administration—effects on tissue catecholamine levels, tissue weights, and rectal temperature in rats □ Catecholamine tissue levels—effect of chronic isoproterenol administation, rats □ Tissue weight and catecholamine levels—effect of chronic isoproterenol administration, rats

The ability of isoproterenol to produce hypertrophy and hyperplasia of the submaxillary and parotid glands of rats has been studied by various investigators (1–5). In addition, isoproterenol treatment resulted in infarct-like lesions and fatty degeneration of the heart (6, 7). Effects in other species have also been reported, *e.g.*, cats (8), hamsters (9), guinea pigs (10), and mice (11, 12). Growth stunting, premature opening of the eyes, and an increase of the ratio of heart weight to body weight have been reported following the chronic administration of isoproterenol to neonatal rats (5). Since acute and short-term treatment resulted in increased organ weights and derangements of catecholamine levels (13–15) and storage (15), and chronic isoproterenol treatment produced growth stunting and changes in organ weights in neonatal rats (5), the effects of chronic isoproterenol treatment on the tissue catecholamine levels, tissue weights, and rectal temperature were studied in neonatal rats and the results are reported in this paper.

METHODS

Animals—Two days after birth, Sprague–Dawley male and female rats from three litters were subcutaneously dosed with 0.85% sodium chloride solution (controls) or 5 mg./kg. isoproterenol twice a day for 6 days and thereafter with 15 mg./kg. twice a day for up to 43 days. Animals of two other litters received 10 mg./kg. subcutaneously twice a day for 7 days, the first dose being given on the 6th day after birth. At the end of the 1st week of drug administration, nearly 50% of the animals of this group had died and the dose was reduced to 10 mg./kg. once a day.

To obtain additional information on the hyperthermia, the frequently observed lethargy, and the sparsity of hair growth (or hair loss), animals of three other litters were treated chronically by three different dose regimens: 20 mg./kg. once a day and 5 mg./kg. twice a day for 5 days (treatment was started on the 6th day after birth) and 15 mg./kg. twice a day for 30 days (treatment was started on the 25th day after birth).

Catecholamine Analysis—For the tissue catecholamine measurements, the treated animals and their littermate controls were sacrificed by exsanguination under sodium pentobarbital anesthesia after 30–43 days of treatment. The heart, submaxillary glands, parotid glands, spleen, kidneys, lungs, small intestine, vas deferens, uterus, adrenal glands, whole brain (or brainstem[1]), superior cervical ganglia, and stellate ganglia were dissected in the cold and weighed[2]. Tissues were analyzed immediately or frozen and analyzed within 3 days after dissection. Norepinephrine and epinephrine were extracted with 1-butanol as previously described (16) and measured spectrophotofluorometrically by a modification (17, 18) of the ferricyanide oxidation method of von Euler and Floding (19).

[1] In this report the brainstem is defined as the medulla, the pons, the midbrain, and the diencephalon.

Table III—Norepinephrine and Epinephrine Concentration and Content of Superior Cervical and Stellate Ganglia of Control and Chronic Isoproterenol-Treated Rats

Ganglia	Treatment	Number of Rats	Weight, mg./Pair	Micrograms per Gram: Norepinephrine	Micrograms per Gram: Epinephrine	Nanograms per Tissue: Norepinephrine	Nanograms per Tissue: Epinephrine
Superior cervical	Control	12	1.70 ± 0.12	21.9 ± 2.3	1.3 ± 0.2	35.9 ± 3.0	2.0 ± 0.3
	Isoproterenol	11	1.54 ± 0.12	21.8 ± 2.2	1.4 ± 0.3	33.6 ± 4.8	2.1 ± 0.4
Stellate	Control	12	2.40 ± 0.10[a]	14.9 ± 0.9[a]	0.7 ± 0.2	35.3 ± 1.7	1.7 ± 0.4
	Isoproterenol	11	1.87 ± 0.15	21.1 ± 1.5	0.8 ± 0.3	38.5 ± 3.5	1.4 ± 0.4

[a] $p < 0.01$, t test in nonpaired experiments (26).

Temperature—The rectal temperatures were measured at room temperature (23 ± 1°) with a telethermometer[3] before the isoproterenol administration and every 30 min. for up to 210 min. after dosing. An arterial probe[3] was used for measuring the rectal temperature of newborn rats and thermister probes[4] were used for older animals.

RESULTS

Body Weight—Chronic isoproterenol treatment of neonatal rats for up to 43 days resulted in growth retardation. When treatment was started 6 days after birth with 10 mg./kg., a mean difference in body weight (9%) became apparent after 5–6 days and statistically significant after 7–8 days of treatment (14%; $p < 0.05$). With continuation of the treatment for 15 days, the mean body weight of the isoproterenol-treated group amounted to 69.5% of that of control littermates ($p < 0.01$). When isoproterenol treatment with 5 mg./kg. twice a day was started on the 2nd day after birth and then increased to 15 mg./kg. twice a day, slowing of growth was first observed after approximately 8 days of treatment and a statistically significant difference was observed at 11 days. Growth retardation was still evident at the time of sacrifice and amounted to 15% when compared to control littermates.

Tissue Wet Weights and Ratios—Chronic isoproterenol treatment affected the wet weights and/or the ratios of the tissue weight to the body weight (milligrams per gram) of several organs (Table I). The wet weights of the submaxillary and parotid glands were increased while the spleen, uterus, and adrenal glands of treated rats were smaller than those of controls. The absolute weights of the hearts were similar in the treated and the control groups, but the ratios of the wet weight to body weight were elevated. These ratios were also increased for the submaxillary and parotid glands, unaltered for the spleen and adrenal glands, and decreased for the uterus.

Catecholamines—Similarity of results on the catecholamine levels from rats treated for 30–43 days permitted the pooling of these data (Table II). Significant decreases in the norepinephrine concentrations of the heart and submaxillary and parotid glands were noted after chronic isoproterenol treatment, but the norepinephrine contents of these tissues were not altered. Statistically significant changes of epinephrine concentrations of the heart, submaxillary glands, and parotid glands did not occur, but the epinephrine content of the submaxillary glands was increased. The catecholamines of other peripheral tissues such as the spleen, uterus, vas deferens, kidneys, lungs, pancreas and adrenal glands, whole brain, and brainstem did not differ from control values. Although the catecholamine concentration and content of superior cervical ganglia were not altered, the norepinephrine concentration of stellate ganglia was increased after chronic treatment (Table III); this was apparently due to a significant reduction in wet weight.

Rectal Temperature—The administration of the first dose of isoproterenol (5 or 20 mg./kg. subcutaneously) to 6-day-old rats resulted in a statistically significant increase in the rectal temperature that lasted about 90 min. Subsequent doses administered once or twice a day for several weeks did not significantly accentuate the hyperthermia (Tables IV and V). Sex difference in the temperature effect of isoproterenol was not studied in detail. However, no statistically significant difference was found in the hyperthermic

response between young male and female rats after 35 doses (five male and six female rats).

The hyperthermic response following the a.m. administration of the chronic dose was similar to the response of the second daily dose (p.m. administration), which was given about 8 hr. later.

The predose rectal temperature of chronically treated young rats was significantly lower than the comparable rectal temperature of control animals (Table V). In mature rats the first dose of isoproterenol (15 mg./kg.) produced hypothermia (Table V).

Other Observations—In neonatal rats, chronic treatment produced premature opening of the eyelids and scanty fur development. When treatment was started after weaning, marked hair loss was observed usually on the head, back, and/or flanks in approximately half of the treated animals. After chronic dosing, weanling and adult rats became lethargic. The lethargy was interspersed by brief periods of activity which appeared similar to that described by Ingenito and Bonnycastle (20) for *dl*-4-chloro-*N*-methylamphetamine. These authors described the activity as "a peculiar backing up and circling movement." Occasionally, the rats in the present study also exhibited a seemingly purposeless repetitious scratching motion of the wire grid with the forepaws.

Of 54 rats from five litters (14 female and 15 male treated rats and 14 female and 11 male control rats) that were dosed for 30–43 days, seven animals died (five female and two male treated rats). No deaths occurred in three other litters which were treated to obtain additional information on the hyperthermia, lethargy, and hair loss.

DISCUSSION

Growth stunting of neonatal rats treated with isoproterenol was reported by Schneyer and Shackleford (5). Despite the large difference in the doses used by these authors and the dose regimens used in the present investigation, the initial growth retardation was similar in both studies. Schneyer and Shackleford (5) administered 1.5 mg./rat twice a day; depending upon the weight of the young rats, this amounted to approximately 30–200 mg./kg. With these large doses, little effect on growth was seen during the first 7 days, but growth was retarded by 15–20% after 15 days.

According to Schneyer and Shackleford (5), animals treated for 35 days were only one-half the size of control littermates. Such profound growth retardation was not encountered with the smaller doses used in the present study.

The enlargement of the submaxillary and parotid glands and the relative increase in the heart weight (in relation to the body weight) noted in the present study were in agreement with the changes reported by Schneyer and Shackleford (5). In mice, however, the wet weights and ratios were increased for the hearts of male but not female mice (21). The smaller wet weights of the spleen and the adrenal glands observed in young chronically treated rats were in proportion to the somatic growth retardation and, therefore, the ratios were not different from those of the controls.

Since isoproterenol is a potent catecholamine closely related to epinephrine in structure and action, an endocrinological effect mediated *via* the hypothalamic–hypophysial–adrenal or ovarian axis could be responsible for the decreased uterine weight and the smaller tissue to body weight ratio after chronic treatment. A direct action on the uterine smooth muscle cannot be ruled out. In adult mice (21) and rats[5], uterine wet weights showed mean decreases, but these reductions were statistically nonsignificant. However, it is possible that chronic isoproterenol treatment during

[5] G. I. Klingman, unpublished observation.

neonatal development may have a more pronounced or even a different effect than in adult animals.

The absence of a decrease in the total norepinephrine content of the heart and submaxillary and parotid glands in the presence of decreased concentrations and increased tissue weights following chronic isoproterenol treatment could be best explained on the basis of the hypertrophy and/or hyperplasia. However, evidence presented by Mueller and Axelrod (15) indicated that short-term isoproterenol treatment resulted in an accelerated release of norepinephrine from the nerve endings of the heart. A storage defect and an increase in sympathetic activity appeared to be responsible for the decrease in cardiac norepinephrine (15). If this postulate can be extended to long-term treatment that is unaccompanied by changes in the total norepinephrine content, an additional, perhaps adaptive, mechanism must be assumed. It should be recalled at this point that only the cardiac norepinephrine concentration and the ratio (tissue weight to body weight) but not the norepinephrine content and the absolute weight were affected by the treatment.

In view of the fact that the norepinephrine content of the stellate ganglion was similar to that in control rats, the increased norepinephrine concentration cannot be readily interpreted without the acquisition of additional data. The smaller wet weight of the stellate ganglia could be explained in terms of differences in the body weights between treated and control littermates; the difference in ganglionic wet weight amounted to 23% and the difference in body weight to 26%. However, the superior cervical ganglion, the wet weight of which is very uniform among littermates, showed only a small statistically nonsignificant decrease after treatment (Table III).

The diversity of the responses of the rectal temperature following acute and chronic isoproterenol treatment in young and adult rats is difficult to interpret. Pretreatment with α- and β-adrenergic receptor blocking agents prevented or ameliorated the hyperthermia in adult rats, but these agents, when administered alone, produced hypothermia (22). The role of epinephrine and related amines on body temperature, control of body temperature, and heat production has been extensively studied and reviewed (23, 24). The direction of the change in body temperature following the administration of amines (as well as other drugs) seems to depend upon the species, route of administration, and dose. Different ambient temperatures before and after drug administration and the predrug body temperature of the experimental animal can also influence the direction of the change. The different response in adult and neonatal rats to isoproterenol observed in this study requires further exploration. Opposite responses in young and adult chickens have been reported with acute doses of epinephrine, norepinephrine, and several other amines (25). Previous investigations almost exclusively dealt with acute drug administration. Little information is available in regard to chronic drug use, body temperature, and temperature regulation.

The mortality rate encountered in the current investigation was similar to rates (5–30%) seen in several studies carried out in this laboratory when neonatal, young, and adult rats were chronically treated with relatively low doses of isoproterenol (5–15 mg./kg.)[6]. No deaths occurred in young female rats (Wistar strain, 110 ± 2.4 g.) treated for 12 days with large doses of isoproterenol: 50 mg./kg. twice a day and 400 mg./kg. once a day (2).

Synthesis and Bioactivity of Lincomycin 2-Monoesters

W. MOROZOWICH▲, A. A. SINKULA, F. A. MacKELLAR, and C. LEWIS

Abstract □ A homologous series of straight-chain lincomycin 2-monoesters, comprised of both acyl and carbonate esters, was synthesized. Good antibacterial activity was observed with esters of chain lengths from C_4 to C_{16}. Esters with chain lengths from C_{12} to C_{16} are tasteless and highly active *in vivo* in mice infected with *Staphylococcus aureus*. The carbonate esters show essentially the same taste and bioactivity as the acyl esters. The long-chain lincomycin 2-esters appear to have the desired properties required for formulation as a tasteless pediatric preparation.

Keyphrases □ Lincomycin 2-monoesters—synthesis, antibacterial activity, tasteless long-chain esters □ Antibacterial agents, potential—synthesis of lincomycin 2-monoesters □ Pediatric formulations, potential—synthesis, antibacterial activity of long-chain lincomycin 2-monoesters □ Tasteless lincomycin derivatives—synthesis, antibacterial activity of 2-monoesters

This work is part of a project designed to improve the pharmaceutical properties (*e.g.*, taste and solubility) and biological properties (*e.g.*, absorption and prolonged activity) of the antibiotic lincomycin (I) (1–3) by means of various *in vivo* reversible monoesters.

Molecular models show that each of the four hydroxyl groups in lincomycin is confronted with different steric and electronic environments. The *in vivo* rate of hydrolysis of the four possible positionally isomeric esters is probably determined by the ease of hydrolysis by esterase enzymes or by nucleophiles, such as hydroxide ion. Polyesters of lincomycin show poor antibacterial activity *in vivo*, probably because some esterified hydroxyl groups are more difficult to hydrolyze than others. In view of this possibility, monoesters at each of the four hydroxyl groups in I were synthesized in an attempt to find a hydroxyl that would provide biologically active *in vivo* reversible esters with the desired pharmaceutical or biological properties. Protective group routes were perfected for the synthesis of each of the four isomeric lincomycin monoesters. This report describes the synthesis and properties of lincomycin 2-monoesters, and future reports will deal with the 3- and 4-monoesters.

The primary objective of this work was to uncover a tasteless, bioactive lincomycin ester with low water solubility, which would permit formulation of a pharmaceutically elegant pediatric suspension. This objective was met with the long-chain lincomycin 2-monoesters.

RESULTS AND DISCUSSION

Chemistry—The lincomycin 2-monoesters were synthesized (Scheme I) by reaction of the key intermediate 7-*O*-trityl-3,4-*O*-anisylidene lincomycin (II) (4) with an acid chloride, an acid anhydride, or a chlorocarbonate in the presence of pyridine. The resulting 7-*O*-trityl-3,4-*O*-anisylidene lincomycin 2-esters (III) were treated with 80% aqueous acetic acid at 100° for 15–30 min. to remove the trityl and anisylidene protective groups. In most cases, the lincomycin 2-monoesters (IV) were maintained as the hydrochloride salts during workup and purification. The esters are un-

Scheme I—$R = -(CH_2)_nCH_3$ or $-O(CH_2)_nCH_3$

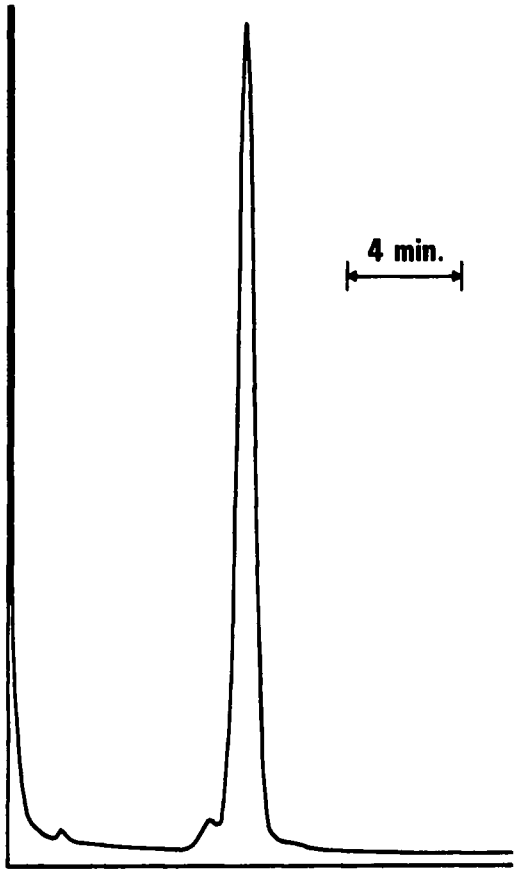

Figure 1—*Gas chromatogram of lincomycin 2-palmitate as the tris-O-trimethylsilyl derivative at 290°.*

stable under alkaline conditions; and in a few cases where crystallization failed to remove the impurities, the esters were extracted from mildly acidic, aqueous solutions with ether. The free base form of the ester in the organic phase was promptly converted to the stable hydrochloride salt.

TLC and GLC analyses of the esters showed only minor impurities in the final products. The GLC of lincomycin 2-palmitate as the *tris-O*-trimethylsilyl ether (Fig. 1) showed a trace impurity at 2 min. The small peak (7.1 min.) preceding the major peak is probably the 2-palmitate ester of lincomycin B (the 4′-ethyl analog of lincomycin), since a similar peak is seen in the GLC of the starting material (1) (5). The isomeric lincomycin 3- and 4-monopalmitates can be separated from lincomycin 2-palmitate, and these results will be reported later.

Bioactivity—The standard curve plate antibacterial assay using *Sarcina lutea* (UC 130) showed maximal activity with C_4–C_8 esters (Fig. 2). It is not clear whether these esters are intrinsically active or whether hydrolysis on the plate accounts for the activity. The effect of ester chain length on the oral CD_{50} (medium protective dose) in mice challenged with *Staphylococcus aureus* (UC 76) showed

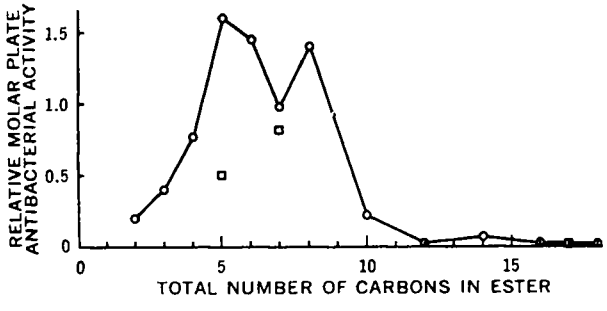

Figure 2—*Ratio of the molar plate antibacterial activity of lincomycin 2-esters to that of lincomycin using* S. lutea *(lincomycin = 1). Key: ○, acyl esters; and □, carbonate esters.*

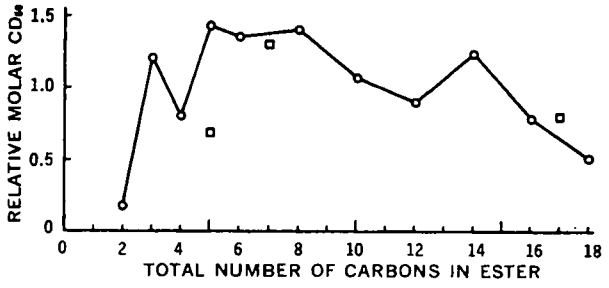

Figure 3—*Ratio of the molar oral CD_{50} of lincomycin 2-esters to that of lincomycin in mice infected with* Staph. aureus *(lincomycin = 1). Key: ○, acyl esters; and □, carbonate esters.*

that good activity was obtained with esters of chain lengths from C_4 to C_{16} (Fig. 3). The subcutaneous CD_{50} results (Fig. 4) were somewhat erratic but, in general, the results showed that the medium-chain length esters had better activity than the short-chain or the long-chain esters. The bioactivity of the carbonate esters was slightly less than the corresponding acyl esters.

Taste and Solubility—The water solubility of the hydrochloride salts of the lincomycin 2-acyl esters approaches zero above C_{12} (Fig. 5). Esters with chain lengths of C_{12} or greater are essentially tasteless. The laurate ester (C_{12}) is remarkable, since it is rather soluble and yet almost tasteless. The solubility of the esters, calculated (6) at pH 6.5, approaches zero above C_6 (Fig. 5). The lack of taste with the moderately water-soluble laurate ester can probably be explained by precipitation of the free base form of the ester in the mouth, since the pH of saliva is approximately 6.5 (7).

The 2-palmitate ester and the 2-*n*-hexadecylcarbonate ester of I have the desired properties of good CD_{50} activity and very low water solubility, indicating potentially good chemical stability in aqueous suspensions, and they are tasteless.

EXPERIMENTAL

Chromatography—TLC was conducted on silica gel G using the solvent system of hexane–ether–2-pentanone–methanol–concentrated ammonium hydroxide (60:20:20:9:1). The compounds were located by spraying the plates with ammonium sulfate followed by heating to about 180°.

GC was conducted after conversion of the lincomycin 2-acyl esters to the corresponding 3,4,7-*tris-O*-trimethylsilyl ethers, as described by Houtman *et al.* (5). A 1% solution of the ester in pyridine containing 20% hexamethyldisilazane and 20% trimethylchlorosilane was used to give the silyl ethers. After a 5-min. reaction period, 1 μl. of the solution was injected into a flame-ionization gas chromatograph[1] using a 0.61 × 33-cm. (0.125 × 17-in.) stainless steel column containing 3% OV-1 on Gas Chrom Q (100–120 mesh), with an oven temperature of 235–290°, depending on the chain length of the ester.

Synthesis—Lincomycin 2-esters were synthesized by reaction of an acid chloride, an acid anhydride, or a chlorocarbonate with II in

[a] Combustion analyses and water determination (Karl Fischer) were conducted at The Upjohn Co. [b] The melting points reported were determined on a Thomas-Hoover capillary melting-point apparatus. The crystals appear to go through several stages of melting to give a wide melting range. The exact melting points are indefinite, since in most cases the compounds darken before melting. GLC showed that all compounds had a purity greater than 95% as estimated by area measurements.

pyridine. Representative examples of the synthesis of acyl esters and carbonate esters are described here, and the other esters were synthesized by similar methods. The analytical data are reported in Table I.

Method A: Esterification with Acyl Chlorides (Lincomycin 2-Stearate Hydrochloride)—A solution of 23.01 g. (0.03 mole) II in 100 ml. pyridine was treated with a solution of 12.12 g. (0.04 mole) stearoyl chloride in 40 ml. chloroform. After 15 min., 10 ml. of

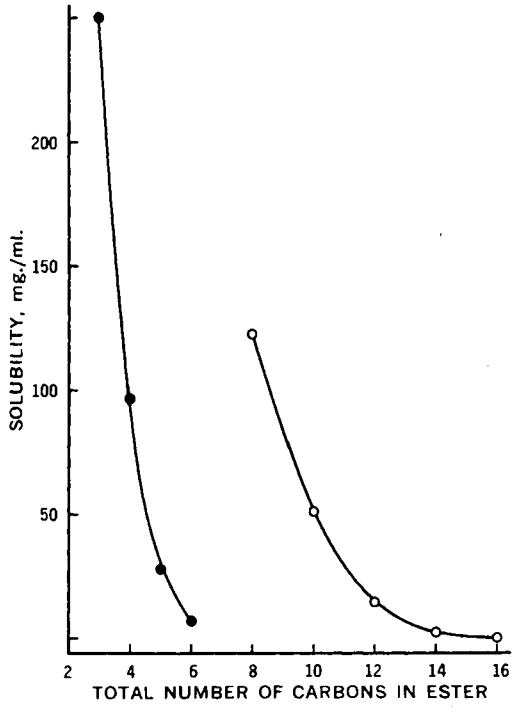

Figure 5—*Aqueous solubility of lincomycin 2-acyl esters* versus *total number of carbons in ester group. Key:* ○, *solubility of the hydrochloride salts of the esters; and* ●, *solubility of the esters calculated at pH 6.5.*

methanol was added and the solvent was removed under vacuum at 60°. The residual yellow semisolid was dissolved in 200 ml. 80% aqueous acetic acid, and the solution was heated on a steam bath for 25 min. Tritanol was removed by filtration after cooling the solution to room temperature, and the filtrate was taken to dryness under vacuum at 60°. The residue was dissolved in 120 ml. 80% aqueous acetone with heat, and the solution was diluted with 250 ml. acetone. The resulting white crystals (18.8 g., 76%) were isolated by filtration and air dried.

Method B: Esterification with Acid Anhydrides—A 2:10 mole ratio of acid anhydride to II was normally used. The reactions were conducted at room temperature or on a steam bath for 5–30 min. After removal of the protective groups, a slight excess of aqueous hydrochloric acid was added to an acetone solution of the ester to give the crystalline hydrochloride salts.

Method C: Esterification with Chlorocarbonates (Lincomycin 2-n-Butylcarbonate Hydrochloride)—A cold (−35°) solution of II (23.5 g.) in 200 ml. pyridine was treated with 5 g. *n*-butyl chlorocarbonate. The stirred suspension was allowed to warm to room temperature, then recooled to −35°, and treated with an additional 15 g. *n*-butyl chlorocarbonate. After warming to room temperature, the suspension was poured into 2 l. cold (0°) 0.01 *N* aqueous hydrochloric acid. The resulting precipitate was dissolved in 1 l. ether, and the phases were separated. The ether was removed under vacuum, and the residue was dissolved in a mixture of 1 l. methanol and 75 ml. water. The solution was adjusted to pH 1.0 with concentrated hydrochloric acid, and after 3 hr. at room temperature the solution was adjusted to pH 3 by addition of sodium bicarbonate. The solvent was removed under vacuum, and the residue was dissolved in 150 ml. chloroform. The chloroform solution was extracted twice with 150 ml. water. The combined aqueous layers were freeze dried to give 9 g. (54%) of white amorphous product.

Solubility Determinations—The solubility of the hydrochloride salts of the esters was determined at 24 ± 1° using excess compound equilibrated with water for 72 hr. Aliquots of the filtrates were evaporated to dryness at 120°, and the residue was weighed.

The solubility of the free base forms of the esters was determined by titration of aqueous solutions of the hydrochloride salts of the esters (1%) with 0.1 *N* aqueous sodium hydroxide. The solutions were filtered through a Millipore filter (1.5 μ) before titration. Titration was followed by periodically measuring the absorbance in a 1-cm. cell at 400 nm. At a certain point during titration, precipitation of the oily free base form of the ester occurred with a concomitant rapid increase in absorbance at 400 nm. Hypersaturation (8) did not occur, since there was no pH drop at the point of precipitation. The amount of base required to produce an absorbance of 0.10 divided by the volume of the solution gave the intrinsic solubility. The solubility at pH 6.5 was calculated (6):

$$S_0 = S_i[1 + \text{antilog}(\text{pKa} - \text{pH})] \qquad \text{(Eq. 1)}$$

where S_0 = solubility at pH 6.5, S_i = intrinsic solubility of the free base form, and pH = pH at which precipitation of the free base occurred.

The solubility determinations were conducted in duplicate, and the results were averaged. Repeat analyses differed by no more than 10%.

NMR Spectra at 60 MHz.—The NMR spectral features were similar to those reported previously (9). The long-chain esters such as the palmitate ester required probe temperatures of 75° to obtain well-resolved spectra.

Chemical Modification of Clindamycin: Synthesis and Evaluation of Selected Esters

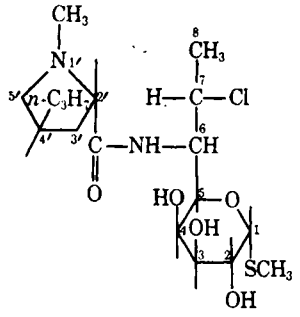
A. A. SINKULA▲, W. MOROZOWICH, and E. L. ROWE

Abstract □ Clindamycin was chemically modified to provide *in vivo* reversible derivatives that might suitably be utilized in special dosage forms. To improve taste properties, a series of 2- and 3-monoesters and some 2,3-dicarbonate esters of clindamycin were synthesized. A number of highly water-soluble salts were prepared in an attempt to provide an injectable intramuscular preparation with low incidence of pain. The long-chain clindamycin 2-monoesters (palmitate and hexadecylcarbonate) are virtually devoid of the characteristic bitter taste of clindamycin. The water-soluble salts (gluconate and lactobionate) of clindamycin showed no significant improvement over clindamycin in muscle irritation studies. Clindamycin blood levels were determined in dogs following oral administration of some esters. Clindamycin 2-palmitate and clindamycin 2-hexadecylcarbonate exhibited blood levels equivalent to clindamycin hydrochloride. The CD_{50} results using mice infected with *Staphylococcus aureus* showed that several esters possess antibacterial activity equivalent to that of clindamycin hydrochloride.

Keyphrases □ Clindamycin esters and salts—synthesis, bioactivity compared to hydrochloride salt, tasteless long-chain esters □ Antibacterial agents, potential—synthesis of clindamycin esters and salts, compared to hydrochloride salt □ Tasteless clindamycin derivatives—synthesis, blood levels in dogs and antibacterial activity in mice compared to hydrochloride salt □ Pediatric formulations, potential—synthesis, antibacterial activity of long-chain clindamycin esters

Clindamycin [7(S)-chloro-7-deoxylincomycin] (I) hydrochloride is a new, semisynthetic antibiotic having a high degree of antibacterial activity against Gram-positive organisms and a lower order of activity against Gram-negative organisms (1, 2). Its spectrum of activity approximates that of erythromycin and lincomycin (3). Clindamycin is well absorbed from the GI tract and affords serum levels approximately twice those of lincomycin (1, 4).

The fact that clindamycin is extremely bitter *per se* precludes its formulation as an acceptable pediatric syrup. Furthermore, the incidence of pain at the injection site is quite high on intramuscular administration of clindamycin hydrochloride. These factors prompted this investigation of the chemical modification of clindamycin for the purpose of enhancing its pharmaceutical acceptability. This article reports the synthesis and evaluation of selected 2- and 3-monoesters and 2,3-dicarbonate esters of clindamycin.



I: clindamycin

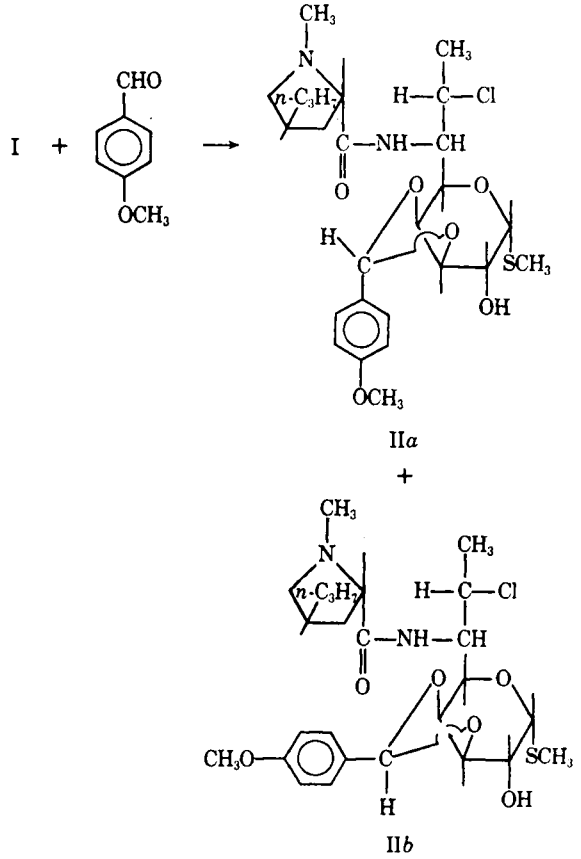
DISCUSSION

Chemistry—The synthesis of 2-esters of clindamycin was achieved by protection of the 3- and 4-hydroxyl groups of clindamycin (I) with the acid labile anisylidene moiety (5, 6). The reaction of anisaldehyde with I gave two spots by TLC, which were identified by NMR as the benzylic isomers II*a* and II*b* (Scheme I). Esterification of the 2-hydroxyl group of 3,4-*O*-anisylidene clindamycin (II), followed by treatment of the resulting ester acetal with acid, afforded pure clindamycin 2-acyl and 2-carbonate esters (Scheme II).

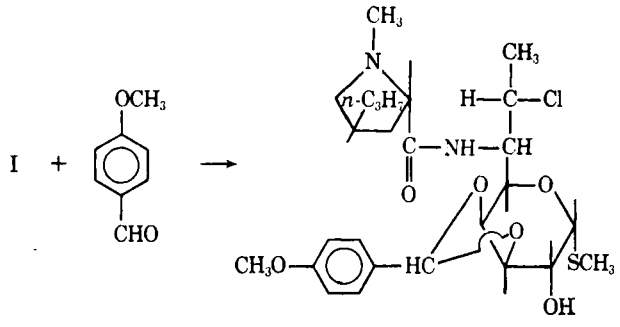
Clindamycin 3-pentylcarbonate was prepared in 54% yield by selective esterification of I in pyridine at low temperatures (−25°) (Scheme III) (7). Purification was achieved by selective solvent extraction under controlled pH conditions while purity was monitored by GLC (Figs. 1 and 2).

Clindamycin 2,3-dicarbonate esters (Scheme IV) were prepared by selective acylation of clindamycin in pyridine using excess acylating agent. The gluconate and lactobionate salts of clindamycin were prepared by mixing aqueous solutions of stoichiometric amounts of clindamycin base with either δ-gluconolactone or lactobiono-δ-lactone and then allowing them to stand for 1 hr., with subsequent removal of water *in vacuo*.

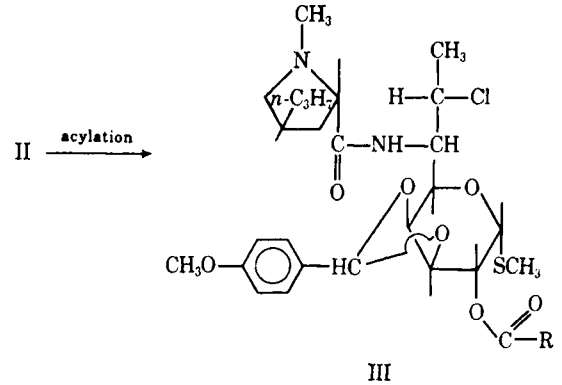
NMR—The 60-MHz. spectra of the benzylic isomers II*a* and II*b* in $CDCl_3$ showed the benzylic proton at 6.28 δ in one isomer and at



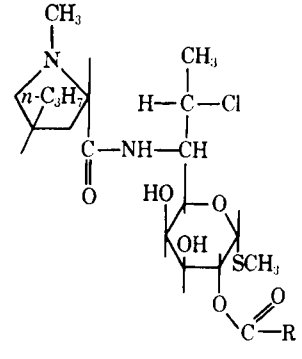
Scheme I—3,4-O-Anisylidene clindamycin



II



III



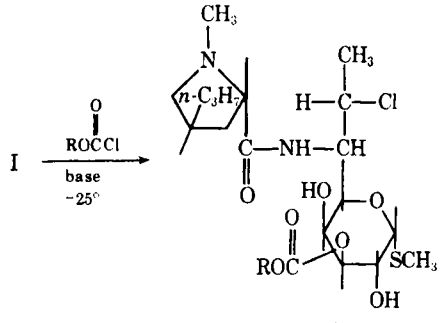
IV

Scheme II—Clindamycin 2-monoesters (R = alkyl and R = O-alkyl)

5.80 δ in the other (dimethylformamide-d_7). The isomer with a signal at 6.16 δ was assigned to II*b* since 3,4-*O*-anisylidene lincomycin shows the benzylic proton at 6.16 δ.

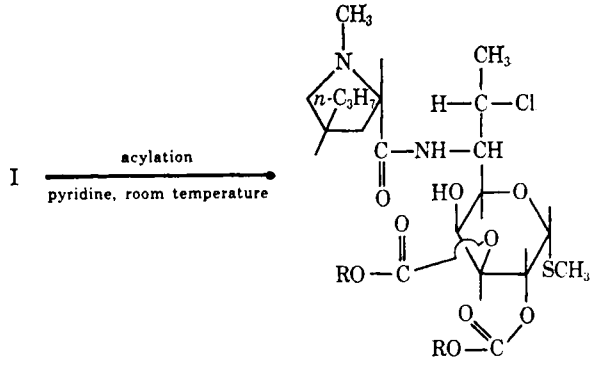
The 60-MHz. NMR spectra of the 2-clindamycin monoesters were similar to the spectra of the 2-monoesters of lincomycin and were thoroughly reviewed in previous reports (8, 9).

Bioactivity—The methods used for determining *in vitro* and *in vivo* bioactivities of clindamycin esters are the same as those used for lincomycin esters and were discussed previously (10).



54%

Scheme III—Clindamycin 3-monocarbonate esters (R = $-C_5H_{11}$)



Scheme IV—Clindamycin 2,3-dicarbonate esters

The bioactivities of the various clindamycin esters (both *in vitro* and *in vivo*) are summarized in Table I. The *in vitro* data show all esters to be less bioactive than clindamycin. This is to be expected since ester hydrolysis must occur to liberate free clindamycin. Many esterified antibiotics have been shown to be inactive until ester hydrolysis occurs (11, 12). In all probability, this is the situation with clindamycin 2-hexanoate, 2-hexylcarbonate, 2-cinnamate, and 3-pentylcarbonate. The above-mentioned short- to medium-chain length derivatives would be more soluble in the culture media than, for example, clindamycin 2-palmitate[1], 2-hexadecylcarbonate, or 2,3-dicarbonates. Increased solubility would increase the availability of enzymatic hydrolysis. This is apparent from the plate bioactivity data for the short- to medium-length chain compounds *versus* the longer chain derivatives.

The mouse subcutaneous *in vivo* data for the clindamycin 2-derivatives indicate that bioactivity is comparable to clindamycin up to and including an ester chain length of six carbons. The bioactivity decreased with esters containing 12 or more carbon atoms. Clindamycin 2-(*o*-benzoyl)benzoate bioactivity is low due probably to difficulty of hydrolysis of the sterically hindered ester. The clindamycin 2,3-dicarbonate esters possess low subcutaneous activity due to the probable low solubility of these compounds. The oral antibacterial activity of the esters roughly correlates with the subcutaneous activity pattern.

Dog serum levels for selected clindamycin esters and salts are shown in Table II. Many of the esters show an area under the blood level curve comparable to clindamycin hydrochloride, indicating high bioavailability.

Taste Studies—Four clindamycin 2-acyl esters of varying chain length (palmitate, laurate, hexanoate, and acetate) were dissolved in 30% sucrose solutions. The clindamycin ester solutions were coded A, B, C, and D, and 5-ml. samples of each were given to a taste panel of 26 people. The usual protocol was followed, with 1 hr. allowed between samples. The taste of each was rated on a scale of 1 to 9 (1 = poor, 9 = excellent). The raw score data were analyzed by computer to show any significant differences between samples.

Clindamycin gluconate	620 (62)	0.63	1.05

[a] Activities calculated as clindamycin base equivalents. [b] As measured on a standard curve agar assay *versus Sarcina lutea*. Results expressed as micrograms of clindamycin base activity per milligram of ester and as percent of lincomycin base activity (in parentheses). [c] Median protective dose relative to that of clindamycin (clindamycin = 1.0) in the mouse. [d] Data not available.

The average scores shown in Fig. 3 indicate a linear trend of taste improvement with increasing chain length. The palmitate ester is significantly better than the laurate at the 5% level of confidence. The laurate, in turn, is significantly better than both the hexanoate and acetate. These latter two were ranked equally low, being very bitter-tasting compounds.

Clindamycin 2-palmitate hydrochloride is essentially tasteless, and dog blood level studies (Table II) showed that *in vivo* regeneration of clindamycin is quantitative. For these reasons, clindamycin 2-palmitate hydrochloride is being extensively tested in humans as a tasteless pediatric formulation.

EXPERIMENTAL

GLC was run on the silanized clindamycin esters. The silyl ethers were made by mixing a pyridine solution containing approximately 2% of the ester to be silanized, 20% trimethylchlorosilane, and 20% hexamethyldisilazane. One microliter of this solution was injected into a gas chromatograph[2] containing a flame-ionization detector. The column was 0.3 × 43.2-cm. (0.12 × 17-in.) stainless steel, containing 1% OV-1 on Gas Chrom Q (100–120 mesh). Oven temperatures ranged from 200 to 245° and were linearly programmed at 3°/min.

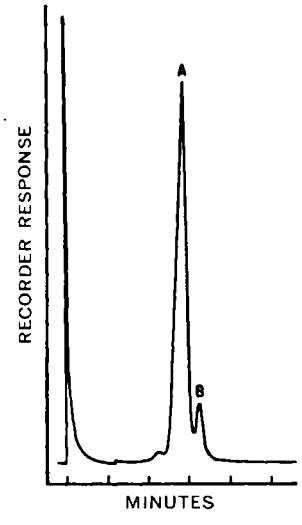

Figure 2—*Two-extraction purification of 7(S)-chloro-7-deoxylincomycin 3-pentylcarbonate. Key: A, 7(S)-chloro-7-deoxylincomycin 3-pentylcarbonate; and B, 7(S)-chloro-7-deoxylincomycin 2-pentylcarbonate.*

TLC was conducted on TLC plates[3] precoated with silica gel GF (250-μ thickness). A solvent system of hexane–ether–methyl propyl ketone–methanol–ammonia (60:20:20:9:1) (Solvent A) was used. Spots were developed with 20% aqueous ammonium sulfate, and the plate was then heated after spraying to char the organic material present.

Typical examples of reaction conditions for the synthesis of various clindamycin esters are illustrated. Analytical data are listed in Table III.

3,4-*O*-*p*-Anisylidene-7(S)-chloro-7-deoxylincomycin Hydrochloride—*Synthesis*—A solution of 65.0 g. 7(S)-chloro-7-deoxylincomycin hydrochloride hemihydrate dissolved in a mixture of 90 ml. dimethylformamide, 120 ml. anisaldehyde, and 250 ml. benzene was heated to 90°. The benzene–water azeotrope was allowed to distil at 90–95° and, upon collecting each 100 ml. distillate, an additional 100 ml. dry benzene was added. After the collection of 1000 ml. benzene, an extra 100 ml. dry benzene was added and some crystallization occurred. After 4500 ml. distillate was collected, an additional 500 ml. benzene was added. Fifty milliliters distillate was collected and the reaction mixture was allowed to cool to room temperature. The yellow reaction mixture became thick with crystals. The solids were isolated by filtration, washed with 100 ml. benzene–dimethylformamide (9:1), and finally washed with benzene. The resulting crystals were dried *in vacuo* at 45°.

Separation of Isomers by Preparative TLC—The isomers of 3,4-*O*-*p*-anisylidene-7(S)-chloro-7-deoxylincomycin were separated by preparative TLC, using silica gel G (0.25-mm. layers) with Solvent A. After development, the chromatograms were visualized with UV light and the isomers were scraped off the plate and eluted with methanol. The methanol extracts of the acetals were taken to dryness, yielding viscous tan liquids. The mass spectra of the two isomers were identical.

Clindamycin 2-Monoesters—*7(S)-Chloro-7-deoxylincomycin 2-Hexylcarbonate Hydrochloride*—3,4-*O*-Anisylidene-7(S)-chloro-7-deoxylincomycin hydrochloride (11.59 g., 0.02 mole) was dissolved in 100 ml. of analytical reagent grade pyridine, and the solution was cooled to −30°. Hexyl chloroformate[4] (6.29 g., 0.0382 mole) was added dropwise with good stirring. An additional 2 g. of hexyl chloroformate was added at 1-hr. intervals. The reaction was terminated after 3.5 hr. of stirring by pouring into 1 l. of ice water acidified to pH 2 with concentrated hydrochloric acid. The resulting aqueous suspension was extracted with three 250-ml. portions of chloroform, the chloroform extracts were combined and dried with anhydrous magnesium sulfate, and the chloroform was

[a] Number in parentheses equals time in hours. [b] Area expressed as concentration × time.

removed under reduced pressure at 38°. The residue was dissolved in 100 ml. of methanol and 40 ml. of distilled water. The pH of the solution was adjusted to 1.5 with concentrated hydrochloric acid and stirred for 75 min. The pH was then lowered to 1, and the solution was stirred for 3.75 hr. Sodium bicarbonate solution was then used to adjust the solution to pH 3.5, and all solvent was removed under reduced pressure at 36°. Two hundred milliliters of chloroform was then added to precipitate the sodium chloride, and the solvent was removed at high vacuum at 60°. One hundred milliliters of acetone was added to precipitate the desired product, which was subsequently washed with two 50-ml. portions of ether. The yield was 8.85 g. (75%).

7(S)-Chloro-7-deoxylincomycin 2-Palmitate Hydrochloride—A solution of 23.18 g. (0.04 mole) of 3,4-*O*-*p*-anisylidene-7(S)-chloro-7-deoxylincomycin hydrochloride dissolved in 400 ml. dry pyridine and 40 ml. analytical reagent grade chloroform was treated with a solution of 24.38 g. (0.08 mole) of palmitoyl chloride dissolved in 50 ml. chloroform. The acid chloride solution was added dropwise to the stirred pyridine solution over 1 hr. The pale-orange solution was diluted with 100 ml. isopropyl alcohol, and the solvent was removed under high vacuum at 60°. Then the viscous orange residue was dissolved in 200 ml. hot glacial acetic acid, and the resulting solution was diluted with 40 ml. of water. The solution was heated on a steam bath for 15 min., and the solvent was removed under high vacuum at 60°. The orange residue was dissolved in 100 ml. isopropyl alcohol and evaporated as before. The orange residue was dissolved in 150 ml. hot acetone, and the solution was added dropwise to 1500 ml. acetonitrile while stirring. The resulting precipitate of 7(S)-chloro-7-deoxylincomycin 2-palmitate hydrochloride was isolated by filtration under nitrogen pressure. The cake was washed with acetonitrile and dried by passing nitrogen through the filter for 15 min. Final drying was carried out at room temperature under high vacuum. The yield was 23.5 g. (84%).

7(S)-Chloro-7-deoxylincomycin 2-(p-Benzoyl)benzoate Hydrochloride—The preparation of *p*-(benzoyl)benzoyl chloride is as follows. *p*-Benzoyl benzoate (6.78 g.), recrystallized from water, was placed in a 125-ml. conical flask. Enough thionyl chloride was then added to cover the white powder and form a thin slurry. Excess thionyl chloride was removed, along with evolved sulfur dioxide and hydrogen chloride gas, by heating on a steam bath. The pale-yellow crystals were dried overnight at 45°, and the yield was 5.5 g.

The esterification procedure used is as follows. 3,4-*O*-*p*-Anisylidene-7(S)-chloro-7-deoxylincomycin hydrochloride (5.8 g., 0.01 mole) was dissolved in 35 ml. pyridine. *p*-(Benzoyl)benzoyl chloride (2.94 g., 0.012 mole) was dissolved in 10 ml. chloroform and added dropwise to the stirred pyridine solution. About halfway through the addition, a white precipitate formed which remained until heating (~50°) caused it to redissolve. Subsequent cooling to room temperature caused no further precipitation. TLC indicated that the reaction was half complete after 4 hr. at room temperature. Another 1.5 g. *p*-(benzoyl)benzoyl chloride dissolved in 5 ml. chloroform was added dropwise, and the reaction flask was warmed to 45°. TLC showed the reaction to be 90% complete. After addition of 3 ml. water the solvents in the reaction flask were removed *in vacuo*. The residue was washed with three 100-ml. portions of isopropyl alcohol, which in turn was removed *in vacuo*. The light-yellow residue was dissolved in 40 ml. glacial acetic acid and heated on a steam bath. To this was added 10 ml. water, and the solution was heated for 40 min. The yellow solution was evaporated *in vacuo;* the residue was washed with 100 ml. isopropyl alcohol, 90 ml. isopropyl alcohol plus 15 ml. 1 *N* HCl, and then 100 ml. isopropyl alcohol again, with the solvents being removed *in vacuo*. The residue was dissolved in 50 ml. chloroform, and the clear solution was added slowly to 500 ml. of cold anhydrous ether. The white precipitate was filtered and dried under nitrogen. TLC showed essentially pure compound.

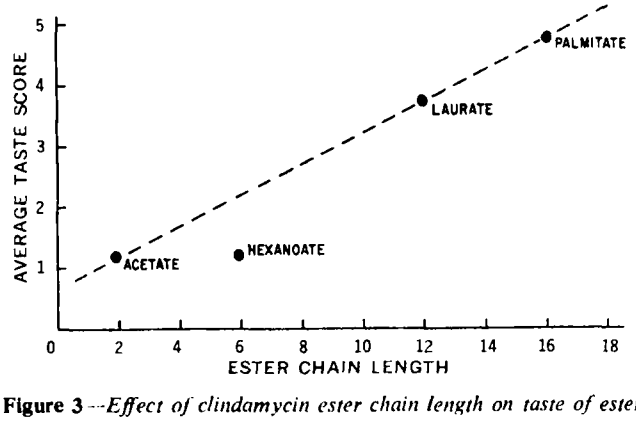

Figure 3—*Effect of clindamycin ester chain length on taste of ester in syrup.*

Table III—Analytical Data Obtained with Clindamycin Ester Hydrochlorides and Salts

Clindamycin Derivative	Empirical Formula	Molecular Weight	Analysis[a] Calc.	Found	Yield, %	Melting Point[b]

[a] Corrected for water content. [b] Melting points are of hydrated samples and were determined on a Thomas-Hoover melting-point apparatus and are uncorrected.

7(S)-Chloro-7-deoxylincomycin 2-(1-Adamantoate) Hydrochloride—3,4-*O*-*p*-Anisylidene-7(S)-chloro-7-deoxylincomycin hydrochloride (5.8 g., 0.01 mole) was dissolved in 35 ml. pyridine, and the solution was cooled to 4°. Then 2.4 g. (0.012 mole) adamantoyl chloride was dissolved in 10 ml. chloroform, and this was added dropwise to the stirred pyridine solution. The temperature was held between 5 and 8° during the addition and for 30 min. thereafter. TLC after 2 hr. indicated that 90% of the starting material had reacted. One gram adamantoyl chloride in 5 ml. chloroform was added dropwise to the pyridine solution (0–5°). After standing at room temperature overnight, the solvents were removed *in vacuo*.

The residue was treated with 80 ml. methanol and once with 80 ml. methanol plus 10 ml. 1 *N* HCl; each time the resulting solution was evaporated to dryness. The yellow gummy residue was dissolved in 40 ml. glacial acetic acid and heated on the steam bath for 5 min. Twenty milliliters water was added, and the solution was heated for another 30 min. The solvent was removed *in vacuo* as before, and the residue was washed three times with 80 ml. isopropyl alcohol, which was removed *in vacuo*. The product, a yellow oil, was dissolved in 40 ml. chloroform and extracted twice with 40-ml. portions of pH 2.2 buffer. The organic phase was dried (anhydrous sodium sulfate), made acidic with anhydrous hydrochloric acid (pH 1–2, pHydrion paper), and reduced to dryness. The residue was dissolved in 10 ml. chloroform and poured slowly into 500 ml. of stirred ether at room temperature. The white precipitate was isolated by filtration, washed with 75 ml. ether, and dried at 45° *in vacuo*.

Clindamycin 3-Monoesters [7(S)-Chloro-7-deoxylincomycin 3-Pentylcarbonate Hydrochloride]—A solution of 9.63 g. (0.02 mole) of 7(S)-chloro-7-deoxylincomycin hydrochloride in 100 ml. of pyridine was cooled to about −30°, and 6.02 g. (0.04 mole) of *n*-amyl chlorocarbonate was added dropwise. This solution was warmed to room temperature, stirred for about 1 hr., and cooled to about −30°. Then 2 g. of *n*-amyl chlorocarbonate was added, and the solution was stirred for an additional 2 hr. The pyridine solution was poured into 1 l. of ice water acidified to pH 2 with concentrated hydrochloric acid. The resulting aqueous suspension was extracted with two 250-ml. portions of chloroform, and the chloroform extracts were combined and dried over anhydrous magnesium sulfate. The chloroform was removed under vacuum at 38°. The resulting white precipitate was shaken with 750 ml. of anhydrous ether; the product was collected by filtration, air dried for about 1 hr., and then dried for about 16 hr. under vacuum at 45°. The crude product (6.75 g.) contained both the 3-ester and the 2-ester in about a 2:1 ratio (Fig. 1) and was equilibrated between 700 ml. of ether and 460 ml. of aqueous buffer of pH 2.2. The ether layer was removed and discarded, and the aqueous layer was extracted again with 800 ml. of ether. The aqueous layer was extracted with 780 ml. of chloroform (in two portions), and the chloroform extracts were pooled, dried with anhydrous sodium sulfate, and evaporated to dryness under vacuum at about 50°. The resulting residual light-yellow oil was taken up in 80 ml. of chloroform, which was made acidic with anhydrous hydrogen chloride, and again reduced to dryness under vacuum at about 50° to give 2.65 g. (49%) of white solid, 7(S)-chloro-7-deoxylincomycin 3-pentylcarbonate hydrochloride. The GLC[5] pattern (Fig. 2) showed only a trace of the 2-ester.

Clindamycin 2,3-Dicarbonate Esters [7(S)-Chloro-7-deoxylincomycin 2,3-Dihexylcarbonate Hydrochloride]—7(S)-Chloro-7-deoxylincomycin hydrochloride monohydrate (4.79 g., 0.01 mole) was dissolved in 75 ml. of analytical reagent grade pyridine and cooled to −30°. Hexyl chloroformate[4] (6.59 g., 0.04 mole) was added dropwise with rapid stirring. The reaction mixture was slowly warmed to room temperature and stirred for 2 hr. TLC (silica gel plates, Solvent A) indicated that the reaction was not complete, so an additional 1.5 g. of hexyl chloroformate was added to the recooled (−30°) reaction mixture. The mixture was again warmed to room temperature and stirred for 1 hr. The reaction mixture was again cooled and an additional 0.5 g. of hexyl chloroformate was added. The pyridine solution was poured into 1 l. of ice water and extracted with two 250-ml. portions of ether. The combined ether fractions were dried with anhydrous magnesium sulfate. Ether and pyridine were removed under reduced pressure, and the resulting syrup was dissolved in 100 ml. of anhydrous ether. Anhydrous hydrogen chloride gas was bubbled through the ether solution for 2 min. After standing for 10 min., a gelatinous precipitate formed. The ether was removed under reduced pressure (water aspirator), and the resulting tan syrup solidified on standing. The solidified syrup was shaken with two 75-ml. portions of anhydrous ether and filtered.

Clindamycin Salts—*7(S)-Chloro-7-deoxylincomycin Lactobionate*—Lactobiono-δ-lactone (13.61 g., 0.04 mole) was dissolved in 100 ml. of water, heated on a steam bath for 1 hr., and filtered. This solution was added slowly to 17 g. (0.04 mole) of 7(S)-chloro-7-deoxylincomycin base dissolved in 50 ml. of acetone. The resulting yellow solution was stirred for 1 hr., and then all solvent was removed *in vacuo* (200 μ) at 38°. The resulting syrupy precipitate was shaken with 100 ml. of anhydrous acetone for 1.5 hr. The resulting gum was rubbed in a mortar with a small amount of acetone until a homogeneous suspension was formed. The suspension was filtered, and the precipitate was dried *in vacuo* for 1 hr. at 55°.

7(S)-Chloro-7-deoxylincomycin Gluconate—δ-Gluconolactone (7.1 g., 0.04 mole) was dissolved in 50 ml. of distilled water, heated on a steam bath for 1.5 hr., and then cooled to room temperature. This solution was added dropwise to 17 g. (0.04 mole) of 7(S)-chloro-7-deoxylincomycin base dissolved in 25 ml. of anhydrous acetone. The resulting solution was stirred at room temperature for 1 hr. The solvent was removed *in vacuo*, and the resulting gum was treated with acetone. About 20 g. (80%) of white amorphous powder was obtained and dried *in vacuo*.

[5] Instrument, F&M 700 with flame-ionization detector; carrier gas, helium (20 ml./min.); column, 43.2 × 1.3-cm. (17 × 0.5-in.) stainless steel; support, Gas Chrom Q (100–200 mesh); stationary phase, 1% OV-1; injector port temperature, 275°; detector temperature, 275°; oven temperature, linearly programmed from 200 to 245° at 3°/min.; chart speed, 0.5 in./min.; and attenuation, $10^2 \times 5$.

ACKNOWLEDGMENTS AND ADDRESSES

Received September 14, 1972, from the *Pharmacy Research Department, The Upjohn Co., Kalamazoo, MI 49001*

Accepted for publication February 23, 1973.

Presented in part to the Basic Pharmaceutics Section, APhA Academy of Pharmaceutical Sciences, Washington, D. C. meeting, April 1970.

The authors gratefully acknowledge the technical assistance of the late F. E. Young, Jr., for the synthesis of several of the compounds utilized in this work and P. C. Ruenitz for synthesis of certain clindamycin esters and for purification of clindamycin 3-pentylcarbonate. Thanks are also extended to C. Lewis, K. F. Stern, D. J. Mason, and associates for biological data and to F. A. MacKellar for NMR data.

Lacrimal and Instilled Fluid Dynamics in Rabbit Eyes

SUKHBIR S. CHRAI, THOMAS F. PATTON, ASHOK MEHTA, and JOSEPH R. ROBINSON▲

Abstract □ Drainage of an instilled drug solution away from the eye is responsible for a considerable loss of drug and, hence, affects the biological activity of drugs in the eye. The rate of this drainage is related to the volume of drug solution instilled and increases with increasing volume. A demonstration of the influence of this solution drainage on drug activity is presented using miosis studies in albino rabbits. It is shown that over a range of 5–50 μl. of instilled volumes, using various concentrations of pilocarpine nitrate so that the total amount of drug instilled at each volume is the same, there is a fourfold change in the area under the pupillary diameter–time curves. A simple isotopic technique, using radioactive technetium-adsorbed colloid, was developed and utilized in this study to determine lacrimal volume and turnover rate of lacrimal fluid as well as to evaluate drainage of instilled solutions in albino rabbits. By using both a sampling and a nonsampling technique with the technetium colloid, it is shown that unanesthetized rabbits have a lacrimal volume of 7.5 ± 2.5 μl. whereas anesthetized rabbits have a slightly larger volume of 12.0 ± 2.5 μl. In addition, lacrimal fluid turnover rate in unanesthetized rabbits is approximately 0.53 μl./min., with a range of 0.47–0.66 μl./min., while in anesthetized animals it is negligibly small or absent. Drainage loss of instilled solutions was also determined and analyzed. It is shown that the loss of instilled solution *via* drainage is first order with respect to time. The apparent first-order rate constant in unanesthetized rabbits contains a volume-dependent and a volume-independent term, whereas in anesthetized rabbits the apparent rate constant is independent of volume instilled. A discussion of the meaning of these results as related to the mechanism of fluid drainage from the eye is presented. A comparison of the present studies in rabbits to expected behavior in humans is made. It is suggested that drainage rates of instilled solutions in humans should be larger than those of rabbits; therefore, to maximize activity of drugs in humans, the drop size of ophthalmic delivery systems ought to be reduced from its present 50–75-μl. size to at most a 5- or 10-μl. drop.

Keyphrases □ Ophthalmic solutions—determination of lacrimal and instilled fluid dynamics, relationship to drug activity, rabbits □ Miosis—used to study lacrimal and instilled fluid dynamics in the rabbit eye, relationship to drug activity, rabbits □ Fluid dynamics, ophthalmic—lacrimal fluid turnover and instilled volume drainage, rabbits □ Technetium, ^{99m}Tc, colloid—used to study lacrimal volume, lacrimal fluid turnover rate, and drainage of instilled solutions, rabbits □ Lacrimal volume and fluid turnover—determined for albino rabbits

A severe problem accompanying the instillation of a drug into the eye is the loss that occurs *via* drainage into and through the drainage apparatus. This loss increases in severity as the instilled volume increases and can have a large influence on the biological activity of a drug, since it removes drug from the area of the eye, making it less available to exert a local effect or to be absorbed into the eye. The present report demonstrates that the volume of instilled dose in the eye influences the activity of drugs through drainage loss. In addition, an attempt was made to describe quantitatively the relationship between volume present and rate of drainage in albino rabbits.

Since lacrimal fluid is turned over at an appreciable rate, reported to be some 16%/min. in humans (1), high concentrations of the drug in lacrimal fluid are required for the first few minutes after instillation to maximize biological activity. Viscosity alterations of solutions, suspensions, and emulsions, as well as the use of solid delivery systems such as soft contact lenses (2, 3), are popular methods attempting to reduce or avoid drainage rate problems and, hence, to increase corneal contact time. Clearly, the volume of instilled dose must have a sizable influence on the quantity and rate of drug solution loss to the drainage apparatus.

Mishima *et al.* (1) reported that the normal lacrimal volume in humans is approximately 7 μl. and that the human eye can hold about 30 μl. without overflow or spillage at the lacrimal lake or outer angle, provided that great care is exercised and the subject does not blink. If blinking is allowed, then the eye can hold approximately 10 μl. (4). The normal dropper used in commercial ophthalmic preparations delivers approximately 50–75 μl. Apparently, when this volume of solution is instilled into the cul-de-sac, the reflex action of blinking causes a substantial portion of the drop to be sucked into the drainage apparatus while another portion may be spilled onto the cheek. Removal of the instilled solution continues until the total tear volume is back to the normal lacrimal volume of 7 μl.

Thus, as the volume of instilled dose is increased, the volume of solution lost by spillage on the cheek and drainage increases. This suggests that the optimum volume of drug solution to instill into the eye is *no volume*, since increasing the instilled volume increases the volume lost and the corresponding percentage of drug that is lost. However, an additional factor that complicates the picture is the effect of turnover rate of lacrimal fluid on the concentration and amount of drug remaining in the eye. If one assumes a constant turnover rate of lacrimal fluid of 16%/min., it seems clear that as the precorneal volume of fluid in the eye (lacrimal plus instilled) gets smaller, the turnover rate of lacrimal fluid will have a greater influence on the residual drug concentration. Thus, the rate of turnover of lacrimal fluid favors a *larger instilled volume* to maximize the bioavailability of ophthalmic drugs.

Selection of an "ideal" volume for instillation of drugs into the eye requires information on the magnitudes of the rate constants for lacrimal fluid turnover and for drainage of instilled solutions. Lacrimal fluid turnover studies have been conducted in humans (4–10), but instilled volume drainage studies have apparently not been reported. In addition, although rabbits are the main experimental animals in ophthalmic research, neither lacrimal fluid turnover nor instilled volume drainage has been studied in this animal. Thus, the problem of lacrimal and instilled fluid dynamics as it relates to drug activity seems to have been largely ignored in the ophthalmic field. The paucity of reported work in this area is somewhat surprising, since these fluid dynamics have great bearing on studies of release rates and dissolution of dosage forms and drugs as well

as the transport and general movement of drugs into the eye.

EXPERIMENTAL

Materials—Water was doubly distilled from alkaline permanganate in an all-glass distillation apparatus.

Pilocarpine nitrate USP was obtained from a commercial source[1] and used without further purification. Technetium solutions were prepared using a package[2] of solutions and equipment used to prepare technetium, ^{99m}Tc, suspensions. All other chemicals were either reagent or analytical grade.

Adult, male, albino rabbits[3] were used throughout this study. The rabbits were fed a regular diet with no restrictions on the amount of food or water consumed. All rabbits used weighed between 1.80 and 2.40 kg.

Solution Preparation—Pilocarpine nitrate solutions were prepared fresh and were discarded immediately after the experiment. The solutions were prepared by addition of pilocarpine nitrate to Sorensen's pH 7.38, 0.067 *M*, phosphate buffer. Solution pH was checked and adjusted where necessary. All pH measurements and adjustments were made on a digital pH meter[4], using a wide range glass electrode[5]. The pH meter and electrode system were standardized against phosphate buffer as described by Bates (11). No attempt was made to sterilize the solutions. The highest drug concentration used yielded a slightly hypertonic solution; the tonicities of all drug solutions were adjusted to this value.

Technetium colloidal solutions were prepared by addition of technetium, ^{99m}Tc, to solutions provided in a colloidal sulfur technetium kit[2], from which the sulfur colloid is prepared *in situ*[6]. Technetium, ^{99m}Tc, was obtained by elution off the generator column, in which it was prepared, with normal saline. The technetium solution was added to a thiosulfate–mannitol solution, and the resulting solution was treated with hydrochloric acid and heated to produce a technetium sulfide colloid. The colloid was then added to a buffer solution and again heated to produce the final product. Throughout the study the final technetium, ^{99m}Tc, suspension contained approximately 1 mc. of activity/ml. of solution.

Anesthetic solutions were composed of a mixture of sodium pentobarbital and sodium phenobarbital. Separate solutions of sodium pentobarbital and sodium phenobarbital were prepared in a vehicle containing 20% (v/v) propylene glycol and 10% (v/v) ethyl alcohol (95%). The pentobarbital solution contained 50 mg./ml. of drug, and the phenobarbital solution contained 100 mg./ml. of drug. Both solutions were refrigerated between uses and were never kept for more than 2 weeks.

Anesthesia—A combination of sodium pentobarbital and sodium phenobarbital was used to induce and maintain the desired level of anesthesia. A dose of 33 mg. of sodium pentobarbital and 100 mg. of sodium phenobarbital/kg. of animal body weight was sufficient in most cases to anesthetize the rabbits for 8–12 hr. With this dose level of drugs, the onset of anesthesia usually occurred in 15–30 min. Drugs were administered by intraperitoneal injection.

Miosis–Time Studies—Anesthetized animals were used in these experiments to minimize possible lacrimation from any stimulus, since this would influence the results. After onset of anesthesia, the test animals were placed in a restraining box with the head elevated in such a manner that the lid line, upon closure, was approximately horizontal. This position, which is not the natural posture for the rabbit, was used to facilitate pupillary diameter measurements. The unnatural posture should have the effect of decreasing the rate of lacrimal drainage, thus modifying the magnitude of the effect for which the experiment was designed. Both upper and lower eyelids were then taped open to enable accurate measurements of pupillary diameter. The lower tape was loosened at time of instillation to allow for manual mixing of drug with lacrimal fluid, after which it was replaced. Keeping the eyelids open hastens evaporation of water from the eye and again modifies the effect expected from this experiment. Since the interest was in a reproducible system giving at least a qualitative indication that volume of instilled dose affects drug activity, the experiment was conducted under these conditions. No desiccation of the cornea was observed.

Lighting in the test room was accomplished by use of one 200-w., half-silvered overhead light and remained constant throughout the study. Temperature in the room was maintained at 25 ± 1.0°. The entire room was as isolated as conditions would permit to keep audiovisual stimuli to the test animal at a minimum.

The observer was hidden from the test animal by a cardboard shield; this shield contained a vertical slit through which measurements of pupillary diameter could be made. The observer, once inside the room, was not allowed movement in or out of the room until the experiment was complete. All of these precautions were necessary to obtain reproducible results.

Measurement of pupillary diameter was made by use of a cathetometer[7], positioned approximately 50 cm. from the test animal. These measurements could be made with an accuracy of ±0.1 mm.

After positioning the animal in the restraining box, in line with the cathetometer and prior to drug instillation, pupillary diameter readings were made at 100-sec. intervals. This procedure was continued until the test animal had adapted to its environment, as judged by the constancy of pupillary diameter (±0.1 mm. for 10 min.). The adaptation period varied from 15 to 30 min., and the initial diameter ranged from 6.0 to 7.8 mm.

Pipets[8] with blowout delivery were used to instill the drug solution and were checked for accuracy of delivery prior to use by weighing the delivered solutions.

Drug solutions were instilled onto the cornea, so that they collected in the lower cul-de-sac. To prevent loss of solution during instillation, the lower eyelid was pulled slightly away from the globe of the eye to form a pocket. This particular form of solution instillation was followed at all times.

After instillation of drug solution, the lower lid was lifted back and forth over the cornea to mix the drug solution with lacrimal fluid. At no time was the lid ever massaged against the cornea, so only movement of the drug solution over the cornea occurred. To exert some degree of control in this method, the eyelid was lifted over the cornea exactly four times, during about 5 sec., in all cases. To aid in reproducibility, all procedures were performed in precisely the same manner and with the same time intervals.

After instillation of the drug solution, the lower eyelid was taped open and pupillary diameter was measured as a function of time. The other eye of the test animal served as a control. One hundred-second intervals were used for the first 50 min. of the experiment, 300-sec. intervals were used from 50 to 80 min., and 600-sec. intervals were used thereafter. Measurements were terminated when the measured diameter reached a constant value close to the initial value.

No experimental animal was used more than once, and each experiment was repeated at least four times.

Technetium Studies: Sampling Method—*Animal Preparation*—Test animals for this study were either: (*a*) anesthetized, where manual mixing of tracer solution with lacrimal fluid was employed, or (*b*) unanesthetized, where natural mixing occurred. The unanesthetized test animal was placed in a restraining box in its normal posture. The eyelids were *not* taped open and, after instillation of the technetium suspension, the lid was returned to its former position. Thus, normal movement of the eye was used to mix the colloidal suspension of technetium with lacrimal fluid. After instillation of the tracer, the animal would close its eyelids but would, in all cases, open the lids within 10–15 sec. after instillation. Closing of the lids was not due to irritation from the tracer substance, since instillation of normal saline produced the same response.

Anesthetized animals were placed in restraining boxes, and experiments were conducted with the animals in their normal posture. The eyelids were *not* taped open. Technetium suspension was instilled in the same manner as in the pilocarpine studies.

Procedures—Radioactive technetium colloidal suspensions were instilled into the rabbit eye from a syringe[9] which had been prechecked for accuracy of delivery by weighing the delivered solutions. Volumes as small as 0.1 μl. could be accurately delivered from the

various size syringes, although it was necessary to shake the syringe gently to discharge the drop in the case of the 0.5- and 0.1-μl. volumes.

After instillation of a suitable volume of technetium colloid, 15 sec. was allowed to elapse for either manual or natural mixing of the colloid with lacrimal fluid. A sample of tears was then obtained at appropriate time intervals by placing a 1-μl. capillary tube[10] in contact with the marginal tear strip. The capillary tube would immediately fill with tears. All samples were withdrawn from the lower marginal tear strip, approximately in the middle of the strip. The samples were counted[11] for 1 min.

Before and during the study, background readings were taken to determine the level of radioactivity in the test room. Before instillation of the technetium colloid, three readings of the activity of isotope being introduced into the eye also were made. In general, the number of counts per microliter of technetium colloid was in the range of 100,000/min. Suitable corrections for the normal decay of technetium isotope were employed wherever necessary.

Lacrimal Volume Determination—Various volumes, ranging from 0.1 to 50 μl. of technetium suspension, were instilled into the eye, 15 sec. was allowed to elapse, and then a sample was withdrawn and its radioactivity was determined. Both eyes of the animal were used, and no animal was used more than once. Knowing the initial radioactivity of the technetium colloid instilled into the eye, as well as the radioactivity after dilution, allows calculation of the lacrimal volume present as described in the *Appendix*.

Normal Lacrimal Volume Turnover Rate—Various volumes of technetium suspension, ranging from 1.0 to 50 μl., were instilled into the eye; samples were withdrawn and assayed for activity at 5-, 10-, or 20-min. intervals. No initial sample was taken after 15 sec. in this study. Sampling was continued until the isotopic activity had decreased to approximately background level, which, depending upon the volume of isotope instilled, varied from 30 min. to 2 hr. Only one eye of each experimental animal was used, and no animal was used more than once. From a plot of the logarithm of technetium concentration *versus* time, it is possible to determine the turnover rate as shown in the *Appendix*.

Drainage Rate Determination—After instillation of various volumes of technetium colloid into the eye, samples were withdrawn and radioactivity was measured at 5-, 10-, 15-, or 20-sec. intervals. The sampling technique for drainage rate determination was not pursued because of the difficulty in obtaining frequent samples without irritating the eye. More importantly, this technique measures technetium concentration. Thus, as drug is drained out of the eye, concentration does not change appreciably whereas the total *amount* of drug is altered.

Technetium Studies: Nonsampling Method—*Animal Preparation*—All procedures were the same as in the sampling method.

Procedures—The various volumes of colloidal technetium solution were instilled into the eyes of both anesthetized and unanesthetized animals, and the decline in radioactivity was monitored with a thin-probe scintillation detector[12] attached to a well counter[11]. The thin-probe detector is a cylindrical vessel, approximately 22 cm. long and 5 cm. in diameter, containing a sodium iodide crystal and capable of detecting β-emitters. Since the entire outer wall and bottom of the probe can respond to radioactivity, it was necessary to cover the entire probe, except for a 1.5-cm. opening at the bottom, with a 0.3-cm. (0.125-in.) thick lead shield. Thus, the only radioactivity picked up by the probe would be that coming through the orifice at the bottom, and this orifice was placed directly over the cornea of the test animal approximately 1 or 2 cm. away from the eye. Preliminary testing had shown that this distance from the eye, as well as the size of the orifice in the lead shield at the bottom of the probe, was a compromise to obtain maximum isotope counts from the eye as well as to exclude extraneous radiation from the surroundings or from technetium that might have passed into the drainage apparatus.

With anesthetized animals, no special precautions were followed. With unanesthetized animals, it was necessary to precondition the animals to the testing procedure so that head and eye movements were eliminated during the experiment. For preconditioning, the test animals were placed in the restraining box with the probe over their eyes once a day for 1-hr. duration on 7 successive days prior to the experiment. After this conditioning, the animals showed no head or eye movement for the duration of the experiment; if they did, it was clear from the results and the experiment was terminated at that point.

Various volumes of technetium colloidal suspension were instilled into the rabbit eye, as described in the *Sampling Method* section, and the probe was placed in front of the eye. Measurements of radioactivity in the eye were made every 5 sec., and counts were determined for periods of 5 sec. This measuring technique determines the amount of drug in the eye and *not* concentration. Measurements were made until the technetium radioactivity had decreased to approximately background level, which usually took about 60–90 min., although shorter and longer times occurred depending upon the type of experiment. Only one of the rabbit's eyes was used, and no rabbit was used more than once.

Normal lacrimal turnover rate and instilled volume drainage rate constants were obtained by computation. Derivation of the appropriate equations is shown in the *Appendix*.

Evaluation of Technetium Dilution Technique for Lacrimal and Instilled Fluid Dynamic Studies—To use a tracer substance such as isotopic technetium as a test substance for tear and instilled fluid dynamic studies, it is necessary to satisfy several criteria. These criteria are: (*a*) the test substance must be lost from the eye solely *via* the drainage apparatus, *i.e.*, no spillage; (*b*) no absorption/adsorption must occur or, if sorption occurs, its extent must be known; (*c*) the test substance must be nonirritating; and (*d*) if the substance is an insoluble solid, it must not interfere with loss of fluid into the tear drainage apparatus.

To show that neither loss nor retention of a significant portion of the technetium colloid occurred through binding to eye tissue and/or absorption, the amount of drug consumed in these possible routes was determined. Because of the differences between the two techniques (sampling and nonsampling) employed in the determination of the amount of ^{99m}Tc present, the amount shown to be present by each method could be different if any significant binding or absorption occurred. Since the ^{99m}Tc is a 142-kev. β-emitter, its presence can be detected by the probe through the conjunctiva and eyelid. Consequently, ^{99m}Tc bound to eye tissue or absorbed into the eye, with the exception of the portion that passed into the bloodstream and was swept away, would still be seen by the probe whereas ^{99m}Tc determined by the sampling technique would not show this retention. For this study, 25 μl. of technetium solution was instilled into the eyes of several anethetized animals. At various time intervals over 4-hr., representing the maximum duration of the experiments, the animals were sacrificed and isotope activity in aqueous humor, cornea, sclera, conjunctiva, and eyelids was determined. Less than 0.1% of the instilled colloid was absorbed or adsorbed into any portion of the eye tested during this time period. This small activity could have been due to contamination of the tissue samples rather than absorption/adsorption. Thus, all loss appears to be through the drainage apparatus.

Since the technetium isotope is adsorbed on a colloid, there is the possibility of blockage or interference with drainage into the nasolacrimal duct. In preliminary studies using gelatin-stabilized technetium colloid, the drainage apparatus was apparently blocked by the colloid as judged by impaired or inhibited disappearance of the technetium isotope. This problem did not appear when mannitol-stabilized technetium was used, and repetitive application of the isotope solution at various times and under various conditions gave highly reproducible results.

Insofar as irritation is concerned, the isotope, at very high concentrations, does irritate the rabbit eye as judged by animal reaction and lacrimation. Concentrations of isotope used in this study did not cause observable irritation to the test animal.

RESULTS

Miosis–Time Study to Demonstrate Effect of Dose Volume on Drug Activity—To determine the influence of dose volume on drug activity, several solutions of varying concentration of pilocarpine nitrate were prepared and instilled into the eyes of anesthetized rabbits. The volumes of solution instilled were adjusted so that the amount of drug delivered to all rabbit eyes was the same; *i.e.*, the amount of drug delivered from the 75-μl. dose was the same as that

from the 5-μl. dose. If there is *no* loss of drug solution from the eye, it would be expected that the areas under the pupillary diameter–time curves would be the same, although the shape of curves for various concentrations of drug would be expected to be different.

Previous extensive work on the miotic effect of pilocarpine nitrate (12) had determined the dose-response curve.

A typical pupillary diameter–time relationship is shown in Fig. 1, along with standard deviations which are presented as vertical bars. The results shown in Fig. 1 were obtained from five animals in five different experiments and are typical of all the experiments.

Table I shows the area under the pupillary diameter–time curves for various instilled volumes. These areas are proportional to the concentration of drug reaching the target and are presumably proportional to the *amount* of drug present in the tear fluid. Since all of these solutions had identical amounts of drug, it would be expected that all would show the same area under the curve if no drug solution was lost from the application site. The ratio of productive to nonproductive drug loss by adsorption/absorption will be the same whether low volume (high concentration) or high volume (low concentration) is used. Thus, fluid loss by drainage would determine differences in area under the curve. Clearly, the increased area under the curve that is observed as the instilled volume decreases demonstrates that a substantial portion of the instilled dose is unavailable for absorption to the target area, due apparently to the drainage loss.

The range of volumes employed was restricted at the lower end by drug irritancy and at the upper end by the maximum volume the eye can hold without overflowing onto the lid and cheek. In the case of the largest dose volume, 75 μl., great care was needed in mixing the drug solution with lacrimal fluid to prevent overflow onto the cheeks.

Determination of Lacrimal Volume and Normal Lacrimal Fluid Turnover Rate by Sampling Technique—*Lacrimal Volume Determination*—Instillation of a known volume and activity of a technetium colloidal suspension, followed by sampling of the tear fluid for activity, allows determination of the volume of fluid originally present in the eye as described in the *Appendix*. This procedure assumes that good mixing takes place and that no tear production occurs from time of instillation until sampling time, which was 15 sec. in the present study.

Both anesthetized and unanesthetized animals were used, and each involved a different method of mixing the technetium suspension with lacrimal fluid as described in the *Experimental* section.

The results of the study are shown in Table II together with the range of values, mean value, and standard deviation for various instilled volumes. A broad range of volumes was used to determine if adequate mixing or loss of unmixed solution was occurring. As can be seen from Table II, the range of median values for both unanesthetized and anesthetized animals is not excessively large, considering that a 500-fold range of instilled solution was used. The standard deviation increases in the unanesthetized animals as the instilled volume increases, presumably due to incomplete mixing or loss of unmixed solution. In addition, all standard deviations are larger than desirable, pointing to the disadvantage of the sampling procedure as described by Mishima *et al.* (1).

Table I—Effect of Instilled Volume on Activity of Pilocarpine Nitrate in the Rabbit Eye

Instilled Volume, μl.	Concentration[a], *M*	Number of Animals	Peak Height, mm.[b]	Area under Curve, cm.[2c]	Activity[d], %
75	6.7 × 10^{-3}	5	2.05 ± 0.10	63.7	27.7
50	1 × 10^{-2}	5	2.40 ± 0.17	72.6	31.5
25	2 × 10^{-2}	5	2.53 ± 0.21	83.9	36.5
10	5 × 10^{-2}	4	3.53 ± 0.15	131.3	57.0
5	1 × 10^{-1}	5	4.17 ± 0.40	230.2	100.0

[a] The amount instilled is 0.136 mg. [b] Units refer to average peak height plus or minus standard deviation. [c] Units are millimeters-minute. On the vertical axis, 1 cm. = 0.25 mm.; on the horizontal axis, 1 cm. = 10 min. [d] For comparison purposes only, it was assumed that the 5-μl. instilled volume case gives 100% activity.

In unanesthetized animals, the calculated lacrimal volumes show a range of values depending on the instilled volume. For the lower instilled volumes of 0.1, 0.5, and 1.0 μl., the mean lacrimal fluid volume value of approximately 7.5 ± 2.5 μl. is essentially constant, and this value is interpreted to be the true lacrimal volume in the unanesthetized rabbit. With larger instilled volumes of 5.0, 25, and 50 μl., the calculated values for lacrimal fluid volume are considerably higher than for the smaller instilled volumes. These higher values are interpreted as being due to a loss of unmixed technetium solution or perhaps to better mixing with lacrimal fluid under the lids. The larger standard deviations with larger instilled volumes, as well as the broader range of values, suggest that loss of unmixed solution is the more likely explanation.

Anesthetized animals show a relatively constant lacrimal volume for instilled volumes ranging from 1 to 50 μl. This relatively constant value of approximately 11–12 μl. is considerably larger than the values for the lower instilled volumes in the unanesthetized animals. These higher values are probably due to relaxation of the eye musculature under anesthesia to accommodate a larger volume. Alternative explanations of loss of unmixed solutions or of irritation on mixing were considered and discarded. It is conceivable, however, that manual mixing is more efficient than natural mixing and that the true lacrimal fluid volume in both anesthetized and unanesthetized rabbits is approximately 12 μl.

Normal Lacrimal Turnover Rate Determination—Different volumes of technetium solution were instilled into the eyes of both anesthetized and unanesthetized rabbits, and samples were with-

[a] Obtained by multiplying the observed first-order rate constant times the lacrimal volume, 7.5 μl. for unanesthetized and 12.0 μl. for anesthetized rabbits, and subtracting the sampling withdrawal rate constant. [b] Subtracting the withdrawal rate gives a negative number to the turnover rate.

drawn at various time intervals. The logarithm of the decline in technetium concentration was plotted against time and the first-order rate constant was determined from the slope of the line as shown in the *Appendix*. The results of this study are presented in Table III, together with standard deviations and resultant turnover rates based on a lacrimal fluid volume of 7.5 μl. for unanesthetized rabbits and of 12.0 μl. for anesthetized rabbits.

In the case of unanesthetized rabbits, good linearity is observed when the logarithm of decline in isotope activity is plotted against time (Fig. 2). The range of observed rate constants is fairly narrow for all volumes studied (Table III). The relatively consistent results of the turnover rate under conditions of varying instilled volume as well as different sampling schedules can be seen from the last column on the right of Table III. Various sampling times were

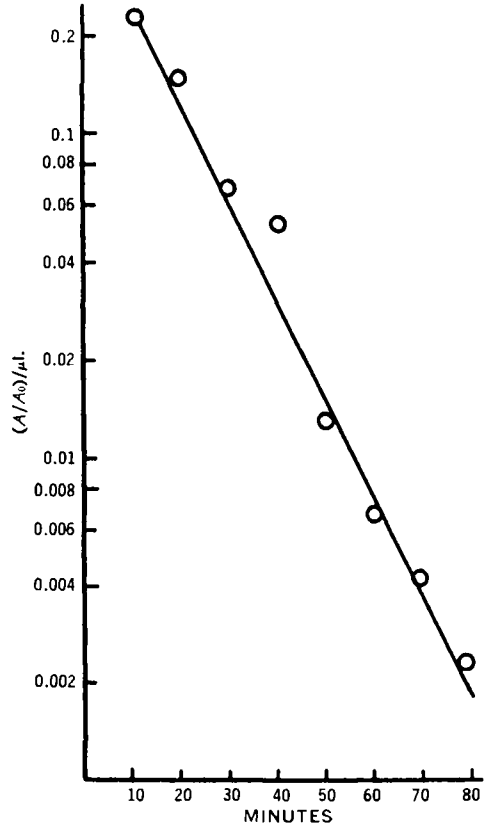

Figure 2— *Typical plot of the decline in isotopic activity of technetium* versus *time in unanesthetized rabbits. The specific run is for a 50-μl. instilled volume, in which the sampling technique was used to determine isotopic activity of technetium.*

studied to assess if the sampling technique was influencing the observed decline in activity of the isotope through irritation and lacrimation. Several different instilled volumes were used to ensure good mixing.

In the case of anesthetized animals, the turnover rate was essentially zero for the 25- and 50-μl. runs and rather large for the 1- and 5-μl. instilled volumes. It was concluded that the turnover rate in anesthetized animals is essentially zero. The large rates observed for the 1- and 5-μl. runs are possibly due to irritation from repetitive sampling, since it was difficult to obtain more than two or three samples in each experiment. Thus, for anesthetized animals it was concluded that the lacrimal turnover rate is either very small or nonexistent, which is not unusual considering that it is reported that humans do not lacrimate while sleeping (13-15). This observation has important bearing on animal studies, where time-concentration curves are generated in corneal absorption experiments. Anesthetized animals are generally used, and the results of these studies would be expected to be far different than results from unanesthetized animals considering the difference in turnover rate of lacrimal fluid.

Determination of Normal Lacrimal Fluid Turnover Rate and Instilled Volume Drainage Rate by Nonsampling Technique—*Unanesthetized Rabbits*—After instillation of technetium colloidal solution into the rabbit eye, monitoring of technetium radioactivity commenced no more than 2 or 3 sec. after instillation. A representative figure of the amount of tracer remaining as a function of time for various instilled volumes in unanesthetized animals is shown in Fig. 3. Also included in the figure are standard deviations, at random points, for the 5-μl. case to illustrate reproducibility of the procedure.

Initial inspection of Fig. 3 suggests that the data might fit a reaction sequence of the following type:

where $A \rightarrow B$ represents the rapid drainage of the instilled solution phase and $A \rightarrow C$ represents turnover of lacrimal fluid. This can be visualized as follows: After instillation of a volume of tracer solution into the eye, the total volume (instilled plus lacrimal) drains out at a given rate, removing tracer solution, until the volume is reduced to the lacrimal volume. Further decline in tracer amount is then due to turnover of lacrimal fluid.

Although the curves in Fig. 3 are depicted as smooth, uniformly changing lines, the terminal portion (turnover of lacrimal fluid) is actually oscillatory. The amplitude of the wave is rather small, and the wave has a period of approximately 400 sec. A smooth line was drawn through the wave function to simplify analysis. The cause of this unexpected behavior could be one or a combination of factors such as an intermittent input of lacrimal fluid or pulsation of the eye musculature which forces lacrimal fluid out. It is not due to either blinking or head and eye movement. Mishima *et al.* (1) did not remark upon this behavior in humans, although the scatter in

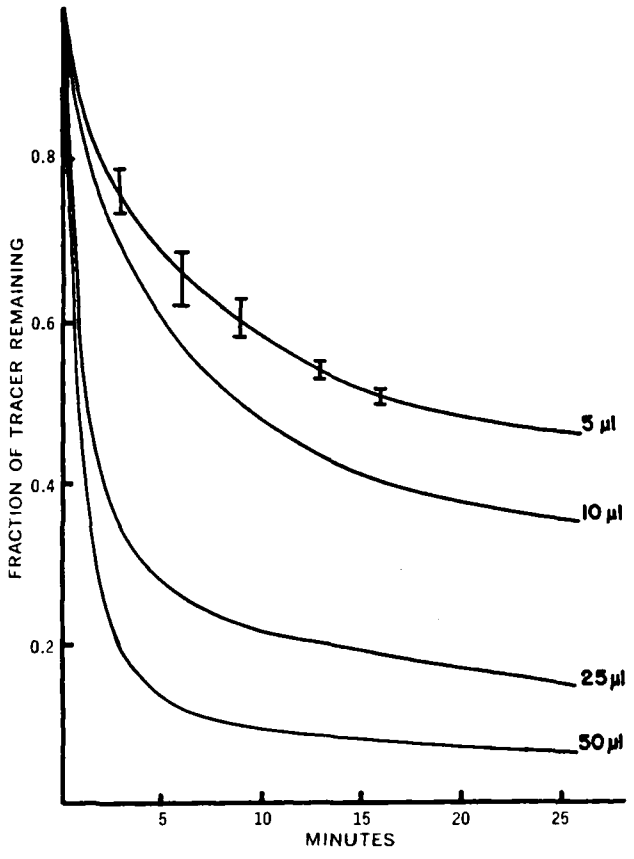

Figure 3—*Fractional amount of drug remaining as a function of time for various instilled volumes in unanesthetized rabbits. At least three separate experiments were conducted at each instilled volume, and the lines represent the mean values for these runs. Standard deviations, at selected time points, are shown only for the 5-µl. volume for the sake of clarity; the remaining runs show similar standard deviations.*

their data suggests that such a phenomenon might exist. The present authors are currently exploring this phenomenon in more detail.

It is easy to provide an underlying mechanism to explain the apparent biphasic nature of the curves in Fig. 3. The terminal portion of each curve is relatively simple to describe in that the fractional decrease in tracer substance is due entirely to the normal turnover of lacrimal fluid; *i.e.*, the tear volume, composed of lacrimal fluid and instilled volume, is back to the normal lacrimal fluid volume. The turnover rate of lacrimal fluid is easily obtained from the slopes of the lines resulting from plots of the logarithm of fractional amounts of tracer remaining *versus* time (Table IV).

The agreement between these results and results obtained from the sampling technique (Table III) is excellent. This suggests that the sampling procedure can be used with confidence to determine lacrimal fluid turnover rate, as long as great care is used to minimize irritation to the eye.

The initial portion of the curves in Fig. 3 shows a rapid decline in the amount of tracer substance due to rapid drainage of the solution present. This decline is also influenced by inflow of additional solution (normal lacrimation). If no inflow is assumed, other than

[a] Neglecting the inflow of lacrimal fluid which is small, approximately 0.50 µl./min., compared to instilled volume, particularly for the 25- and 50-µl. cases. [b] Instilled volume in microliters. [c] Time zero volume includes the instilled volume plus the normal lacrimal volume, which is assumed to be 7.5 µl. [d] All calculated volumes are median values with ±5% error.

the initial instilled volume solution, the mathematical treatment is much simplified as shown in the *Appendix*. This assumption is not unreasonable, since the rate of lacrimal flow is small and the time period of concern is also small, *i.e.*, the first 5 min.

To illustrate the change in volume as a function of time during the initial drainage phase, Table V shows the volume remaining at various time intervals for the different instilled volumes as calculated from equations presented in the *Appendix*. The data in Table V are mean values from a minimum of three runs.

From Eq. A15 presented in the *Appendix*, it is possible to determine the rate constant for drainage. Good linearity is obtained when the logarithm of volume remaining is plotted *versus* time (Fig. 4). This indicates that drainage rate, for various instilled volumes, is directly proportional to the volume present, *i.e.*, apparent first order.

The different slopes of the lines in Fig. 4 suggest that drainage cannot be viewed as simple flow through a conduit or that it is merely proportional to the hydrostatic head developed by the presence of a given volume of solution. A change is occurring somewhere in the drainage mechanism as the volume of instilled solution changes.

To determine the relationship between the drainage rate constant and the instilled volume, the apparent first-order rate constants were determined from the slope of the lines in Fig. 4 (Table VI). The apparent first-order rate constants were then plotted against the instilled volume (Fig. 5). The excellent correlation shown in Fig. 5 suggests that the apparent first-order rate constant contains a volume-dependent term. In addition, the nonzero intercept sug-

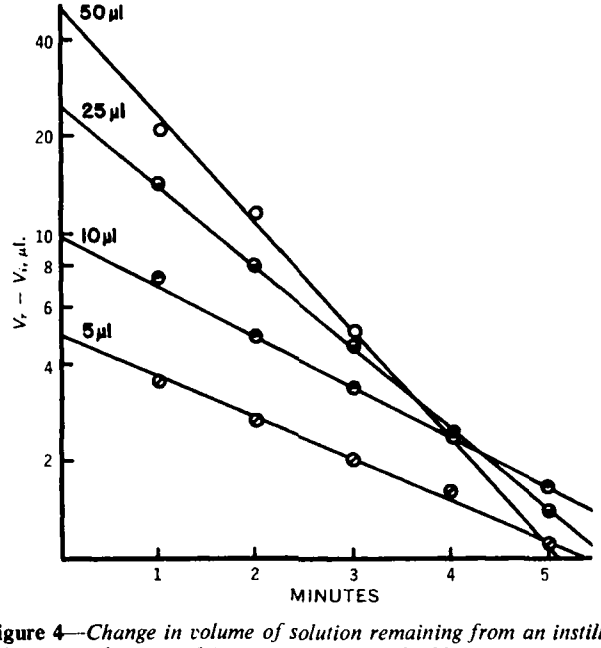

Figure 4—*Change in volume of solution remaining from an instilled solution as a function of time in unanesthetized rabbits.*

Table VI—First-Order Rate Constants for Drainage of Instilled Solution

50	0.815

gests that it also has a volume-independent term. It was expected that if the lacrimal fluid secreted under normal conditions is drained by the same mechanism as that which removes an excess of tears or an instilled solution, the intercept in Fig. 5 would represent the rate constant for normal lacrimal fluid turnover (shown by the arrow in Fig. 5). In fact, the volume-independent term is some 200 times larger than the rate constant for lacrimal fluid turnover. This suggests that removal of normal lacrimal fluid is *via* a mechanism that undergoes some modification when larger volumes are present. Two distinct mechanisms for removal of fluid from the eye, one for small volumes and one for large volumes, are in accord with the description given by Maurice (15) for tear removal in humans.

The drainage rate constant allows one to calculate the amount of tracer remaining from an instilled dose at various times, but this can be more easily seen from Figs. 2 and 4. It is observed that within 1 min. the 50-μl. instilled volume, which is slightly less than the average commercial drop, has diminished to approximately 50% of its initial volume ($V_i + V_l$). And at the end of 5 min., the eye still contains approximately 68% of the radioactivity from the 5-μl. instilled volume; whereas with 50 μl., only approximately 14% of the initial radioactivity remains. This finding corroborates the results with pilocarpine shown in Table I, namely, that instilled volume plays a substantial role in drug loss and, therefore, greatly influences drug activity.

Anesthetized Rabbits—Loss of tracer in anesthetized animals was significantly different from that in unanesthetized animals. Figure 6 illustrates the loss of tracer in both anesthetized and unanesthetized animals, using 5 μl. as the instilled volume.

Some qualitative observations on the total volume removal curve can be made. Whereas in unanesthetized animals the total volume was back to a constant volume in about 6 min., it takes considerably longer with anesthetized animals and the length of time varies

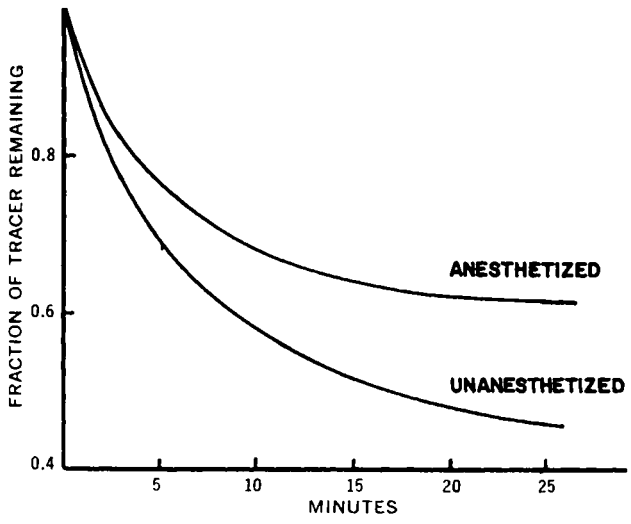

Figure 6—*Fractional amount of drug remaining as a function of time for anesthetized and unanesthetized rabbits using 5-μl. instilled volume. The lines represent the average of four separate determinations.*

with the volume instilled. This is presumably due to a lack of eye movement and a relaxation of eye muscles.

Figure 6 shows that the percentage of isotope in anesthetized animals is less than in the unanesthetized case at all times. As the instilled volume gets larger, the percentage difference in tracer remaining between anesthetized and unanesthetized animals increases. Thus, for 50 μl. instilled volume, the unanesthetized animal shows roughly 14% of tracer remaining at 5 min. whereas the anesthetized animals shows approximately 33% remaining.

As expected, the terminal portions of the percent of tracer amount *versus* time plots for anesthetized animals reach a plateau. The sampling studies of turnover of lacrimal fluid showed that no lacrimation or drainage occurred while the animal was under anesthesia. Therefore, it was expected that the decline in drug amount or concentration would cease when drain-off was complete.

The change in volume as a function of time for various instilled solutions in anesthetized rabbits is shown in Fig. 7. Drainage of an

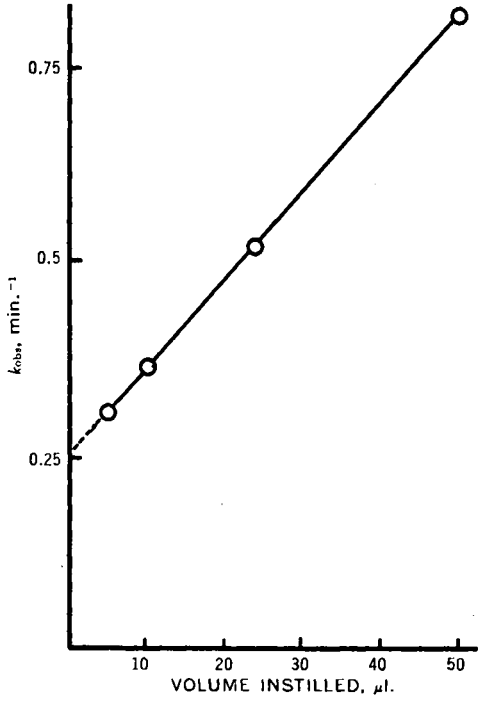

Figure 5—*Relationship between the observed rate constant for the decline in volume and volume instilled. The equation for the line is:* $k_{obs} = 0.25\,(min.^{-1}) + 0.0113\,(1\,\mu l./min.)\,(V_i)$.

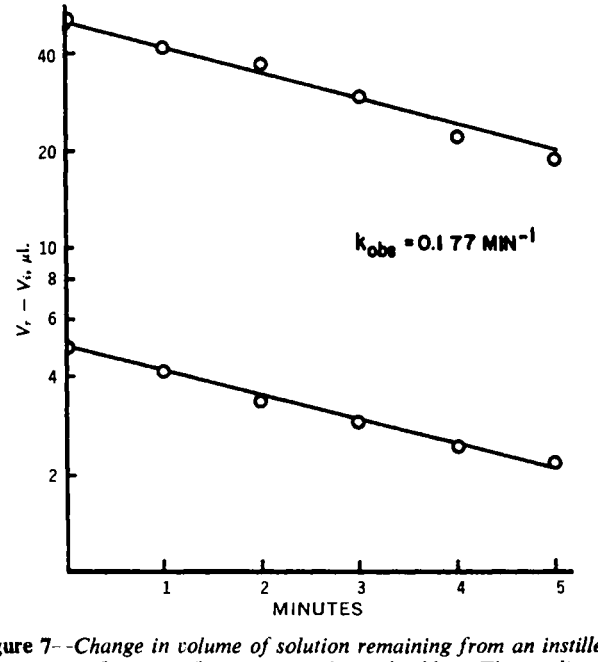

Figure 7—*Change in volume of solution remaining from an instilled solution as a function of time in anesthetized rabbits. The top line is for an instilled volume of 50 μl. and the bottom line is for 5 μl. Both lines represent three different runs, and the data points are mean values ±5%.*

instilled solution in anesthetized rabbits is strikingly different from unanesthetized animals, as can be seen by comparing Figs. 4 and 7 and can perhaps be related to the different mechanisms of drainage.

It has been suggested (16) that gravitational movement of solution is responsible for tear and instilled volume drainage in the rabbit. The data in Fig. 6 do not support this suggestion for instilled volume drainage in both anesthetized and unanesthetized rabbits. The fact that the rate of decline in radioactivity for identical instilled volumes is different in anesthetized and unanesthetized rabbits suggests that simple gravitational movement cannot be the mechanism in both cases. The conclusion with unanesthetized rabbits, based on the volume-dependent term in the apparent rate constant, was that gravitational movement was not the driving force for instilled volume removal. It can be seen from Fig. 7 that the slopes of the lines for the 50- and 5-μl. instilled solutions are identical and, therefore, the rate constants are identical. Since there is no instilled volume dependency in drainage of fluid from the eye of anesthetized animals, it was concluded that this supports the mechanism of drainage by gravitational movement in anesthetized rabbits.

DISCUSSION

It is quite clear from the pupillary diameter study in anesthetized animals that as instilled volume increases the resultant biological activity decreases for equivalent amounts of drug. This effect is expected to be much more dramatic in unanesthetized animals, since lacrimal fluid turnover is slow or absent in anesthetized animals and the drainage rate is considerably slower. Moreover, since human lacrimal fluid turnover rate (1) is twice as large as that found for rabbits and since humans blink considerably more than rabbits, a larger effect is expected in humans, assuming all other factors to be equal.

The various tear and instilled volume variables described in this report require some additional discussion.

Lacrimal Fluid Volume—The rabbit lacrimal fluid volume of 7.5 μl. is remarkably close to that of humans, *i.e.*, 7.0 μl. (1). The rabbit eye globe is somewhat smaller than the human globe, but the rabbit eye possesses a third eyelid, the nictitating membrane, which occupies some of the eye area. Based on the somewhat smaller eye and the nictitating membrane, it was expected that rabbit lacrimal fluid volume would be less than humans, but this is apparently not the case.

It is, of course, possible that the 7.5-μl. lacrimal volume in unanesthetized rabbits is actually an underestimate of the true volume. The majority of lacrimal fluid is held under the upper and lower eyelids, and the methods of mixing technetium tracer with lacrimal fluid may not have reached all of this fluid. In the case of natural mixing, the majority of mixing occurred immediately postinstillation when the rabbit closed its eyelids in response to the instilled solution. The rabbit blinks infrequently and, therefore, the first blink and eye movement were responsible for mixing. In the case of manual mixing, the upper eyelid was not actively involved in the mixing process.

Turnover Rate of Lacrimal Fluid—The turnover rate of lacrimal fluid in rabbits is approximately one-half that of humans (16%/min. in humans and 7.1%/min. in rabbits). Considering the fact that rabbits blink infrequently and that, therefore, the evaporation rate of tears would be expected to be higher in rabbits than humans, it was expected that rabbits would have a larger turnover rate of lacrimal fluid. The fact that turnover rate determinations from both the sampling and nonsampling techniques are in such good agreement lends support to the validity of the turnover rate.

Absence of, or a severe reduction in, turnover rate in anesthetized animals is shown by both the sampling and nonsampling results. Since these techniques measure both concentration and amount changes, reflecting inflow and outflow, respectively, the conclusion seems valid. Support for this was obtained by observing an absence of tears when an anesthetized rabbit was placed on its back with its head hanging down. It is possible that tears are produced under anesthesia and that tear removal by either absorption or evaporation maintains the constant volume. Neither of the techniques used would show this effect.

Drainage Studies—Movement of an instilled solution into the drainage apparatus in rabbits can be described by a first-order rate expression which contains both a volume-dependent and a volume-independent term. The volume-dependent term suggests that simple gravitational movement of the solution is not the prime mechanism for fluid removal. It is not possible to elaborate on the mechanism for fluid drainage on the basis of the results from this study.

Practical Application of Results to Clinical Therapy—From the results presented in this report, considering lacrimal volume, lacrimal fluid turnover rate, and drainage of instilled solutions, it should be possible to determine an optimum volume for drug instillation in the rabbit eye. This optimum volume would allow the maximum amount of drug to be in contact with the eye for the maximum period of time, with a minimum of drug loss.

To illustrate the advantage of an optimum volume, consider the following hypothetical example. If 50 μl. of a 1% drug solution is needed to elicit a given biological response, perhaps 5 μl. of a 2 or 3% solution will generate the same response. In essence, the volume change has been from 50 to 5, a factor of 10, whereas the concentration change has been from 1 to 3%, a factor of 3. The difference between the two factors represents loss of solution through drainage.

For unanesthetized rabbits the appropriate volume would appear to be approximately 5 μl. Smaller volumes will cause the drug to be removed too quickly *via* turnover and are difficult to introduce accurately, whereas larger volumes are washed out too quickly. In anesthetized animals, since there is no turnover of lacrimal fluid, volumes of 1 μl. or less would be optimum. However, the difficulty of manually mixing this small volume with tears must be considered.

An appropriate or optimum volume in humans is difficult to establish without precise knowledge of drainage rates, but some qualitative statements can be made. According to Maurice[13], drainage of an instilled solution in humans is considerably faster than in rabbits. Presumably the rapid rate of blinking causes an acceleration in the rate of drainage. Thus, small volumes of 1–5 μl., provided they can be accurately delivered from an ophthalmic dropper arrangement, would allow for maximum results from an instilled drug.

An important benefit of using a smaller instilled volume, in addition to improved drug activity and lower cost, is a potential decrease in side effects from ophthalmic drugs. Consider, for example, epinephrine solution used to treat glaucoma. For stability reasons, these solutions are weakly buffered to approximately pH 3–4. Instillation of 50–75 μl. of this solution causes considerable pain due at least partially to the acidity, and it can create systemic side effects (17). Using 5–10 μl. as the instilled dose should decrease the pain on instillation and minimize side effects, since less drug will drain into the drainage apparatus and be absorbed. Instillation of 10 μl. of a 2% epinephrine solution to rabbits gave the same pupillary response as 50 μl. of a 1% solution and appeared to generate less pain and lacrimation, an observation that reinforces our suggestion.

Other considerations that result from this study are:

1. Blinking of the eyes, which many people do either as a reflex action or to mix the drug solution with lacrimal fluid, should be minimized if possible. Blinking quickly squeezes solution out of the eye, which accelerates drug loss.
2. Repeated application of drops, either of the same drug or different drugs, should be reconsidered and abandoned. It can easily be shown mathematically, using the drainage rate constants, that when one drop is followed by a second drop the rate of loss of the drug solution is extremely rapid and proportional to the volume present. When two drugs are involved and each is administered separately at a short interval, the first drug will be more rapidly eliminated from the eye as compared to the second, and this loss is a function of the instilled volumes and the time between dosings. This strongly argues for administering two drugs together when combination therapy is needed rather than administering them separately.
3. The suggestion of washing the eye with normal saline or buffer solutions prior to instillation of drug (18, 19) should be viewed in light of the results of this study. The time element between washing of the eye and instillation of drug solution will greatly influence the drainage rate of drug solution since the volume of rinse solution remaining in the eye can be large.

Further Studies—The technique and approaches used in this study can be applied to evaluation of ophthalmic vehicles. Contact time and drainage rate from various vehicles as a function of vis-

[13] D. M. Maurice, Stanford University, Palo Alto, Calif., personal communication.

cosity and other parameters are currently being studied and will be reported in a subsequent publication.

It is desirable to compare these animal studies to humans, and thus drainage studies in humans ought to be more fully explored. In addition, further studies on the drainage mechanism as well as movement of tears in the eye would be helpful.

APPENDIX

Lacrimal Volume Determination *via* Sampling Technique—When a known volume, V_i, and concentration, C_0 (counts/μl.), of technetium are instilled into the eye, the solution will be diluted by the lacrimal fluid, giving rise to a new concentration, C. From the concentration of the solution after dilution it is possible to calculate the volume of lacrimal fluid, V_l, that was present by use of Eq. A1*a* or A1*b*:

$$V_l = V_i \frac{C_0}{C} - V_i \qquad \text{(Eq. A1}a\text{)}$$

$$V_l = V_i \left(\frac{C_0}{C} - 1\right) \qquad \text{(Eq. A1}b\text{)}$$

The assumptions with this method are that complete mixing occurs and that there is no loss of unmixed solution. Both of these assumptions improve as the instilled volume gets smaller.

Normal Lacrimal Fluid Turnover Rate Determination—Disappearance of an applied dose of drug or tracer substance following instillation into the eye can be described by the following equation:

$$\frac{-dC}{dt} = k(C) = \frac{F}{V_l}(C) \qquad \text{(Eq. A2)}$$

where k = first-order rate constant for the decline in tracer concentration, F = turnover rate of lacrimal fluid, and V_l is the lacrimal volume. This equation assumes that loss of applied drug is only through normal lacrimal fluid turnover. Integration of Eq. A2 and rearrangement yield:

$$\log C_0 - \log C = -\frac{F}{2.303V_l}t \qquad \text{(Eq. A3)}$$

A plot, therefore, of the log change in tracer concentration against time should be linear. The slope of the line yields the rate constant, k, for the decline in tracer concentration which, when multiplied by the lacrimal volume, V_l, yields the turnover rate. In the sampling technique, it should be remembered that if the sampling withdrawal rate constant is large with respect to the turnover rate constant, it must be subtracted from the turnover rate constant. For the nonsampling technique, activity (amount) can be substituted for concentration in Eq. A3.

Volume Remaining from Instilled Dose—After a drop of solution is instilled, the volume at various times up to 6 min. can be calculated. The assumption in the following derivation is that one must neglect the volume of inflow of lacrimal fluid, a reasonable assumption, for the first 6 min. postinstillation of solution, since this volume is small compared to the volume of tracer solution instilled.

Upon instillation of a volume of tracer solution into the eye, the concentration will change upon dilution according to a rearranged form of Eq. A1*a* or A1*b*:

$$C_0V_i = C(V_i + V_l) \qquad \text{(Eq. A4}a\text{)}$$

or:

$$\frac{C_0}{C} = \frac{V_i + V_l}{V_i} \qquad \text{(Eq. A4}b\text{)}$$

The amount of tracer substance remaining at any time is given by:

$$A = C \times V_r \qquad \text{(Eq. A5)}$$

where A = amount of drug, and V_r = volume remaining. Substituting for C in Eq. A5 from Eq. A1 yields:

$$A = \frac{V_iC_0}{V_i + V_l} \times V_r \qquad \text{(Eq. A6)}$$

and since V_iC_0 is equal to A_0, one can substitute for V_iC_0 in Eq. A6 and, upon rearrangement, obtain:

$$V_r = \frac{A}{A_0}(V_i + V_l) \qquad \text{(Eq. A7)}$$

and at time zero:

$$V_r = V_i + V_l = V_0 \qquad \text{(Eq. A8)}$$

In this study, original and subsequent radioactivity was used to represent original amount of tracer, A_0, and amount of tracer remaining, A, respectively.

Drainage Rate Constant Determination *via* Nonsampling Technique—After instillation of a known quantity of isotope solution into the eye, there will be a decline in its activity corresponding to a decrease in the volume of solution in the eye. It is possible to obtain the rate constant describing the relationship between drainage rate and volume of solution present, as shown in the following derivation.

The amount of tracer present in the instilled solution can be calculated through Eq. A9:

$$A_0 = V_iC_0 \qquad \text{(Eq. A9)}$$

where C is the concentration of tracer substance in the instilled solution. The differential equation for the change in amount of tracer with respect to time is given by:

$$\frac{dA}{dt} = \frac{C\,dV_i}{dt} + \frac{V_i\,dC}{dt} \qquad \text{(Eq. A10)}$$

Equation A10 is derived on the basis that the change in the amount of drug is due to both a continuous inflow of lacrimal fluid, which changes the concentration of tracer, as well as an outflow or drainage which changes the amount of tracer present.

A complete solution to Eq. A10 produces complex equations and will be presented at a later time. To simplify the treatment and allow solution, it was assumed that the inflow rate of lacrimal fluid is sufficiently small to be neglected for the first 5 min. postinstillation. If there is no inflow of lacrimal fluid, then dC/dt is zero and Eq. A10 reduces to:

$$\frac{dA}{dt} = C\frac{dV_i}{dt} \qquad \text{(Eq. A11)}$$

Substituting for C produces:

$$\frac{dA}{dt} = \frac{A}{V}\frac{dV_i}{dt} \qquad \text{(Eq. A12)}$$

or:

$$\frac{dA}{A} = \frac{dV_i}{V} \qquad \text{(Eq. A13)}$$

which states that the fractional amount of tracer remaining is equal to the fraction of instilled volume remaining.

Thus, it is now possible to examine the relationship between drainage rate and volume present. A first-order relationship between volume present and drainage rate was assumed:

$$dV_i/dt = -k_vV_i \qquad \text{(Eq. A14)}$$

to produce:

$$V_r - V_i = V_ie^{-k_vt} \qquad \text{(Eq. A15)}$$

which relates the change in volume to time.

Effect of Bile Salts on Partitioning Behavior and GI Absorption of a Quaternary Ammonium Compound, Isopropamide Iodide

T. S. GAGINELLA, P. BASS, J. H. PERRIN▲, and J. J. VALLNER

Abstract □ The effect of various bile salts and, in particular, sodium glycocholate upon the partitioning behavior of the quaternary ammonium compound isopropamide iodide was studied *in vitro*. Absorption of this compound from the rat ileum *in situ*, in the presence of various concentrations of bile salt, was also studied. The results indicate that sodium glycocholate progressively increases the partitioning of isopropamide from a physiological aqueous buffer into *n*-octanol below the CMC of the bile salt, but increased partitioning is inhibited above this value. Isopropamide did not partition in the absence of the bile salt counterion. The formation of a lipid-soluble ion-pair between the bile salt anion and the quaternary cation is suggested as the mechanism by which enhanced partitioning occurs, the decrease in maximal transport being related to mixed micelle formation or adsorption of ammonium ions to the outer surface of the bile salt aggregate. Absorption from the rat ileum *in situ* in the presence of sodium glycocholate below and above its CMC appears not to follow a similar pattern. It is suggested that the GI absorption of the isopropamide cation cannot be increased in the presence of bile salt molecules through ion-pair formation or mixed micelle formation. Above the CMC of bile salt, the absorptive process appears actually to be hindered through a decrease in the availability of the drug to the absorptive surface, either by a physicochemical interaction with the micellar phase or by decreased diffusivity of the drug in the presence of bile salt aggregates.

Keyphrases □ Isopropamide iodide—effects of bile salts on partitioning behavior (*n*-octanol–water) and GI absorption, possible ion-pair formation, rat ileum □ Bile salts—effects on partitioning behavior (*n*-octanol–water) and GI absorption of isopropamide iodide, possible ion-pair formation, rat ileum □ Ion-pair formation—isopropamide iodide–bile salts, isopropamide partitioning behavior (*n*-octanol–water) and GI absorption, rat ileum □ Partitioning—isopropamide iodide from buffer to *n*-octanol, effects of bile salts □ Absorption, GI—isopropamide iodide, effects of bile salts, possible ion-pair formation, rat ileum

The mucosal surface of the GI tract acts as a lipoidal barrier to nutrient and drug molecules. To characterize drug absorption through such a barrier, Schanker *et al.* (1) proposed the pH–partition hypothesis, relating the degree of absorption of weak acids and bases to their lipid solubility and degree of ionization. Quaternary ammonium compounds, being fully charged at physiological pH, cannot be characterized adequately using such criteria. However, many drugs of this class are known to be pharmacologically active in very small quantities when given *via* the enteral route.

Quaternary ammonium compounds may possibly be absorbed by combination with an endogenous substance in the lumen or wall of the gut (2). Combination with such a substance could conceivably enhance absorption by acting to facilitate diffusion or to initiate an active transport mechanism.

One might postulate the involvement of the bile salts in such an absorptive process. Bile salts, normally present within the lumen of the gut, form micellar solutions which enable fatty acids and monoglycerides to be absorbed (3). Drugs such as the quaternaries, many

of which are surface active themselves, may incorporate into mixed micelles. Or ion-pairs may form between a bile salt anion and a quaternary cation at concentrations of bile salt below the CMC.

The purposes of this study were to determine if bile salts have the ability to enhance the partitioning of the monoquaternary compound isopropamide iodide across an organic lipoid barrier and to characterize the behavior of this compound in solutions of bile salt, both below and above the CMC. The *in situ* absorption of isopropamide iodide was also studied in the presence of various concentrations of sodium glycocholate.

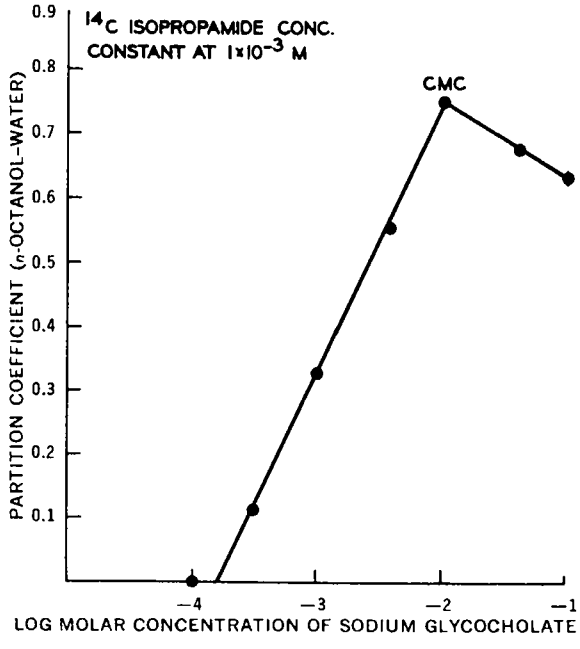

Figure 2—*Apparent partition coefficients of isopropamide iodide equilibrated for 24 hr. between* n-*octanol and pH 7.4 potassium phosphate buffer in the presence of various concentrations of sodium glycocholate. Each data point represents an average of four experimental assay values.*

EXPERIMENTAL

Materials—The following drugs were used as received: isopropamide iodide[1], ^{14}C-isopropamide iodide (specific activity 1.7 mc./mmole[2], sodium cholate[3], sodium glycocholate[4], sodium taurocholate[4], sodium taurodeoxycholate[3], sodium deoxycholate[3], and sodium dehydrocholate[3]. Methyl orange (analytical reagent grade) was used in the colorimetric assay for isopropamide iodide, and Bray's solution (4) was used as the scintillation cocktail in the assay for ^{14}C-isopropamide iodide in the partition studies. A premixed scintillation cocktail[5] was used for counting the ^{14}C-isopropamide iodide recovered from intestinal loops. Grade I (99% pure) *n*-octanol[3] was used as the organic phase in the partition studies. All other solvents and chemicals used in preparing buffers or assay solutions were of analytical reagent grade.

Procedure for *In Vitro* Partition Studies—Partitioning of isopropamide iodide from an aqueous buffer into *n*-octanol in the presence of various concentrations of bile salts was studied colorimetrically and with labeled material. In each case, the concentration of isopropamide iodide was 10^{-3} *M*, with only the bile salt concentration being varied between 10^{-4} and 10^{-1} *M*. At these concentrations of isopropamide iodide, the measured[6] specific conductance showed a linear dependence on concentration, suggesting no formation of large aggregates.

In each case, the isopropamide iodide and bile salts were dissolved together in the same volume of pH 7.4 potassium phosphate buffer[7], which was composed of 3.07 g. KH_2PO_4, 18.36 g. K_2HPO_4, and sufficient deionized water to make 1 l. All solutions were made fresh on the day of use. The pH of all buffer solutions was checked[8].

For the colorimetric assay, a modification of the method of Santoro (5) was employed. Fifteen milliliters of methyl orange buffer[9], pH 10.2, was added to a 1-ml. aliquot of the aqueous phase being assayed (containing at least 0.1 mg. of isopropamide iodide) in a 125-ml. separator. After mixing, this solution was extracted and filtered through a chloroform-saturated pledget of cotton into a 100-ml. volumetric flask, with three 25-ml. portions of chloroform. Ten milliliters of 0.5 *N* HCl in absolute ethanol was then added to develop the color. Volume was brought to a total of 100 ml. with chloroform, and a sample of the final solution was read on a spectrophotometer[10] at 525 nm. against a blank containing chloroform which had been extracted in the same manner. A standard curve was prepared with known concentrations of isopropamide iodide and was linear over the concentration range studied (0.1–0.6 mg./sample). Control experiments indicated that 98–103% of the isopropamide–indicator complex was extractable by the chloroform in the absence, or in the presence, of bile salts after vigorous shaking for 10 min.

Equilibration was with 25 ml. of each phase for 10 min. at 22 ± 1°. After separation by centrifugation, an aliquot (1.0 ml.) of the aqueous phase was assayed and a partition coefficient was calculated by difference. The organic phase, *n*-octanol, was chosen on the basis of its favorable nonpolar lipoid character as suggested by Hansch *et al.* (6).

For determination of partition coefficients using ^{14}C-isopropamide, solutions were prepared as previously described in pH 7.4

[6] Beckman conductivity bridge, model RC-18A, Beckman Instruments, Cedar Grove, N. J.
[7] At this pH the bile salts were all present primarily as ionized species, particularly taurocholic acid (pKa = 1.4) and glycocholic acid (pKa = 4.4).
[8] Beckman Zeromatic pH meter, Beckman Instruments, Cedar Grove, N. J.
[9] Prepared by saturating 1 l. of a solution containing 44 g. dipotassium hydrogen phosphate and 21 g. of sodium carbonate with approximately 2 g. of methyl orange. This solution was purified by extraction with three 50-ml. portions of chloroform and filtration through a Whatman No. 2 filter.
[10] Bausch & Lomb Spectronic-20.

potassium phosphate buffer and equilibrated against *n*-octanol for 24 hr. at 22 ± 1° by continuous shaking[11]. Equal phase volumes of 4 ml. each were placed in a 15-ml. glass centrifuge tube, and the aqueous phase was spiked with a sufficient quantity of ^{14}C-isopropamide. An aliquot (100 μl.) of the aqueous phase was taken before equilibration, counted in 15 ml. of Bray's solution, and considered as 100% of the radioactivity present before partitioning. After equilibration, 100 μl. of the aqueous phase was counted as above and partition coefficients, in the presence of each concentration of sodium glycocholate, were calculated by difference. Each partition coefficient was an average value based on four determinations.

Drug Solutions for Absorption Studies—Isopropamide iodide (10^{-3} *M*) was prepared in isotonic sodium phosphate buffer (pH 6.6) composed of 11.44 g. $NaH_2PO_4 \cdot H_2O$, 8.73 g. Na_2HPO_4, and enough deionized water to make 1 l. Ten-milliliter volumes of these solutions were prepared to contain no sodium glycocholate or 10^{-3}, 10^{-2}, or 10^{-1} *M* sodium glycocholate. Ten milliliters of each solution was spiked with 100 μl. of ^{14}C-isopropamide. A 0.5-ml. volume represented the amount of isotope present in the intestine at the beginning of the absorptive period and gave an average of 8.137×10^3 d.p.m.

Procedure for Absorption Studies—Male albino rats[12], weighing 300–350 g. and fasted overnight, were anesthesized with sodium pentobarbital (35 mg./kg. i.p.). A midline incision was made and the terminal ileum was removed from the abdominal cavity. Two ligations were made, using (00) silk thread, approximately 5 and 15 cm. proximal to the ileocecal junction. Care was taken not to tie off the mesenteric blood supply leading to the segment, and manipulation of the tissue was kept minimal. Following ligation, 0.5 ml. of the test solution was injected using a 27-gauge, 1.27-cm. (0.5-in.) needle. After injection, gentle digital pressure over the injection site for a few seconds prevented solution leakage. The ileal segment was replaced in the abdominal cavity and the incision was covered with a 5.1 × 5.1-cm. (2 × 2-in.) gauze pad saturated with 0.9% saline solution. Six periodic checks were made with an ophthalmoscope[13] to determine the presence and onset of mydriasis. Animals were randomly chosen for any given treatment (isopropamide-bile salt combination).

After a 60-min. absorption period, the animals were sacrificed with an overdose of sodium pentobarbital and the ileal segment was removed. The segment was placed in a scintillation vial and flushed with 4.5 ml. of pH 6.6 sodium phosphate buffer. After appropriate mixing, a 0.5-ml. sample of the wash was withdrawn and added to 15 ml. of premixed scintillation cocktail. The mixture was shaken and then allowed to stand several hours in the dark before counting.

After conversion of counts per minute to disintegrations per minute, the percent of ^{14}C-isopropamide still remaining in the gut was determined and the percent absorbed was calculated by difference.

To determine the extent of binding to the intestinal mucosa, tissue digests were prepared[14] by weighing a piece of the ileal segment (approximately 150 mg.) and digesting it[15] for several hours at 50°. When fully dissolved, 15 ml. of premixed scintillation cocktail was added. A separate efficiency calculation was necessary for each sample since slightly different quenching occurred due to differences in color present.

RESULTS AND DISCUSSION

Partition Experiments—Sodium glycocholate, in increasing concentration, enhanced the interphase transport of isopropamide from an aqueous buffer (pH 7.4) into *n*-octanol. Increased partitioning of isopropamide was observed until a concentration of 10^{-2} *M* bile salt was reached. This value is reported to be the approximate CMC of sodium glycocholate within the pH and counterion concentration used in this study (7). These partitioning data were obtained using both the methyl orange assay (Fig. 1) and ^{14}C-isopropamide (Fig. 2). No partitioning of isopropamide occurred in the absence of the bile salt. With ^{14}C-isopropamide at a 10-fold dilution (10^{-4} *M*), partitioning followed the same pattern (Fig. 3).

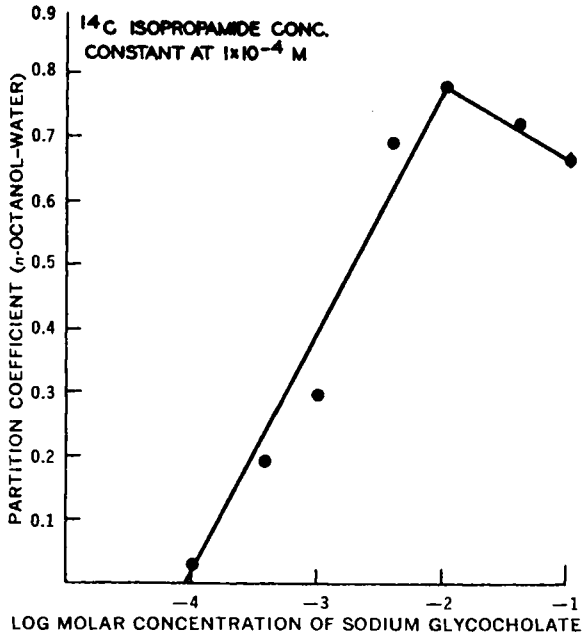

Figure 3—*Apparent partition coefficients of isopropamide iodide equilibrated for 24 hr. between* n-*octanol and pH 7.4 potassium phosphate buffer in the presence of various concentrations of sodium glycocholate.*

Several other bile salts were used in partitioning studies, but not all displayed the same behavior. Sodium taurodeoxycholate behaved very much the same as sodium glycocholate, increasing partitioning to its reported approximate CMC (8) and then exhibiting a plateau (Fig. 4). Other bile salts (Table I) showed increased partitioning of isopropamide at and above their respective CMC values; however, sodium dehydrocholate has been reported not to form micelles (9).

Table I—Apparent Partition Coefficients for Isopropamide Iodide (10^{-3} *M*) in the Presence of Various Concentrations of Different Bile Salts[a]

Bile Salt	Concentration, *M*	Apparent Partition Coefficient (*n*-Octanol–Water)
Sodium cholate	1×10^{-4}	0.31
	1×10^{-3}	0.29
	1×10^{-2}	0.44
	5×10^{-2}	0.81
Sodium deoxycholate	1×10^{-4}	0.35
	1×10^{-3}	0.63
	1×10^{-2}	0.88
	5×10^{-2}	0.96
Sodium dehydrocholate	1×10^{-4}	0.29
	1×10^{-3}	0.38
	1×10^{-2}	0.52
	5×10^{-2}	0.75
Sodium taurocholate	1×10^{-4}	0.40
	1×10^{-3}	0.44
	1×10^{-2}	0.85
	5×10^{-2}	0.85

[a] Isopropamide concentration in the aqueous phase, determined after equilibration by the methyl orange assay method from duplicate extractions.

Studies by Levine and Clark (10) and by Schanker and Solomon (11) indicated that various other monoquaternary compounds can be extracted into an organic phase (ethylene dichloride) in the presence of sodium glycocholate below its CMC. Formation of ion pairs between quaternary ammonium ions and carboxylic acids (12), as well as sulfonates (13), is known to occur. Methyl orange (5) and bromthymol blue (14) also form ion-pairs with quaternary ammonium cations. Tetraheptylammonium chloride was used by Hofmann (15) to extract steriod sulfates quantitatively as well as glycine and taurine conjugates of bile acids from aqueous solvents.

Various possibilities exist for the interaction of bile salt anions *in vitro* among themselves and with quaternary cations in the aqueous phase.

Mixed micelles may form between short-chain alkyl amines and bile salts involving van der Waals' forces between the hydrocarbon chains and hydrophobic surface of the steroid nucleus (16); also, adsorption of the oppositely charged amine may occur onto the micellar surface at concentrations of bile salts above the CMC.

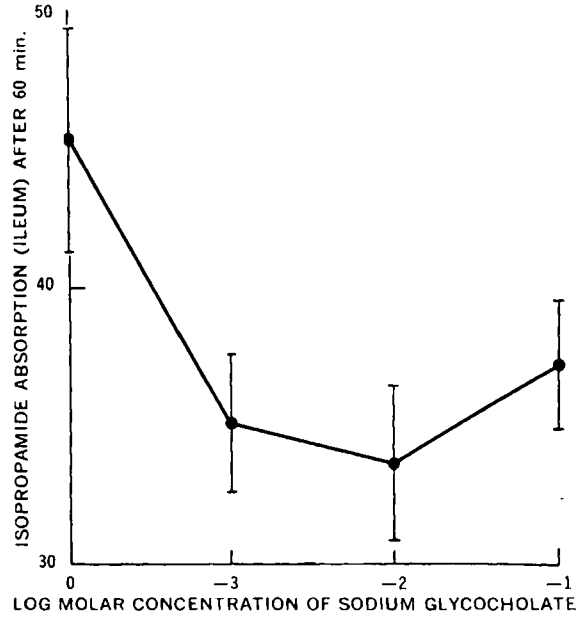

Figure 5—In vivo *absorption of isopropamide iodide from ligated segments of rat ileum. Each data point is the mean of 12 animals, and bars represent the standard error of the mean for each point. Points at zero* versus 10^{-3} *and* 10^{-2} M *were the only means significantly different* ($p < 0.05$) *from one another.*

Below the CMC, the most likely situation is the formation of ion-pairs and the partitioning of these into the organic phase. In the case of the ion-pair partitioning, the following interaction in the aqueous phase might be assumed:

$$B_a^- + Q_a^+ \overset{K_{BQ}}{\rightleftharpoons} (BQ)_a \overset{K_p}{\rightleftharpoons} (BQ)_o$$

Scheme I

Here K_{BQ} is the equilibrium constant for ion-pair formation between the bile salt anion (B_a^-) and quaternary cation (Q_a^+) in the aqueous phase, and K_p is the partition coefficient for partitioning of the neutral species $(BQ)_a$ into the organic phase.

According to the partitioning data, this would seem to be a possible mechanism for interphase transport of isopropamide below the CMC. Micellar transport probably would be inhibited by a dense negative charge surrounding the micelle.

Absorption Studies—The present studies indicate that the absorption of isopropamide iodide is not influenced by the presence of sodium glycocholate. Isopropamide iodide itself is capable of being absorbed from the rat ileum to the extent of 44% over a 60-min. absorptive period (Fig. 5). A decrease in absorption of this cation is seen in the presence of all concentrations of sodium glycocholate. Statistically, the mean value for isopropamide absorption in the absence of any bile salt was significantly different ($p < 0.05$) only from 10^{-3} and 10^{-2} *M* sodium glycocholate, as determined using analysis of variance and a Duncan's multiple-range test. Between 10^{-2} and 10^{-1} *M* bile salt concentration, there was an apparent increase in the amount of isopropamide absorbed, although this rise was still well below the value found in the absence of bile salt. Jejunal absorption followed the same pattern, with the corrected percentages for absorption being essentially the same.

Others (17) showed that above their respective CMC's, sodium glycocholate and sodium taurocholate at pH 6.5 inhibit the absorption of the amide, 2-allyloxy-4-chloro-*N*-(2-diethylaminoethyl)-benzamide hydrochloride, from the rat small intestine.

Digests of the intestinal tissue indicated that approximately 21.2 and 13.0% of the radioactivity remained in the ileal and jejunal gut wall, respectively. The value was subtracted from the graphical values (Fig. 5) and agrees well with a figure of 20% for a dose of anisotropine methylbromide reported recently (18). Corrections for volume changes due to secretion into the lumen were also made, since it appeared in early studies that 10^{-1} *M* sodium glycocholate was causing an intraluminal increase in drug solution volume. The nonabsorbable marker ^{14}C-inulin was used in control experiments involving all bile salt concentrations, and the only detectable effect was seen at the 10^{-1} *M* level. This amounted to a 15% dilution of the amount of drug remaining in the intestinal loop after 1 hr. The corrected value at this concentration of sodium glycocholate is the one expressed in Fig. 5.

During the absorptive period, observations were made to determine the onset and degree of mydriasis. This was not a good indicator of absorption, however, since only one or two animals in each group exhibited this response, and there was no relationship between time of onset of the response and bile salt concentration. Irwin *et al.* (19) suggested that ion-pair formation with trichloroacetate as the anion can enhance the partitioning of isopropamide iodide into chloroform and *n*-octanol, as well as increase the degree of mydriasis in mice given the drug orally with a large molar excess of trichloroacetate. Their conclusion that this anion increases absorption by ion-pair formation in the lumen has been criticized (20), however, since the concentrations of trichloroacetate administered could have decreased protein or tissue binding of the isopropamide, thus increasing the bioavailability of the small amount of drug that might have actually been absorbed *via* a different mechanism.

If an ion-pair or other type of complex is present in the gut at concentrations of bile salt below its CMC, several possibilities for the diffusion of this complex arise. Depending upon various equilibrium constants, the ion-pair may cross the mucosal cell barrier as the neutral species and remain unchanged within the cell, thus subsequently passing to the blood or lymph. It may, however, be disrupted by protein constituents of the membrane surface, as has been described for some dye complexes (21), and thus enter as the free cation. Furthermore, any amount of quaternary cation that is not part of an aggregate or ion-pair may complex within the intes-

tinal mucosa with anionic membrane components and be transported to the circulation as a different complex. In this regard, some related compounds (dialkyl propionamides) were recently shown to have the apparent ability to form a complex within the intestinal membrane itself and thus enhance the absorption of prednisone and prednisolone (22).

Some quaternary ammonium compounds have been found to be rapidly absorbed initially and then more slowly (23), indicating possible saturation of a carrier and a facilitated diffusion mechanism (24).

Tetracycline appears to be absorbed from the rat stomach as the charged species by such a mechanism (25), and Levine (26) postulated an endogenous carrier for quaternary compounds. Other effects, such as cooperative membrane reactions (27) or solvent drag (28), may also play a role in the absorption of quaternary drugs. Isopropamide, which possesses both some lipophilicity and hydrophilicity as do many other monoquaternary compounds, may possibly be taken up into globular micelles (29) of the absorptive cell membrane. This seems relevant in view of the ability of isopropamide to interact with bile salt micelles as reported here.

Isopropamide is absorbed to a greater extent than expected for a charged molecule, but the mechanism does not appear to involve bile salts. A facilitated transport process may be involved, but it is not proven by the data reported here.

Steric Aspects of Adrenergic Drugs XXII: Retention of (+)- and (−)-^{14}C-Norepinephrine by Mouse Heart

B. D. GARG*, R. D. KRELL†, T. SOKOLOSKI, and P. N. PATIL▲

Abstract □ After intravenous infusion (total dose 40 mcg./kg.) of the isomers of norepinephrine to normal or reserpine-pretreated mice, the initial accumulation by the heart was the same for both isomers. The injected isomers disappeared from the normal heart in a single exponential phase. The unnatural isomer disappeared faster, $t_{1/2}$ 2.5 hr., than the natural (−)-isomer, $t_{1/2}$ 7.6 hr. In mice pretreated with iproniazid, iproniazid and guanethidine, or iproniazid and α-methyl-*p*-tyrosine, the rate constants and the $t_{1/2}$ values for the isomers were unaltered. The results indicate that retention, probably by storage vesicles, favors the natural isomer; hence, it is stereoselective. Reserpine, which inhibited the accumulation by storage vesicles, drastically reduced the accumulation of isomers, and the accumulated isomers disappeared at a similar rate constant with a $t_{1/2}$ of approximately 1 hr. Racemic norepinephrine disappeared in two phases, each having a separate rate constant which approximate the values obtained with (+)- and (−)-norepinephrine. In the iproniazid-pretreated mice, injection of equal amounts of (−)- or (+)-^{14}C-norepinephrine resulted in higher *O*-methylated products from the (+)-form.

Keyphrases □ Norepinephrine, ^{14}C-labeled—retention of (+)- and (−)-isomers by mouse heart, effects of iproniazid, guanethidine, or α-methyl-*p*-tyrosine pretreatment, steric aspects of adrenergic drugs □ Adrenergic drugs—steric aspects, retention of (+)- and (−)-isomers of ^{14}C-norepinephrine by mouse heart □ Catecholamines—retention of (+)- and (−)-isomers of ^{14}C-norepinephrine by mouse heart, steric aspects of adrenergic drugs □ Neurochemical transmitters—retention of (+)- and (−)-isomers of ^{14}C-norepinephrine by mouse heart, steric aspects of adrenergic drugs □ False neurotransmitter—retention of (+)- and (−)-isomers of ^{14}C-norepinephrine by mouse heart

Since 1963 there has been considerable interest in the fate of optical isomers of catecholamines (1–5). Lack of optically pure radiolabeled isomers, however, impeded investigations. Many, if not all, physiological processes can discriminate between the stereoisomers of catecholamines, as discussed in previous reviews (6, 7). Since the transport of isomers across the neuronal membrane shows marginal selectivity in favor of the natural isomer, it has been possible to study uptake and release of both isomers from tissues (8–10). Recently, Allen *et al.* (8) suggested that (+)-norepinephrine might be a valuable false neurochemical transmitter. In view of the large differences in adrenergic receptor-activating properties of the isomers (6, 7), the proposal appears quite attractive. However, for an unnatural substance to be an effective false neurotransmitter, the drug must be retained by adrenergic storage vesicles (11, 12). This paper reports studies on the time course of retention of the isomers by the mouse heart. Other pharmacological tools such as α-methyl-*p*-tyrosine, reserpine, 6-hydroxydopamine, and guanethidine pretreatment were used to gain information about the retention of the isomers.

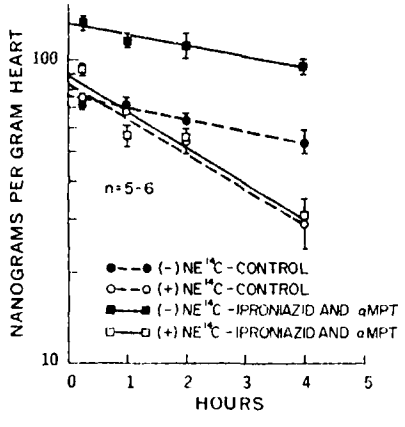

Figure 1—*Uptake and retention of (−)- and (+)-^{14}C-norepinephrines in the normal and drug-treated mouse hearts after intravenous infusion of (−)- and (+)-^{14}C-norepinephrines, 40 mcg./kg. The schedule of treatment with iproniazid and α-methyl-*p*-tyrosine was described in the* Methods *section. Key: n = number of observations, vertical bars = standard error of the mean, NE = norepinephrine, and αMPT = α-methyl-p-tyrosine.*

METHODS

Infusion of (−)- and (+)-^{14}C-Norepinephrine Isomers—Male albino ICR mice (16–26 g.) were used. Each animal was infused with either (−)- or (+)-^{14}C-norepinephrine *via* one of the lateral tail veins. The total dose infused was 0.8 mcg./20 g., which corresponded to 0.1 μc./0.1 ml./20 g. for each isomer. Infusion[1] was constant at a rate of 0.2 ml./min. and required 25–40 sec. for completion.

Mice were decapitated at varying periods postinfusion (5 min. to 24 hr.), and hearts were quickly removed, cleaned of extraneous tissue, minced with scissors, and rinsed five times with cold 0.9% sodium chloride solution. The minced material was blotted with filter paper, weighed, and transferred to 20-ml. beakers containing 5 ml. of 5% cold trichloroacetic acid containing 0.2 ml. of 10% ethylenediaminetetraacetic acid. Hearts were minced with scissors and homogenized[2] for 20 sec. at moderate speed. The homogenates were centrifuged for 10 min. in a clinical centrifuge at room temperature. The resulting supernate was filtered under suction, and the pellet was resuspended in 0.5 ml. of 0.4 *N* $HClO_4$ and recentrifuged for another 10 min. The second supernate was mixed with the first, and the final volume was made up to 8 ml. The filtrates were transferred to 20-ml. beakers containing 10 mg. ethylenediaminetetraacetic acid. The pH of these extracts was adjusted to between 6.2 and 6.5 with 2 *N* NaOH. The unchanged ^{14}C-norepinephrine was separated from the contaminating metabolites by passing the slightly acidic extracts through strong ion-exchange columns prepared[3] according to the method of Häggendal (13, 14) with a small modification. The modification made was in the use of columns 9.0 mm. in diameter and a resin height of 3.5 cm. The fractions of the eluate containing ^{14}C-norepinephrine were placed in 20-ml. beakers and evaporated to dryness. The recovery of ^{14}C-

Table I—Rate Constants and Half-Lives ($t_{1/2}$) of Disappearance of ^{14}C-Norepinephrine Isomers from the Mouse Heart after Different Treatments

Treatment	Isomer	Rate Constant, hr.$^{-1}$	$t_{1/2}$, hr.
Control	(−)	0.09	7.62
	(+)	0.26	2.57
Iproniazid[a]	(−)	0.07	9.32
Iproniazid[a]	(+)	0.17	3.92
Iproniazid[a]	(±)	0.27	2.19
		0.06	10.10
Iproniazid[a] + guanethidine[b]	(−)	0.09	7.52
	(+)	0.15	4.57
Iproniazid[a] + reserpine[c]	(−)	0.64	1.07
	(+)	0.87	0.78
Iproniazid[a] + α-methyl-*p*-tyrosine[d]	(−)	0.08	8.00
	(+)	0.2	2.56

[a] Injected 100 mg./kg. i.p., 16–20 hr. before ^{14}C-norepinephrine infusion. [b] Injected 20 mg./kg. i.p., 8–10 hr. before iproniazid. [c] Injected 5 mg./kg. i.p., 8–10 hr. before iproniazid. [d] Injected in two divided doses, 200 mg./kg. each, at 3-hr. intervals and 10–12 hr. after iproniazid.

norepinephrine from the columns was 72.14 ± 0.76%. Values reported were corrected for 72% recovery. Residues for the air-dried hydrochloride eluates were taken up in 1 ml. of water and counted in 14 ml. of a liquid scintillation solution[4].

In experiments where animals were treated with iproniazid to inhibit MAO, no attempt was made to separate unchanged ^{14}C-norepinephrine from the *O*-methylated metabolites. In a few experiments, where the mice were sacrificed 10 min. after ^{14}C-norepinephrine injection, the *O*-methylated derivatives did not exceed 5% of the unchanged amine. Since metabolites do not accumulate in the tissues and are easily washed out (15), it was expected that when animals were sacrificed at longer time periods after ^{14}C-norepinephrine infusion, the amount of metabolites present would be lower still. Moreover, the minced heart was washed thoroughly to reduce contamination by *O*-methylated derivatives. The trichloroacetic acid extracts were air dried, taken up in 2 ml. of water, mixed with 13 ml. of a liquid scintillation solution, and counted[5].

Schedule of Drug Treatments in Mice—MAO inhibition was accomplished by administering iproniazid, 100 mg./kg. i.p., 16–20 hr. prior to infusion of ^{14}C-norepinephrine isomers. Effects of all other pharmacological treatments were studied in the enzyme-inhibited animals.

Guanethidine, 20 mg./kg. i.p., was given 8–10 hr. before iproniazid. ^{14}C-Norepinephrine isomers were infused 24–30 hr. after guanethidine.

Reserpine, 5 mg./kg. i.p., was given 8–10 hr. before iproniazid. ^{14}C-Norepinephrine isomers were infused 24–30 hr. after reserpine,

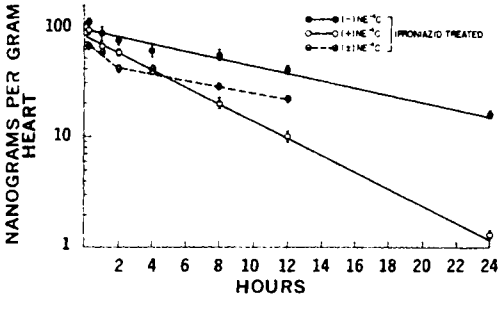

Figure 2—*Uptake and retention of (−)-, (+)-, or racemic ^{14}C-norepinephrines in the hearts of mice that received iproniazid, 100 mg./kg., 16–24 hr. before they received 40 mcg./kg. i.v. of ^{14}C-norepinephrine infusion. Each point is a mean of five to nine observations. Key: vertical bars = standard error of the mean, and NE = norepinephrine.*

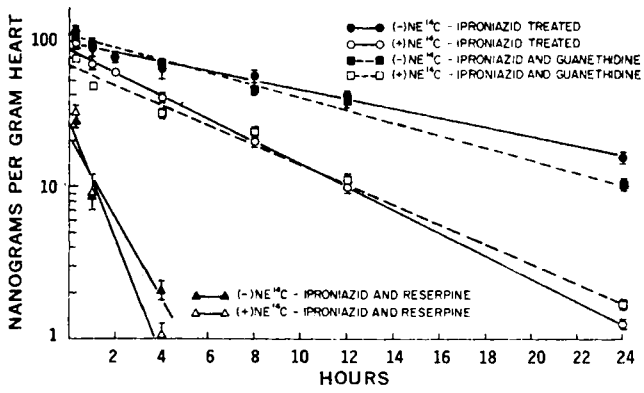

Figure 3—*Uptake and retention of (−)- and (+)-^{14}C-norepinephrines in hearts of mice treated with iproniazid and guanethidine or iproniazid and reserpine after intravenous infusion of ^{14}C-norepinephrine isomers, 40 mcg./kg. The schedule of treatments given is described in the* Methods *section. Each point is a mean of five to nine observations. Key: vertical bars = standard error of the mean, and NE = norepinephrine.*

and animals were sacrificed in the time interval from 15 min. to 4 hr. thereafter.

Tyrosine hydroxylase was inhibited by the administration of two doses of α-methyl-*p*-tyrosine, 200 mg./kg. i.p., 3 hr. apart. Iproniazid was injected 16–20 hr. before the second dose of α-methyl-*p*-tyrosine, which was given 1 hr. before ^{14}C-norepinephrine infusion.

6-Hydroxydopamine was administered in two doses of 75 mg./kg. i.p. at an interval of 1 hr., about 24 hr. before ^{14}C-norepinephrine infusion. Iproniazid was injected as already described. Animals were sacrificed 24–28 hr. after 6-hydroxydopamine treatment.

In other experiments, (−)- and (+)-^{14}C-norepinephrines were mixed in equal amounts (adjusted to equal specific activity), and the resulting (±)-^{14}C-norepinephrine was infused in the iproniazid-treated mice. Animals were sacrificed in the time interval from 15 min. to 12 hr. after (+)-^{14}C-norepinephrine infusion.

Determination of *O*-Methylated Products—Iproniazid-treated mice were given either (−)- or (+)-^{14}C-norepinephrine, 40 mcg./kg. i.v. Five hearts were pooled in one beaker and extracted in trichloroacetic acid as described earlier. *O*-Methylated derivatives were separated from the unchanged or oxidized ^{14}C-norepinephrine by ion-exchange chromatography according to the method of Häggendal (14). The eluates were air dried and counted in the manner described for ^{14}C-norepinephrine estimation.

Drugs and Chemicals—Drugs used in this study were: (−)-norepinephrine (+)-bitartrate monohydrate and (+)-norepinephrine (+)-bitartrate[6]; (−)-^{14}C-norepinephrine-7 (+)-bitartrate, specific activity 57.0 mc./mmole, and (+)-^{14}C-norepinephrine-7 (+)-bitartrate, specific activity 21.2 mc./mmole[7]; iproniazid phosphate[8]; guanethidine hemisulfate and reserpine powder[9]; 6-hydroxydopamine hydrobromide[10], and α-methyl-*p*-tyrosine methyl ester hydrochloride[10].

Reserpine was prepared as a 0.5% solution in 10% ascorbic acid. The solution of 6-hydroxydopamine was prepared in 0.1% sodium metabisulfite at 0° and was deaerated for at least 10 min. using nitrogen. Stock aqueous solutions of iproniazid and guanethidine were prepared and used as needed. Solutions of α-methyl-*p*-tyrosine were prepared fresh daily. Working solutions of labeled (−)- and (+)-norepinephrines were prepared in 1% sodium metabisulfite, protected from light and air, and stored in the refrigerator at 4°. All drugs and chemicals were dissolved in demineralized double-distilled water.

RESULTS

Accumulation and Retention of (−)- and (+)-^{14}C-Norepinephrine Isomers in Mouse Hearts—Mice were given either (−)- or (+)-

Table II—Accumulation and Retention of ^{14}C-Norepinephrine Isomers in Hearts of 6-Hydroxydopamine-Treated[a] Mice[b]

Time after ^{14}C-Norepinephrine Infusion (Total Dose 40 mcg./kg.)	(−)-^{14}C-Norepinephrine ng./g. Heart	(−)-^{14}C-Norepinephrine % of Control	(+)-^{14}C-Norepinephrine ng./g. Heart	(+)-^{14}C-Norepinephrine % of Control[c]
15 min.	4.90 ± 0.23	4.63	6.01 ± 0.76	6.71
4 hr.	0.81 ± 0.21	1.36	0.01	0.02

[a] Treatment with 6-hydroxydopamine was accomplished as described under *Methods*. [b] The results are mean ± standard error of margin of six independent observations. [c] Control refers to the values obtained at corresponding times in the iproniazid-treated animals.

^{14}C-norepinephrine, and the amount of ^{14}C-norepinephrine accumulated and retained in hearts at 15 min. and 1, 2, and 4 hr. was determined. The results obtained were plotted semilogarithmically against time in Fig. 1. It may be seen that at 15 min. both isomers were taken up almost to the same extent but that the (+)-^{14}C-norepinephrine loss was faster than the (−)-isomer loss. First-order rate constants and half-lives for the disappearance of the isomers were calculated (Table I). Both isomers showed a single exponential loss.

Effect of Iproniazid Treatment—(−)-Norepinephrine is a better substrate for MAO than is (+)-norepinephrine (16). Hence, it was necessary to compare accumulation after enzyme inhibition. Mice were pretreated with iproniazid before infusion of ^{14}C-norepinephrine as described in the *Methods* section. Five minutes after infusion, it was found that both isomers accumulated to the same extent (data are not illustrated). The accumulation of both isomers at 15 min. was higher than at 5 min. postinfusion. After 15 min., the concentration of both isomers began to decline. Thus, the maximum accumulation occurred between 5 and 15 min. The concentration of (+)-^{14}C-norepinephrine declined faster than that of (−)-^{14}C-norepinephrine (Fig. 2). Previously, biphasic disappearance of radioactivity was observed after intravenous infusion of (±)-^{3}H-norepinephrine. It is possible that the disappearance of (±)-^{3}H-norepinephrine in two phases may be partly due to the decline of (+)- and (−)-^{3}H-norepinephrine isomers with separate rate constants.

To investigate the disappearance of ^{14}C-norepinephrine, iproniazid-treated animals were infused with racemic ^{14}C-norepinephrine prepared by mixing equal amounts of (−)- and (+)-^{14}C-norepinephrines in the dose and infusion rate identical to those used for the pure isomers. The animals were sacrificed at different times from 15 min. to 12 hr. (Fig. 2 and Table I). Clearly, the racemic ^{14}C-norepinephrine disappeared biexponentially. After feathering the data, the first rate constant was closer to that of (+)-^{14}C-norepinephrine and the second to that of (−)-^{14}C-norepinephrine. It appears that exogenously administered norepinephrine is stored in a single kinetic pool from which it disappears as a first-order process; or if it is stored in multiple pools, they are in rapid equilibrium with each other. For subsequent experiments involving the effects of certain drugs on the accumulation and retention of ^{14}C-norepinephrine isomers, iproniazid-pretreated animals were used.

Disappearance of ^{14}C-Norepinephrine Isomers after Guanethidine or Reserpine Treatment—Both reserpine and guanethidine are known to deplete endogenous norepinephrine from tissues. Reserpine is known to produce this action by blocking uptake by vesicular storage mechanisms (17), and guanethidine is utilized to inhibit the same mechanism (18, 19). Hence, the effects of both these drugs should be similar as far as the accumulation and retention of ^{14}C-norepinephrine are concerned. The disappearance curves obtained are illustrated in Fig. 3, and the first kinetic analysis is given in Table I. The results show that guanethidine had very little influence on the disappearance of the isomers. Reserpine, on the other hand, appeared to cause marked inhibition of uptake and storage of both isomers. Both (−)- and (+)-^{14}C-norepinephrines disappeared at a much faster rate. Reserpine also abolished the stereoselectivity of efflux as observed in the control experiments. Within 4 hr. postinfusion, there was almost the complete disappearance of isomers in reserpine-treated tissues, whereas detectable amounts of ^{14}C-norepinephrine could be found even after 24 hr. in guanethidine-treated tissues.

Table III—*O*-Methylated Metabolites Present in Mouse Hearts[a] 10 min. after Intravenous Injection of (−)- and (+)-^{14}C-Norepinephrines

Isomer	^{14}C-*O*-Methylated Metabolites (c.p.m./g. heart)	Significance
(−)-Norepinephrine	1500[b] ± 221	$p < 0.01$
(+)-Norepinephrine	2672 ± 165[c]	

[a] Total dose for each isomer was 40 mcg./kg. Five hearts were pooled together. [b] Mean of nine observations ± standard error to margin. [c] Mean of eight observations ± standard error of margin.

Effect of α-Methyl-*p*-tyrosine—α-Methyl-*p*-tyrosine was given to inhibit tyrosine hydroxylase, the rate-limiting enzyme in the biosynthesis of norepinephrine. By inhibiting this enzyme, endogenous norepinephrine can be significantly depleted. Accumulation and disappearance of exogenously administered ^{14}C-norepinephrine could thus be studied more clearly without being diluted or exchanged with endogenous norepinephrine. In animals pretreated with iproniazid and α-methyl-*p*-tyrosine, the accumulation and disappearance of ^{14}C-norepinephrine were observed in the interval from 15 min. to 4 hr. (Fig. 1 and Table I). There was a higher accumulation of (−)-^{14}C-norepinephrine as compared to (+)-^{14}C-norepinephrine. The disappearance rates were not significantly different from those observed in control animals.

Effect of 6-Hydroxydopamine Treatment—6-Hydroxydopamine has been shown to cause severe damage to, and specific degeneration of, the adrenergic nerves (20). In mice treated with this drug, the amount of ^{14}C-norepinephrine was determined at 15 min. and 4 hr. after infusion of each isomer of ^{14}C-norepinephrine (Table II). At 15 min., the concentration of ^{14}C-norepinephrine for either isomer was 4–6% of the control; at 4 hr., it was barely above the background.

Slight accumulation of radioactivity at 15 min. postinfusion probably represents the accumulation of ^{14}C-norepinephrine by extraneuronal uptake of *O*-methylated metabolites and, to some extent, accumulation of norepinephrine by the surviving adrenergic nerves. Thus, the accumulation of ^{14}C-norepinephrine by "uptake$_2$" (3) and *O*-methylated metabolites in the present experiments was rather small and was observed only at shorter time intervals.

Metabolism of (−)- and (+)-^{14}C-Norepinephrines by Catechol-*O*-methyltransferase—In the iproniazid-treated animals, normetanephrine formed in hearts of mice after the administration of equal amounts of (−)- or (+)-^{14}C-norepinephrine was isolated by ion-exchange chromatography. As shown in Table III, significantly more *O*-methylated metabolites formed from (+)-^{14}C-norepinephrine than from (−)-^{14}C-norepinephrine. (+)-Norepinephrine may be a better substrate than (−)-norepinephrine for the enzyme or, alternatively, more (+)-isomer may be available to the enzyme due to low vasoconstrictor activity.

DISCUSSION

The infusion of isomers in mice indicates that the accumulation of ^{14}C-norepinephrine by the heart was higher after 15 min. than after 5 min. No selectivity was observed in the initial accumulation of the isomers. Even after blockade of vesicular accumulation by reserpine treatment, the initial uptake was the same for both isomers. If the initial accumulation is considered mainly neuronal (21–23), the results suggest that the transport of the isomers across the neuronal membrane of the mouse heart lacks stereoselectivity. The interpretation is consistent with *in vitro* findings that mouse heart shows little or no stereoselectivity (24).

Neuronal uptake (3) and efflux (25) are considered active processes. The similar rates of disappearance of the isomers from the reserpine-pretreated animals indicate that neuronal efflux from the mouse heart may also be nonstereoselective. However, it could be that reserpine treatment itself destroys the sodium-dependent and optically specific amine carrier mechanism at the adrenergic neuron (26).

In vivo, the selectivity in the vesicular retention is clearly demonstrated. The manipulation of the accumulation by pharmacological tools suggests that the retention of the isomers by the vesicles is truly stereoselective in favor of the (−)-isomer:

1. Reserpine, which is known to inhibit the uptake by the vesicles, abolishes the stereoselectivity.
2. Pretreatment of mice with α-methyl-*p*-tyrosine, which depletes the vesicular stores by inhibiting the enzyme tyrosine hydroxylase, favors the accumulation of the (−)-isomer only.
3. Chemical sympathectomy with 6-hydroxydopamine drastically reduces the accumulation.
4. Almost all of the (+)-isomer is lost from the heart after 24 hr., while a considerable amount of the (−)-form can be found in the tissue.

The results favor the view that the stereochemically "correct" orientation of the β-hydroxyl group is important for the ATP–magnesium-dependent process in the adrenergic nerve granules (2, 27).

An unexpected finding of the present study is that uptake and retention of isomers were not influenced by a relatively large dose of guanethidine (Fig. 3). These observations are similar to those reported by Krell and Patil (9), who could not show the inhibition of uptake of catecholamines in vas deferens obtained from guanethidine-pretreated animals. In line with these observations, Maitre and Staehelin (28) were unable to find inhibition of uptake of catecholamine by the isolated splenic nerve granules in the presence of guanethidine. It may be that guanethidine depletes endogenous norepinephrine without affecting the vesicular uptake. The uptake of isomers would then appear normal. In the present report, the levels of endogenous norepinephrine after guanethidine were not estimated. It may be that the drug was administered at a time when guanethidine was without a depleting effect. However, as low as 8 mg./kg. of guanethidine is known to deplete 80–90% cardiac norepinephrine for 10–15 hr. after intravenous injection in rats (29). Further work is necessary to investigate the mechanism of action of guanethidine and its influence on the accumulation of exogenous norepinephrine.

In many studies, a multiphasic disappearance of labeled norepinephrine from the heart was observed. Most earlier workers used ^{3}H-labeled racemic norepinephrine as a valid tracer of the natural neurotransmitter. Since (±)-^{3}H-norepinephrine is an equal mixture of two compounds, it could be that these isomers are released from the storage sites at different rates and thus manifest the multiphasic disappearance. In this study, a biphasic decline was observed when (±)-^{14}C-norepinephrine was used. After administering pure (−)- or (+)-isomers, in control or drug-treated mice, the radioactivity disappeared in a single exponential phase (Figs. 1–3). (+)-Norepinephrine disappeared much faster than the (−)-isomer. Iversen *et al.* (23) also employed a pure ^{14}C-isomer of norepinephrine, yet they observed that norepinephrine disappeared in two phases for each isomer. Since the experimental conditions in the present study are different from those reported by Iversen *et al.*, the data cannot be critically compared.

Data on the metabolism of (−)- and (+)-norepinephrines by catechol-*O*-methyltransferase are particularly interesting. From Table III, it may be seen that there are more *O*-methylated metabolites formed from (+)-norepinephrine than from equal doses of (−)-norepinephrine. In earlier studies, this enzyme was reported to possess no stereoselectivity for either isomer of norepinephrine [review by Patil *et al.* (7)]. Iversen *et al.* (23) also reported that catechol-*O*-methyltransferase lacked any stereospecificity. Their data, similar to ours, indicated that after equal doses of (−)- or (+)-^{14}C-norepinephrine there were twice as many *O*-methylated metabolites from (+)-norepinephrine as compared to those from (−)-^{14}C-norepinephrine. Furthermore, detailed kinetic analysis of the influence of the enzyme on optical isomers is necessary for the correct interpretation of the results. As far as the false neurotransmitter status of the (+)-norepinephrine is concerned, rapid *O*-methylation and rapid loss from tissue of the substance may be undesirable properties.

Improved, Rapid Spectrophotofluorometric Method for Assay of Epinephrine: A Comparative Study

V. K. PRASAD, R. A. RICCI, B. C. NUNNING, and A. P. GRANATEK▲

Abstract □ A new and improved two-step spectrophotofluorometric method for the determination of epinephrine in decomposed formulations is described. The method depends on the initial oxidation of epinephrine with iodine to "adrenochrome," which is subsequently cyclized with alkali to "adrenolutin," which is responsible for the fluorescence. The fluorescence is stabilized with alkaline ascorbate. The method is unique in that it is simple and accurate, and it has additional advantages over the official (USP XVIII and NF XIII) methods. Several samples can be accurately analyzed within a short time. Extremely dilute epinephrine solutions (1:100,000) can be analyzed, which is not possible with current official methods. The influence of the various reagents on the final fluorescence and the stability of the fluorescence as a function of time are described. The absence of interference from epinephrine decomposition products on the recovery of epinephrine from simulated formulations is also described.

Keyphrases □ Epinephrine solutions—spectrophotofluorometric analysis, compared to compendial methods □ Spectrophotofluorometry—analysis, epinephrine solutions

Numerous methods have been described for the determination of epinephrine, norepinephrine, and related catecholamines in biological material (1, 2). USP XVIII describes an assay procedure (3) for epinephrine injection which measures the optical rotation of the triacetylepinephrine derivative. This method cannot be utilized directly without modification for the estimation of very dilute solutions of epinephrine (1:10,000 or 1:100,000) or very small volumes of these extremely dilute solutions. To assay these very dilute solutions according to the official method, a large number of samples is required and quantitative extraction of a large volume of solution may lead to large errors. NF XIII describes a colorimetric method (4) for the assay of epinephrine. This method does not distinguish between the biologically active epinephrine from the inactive decomposition products. Thus, both of these methods have disadvantages in that they cannot be used directly for the assay of large numbers of samples of extremely dilute solutions or do not distinguish the active species from the inactive decomposition products.

In view of these disadvantages, the preferred assay method is the spectrophotofluorometric method, which has been extensively employed to determine catecholamine derivatives in biological fluids (5, 6). Backe-Hansen *et al.* (7) reported the application of Hellberg's (8) method for the estimation of epinephrine in injections and verified the specificity of the fluorometric method by a comparison with the biological method of elevation in the blood pressure of rats and the rat uterus method. However, neither experimental details nor effects of catecholamine decomposition products on the fluorometric method were reported.

To date the possible application of the fluorometric method to routine assay of epinephrine samples in parenteral formulation has not been investigated in depth. The various parameters including the choice of the oxidizing agent, the period of oxidation, the development and stabilization of the fluorescence, and the influence of various reagents on fluorescence in parenteral formulations have not been reported. Also, the influence of the decomposition products of epinephrine injections, stabilized with the commonly used antioxidants, on the development of fluorescence has not been investigated.

This report describes a simple, accurate, and rapid fluorometric method for the routine assay of epinephrine parenteral formulations, which is also applicable for the assay of very dilute solutions. Statistical evaluation of the fluorometric and USP XVIII methods for the assay of dilute epinephrine solutions is reported, and the advantages of the new procedure are discussed.

EXPERIMENTAL[1]

Reagents—*Potassium Ferricyanide (0.25%)*—Dissolve 250 mg. of potassium ferricyanide (Fisher certified, ACS reagent) in sufficient distilled water to make 100 ml.

Zinc Sulfate (0.25%)—Dissolve 250 mg. of zinc sulfate heptahydrate (Fisher certified, ACS reagent) in sufficient distilled water to make 100 ml.

Ascorbic Acid (2%)—Dissolve 2.0 g. of USP grade ascorbic acid in sufficient distilled water to make 100 ml. This solution must be prepared fresh daily.

Sodium Hydroxide Solution (5 N)—Dissolve 200 g. of sodium hydroxide (Fisher certified, ACS reagent) in sufficient distilled water to make 1 l.

Phosphate Buffer (0.2 N), pH 6.5—Dissolve 2.8 g. $NaH_2PO_4 \cdot H_2O$ in distilled water to make 100 ml. Dissolve 5.4 g. $Na_2HPO_4 \cdot 7H_2O$ in sufficient distilled water to make 100 ml. Titrate NaH_2PO_4 solution with Na_2HPO_4 to a pH of 6.50 using an expanded scale pH meter[2].

Citrate-Phosphate Buffer (McIlvaine's Buffer), pH 4.0—Prepare 0.1 *M* citric acid solution by weighing 21.0 g. of citric acid monohydrate (ACS certified) into a 1-l. volumetric flask and diluting to volume with distilled water. Prepare 0.2 *M* dibasic sodium phosphate solution by weighing 28.4 g. of anhydrous dibasic sodium phosphate (ACS certified) into a 1-l. volumetric flask and diluting to volume with distilled water. Prepare pH 4.0 buffer by adding

[1] An Aminco-Bowman spectrophotofluorometer (American Instrument Co., Silver Spring, Md.) was used. The excitation wavelength was 410 nm., and the emission wavelength was 530 nm. For the epinephrine concentrations described in the procedures, the Meter Multiplier was set at 0.03, with a slit width of 1.0 and sensitivity at 30.

[2] Beckman.

600 ml. of 0.1 *M* citric acid solution to 400 ml. of 0.2 *M* dibasic sodium phosphate solution.

Potassium Carbonate Solution (0.2 N)—Dissolve 1.38 g. of potassium carbonate (ACS certified reagent) in sufficient distilled water to make 100 ml.

Sodium Ascorbate Solution—Pipet 5.0 ml. of ascorbic acid solution into a 50-ml. volumetric flask and dilute to volume with 5 *N* sodium hydroxide. This solution must be prepared immediately before use. Unless this reagent is clear and colorless, it should not be used.

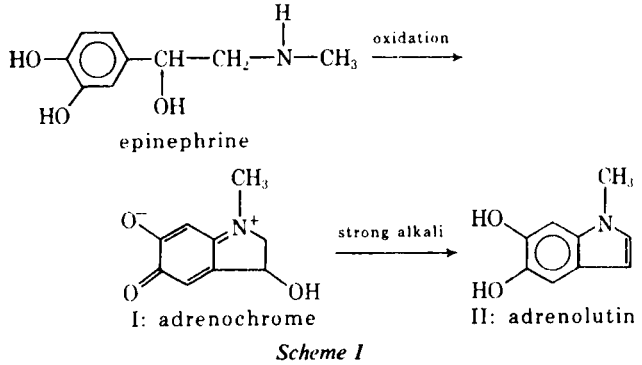
Iodine Solution (0.005 N *in 1.25% w/v Sodium Iodide)*—Weigh 5.0 g. of sodium iodide (Fisher certified, ACS reagent) into a 100-ml. volumetric flask containing 30 ml. of distilled water. Pipet 20 ml. of 0.1 *N* iodine solution and dilute to 100 ml. with distilled water. Pipet 25.0 ml. of this solution into a 100-ml. volumetric flask and dilute to volume with distilled water.

Epinephrine Standard—Accurately weigh 100 mg. of epinephrine base[3] or 182 mg. of epinephrine bitartrate[3] into a 1-l. flask. Pipet 10 ml. of 0.1 *N* HCl, swirl flask to dissolve the material in the acid, and dilute to volume with nitrogen-purged distilled water. When stored in the refrigerator, this solution is stable for several weeks.

Procedures—*Potassium Ferricyanide Method*—Dilute the unknown epinephrine solution with pH 6.5 phosphate buffer to result in approximately 10 mcg./ml. solution. Pipet 2 ml. of this solution into two test tubes, and add 1.0 ml. of distilled water. Adjust the pH of this solution to 6.50 by the addition of 0.2 *N* potassium carbonate solution. To one test tube, add 0.1 ml. of 0.25% zinc sulfate followed by 0.1 ml. of 0.25% potassium ferricyanide reagent. Mix them thoroughly and let stand for exactly 3 min. To both tubes, add 1.0 ml. of sodium ascorbate reagent (freshly made), mix well, and allow to react for 10–20 min. To the tube that did not contain any oxidant, add 0.1 ml. of 0.25% zinc sulfate and 0.1 ml. of 0.25% potassium ferricyanide reagents, in that order. Mix thoroughly and use this solution as the blank. Readings are to be taken at the wavelengths described (*Footnote 1*) on the spectrophotofluorometer 10–20 min. after the addition of the alkaline ascorbate reagent.

Prepare a standard curve using the same procedure as that described for the unknown sample. Use concentrations of 2.5, 5.0, 10.0, 15.0, and 20.0 mcg./ml. for the standard curve. Read the unknown sample from the graph.

Iodine Method—The following procedure was used to assay epinephrine solutions initially containing 100 mcg./ml. of the base. Dilute 4.0 ml. of the unknown sample solution to 100 ml. with the pH 4.0 citrate–phosphate buffer. To each of two different 100-ml. volumetric flasks, labeled Samples A and B, add 10.0 and 15.0 ml., respectively, of this diluted solution and make up to volume with the same buffer. Pipet 5.0 ml. of solution from each of these flasks (containing about 0.4 and 0.6 mcg./ml. of epinephrine base, respectively) into separately labeled 10-ml. volumetric flasks, add 1.0 ml. of 0.005 *N* iodine reagent, and shake well. After exactly 3 min., dilute to 10 ml. with freshly prepared sodium ascorbate reagent. Shake thoroughly and read the fluorescence on the spectrophotofluorometer at the specified wavelengths and settings. The readings should be taken between 10–25 min. after the addition of the sodium ascorbate reagent. The standard solution of epinephrine containing 100 mcg./ml. is also diluted in an analogous manner. Each sample and standard are diluted to two different levels and assayed simultaneously. At least two blanks are always determined, consisting of 5.0 ml. of pH 4.0 citrate–phosphate buffer to which is added 1.0 ml. of the 0.005 *N* iodine solution, and the entire procedure is carried through in the same manner as described for samples and standards.



Scheme I

Calculations—

$$\text{mcg./ml. epinephrine in Sample A} = \frac{4\,(\%\text{ transmission of sample 1} - \%\text{ transmission of blank})}{(\%\text{ transmission of Standard A} - \%\text{ transmission of blank})} \quad \text{(Eq. 1)}$$

$$\text{mcg./ml. epinephrine in Sample B} = \frac{4\,(\%\text{ transmission of sample 2} - \%\text{ transmission of blank})}{(\%\text{ transmission of Standard B} - \%\text{ transmission of blank})} \quad \text{(Eq. 2)}$$

$$\text{mcg./ml. epinephrine in unknown sample} = 12.5\,(\text{mcg./ml. epinephrine in Sample A} + \text{mcg./ml. epinephrine in Sample B}) \quad \text{(Eq. 3)}$$

Recovery of Epinephrine in Presence of Its Oxidation Products—A solution of epinephrine hydrochloride, 115 mcg./ml., was made in distilled water and the pH was adjusted to 2.50 with hydrochloric acid. This solution was kept at 56°, with no precaution taken to prevent oxidation of epinephrine, and was analyzed by the fluorometric method at the end of 6 months. A fresh solution of epinephrine, 1.0 mg./ml., containing 10 mg./ml. of sodium bisulfite was made up in 0.1 *N* hydrochloric acid. To 5.0, 5.0, 5.0, 5.0, and 10.0 ml. of the partially decomposed solution of epinephrine at 56° were added 2.0, 1.5, 1.0, 0.5, and 0 ml., respectively, of the freshly made solution of epinephrine–sodium bisulfite solution already described. The solutions were then diluted to 10 ml. with distilled water and were subsequently analyzed by the fluorometric method.

TLC—Thin-layer plates (5 × 20 cm.) coated with silica gel F_{254}[4] were spotted with 20 μl. of the following solutions: (*a*) freshly made epinephrine solution (100 mcg./ml.), (*b*) epinephrine (100 mcg./ml.) containing sodium bisulfite (10 mg./ml.) which was previously heated at 65° for 2 weeks, and (*c*) epinephrine (100 mcg./ml.) heated in the presence of air for 9 weeks. The plates were developed with a solvent system consisting of 1-butanol–100% ethanol–acetic acid–water (50:10:10:15). With the sample of epinephrine heated in the presence of air, no clearcut separation could be achieved. However, the epinephrine heated with excess sodium bisulfite resulted in another product (R_f 0.26) with excellent separation. In this system, pure epinephrine had R_f 0.45.

RESULTS AND DISCUSSION

By using epinephrine as an example of a substituted catecholamine, the principle involved in the fluorometric method is illustrated in Scheme I. With a mild oxidizing agent, epinephrine is oxidized to adrenochrome (I), which in strong alkaline solution is cyclized to the relatively unstable adrenolutin (II), which is responsible for the fluorescence (9).

Catecholamines such as epinephrine and norepinephrine that occur in biological fluids have been successfully assayed by the fluorometric method (5, 6). However, this method is lengthy and involves an initial extraction with butanol, followed by alumina adsorption to remove noncatechol fluorescent substances (5). This method also requires the addition of reagents at precise intervals, and the final fluorescence is extremely unstable in the acidic medium in which it is determined. Moreover, this method has the serious drawback of a critical oxidation time period followed by an exacting time interval between the addition of the reagents and the actual determination of the fluorescence. Due to the number of steps involved during assay, along with the very specific time intervals, it is very difficult to analyze a large number of samples at a time without seriously affecting the accuracy.

Hellberg (8) reported a method for the estimation of epinephrine and norepinephrine in solutions containing local anesthetics and sulfite as the antioxidant. This method separates the epinephrine from the local anesthetic by column chromatography, with subsequent oxidation of the sulfite with iodine in acidic solution. The excess iodine is oxidized with arsenite, and the epinephrine is then oxidized at pH 6.0 with potassium ferricyanide to adrenochrome,

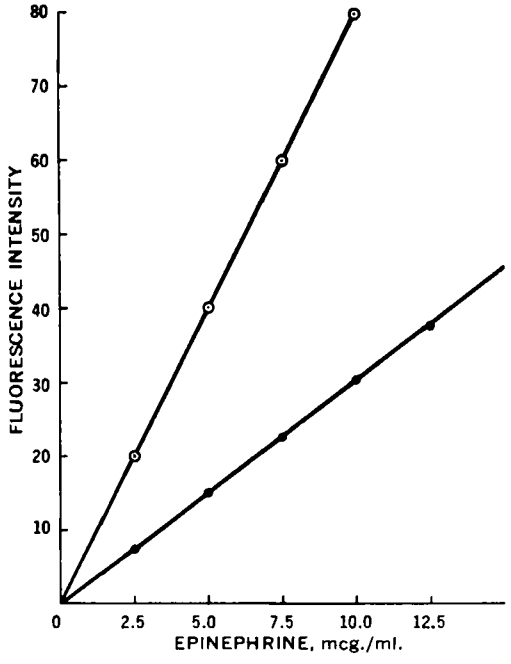

Figure 2—*Assay of epinephrine hydrochloride in the presence and absence of excess sodium bisulfite employing excess potassium ferricyanide (0.58%)–zinc sulfate (0.58%) reagent. Key: ⊙, absence of sodium bisulfite; and ●, presence of sodium bisulfite.*

which is then cyclized to adrenolutin with strong alkali. The fluorescence of these solutions is determined between 15 and 30 min. after the alkali treatment. Since this paper did not mention the wavelength at which the fluorescence was measured, the excitation and emission maxima for epinephrine were determined and found to be 410 and 530 nm., respectively.

Various oxidizing agents have been used for the initial oxidation of epinephrine to adrenochrome. The initial oxidation could be carried out with iodine (5), manganese dioxide (10), or a mixture of potassium ferricyanide and zinc sulfate (9). Manganese dioxide was eliminated from consideration as an oxidizing agent because of its insolubility and the problem of cumbersome removal from solution by centrifugal action. The use of a mixture of potassium ferricyanide–zinc sulfate and iodine solution was investigated in detail. Adrenolutin, which is responsible for the fluorescence, is quite susceptible to further oxidation, resulting in a decrease of the fluorescence. This can be prevented by the addition of a solution of an antioxidant. Of the various antioxidants suggested, the most commonly used are sodium sulfite (5) and sodium ascorbate (10). The antioxidant used not only prevents the further oxidation of adrenolutin but also reduces any excess oxidizing agent that may have been used to convert epinephrine to adrenochrome.

Potassium Ferricyanide–Zinc Sulfate Method—The majority of the commercial parenteral formulations of epinephrine contain sodium bisulfite or sodium metabisulfite as the antioxidant. Hellberg (8) recommended the initial oxidation of the antioxidant with iodine in acidic solution. However, if an excess of iodine is used, an interference with the fluorescence results. The exact amount of the antioxidant left in commercially available products is not known and, therefore, it is difficult to avoid using an excess iodine solution. Von Euler and Floding (9) used a mixture of potassium ferricyanide and zinc sulfate for the oxidation of epinephrine. A modification of this procedure was used to estimate epinephrine where the fluorescence was stabilized with alkaline sodium ascorbate. Excellent correlation between epinephrine concentration and fluorescence was observed with pure epinephrine solutions. However, for solutions containing sodium bisulfite, there was no linearity of response of fluorescence to concentration changes of epinephrine in solution (Fig. 1).

Since sodium bisulfite interferes with the development of fluorescence, the removal of sodium bisulfite by oxidation with excess potassium ferricyanide (0.58%) and zinc sulfate (0.58%) was attempted. The results show (Fig. 2) that the interference of bisulfite cannot be completely eliminated with potassium ferricyanide oxidation, as indicated by the differences in the slopes of the line in Figs. 1 and 2. In the presence of sodium bisulfite, with a lower concentration of the potassium ferricyanide–zinc sulfate reagent, epinephrine oxidation seems to be incomplete (Fig. 1). However, when the concentration of the oxidizing agent is increased, the slope of the standard curve decreases (Fig. 2) with respect to the slope of the curve obtained when a lower concentration of oxidizing agent was used (Fig. 1). This means that the fluorescence is affected by the amount of the oxidizing agent and also the presence of sodium bisulfite. These results indicate that the interference due to the presence of bisulfite cannot be eliminated by increasing the potassium ferricyanide–zinc sulfate concentration. Therefore, iodine solution containing potassium iodide was considered as an oxidizing agent.

New and Improved One-Step Method—A solution of iodine in potassium iodide was described as the oxidizing agent in the estimation of catecholamines in tissues (11). However, the initial oxidation step, the subsequent cyclization of the adrenochrome to adrenolutin, and the measurement of the fluorescence were reported to be extremely sensitive and very time dependent. Attempts to assay several samples at a time by this method failed to yield consistent results. In this method (11) the fluorescence is determined in acidic solution (pH 5.4) immediately after its development. The author also recommended the reduction of excess iodine with alkaline sodium sulfite, with the concurrent cyclization of adrenochrome to adrenolutin. The entire process should be completed within 2 min.

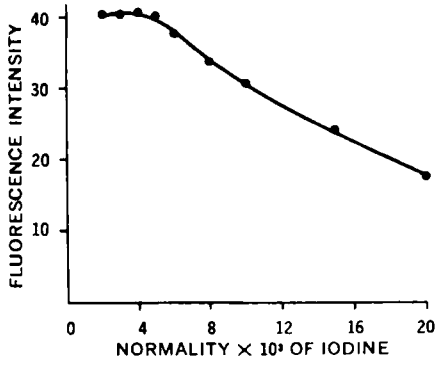

Figure 3—*Effect of iodine concentration on fluorescence of 0.6 mcg./ml. of epinephrine hydrochloride in the presence of 6 mcg./ml. of sodium bisulfite.*

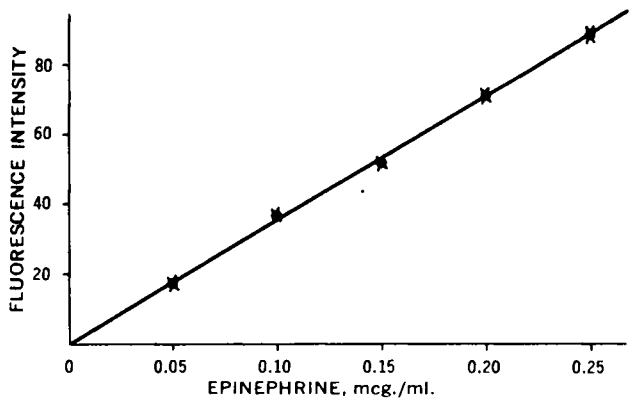

Figure 4—*Assay of epinephrine hydrochloride by fluorometric method using iodine–potassium iodide as the oxidizing agent. Key: ×, epinephrine hydrochloride alone; and ○, epinephrine hydrochloride with 20-fold excess of sodium bisulfite.*

and, subsequently, the solution is acidified with 5 *N* acetic acid to stabilize the fluorescence which must be determined immediately on the fluorometer.

To circumvent these problems and to analyze several samples at a time, the efficiency was investigated of iodine–potassium iodide solution to oxidize not only epinephrine in pH 4.0 buffer solution but also sodium bisulfite and metabisulfite, the most common antioxidants used in parenteral formulations. In the new and improved method, described in the *Experimental* section, alkaline sodium ascorbate was used to reduce the excess iodine and to stabilize the fluorescence. Various parameters such as the concentration of the oxidizing agent, the duration of the oxidation step, the fluorescence stabilizing agent and its concentration, and the duration within which the fluorescence should be determined were all studied in detail.

Effect of Oxidizing Agent on Fluorescence—The effect of iodine–potassium iodide concentration on the fluorescence of the final solution is shown in Fig. 3. Epinephrine solution was spiked with a 10-fold excess of sodium bisulfite. Iodine solution of various normalities was added such that the volumes of the final solutions were held constant, and the resulting fluorescence was measured. From Fig. 3 it is evident that the concentration of the oxidizing agent, iodine, on freshly made solutions of epinephrine containing sodium bisulfite is quite critical. The optimum concentration of the iodine reagent is 0.005 *N*, beyond which the final fluorescence is markedly affected. This concentration of iodine is sufficient to oxidize the epinephrine and the excess sodium bisulfite present in the formulation. Since formulations aged at different temperatures for various times would contain different amounts of sodium bisulfite and epinephrine, the adequacy of iodine solution as the oxidizing agent was checked by keeping the ratio of epinephrine to sodium bisulfite constant (Fig. 4). Since an excess amount of iodine quenches the fluorescence (Fig. 3), this study also indicated that the volume of iodine solution used does not affect the fluorescence in the presence or absence of excess sodium bisulfite. Concentrations of sodium bisulfite as high as 5 mcg./ml. do not interfere with the fluorometric assay of epinephrine. Many of the marketed parenteral formulations contain sodium bisulfite as much as 10 times the weight of epinephrine. Even in the presence of such high concentrations of the antioxidant, the amount of iodine described in the *Experimental* section is found to be adequate, since sodium bisulfite concentration as high as 25 times that of epinephrine does not interfere with the final fluorescence.

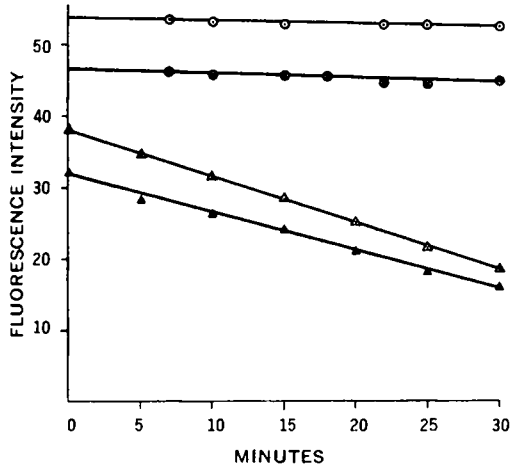

Figure 5—*Stability of fluorescence as a function of time, pH of the final solution, fluorescence stabilizer used, and final epinephrine hydrochloride concentration. Key: sodium sulfite as fluorescence stabilizer with final pH 5.0 and final epinephrine hydrochloride 0.2 mcg./ml. (▲) or 0.3 mcg./ml. (△); and sodium ascorbate as fluorescence stabilizer with final pH greater than 10 and final epinephrine hydrochloride 0.2 mcg./ml. (⊗) or 0.3 mcg./ml. (⊙).*

Table I—Effect of Iodine as Oxidizing Agent and Ascorbic Acid as Fluorescence Stabilizing Agent in the Assay of Epinephrine Hydrochloride Injections by Fluorometric Method

Ascorbic Acid, mg./ml.	Fluorescence Intensity, % Samples[a] 0.001 *N* Iodine 1	2	3	4	0.005 *N* Iodine 5	6	7	8
1.0	52.8	76.8	41.3	61.3	44.0	64.5	33.5	51.2
2.0	49.3	74.4	39.3	58.2	44.3	65.7	34.2	50.2
3.0	46.5	68.8	36.7	55.0	43.5	65.4	35.1	51.5

[a] Sample sets 1,2; 3,4; 5,6; and 7,8 were made by the appropriate dilution of four different samples such that the final concentration of epinephrine hydrochloride was in the ratio of 2:3 for each set. Final epinephrine hydrochloride concentrations were 0.2 and 0.3 mcg./ml., respectively, at these two dilutions.

The optimum pH of the solution to be oxidized was reported (6) to be 4.0. Solutions buffered with citrate–phosphate buffer at pH 4.0 also resulted in maximal fluorescence in the present investigation. Laverty and Taylor (6) recommended 1 min. as the oxidation time; however, in this study, a 3-min. oxidation period was necessary to oxidize the antioxidant normally present in formulations and also to oxidize the epinephrine to adrenochrome.

Choice of Antioxidant to Stabilize Final Fluorescence—The fluorescence of adrenolutin is quite unstable, probably due to easy oxidation, and, therefore, it needs stabilization with an antioxidant. Sodium sulfite and ascorbic acid were most often used to stabilize the fluorescence. Laverty and Taylor (6) described the use of sodium sulfite initially and subsequent acidification with glacial acetic acid, measuring the fluorescence in acidic solution (pH 5.0). Their paper failed to mention the stability of the fluorescence in the assay of epinephrine; however, the statement: "fluorescent derivatives were stable for at least 100 minutes" was made without presentation of any data to substantiate it. The stability of fluorescence in epinephrine assay was investigated in this study, using essentially the procedure of Laverty and Taylor and employing sodium sulfite as antioxidant and glacial acetic acid to make the final solution acidic. Under these conditions, the fluorescence is not as stable as was reported (6). The results according to the literature method (6) are shown in Fig. 5. When the fluorescence is determined under acidic conditions, it should be determined immediately, as was reported by Chang (5). The method reported by Laverty and Taylor (6) is identical with that reported by Chang. The relative instability of the fluorescence at pH 5.0 is evident from Fig. 5. It is also evident that the fluorescence is stable up to 25 min. when stabilized with ascorbic acid under strongly alkaline conditions.

To determine the optimum concentration to stabilize the fluorescence, ascorbic acid concentrations ranging from 1 to 3 mg./ml. were used, with parallel iodine concentrations of 0.001 and 0.005 *N* as the oxidizing agent. The results shown in Table I indicate that the readings were higher when 0.001 *N* iodine solution was used as the oxidizing agent along with 1 mg./ml. ascorbic acid as the fluorescence stabilizing agent. However, the fluorescence was less stable under the above set of conditions than when the 0.005 *N* iodine solution and 2 mg./ml. ascorbic acid combination was used. The use of 0.005 *N* iodine also assures complete oxidation of the antioxidant used in the formulation. It was also found that fluorescence with intensity readings higher than 70 units would quench faster. Fluorescence was stable for longer periods when the final readings were

Table II—Comparison of USP XVIII and Fluorometric Methods for the Assay of 1:1000 Epinephrine Solutions[a] Stored at 65° for Several Weeks

Sampling Time, Weeks	Epinephrine Hydrochloride, mcg./ml. USP XVIII Method	Fluorometric Method
Original	1000	1000
1	360	355
2	264	260
4	175	170
7	085	090

[a] These formulations contained 10 mg./ml. of sodium bisulfite, and the final pH was adjusted to 2.50.

in the range of 30–70. It is also evident from Table I that when 3 mg./ml. of ascorbic acid was used, the value of the fluorometric readings dropped sharply compared to 1 mg./ml. of ascorbic acid.

Comparison of USP XVIII and Fluorometric Methods—To determine the precision of the USP XVIII method for the assay of epinephrine, a 1:1000 stock solution was made in hydrochloric acid and stored in the refrigerator. This solution was analyzed by the USP XVIII method, which involved the conversion of the unchanged epinephrine to triacetylepinephrine, its extraction with chloroform, and subsequent determination of its optical rotation. The amount of unchanged epinephrine is calculated from the given formula. Replicate determinations of the epinephrine assay according to the USP XVIII method resulted in a standard deviation of 0.5% with a standard error of 0.2% and precision of 0.5%. Similar replicate determinations by the USP XVIII method were carried out with 1:10,000 epinephrine solution, which is 10 times more dilute than the USP solution. The solutions were assayed by a slight modification of the extraction procedure with chloroform. The standard deviation is 0.62% with the standard error being 0.28%. Simultaneous determination of epinephrine by the fluorometric method resulted in a standard deviation of 0.48% and a standard error of 0.22%. According to Hellberg's (8) method, the standard deviation of a single determination was about ±2% for epinephrine. Therefore, this new procedure is precise and reproducible.

Assay of Epinephrine Formulations—A comparison of the two analytical procedures was made using 1 mg./ml. epinephrine formulation containing 10 mg./ml. of sodium bisulfite. The final pH was adjusted to 2.50, and the samples were kept at 65° for several weeks. These samples were withdrawn at various intervals and analyzed by the USP XVIII and fluorometric methods (Table II). The excellent agreement between the two methods points to the facts that: (*a*) by the fluorometric method, only the unchanged epinephrine is measured as verified by the acetylation procedure described in USP XVIII; and (*b*) the inactivation product, namely epinephrine sulfonic acid (III), does not interfere in the fluorometric assay. In the presence of a large excess of sodium bisulfite, the only decomposition product observed by TLC is epinephrine sulfonic acid. This was reported earlier by Schroeter *et al.* (12) to be the major route of degradation.

The applicability of the fluorometric procedure to formulations containing other antioxidants was investigated. Parenteral epinephrine formulations containing up to 10 mg./ml. ascorbic acid or up to 4 mg./ml. α-monothioglycerol were made anad analyzed by the new procedure. Since ethylenediaminetetraacetic acid is often used as an antioxidant synergist, formulations containing as high as 1 mg./ml. were made and analyzed. In all instances, no interference from any of the formulation stabilizers was observed. Thus, it can be safely concluded that the new fluorometric method is of great value in analyzing epinephrine formulations containing a variety of stabilizers.

Recovery of Epinephrine from Solutions Containing Its Oxidation Products—To study the interference of oxidation products on the recovery of epinephrine, solutions at a concentration of 1:10,000 and with pH adjusted to 2.5 were allowed to degrade in the absence of antioxidant. When more than 70% of the epinephrine decomposed, a constant volume of the degraded solution was added to

Table III—Comparison of Biological and Fluorometric Methods for the Assay of Aged Epinephrine Injection (1:10,000) at Different Temperatures[a]

	Sample	37°, 8 Weeks	37°, 12 Weeks	25°, 8 Weeks	25°, 12 Weeks
Biological assay[b], %	A	91.8	69.7	93.4	87.4
	B	80.4	63.5	81.6	86.8
Fluorometric assay, %	A	85.6	66.7	94.5	92.6
	B	89.3	64.3	97.1	94.5

[a] Epinephrine injection (1:10,000) contained sodium chloride and sodium bisulfite, and the pH of the original solution was 2.50. Results are expressed as percentage of original activity remaining. [b] Standard error, expressed as percent of potency, ranged from 0.98 to 7.03.

known amounts of epinephrine hydrochloride in solution. The resulting solution mixtures were analyzed by the fluorometric method, with concurrent determination of pure epinephrine hydrochloride solutions. The results of such a recovery experiment showed that the fluorometric method only measures the unchanged epinephrine even in formulations containing epinephrine oxidation products. Such recovery experiments carried out according to the USP XVIII method were unsuccessful due to the interference from the oxidation products. Thus, the USP XVIII method cannot successfully estimate epinephrine when its oxidative decomposition products are also present. However, these epinephrine oxidation products do not interfere in the fluorometric method.

Further evidence of the specificity of the fluorometric method to unchanged epinephrine came when completely oxidized epinephrine solutions (as evidenced by TLC) in different amounts were added to a constant amount of epinephrine hydrochloride solution, which was later analyzed by the fluorometric method. The recoveries of epinephrine were quantitative, and the results conclusively proved that the various epinephrine oxidative degradation products, even when present in high concentrations, have no effect on the determination of epinephrine by the fluorometric method.

Comparison between Fluorometric Method and Biological Method with Epinephrine Formulations—Epinephrine injections (1:10,000) containing sodium bisulfite as the antioxidant were stored at 25 and 37° and were assayed by the fluorometric method. The rise in the mean blood pressure of dogs upon the intravenous administration of epinephrine hydrochloride injection was measured according to the method described by Noel (13). The results summarized in Table III indicate that there is a remarkable correlation between the two methods. Backe-Hansen *et al.* (7) also established such a correlation between blood pressure measurement and the fluorometric method described by Hellberg (8).

In summary, the unique feature of the described fluorometric method lies in the fact that the stabilization of the fluorescence is amenable to the routine assay of several samples at a time. The USP XVIII method is time consuming and cannot be successfully applied to the assay of a large number of samples at a time. The other major advantages of this new method are:

1. It can be used to assay dilute (even 1:100,000) epinephrine hydrochloride injections with accuracy.
2. The specificity of the new method even in the presence of epinephrine oxidation products has been established, whereas interferences were observed with the USP XVIII method.
3. The method is simple, precise, and timesaving, with the added potential for automation.
4. The fluorometric method requires a small volume of sample, whereas the USP XVIII method requires a sample containing 30 mg. of epinephrine. Thus the latter method requires a large number of samples, resulting in very large volumes to handle.
5. This new method can be used for the assay of epinephrine injections containing antioxidants other than sodium bisulfite.

Improved, Rapid Spectrophotofluorometric Method for Assay of Isoproterenol Hydrochloride Injections: A Comparative Study

V. K. PRASAD, R. A. RICCI, B. C. NUNNING, and A. P. GRANATEK▲

Abstract □ A spectrophotofluorometric method for the determination of isoproterenol hydrochloride in parenteral formulations is described. This method is quite simple, precise, and extremely specific for unchanged isoproterenol in decomposed formulations. The method depends on the initial oxidation of isoproterenol hydrochloride with iodine–potassium iodide solution in pH 4.0 (McIlvaine's citrate–phosphate) buffer. The partially oxidized isoproterenol "chrome" derivative is cyclized to the fluorescent "lutin" derivative with strong alkali. The fluorescence is stabilized with alkaline ascorbate solution, which is subsequently determined. The influence of the various decomposition products of isoproterenol, such as isoproterenol sulfonic acid and isoproterenone, on the fluorometric procedure was investigated with concurrent determination of the same solutions by the USP XVIII method. The usefulness of the fluorometric procedure to analyze fresh as well as partially decomposed isoproterenol solutions, stabilized with other antioxidants, is evaluated. The inapplicability of the existing methods to analyze very dilute (1:50,000) solutions of isoproterenol is also described. The specific advantages of the fluorometric procedure in the routine analysis of a large number of samples with speed and accuracy are discussed. Statistical evaluation of the fluorometric method is also reported.

Keyphrases □ Isoproterenol hydrochloride solutions—spectrophotofluorometric analysis, compared to compendial method □ Spectrophotofluorometry—analysis, isoproterenol hydrochloride solutions

The official USP XVIII method (1) for the analysis of isoproterenol hydrochloride injection in specific formulations and isoproterenol hydrochloride in other formulations involves the column chromatographic separation of unchanged isoproterenol from its degradation products. This is achieved by ion-pair extraction of the intact isoproterenol with bis(2-ethylhexyl)phosphoric acid in ether solution, leaving decomposition products behind on the column (2). The major product of decomposition of isoproterenol injections containing the most commonly used antioxidant sodium bisulfite is isoproterenol sulfonic acid (I). The formation of this derivative is pH dependent, and the reaction is favored at higher pH values. This fact was demonstrated by Higuchi and Schroeter (3). However, when an insufficient quantity of sodium bisulfite is used or when other antioxidants are employed, complications arise due to the presence of other isoproterenol decomposition products such as isoproterenone (II). In such instances, the USP XVIII method may not work satisfactorily. This fact was investigated in depth, and the data are presented in this paper.

Another major disadvantage with the USP XVIII method is that it cannot be used to assay isoproterenol injections in very dilute solutions such as 1:50,000 concentrations. The official method does not work when large volumes of sample have to be eluted from the column. Other disadvantages are: (*a*) the method is lengthy and time consuming; (*b*) the method cannot be successfully used to assay several samples at a time; and (*c*) it is extremely difficult to reproduce results, since the USP XVIII does not describe any of the column chromatographic variables such as tightness of the

packing of the stationary phase in the column, the rate of elution, and other pertinent factors.

Welsh and Sammul (2) reported on the analysis of aged isoproterenol solutions using a modification of Hellberg's (4) fluorometric assay for epinephrine. However, no details of the procedure were given. The purpose of this report is to present a simple, rapid, accurate, and selective fluorometric procedure for the quantitative determination of unchanged isoproterenol in aged formulations. The fluorometric method is based on the fact that isoproterenol in an acidic buffer solution can be selectively oxidized to its "chrome" derivative, which subsequently is cyclized in strong alkaline solution to the fluorescent "lutin" derivative, which is stabilized with sodium ascorbate. The described method has the additional advantage that it can be used to assay dilute (1:50,000) solutions of isoproterenol even in the presence of unusually higher concentrations of its two known decomposition products: isoproterenol sulfonic acid (I) and isoproterenone (II). The merits of the fluorometric method over that of the USP XVIII method, including a statistical evaluation of the method, are reported here.

EXPERIMENTAL[1]

Preparation of Isoproterenol Sulfonic Acid (I)—Isoproterenol hydrochloride (10.0 g., 0.04 mole) and sodium bisulfite (6.78 g., 0.04 mole) were dissolved in 50 ml. of water. The mixture was heated on a steam bath under nitrogen for 2 hr. and then was stored in the dark under nitrogen for 3 days. At the end of 3 days, 25 ml. of water was removed on a flash evaporator and the residue solution was stored in the dark at room temperature under nitrogen for a further period of 6 days. At the end of 6 days, the remaining solution was concentrated on a flash evaporator. The residue was suspended in 25 ml. of ethanol and saturated with ether. The precipitate was filtered, washed with ether, and air dried. The precipitate was suspended in 150 ml. of water, stirred for 10 min., filtered, and then crystallized from water to produce a white crystalline compound. This compound was dried at 40° under vacuum overnight to give isoproterenol sulfonic acid·1/2 H_2O. On drying the sample at 80° under vacuum over phosphorus pentoxide for 48 hr., anhydrous isoproterenol sulfonic acid was obtained, 7.6 g. (68%), m.p. 185–190° (softens), 225–230° dec.; UV (95% ethanol): λ_{max} 284 (ϵ, 3593) and 232 (ϵ, 7558) nm.; IR (KBr): 1135, 1045 (—SO_3), and 650 (—S—O) cm.$^{-1}$; NMR (dimethyl sulfoxide-d_6): δ 8.70 (br, 3, —OH + NH), 6.66 (m, 3, aromatic H), 3.80 [br, t, 1, —(—SO_3H)CH—], 2.34 (m, 3, —CH + CH_2O), and 1.20 (d, 6, —CH_3).

Anal.—Calc. for $C_{11}H_{17}NO_5S$: C, 47.97; H, 6.23; N, 5.08; S, 11.64. Found: C, 47.72; H, 6.29; N, 5.08; S, 12.13.

Preparation of Isoproterenone (II)—Ten grams (0.053 mole) of 3,4-dihydroxy-α-chloroacetophenone[2] was suspended in 100 ml. of 95% ethanol. Isopropylamine, 80 ml. (an excess), was added slowly with stirring. The mixture was refluxed for 2.5 hr., and the solvent was removed under vacuum. The solid was taken up in 400 ml. of acetone, stirred for 30 min., and filtered, and the insoluble solid was washed with more acetone. The crude isoproterenone was suspended in 200 ml. of distilled water, filtered, and washed with distilled water several times. The material was recrystallized from dimethyl sulfoxide–water, resulting in a light-tan compound which, after drying at 60° under vacuum overnight, yielded the desired material, 8.6 g. (76%), m.p. 168–169° dec.; UV (95% ethanol): λ_{max} 312 (ϵ, 7555), 280 (ϵ, 8475), and 232 (ϵ, 12,555) nm.; IR (KBr): 1655 [C_6H_5—C(=O)—CH_2—], 1600, 1550, 1495 (phenyl ring), 1470 (—CH_2—, scissoring), 1345 (CH_3—), 1250 (aromatic ketone), 1125, 1105 (the —CH— out-of-plane vibrations), and 800 (adjacent 3H) cm.$^{-1}$; NMR (dimethyl sulfoxide-d_6): δ 7.10 (m, 6, aromatic H, —OH + NH), 4.02 [S, 2, —C(=O)—CH_2—NH—], 2.85 (m, 1 ϵ H), and 1.05 (d, 6, —CH_3).

Anal.—Calc. for $C_{11}H_{15}NO_3$: C, 63.12; H, 7.23; N, 6.69. Found: C, 62.48; H, 7.12; N, 6.34.

Isoproterenol Standard—Isoproterenol hydrochloride USP, 200 mg., was placed into a 1-l. flask containing 10 ml. of 0.1 *N* hydrochloric acid. The solid was dissolved and the volume was adjusted to 1 l. with nitrogen-purged distilled water. The resulting solution is stable over a period of several weeks when stored in the refrigerator.

Reagents—The preparation of McIlvaine's citrate-phosphate buffer of pH 4.0, of the iodine solution (0.005 *N*) in 1.25% (w/v) sodium iodide, and of the 0.2% ascorbic acid in 5 *N* sodium hydroxide was previously described (5).

Procedures—Isoproterenol hydrochloride injection USP (200 mcg./ml.) is assayed exactly according to the method described for the assay of 100 mcg./ml. epinephrine injection (5). For the assay of isoproterenol hydrochloride injection USP (200 mcg./ml.), 2.0 ml. is diluted to 100 ml. with buffer. To assay the more dilute 20 mcg./ml. isoproterenol hydrochloride injection, 5 ml. of the standard and the sample is diluted to 25 ml. with the citrate–phosphate buffer. Five and 15 ml. of the diluted solutions are further diluted to 50 and 100 ml., respectively, with the citrate–phosphate buffer. The procedure from here on is the same as described for 100 mcg./ml. epinephrine injection (5).

RESULTS AND DISCUSSION

The selective determinations of isoproterenol hydrochloride in the presence of its two known degradation products, isoproterenol sulfonic acid (I) and isoproterenone (II), using the fluorometric method has not been described. Numerous modifications of the fluorometric method for the analysis of other catecholamine derivatives have been published, but none of them is useful as a routine procedure because:

1. The methods described for the initial removal of the interfering material, sodium bisulfite, are cumbersome and have to be carried out in a precise fashion (4).
2. The reported methods have not checked out the fluorometric procedure to find out whether the two above-mentioned decomposition products of isoproterenol or other unknown degradation products interfere in the assay.
3. The fluorescence produced according to the reported methods is quite unstable and necessitates precise timing between the development of fluorescence and its determination on the fluorometer. For this reason, most of the published methods recommend that the fluorescence be determined immediately.
4. Finally, the number of steps involved in the actual procedure of the older methods (4) are many and cumbersome. Fewer steps are involved in the new method described in this paper.

Effect of Various Reagents on Fluorescence—In general, the effect of the concentration of the oxidizing agent, iodine, was found to be of the same nature as was described for the assay of epinephrine (5). The optimum iodine concentration that results in maximum fluorescence was 0.005 *N*. Higher concentrations resulted in decreased fluorescence and lower concentrations were not adequate to oxidize the high concentration of bisulfite used in the simulated formulations. In general, the commercial formulations tested contained 10-fold excess by weight of sodium bisulfite as compared to the isoproterenol hydrochloride. The oxidation of isoproterenol to the chrome derivative with iodine reagent was complete at the end of 3 min. after the addition of the reagent, beyond which lowering of the fluorescence was observed. The chrome derivative of isoproterenol was then cyclized by alkali to the lutin derivative, which is responsible for the fluorescence. The lutin derivative is quite unstable and can undergo further oxidation.

Several antioxidants such as sodium sulfite and ascorbic acid have been recommended not only to stop the further oxidation with iodine but also to prevent the quenching effect of oxygen on the fluorescence. Sodium sulfite was used as the antioxidant in the fluorometric determination of epinephrine at pH 5.0 in acetic acid solution (6). When employing these conditions for the assay of isoproterenol solutions, the fluorescence was found to be extremely

[1] An Aminco-Bowman spectrophotofluorometer (American Instrument Co., Silver Spring, Md.) was used. For the isoproterenol concentrations described in the procedures, a Meter Multiplier of the instrument was set at 0.03, with slit width at 1.0 and sensitivity at 30. The excitation wavlength was 420 nm., and the emission wavelength was 510 nm.

[2] 3,4-Dihydroxy-α-chloroacetophenone was obtained from Winthrop Laboratories, Rensselaer, NY 12144

Table I—Comparison of Fluorometric and USP XVIII Methods for the Assay of Fresh Isoproterenol Solutions

Concentration of Isoproterenol Hydrochloride, mcg./ml.	USP XVIII Method		Fluorometric Method	
	Amount Recovered, mcg./ml.	% Recovered	Amount Recovered, mcg./ml.	% Recovered
180	175	97.3	178.2	99.0
150	155	103.3	149.6	99.7
100	102	102	100.5	100.5
50	49	98	50.0	100

unstable and readings had to be taken immediately after the addition of the glacial acetic acid (6). However, alkaline ascorbate solutions stabilize the fluorescence up to 30 min., thus permitting the reading of several samples at a time on the fluorometer (5). It was found that determination of the fluorescence between 15 and 20 min. after the addition of sodium ascorbate resulted in consistent recovery of isoproterenol from simulated formulations. The concentration of ascorbic acid used was between 1 and 3 mg./ml., with high and stable fluorescent readings resulting when 2 mg./ml. of ascorbic acid was employed. In general, the effects of different reagents on the stability and duration of maximum fluorescence were identical to those described in the assay of epinephrine by this method (5).

Comparison of USP XVIII Method with Fluorometric Method—To evaluate the official method and the fluorometric procedure, fresh solutions of isoproterenol hydrochloride as well as solutions after aging at higher temperatures for several months were employed. Thus, the effect of the interfering decomposition products could be checked, which was not done by an earlier reported fluorometric method (7).

Fresh solutions of different concentrations of isoproterenol hydrochloride containing sodium bisulfite were made and analyzed both by the USP XVIII and fluorometric methods (Table I). The USP XVIII method led to large errors with minor alterations in the technique. For example, the packing of the adsorbent into the column was critical. Best results were obtained when the initial water-saturated ether was allowed to pass through the column for 45–55 min. The results were consistent only when the column was eluted with bis(2-ethylhexyl)phosphoric acid–ether solution for about 50 min. Such details as the tightness of packing the adsorbent into the column and the elution times are not given in USP XVIII but are extremely important to get consistent results. Fresh solutions of isoproterenol were analyzed according to USP XVIII, taking all the above-mentioned precautions. It is evident from Table I that such results are in excellent agreement with the results of the fluorometric method. The USP XVIII method as well as the described fluorometric method gives excellent results when the initial concentration is 50–180 mcg./ml. The limitation of the USP XVIII method is that below 50 mcg./ml. of isoproterenol hydrochloride the final absorbance is less than 0.1, where the accuracy of the results was seriously affected. When a larger volume of the sample was applied to the column (to compensate for dilute solutions), the results were erratic, especially when partially decomposed solutions were analyzed. This was probably due to the excess moisture on the column, which seriously affected the partitioning of the decomposition product between the adsorbent and the bis(2-ethylhexyl)-phosphoric acid–ether solution. However, with the fluorometric method, the solutions can be appropriately diluted so that the final concentration of isoproterenol hydrochloride is between 0.2 and 0.3 mcg./ml. and estimated with accuracy.

[a] This sample consisted of isoproterenone only.

Comparison of USP XVIII and Fluorometric Methods for Assay of Simulated Isoproterenol Formulations—Two known decomposition products of isoproterenol are the sulfonic acid derivative (I), which is formed in solutions containing sodium bisulfite, and the oxidation product isoproterenone (II). Simulated formulations consisting of isoproterenol and its decomposition products were made to determine their effects on the recovery of isoproterenol. To evaluate the merits of the fluorometric method, the simulated formulations were analyzed by the USP XVIII and the fluorometric methods. The effect of each of the degradation products on the recovery of isoproterenol is described below.

Influence of Isoproterenol Sulfonic Acid—Results of the effect of isoproterenol sulfonic acid on the recovery of simulated isoproterenol hydrochloride formulations are shown in Table II. For the simulated formulation containing 75% isoproterenol sulfonic acid, the recovery of isoproterenol according to the USP XVIII method was always low. However, in the concentration range tested, the fluorometric method produced excellent agreement between the actual amount of isoproterenol used in the simulated formulation and its percent recovery. Even 200-mcg./ml. concentrations of isoproterenol sulfonic acid did not result in any fluorescence. Kaistha (8) mentioned that the column chromatographic method always resulted in a positive bias with formulations containing isoproterenol sulfonic acid, so he recommended a preliminary washing of the ether–bis(2-ethylhexyl)phosphoric acid layer containing the unchanged isoproterenol with the phosphate buffer solution to remove any isoproterenol sulfonic acid.

A pertinent observation made in the present study was that if any sodium bisulfite was eluted from the column with the bis(2-ethylhexyl)phosphoric acid–ether solution, the absorbance reading was higher than expected. Perhaps Kaistha's recommendation for washing the eluate initially with phosphate buffer might result in the effective removal of bisulfite or other bisulfite-derived products. In spite of this, Kaistha (8) mentioned higher recovery due to some additionally encountered decomposition products. The metaperiodate method (8) has the particular disadvantage in that higher concentrations of isoproterenol sulfonic acid, when present, adversely affect the assay method. Therefore, Kaistha recommended that the official compendia set upper and lower limits for isoproterenol sulfonic acid when the formulations contain sodium bisulfite as an antioxidant. The particular advantage with this new fluorometric method is that isoproterenol sulfonic acid, even if present in high concentrations, has no effect on the recovery of isoproterenol from formulations stabilized with sodium bisulfite or metabisulfite. When the fluorometric method is used, there is no necessity for stipulating any limits on the isoproterenol sulfonic acid concentration.

Effect of Isoproterenone on Recovery of Isoproterenol—USP XVIII describes a limit test for isoproterenone (λ_{max} 310) in isoproterenol hydrochloride. Since isoproterenone can be formed as one decomposition product of isoproterenol, the possible interference of isoproterenone on the fluorometric method was studied in detail. Simulated formulations consisting of isoproterenone and isoproterenol hydrochloride were made and analyzed both by the USP XVIII and fluorometric methods (Table III). The UV spectra of isoproterenol hydrochloride and isoproterenone when present as a mixture are

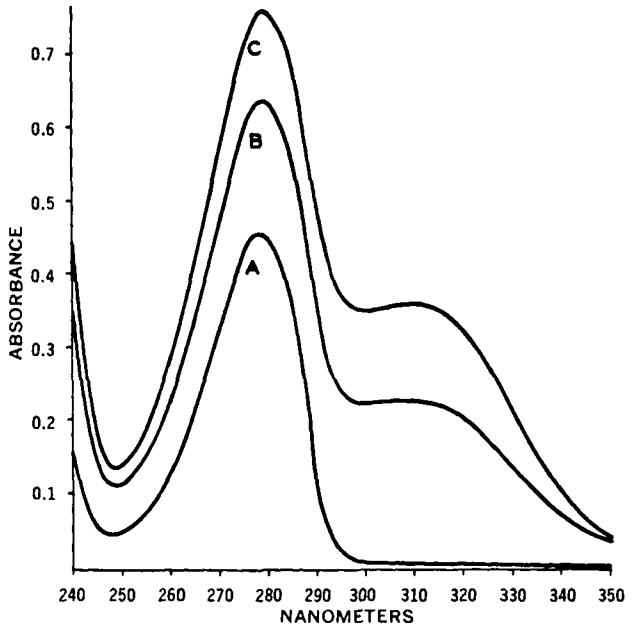

Figure 1—*UV spectra showing the effect of different amounts of isoproterenone on the USP XVIII method for determination of isoproterenol hydrochloride solutions. Key: A, isoproterenol hydrochloride, 200 mcg./ml.; B isoproterenol hydrochloride, 170 mcg./ml., and isoproterenone, 30 mcg./ml.; and C, isoproterenol hydrochloride, 150 mcg./ml., and isoproterenone, 50 mcg./ml.*

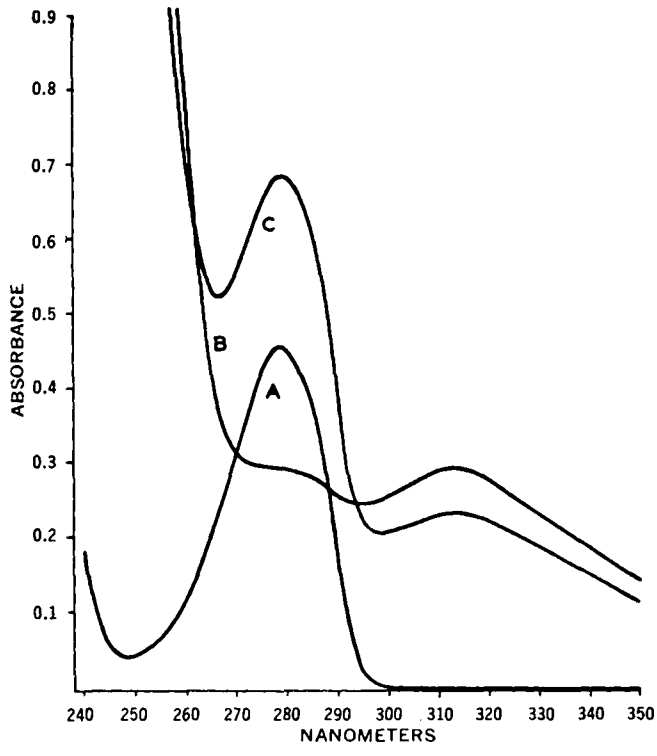

Figure 2—*UV spectra showing the effect of unknown isoproterenol decomposition products on the recovery of isoproterenol from solutions assayed by the USP XVIII method. Key: A, isoproterenol hydrochloride, 200 mcg./ml.; B, isoproterenol hydrochloride solution, 200 mcg./ml., completely decomposed in the presence of 350 mcg./ml. of sodium bisulfite; and C, mixture of A and B.*

shown in Fig. 1. Isoproterenone (molar absorptivity $\epsilon_{280}^{25} = 8053$ and $\epsilon_{310}^{25} = 6737$), when present in low concentrations, does interfere in the assay of isoproterenol (molar absorptivity $\epsilon_{280}^{25} = 2695$) when determined by the USP XVIII method. This is obvious because of the approximately threefold difference in the molar absorptivities of isoproterenone and isoproterenol at the 280-nm. absorption maximum. According to USP XVIII, the absorbance due to pure isoproterenol is determined at 278 nm. Serious errors can result if isoproterenone (λ_{max} 280 nm.) is also present in the samples of isoproterenol because both have nearly identical absorption maxima and because of the higher molar absorptivity of isoproterenone. Thus, both the USP XVIII method and the bis(2-ethylhexyl)phosphoric acid–ether extraction method (8) give false results when isoproterenone is also one decomposition product. As shown in Table III, when 200 mcg./ml. of isoproterenone was assayed by the fluorometric method, the final fluorescence was negligible. It can, therefore, be inferred that under these circumstances the new fluorometric method should be preferred over the USP XVIII method or the bis(2-ethylhexyl)phosphoric acid–ether extraction method (8) to assay isoproterenol formulations.

TLC of simulated inhalations and injections stored in the dark over a period of 4 months showed that they consisted of decomposition products other than the sulfonic acid derivative of isoproterenol (8). Although the exact nature of these additionally encountered artifacts could not be established unequivocally, it was theorized that one of them could be aminochrome–sodium bisulfite addition compound by analogy with a similar compound described by Tse and Oesterling (9) in their determination of total catecholamines in urine. According to Kaistha (8), when simulated isoproterenol formulations were analyzed by the method of Welsh and Sammul (2) (which was essentially adopted by USP XVIII), high and inconsistent values for the parent drug were obtained. This was attributed to the presence of additional decomposition products besides the sulfonic acid derivative (8). Kaistha reconciled this discrepancy by introducing a step to wash the ether effluent from the column with potassium phosphate buffer prior to acid extraction. Although this modification resulted in increased specificity for the USP XVIII method, the procedure is long and cannot be applied to very dilute solutions. The fluorometric method does not require preliminary separation of decomposition products. The fluorescence, due to the lutin derivative, results only from intact isoproterenol and not from its decomposition products.

Table IV—Comparison of USP XVIII and Fluorometric Methods for the Assay of Aged Isoproterenol Injections (1:5000)[a]

Sample[b]	USP XVIII Method, %	Fluorometric Method, %	Isoproterenol Sulfonic Acid[c], %
A	85.9	88.2	13.4
B	62.8	63.5	39.4
C	58.0	58.0	44.2
D	61.2	58.8	42.4

[a] These injections also contained a buffer consisting of lactic acid–sodium lactate, sodium chloride (7.0 mg./ml.), and sodium bisulfite (1.00 mg./ml.) as antioxidant, the final pH adjusted to 3.50. Celite 545 AW was used as the adsorbent in the USP XVIII method. [b] Sample A was stored for 2 months at 25°, while Samples B, C, and D were stored 10.5 months at 25°. [c] Isoproterenol sulfonic acid was estimated according to the method described by Kaistha (8).

Comparison of USP XVIII and Fluorometric Methods for Assay of Aged Commercial Isoproterenol Injections—Formulations of isoproterenol hydrochloride injection USP were made containing sodium lactate–lactic acid buffer, sodium bisulfite antioxidant, and sodium chloride for isotonicity. These were stored at room temperature for several months and analyzed both by the fluorometric and USP XVIII procedures. In addition, the amount of isoproterenol sulfonic acid formed was estimated according to the method described by Kaistha (8) (Table IV). The close agreement between the two methods indicates that the fluorometric method is comparable to the USP XVIII method when the method is exactly followed, as indicated previously in this report. The material balance between isoproterenol hydrochloride and isoproterenol sulfonic acid was in good agreement with the original isoproterenol hydrochloride concentration. A point worth noting here is that, in the presence of a large excess of sodium bisulfite, the isoproterenol solutions remained clear and colorless even though the solutions were completely decomposed. This suggests that the sulfonic acid derivative of isoproterenol is the only decomposition product for formulations containing high amounts of sodium bisulfite. However, as

Table V—Statistical Evaluation of Fluorometric Method to Analyze Isoproterenol Hydrochloride Solutions

	Concentration of Isoproterenol Hydrochloride, mcg./ml.

SD, %	1.118	0.894
SEM %	0.5	0.400
Mean error	−0.5	+0.6

pointed out earlier, if other unknown decomposition products such as isoproterenone are present, the USP XVIII method results in large errors.

Influence of Other Unknown Isoproterenol Oxidation Products on Fluorometric Method—It was stated earlier that isoproterenol decomposes to its sulfonic acid derivative in the presence of excess sodium bisulfite. However, in the presence of lower amounts of sodium bisulfite, additional decomposition products have been reported (8). The completely decomposed solutions in such cases were not clear and colorless and occasionally were accompanied with black precipitate. Therefore, it is essential to establish that the fluorometric method is specific only for the unchanged isoproterenol. Isoproterenol hydrochloride (230 mcg./ml.) in lactic acid–sodium lactate buffer (pH 3.50–3.60) stabilized with 350 mcg./ml. of sodium bisulfite was made. These solutions were stored in the dark at 56° for an extended time and were analyzed by the fluorometric method. TLC of the completely decomposed solutions indicated the presence of products other than isoproterenol sulfonic acid[3]. The completely decomposed solution was added in varying amounts to solutions of isoproterenol hydrochloride of known concentration, and the samples were analyzed by the fluorometric method. There was no fluorescence due to the completely degraded isoproterenol under the conditions tested. The results indicated that isoproterenol decomposition products other than the sulfonic acid, when present in high concentrations, do not influence the recovery of isoproterenol hydrochloride when assayed by the fluorometric method. The same decomposed isoproterenol solution was added to a known concentration of fresh isoproterenol hydrochloride solution. The decomposed isoproterenol and the mixture were separately analyzed by the USP XVIII method. The UV spectra of the results shown in Fig. 2 indicate interference from the unknown degradation products. The USP XVIII procedure requires the drawing of a baseline between the two minima (about 300 and 250 nm.) of isoproterenol hydrochloride to measure the absorbance due to unchanged isoproterenol hydrochloride. From Fig. 2, it is obvious that the minima do not occur at these prescribed wavelengths when these unknown oxidation products are present. This experiment thus proves that the fluorometric method described here is specific for the unchanged isoproterenol hydrochloride and that its decomposition products, when present, do not have any effect.

Statistical Analysis of Fluorometric Method—To check the precision and accuracy of the procedure, several samples containing isoproterenol hydrochloride of low and high concentrations were analyzed by the fluorometric method. The statistical treatment of the data is summarized in Table V. The percent standard deviation ranged from 0.89 to 1.12. However, the standard error of the mean was 0.4–0.5 at the low and high levels of isoproterenol hydrochloride. The mean error, which is the difference between the average test results and the true result, ranged from +0.6 for the lower concentration to −0.5 for the higher concentration of isoproterenol hydrochloride.

Influence of Other Antioxidants on USP XVIII and Fluorometric Methods of Isoproterenol Assay—The effect of other antioxidants, such as ascorbic acid and α-monothioglycerol, on the recovery of isoproterenol from aged solutions was investigated. Fresh solutions of isoproterenol containing ascorbic acid or α-monothioglycerol were analyzed by the fluorometric method. There was no interference from either of these two antioxidants on the fluorescence.

[3] F. Bangert, Chemical Control, Bristol Laboratories, personal communication.

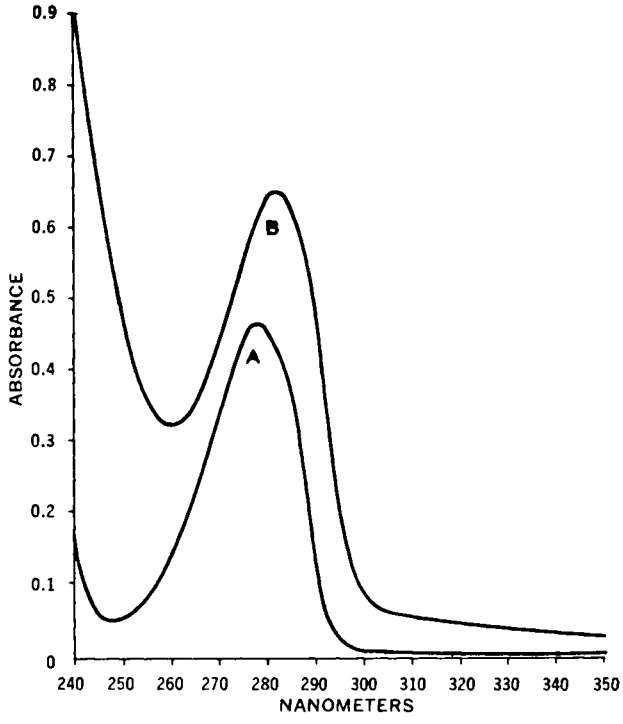

Figure 3—*UV spectra indicating the effect of isoproterenol hydrochloride decomposition products resulting from solutions stabilized with α-monothioglycerol as the antioxidant and assayed by the USP XVIII method. Key: A, isoproterenol hydrochloride, 200 mcg./ml.; and B, solution of 230 mcg./ml. isoproterenol hydrochloride reacted with 2 mg./ml. of α-monothioglycerol. This solution did not have any isoproterenol activity by the fluorometric method.*

In addition, isoproterenol formulations stabilized with either ascorbic acid or α-monothioglycerol were stored at elevated temperatures. These samples were analyzed by the fluorometric method and were shown to be completely devoid of any isoproterenol activity. The completely decomposed solution and another sample of isoproterenol were then assayed by the USP XVIII method (Fig. 3). It is obvious that the UV spectra of the intact isoproterenol hydrochloride and its degradation product in the presence of excess α-monothioglycerol are similar. It is also interesting to note that the absorbance due to this decomposition product is much higher at its maximum (about 278 nm.) when compared to the unchanged isoproterenol. Similar interferences were observed with isoproterenol solutions preserved and aged in the presence of ascorbic acid. Thus, the USP XVIII method or its modification, the bis-(2-ethylhexyl)phosphoric acid shakeout method (8), can be misleading if used to analyze solutions preserved with antioxidants other than sodium bisulfite. The reliable method in such instances is the fluorometric method, which is specific for the unchanged isoproterenol hydrochloride.

SUMMARY

The described fluorometric method is unique because of its applicability to the analysis of extremely dilute solutions of isoproterenol. The simplicity of the procedure lends itself to the assay of several samples at a time; with the official methods, it is difficult to carry out several determinations simultaneously. The fluorometric method is timesaving, whereas the USP XVIII method is lengthy and tedious. Moreover, it has been shown that the fluorometric method is unique in that it does measure only the unchanged isoproterenol; decomposition products, when present, do not interfere even in extremely high concentrations. Oxidative degradation products, if present, interfere in the USP XVIII and the bis(2-ethylhexyl)phosphoric acid shakeout methods. These latter two methods were specifically developed with the assumption that isoproterenol sulfonic acid is the only decomposition product present in the formulations.

It has been shown that the fluorometric method is the method of choice to assay isoproterenol formulations, since this procedure is based only on the intact isoproterenol and other decomposition products, even if present in significant amounts, do not influence the final fluorescence. The described fluorometric method has the potential for automation and thus can be of immense value to the pharmaceutical industry to monitor routinely the stability of isoproterenol formulations.

Head-Space GLC Determination of Triethylamine in Pharmaceuticals

MARK A. LITCHMAN▲ and RONALD P. UPTON

Abstract □ A head-space GLC procedure is described for the quantitative determination of residual triethylamine in streptomycin sulfate and methacycline hydrochloride. This method is both rapid and accurate.

Keyphrases □ Streptomycin sulfate—head-space GLC analysis for residual triethylamine □ Methacycline hydrochloride—head-space GLC analysis for residual triethylamine □ Triethylamine residue in streptomycin sulfate and methacycline hydrochloride—head-space GLC analysis □ GLC, head-space—analysis, residual triethylamine in streptomycin sulfate and methacycline hydrochloride

Triethylamine has been determined qualitatively by GC (1–3). Umbreit *et al.* (4) decomposed aliphatic amine hydrochloride mixtures in the injection port of a gas chromatograph. They then analyzed 17–170 p.p.m. of each amine in the mixture. Pesez and Bartos (5) used derivatization and colorimetry to determine triethylamine at the 15-mcg. level. Kertes (6) used colorimetry to measure triethylamine at the 5% level. Derivative formation and TLC were employed by Baudot (7) at the 20-mcg. level. None of these methods involved the determination of triethylamine in pharmaceuticals.

This report describes a simple, rapid method for determining triethylamine in streptomycin sulfate[1] and in methacycline hydrochloride [4-(dimethylamino)-1,4,4*a*,5,5*a*,6,11,12*a* - octahydro - 3,5,10,12,12*a* - pentahydroxy - 6 - methylene - 1,11 - dioxo - 2 - naphthacenecarboxamide hydrochloride][1] to levels as low as 0.05%. The principle on which this method is based is that the head-space gas over a solution of a nonvolatile solute in a sealed container will contain amounts of any volatile substances present in the solution after equilibration at a constant temperature. The quantity of solvent vapors in the head-space gas will be proportional to the concentration of the solvents in the solution.

The method of Bassette *et al.* (8) was modified for this determination.

It has been shown that the fluorometric method is the method of choice to assay isoproterenol formulations, since this procedure is based only on the intact isoproterenol and other decomposition products, even if present in significant amounts, do not influence the final fluorescence. The described fluorometric method has the potential for automation and thus can be of immense value to the pharmaceutical industry to monitor routinely the stability of isoproterenol formulations.

Head-Space GLC Determination of Triethylamine in Pharmaceuticals

MARK A. LITCHMAN▲ and RONALD P. UPTON

Abstract □ A head-space GLC procedure is described for the quantitative determination of residual triethylamine in streptomycin sulfate and methacycline hydrochloride. This method is both rapid and accurate.

Keyphrases □ Streptomycin sulfate—head-space GLC analysis for residual triethylamine □ Methacycline hydrochloride—head-space GLC analysis for residual triethylamine □ Triethylamine residue in streptomycin sulfate and methacycline hydrochloride—head-space GLC analysis □ GLC, head-space—analysis, residual triethylamine in streptomycin sulfate and methacycline hydrochloride

Triethylamine has been determined qualitatively by GC (1–3). Umbreit *et al.* (4) decomposed aliphatic amine hydrochloride mixtures in the injection port of a gas chromatograph. They then analyzed 17–170 p.p.m. of each amine in the mixture. Pesez and Bartos (5) used derivatization and colorimetry to determine triethylamine at the 15-mcg. level. Kertes (6) used colorimetry to measure triethylamine at the 5% level. Derivative formation and TLC were employed by Baudot (7) at the 20-mcg. level. None of these methods involved the determination of triethylamine in pharmaceuticals.

3	4360	4055	93

Table V—Determination of Triethylamine Content of Replicate Weights of a Streptomycin Sulfate Sample

Sample Number	Triethylamine Content, %
1	0.354
2	0.352
3	0.371
4	0.367
5	0.365

temperature, 235°; detector temperature, 250°; carrier gas, nitrogen, 35 ml./min.; detector gas, hydrogen, 40 ml./min.; and air, 500 ml./min.

Calculations—The area of the triethylamine peak in the samples is compared to a standard curve[13] of micrograms triethylamine per vial *versus* area found. The following formula is then used:

$$\frac{\text{micrograms triethylamine from standard curve}}{\text{weight of sample, mcg.}} \times 100 = \text{percent triethylamine} \quad \text{(Eq. 1)}$$

RESULTS AND DISCUSSION

The levels of triethylamine determined were from 0.15 to 0.36% for production samples of streptomycin sulfate, and they were from 0.06 to 0.13% for production samples of methacycline hydrochloride.

The recoveries of spikes of triethylamine in streptomycin sulfate and methacycline hydrochloride are given in Tables III and IV, respectively. The values ranged from 94.3 to 98.3% for streptomycin sulfate and from 93.0 to 111% for methacycline hydrochloride.

Table VI—Determination of Triethylamine Content of Replicate Weights of a Methacycline Hydrochloride Sample

Sample Number	Triethylamine Content, %
1	0.117
2	0.119
3	0.125
4	0.123
5	0.120

Five replicate weighings of a sample of streptomycin sulfate and methacycline hydrochloride were made, and the triethylamine content was determined (Tables V and VI). The data indicate a precision of 2 and 5%, respectively.

Examples of chromatograms for samples of streptomycin sulfate and methacycline hydrochloride are shown in Figs. 2 and 3, respectively.

The head-space method has been found to be a simple, direct, and precise method for trace volatiles component analysis. This method is currently being applied to other compounds.

[13] An example of a typical triethylamine standard curve is given in Fig. 1.

Use of Circular Dichroism in Analysis of Mixtures of Tetracycline and 4-Epitetracycline and Its Application to Assay of Commercial Products

ROBERT F. MILLER*, THEODORE D. SOKOLOSKI▲, LESTER A. MITSCHER, ANTHONY C. BONACCI†, and BETTY-ANN HOENER

Abstract □ Mixtures of tetracycline and 4-epitetracycline were assayed utilizing the large difference in their circular dichroism spectra at 262 nm. The assay was evaluated using synthetic mixtures and applied to the analysis of commercial tetracycline hydrochloride capsules. The results obtained with the newly developed procedure compare favorably with a published spectrophotometric method. In comparison with other techniques, the proposed method has several advantages. It is specific in that it permits differentiation between tetracycline and its 4-epimer, permitting calculation of the actual level of each epimer. It is accurate and precise, having an average error of 2% for tetracycline detection and 3.3% for 4-epitetracycline. It involves a simple procedure that requires no prior separation of degradation products under usual use conditions. Furthermore, it is very rapid, requiring only the experimental measurements of ellipticity at 262 nm. and absorbance at 356 nm. The disadvantages of the assay are its inability to determine analytically the content of anhydrotetracyclines and the possible interference of these materials if they are present in large amounts. However, levels of 10% anhydrotetracyclines affect the assay for tetracycline by only 1%. In the analysis of eight commercial products, the tetracycline content varied from 92 to 111% of the labeled amount and 4-epitetracycline was present in amounts of 3–17%. When compared with a spectrophotometric assay that required prior separation of anhydro compounds, the method introduced here gave the same analytical results for tetracycline content in the various products.

Keyphrases □ Tetracycline–epitetracycline mixtures—analysis by circular dichroism, determination in commercial products, compared with spectrophotometric method □ Epitetracycline–tetracycline mixtures—analysis by circular dichroism, determination in commercial products, compared with spectrophotometric method □ Degradation products—circular dichroism analysis of tetracycline–epitetracycline mixtures, applied to commercial products □ Circular dichroism—used to analyze tetracycline–epitetracycline mixtures, applied to commercial products

Tetracyclines may degrade through at least four possible mechanisms: epimerization, dehydration, hydrolysis, and oxidation. The first two mechanisms are the most commonly encountered reactions, so their degradation products are of specific interest in this study. Epimerization at carbon-4 leads to an inactive and nontoxic drug form (1). The kinetics of this reaction were studied by several workers (2, 3), showing that epimerization follows a reversible first-order process occurring most rapidly between pH 3 and 5. Dehydration and aromatization of the C-ring of tetracycline lead to anhydro derivatives at low pH. Anhydrotetracycline appears to be inactive *in vivo*, but its 4-epimer has been implicated in the toxic effects following use of outdated tetracycline products (4). The potential severity of this hazard provided the impetus to develop practical analytical procedures to detect and quantify both inactive and toxic tetracycline derivatives.

Titrimetric, polarographic, chromatographic, spectral, and microbiological methods have been used to analyze the tetracyclines. The latter three techniques seem to have received the most attention. The most widely used assay is the official microbiological method (5, 6). The disadvantages inherent in this method are that it has an accuracy of ±15% (7) and it is of limited specificity since several tetracycline-like materials have biological activity. Furthermore, the assay is carried out under conditions where some *in situ* epimerization is possible (pH 4.5 and incubation at 32–35° for 3–4 hr.). Among the several spectral methods used, absorbance ratios at two wavelengths have received the most attention. McCormick *et al.* (8) introduced an absorbance ratio method for tetracycline and 4-epitetracycline mixtures where ratios at 254 and 267 nm. are utilized. The sensitivity of the method is expected to be low, since the absorbance ratios range from 0.86 for tetracycline to 1.07 for epitetracycline. Because anhydrotetracycline and 4-epianhydrotetracycline absorb strongly in the 250–275-nm. range, the absorbance ratio technique by itself is not useful for samples containing these decomposition products. Pernarowski *et al.* (9) used an absorbance ratio at 357 and 391 nm. to detect tetracycline in the presence of anhydrotetracycline and epianhydrotetracycline. The assay, however, does not distinguish between epimers and essentially measures total content of tetracycline and epitetracycline when epitetracycline is present, as it usually is.

The number and variety of chromatographic methods applied to the analysis of tetracyclines probably exceed those of any other general assay method investigated. The inadequate and inconsistent recovery of tetracycline and degradation products by paper chromatography (10) is improved by using column chromatography. Griffiths (11), for example, made use of a column[1] that provided reproducibility but lacked specificity; tetracycline and epitetracycline elute in one fraction and anhydrotetracycline and epianhydrotetracycline elute in another. Ascione *et al.* (7, 12) reported both column chromatographic and TLC procedures for tetracyclines. Although these methods provide separation of tetracycline and its degradation products, detailed requirements for column preparation and repeated plate development in the TLC method make the techniques tedious. An automated procedure was recently introduced based on this technique (13), but it does not provide separate analysis for decomposition products. The procedure reported by Fike and Brake (14) does apparently separate and analyze degradation products. TLC separation followed by a conversion to anhydrotetracyclines serves as the basis for

[1] Sephadex G-25.

additional methods of analysis of mixtures of tetracyclines and their degradation products (15, 16). The methods appear useful for assay of commercial samples, but success requires strict attention to procedural detail (17) and they are unsuited for routine analysis of large numbers of samples.

In studies involving the solution conformation and sites of metal-ion binding of tetracycline derivatives (18–20), note was made of the large difference in the circular dichroism spectra of acidic solutions of tetracycline and epitetracycline at 262 nm. It appeared that this large difference could be used to analyze tetracycline in the presence of epitetracycline. The approach seemed feasible because circular dichroism measurements are rapid and relatively sensitive and require small samples; moreover, they are selective for tetracycline and epitetracycline. Anticipating that such an approach would offer advantages over existing techniques and because circular dichroism has yet to realize its potential for analysis of natural product mixtures, we developed and evaluated an analytical method to determine tetracycline content in the presence of its degradation products. Eight different brands of tetracycline hydrochloride capsules were analyzed by both circular dichroism and traditional UV chromatographic methods to determine the practicality of the method and the significance and incidence of tetracycline epimerization in finished products. All of these products had passed FDA batch certification but were intercepted at the point of dispensing. Therefore, they are representative of what the patient is receiving rather than what the pharmacist receives.

EXPERIMENTAL[2]

The ellipticity and absorbance of pure tetracycline, epitetracycline, anhydrotetracycline, and epianhydrotetracycline were determined as a function of concentration at 262 nm. (ellipticity, circular dichroism), and 356, 267, and 254 nm. (absorbances, UV). UV scans were made between 450 and 240 nm. All solutions were made in 0.03 *N* HCl where epimerization and dehydration are minimized (1). The concentration range for circular dichroism measurements was generally 0.001–0.005% and, when necessary, from 2 to 5 times more dilute for UV measurements.

Known mixtures of tetracycline and epitetracycline were made where the fraction of tetracycline ranged from 0.2 to 0.9. The total concentration of the mixture was about 9×10^{-5} *M* in the circular dichroism measurements and, when necessary, from 2 to 5 times more dilute to obtain measurable UV absorbances. The blank in all cases was 0.03 *N* HCl.

The commercial samples were analyzed in the following manner. The contents of 10 capsules from each product were pooled. The samples were then analyzed for total anhydrotetracycline content using a method based on the FDA screening procedure[3]. An amount of the pooled sample containing 250 mg. of tetracycline was mixed with 50 ml. of 0.15 *N* HCl for 5 min. The mixture was then vacuum filtered, the residue was washed with water, and the filtrate was diluted to 250 ml. with water. The resulting solution contained 0.1% tetracycline in 0.03 *N* HCl. This stock solution was then used to prepare 0.04 and 0.001% solutions. The absorbance of the 0.04% solution was read at 430 nm. and the 0.001% solution at 356 nm. These two measurements were used in the calculation of total anhydro content. For application to the new method of analysis, the stock solution was diluted to 0.005% and its circular dichroism spectrum was measured. The absorbance of a 0.0014% solution (1:4 dilution of the circular dichroism solution) was measured at 356 nm.

For comparative purposes, a spectrophotometric assay was carried out on three sample products. In this method, it is necessary to separate anhydrotetracyclines from the mixture. The chromatographic technique reported by Griffiths (11) was used for this purpose. A resin column[1] preswollen in 0.03 *N* HCl was used. A portion of commercial sample containing 200 mg. of tetracycline was diluted to 10 ml. with 0.03 *N* HCl and shaken in a glass-stoppered centrifuge tube for 5 min. The suspension was centrifuged, and 0.5 ml. of the supernate was applied to the column. The column was eluted with 0.03 *N* HCl, and 5-ml. fractions were automatically collected. Fractionation was followed by measuring absorbance at 273 nm. Tubes containing the tetracycline–epitetracycline fraction (approximately the first 70–80 ml. eluted) were carefully combined and diluted to 250 ml. with 0.03 *N* HCl. The absorbance of this solution was measured at 267 and 254 nm. for spectrophotometric analysis of tetracycline and epitetracycline.

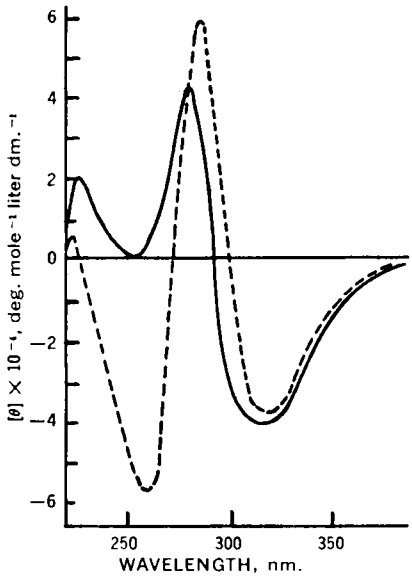

Figure 1—*Molar ellipticity* [θ] *of tetracycline hydrochloride* (- - -) *and 4-epitetracycline ammonium salt* (— —) *as a function of wavelength in 0.03* N *HCl.*

RESULTS AND DISCUSSION

The circular dichroism curves of tetracycline and epitetracycline (Fig. 1) show that there is a large difference in ellipticity between the two epimers at 262 nm. At this wavelength a mixture of the two compounds would give an ellipticity that is a sum of the ellipticities for each species:

$$\psi_{MIX} = k_{TC}C_{TC} + k_{ETC}C_{ETC} \qquad \text{(Eq. 1)}$$

where ψ_{MIX} is the observed ellipticity; and k_{TC} and k_{ETC} are the proportionality constants defining the linear relation between ellipticity and molar concentration, C_{TC} and C_{ETC}, for tetracycline and epitetracycline, respectively, where the path length of the cell

[1] Circular dichroism spectra were determined using a Durrum-Jasco ORD/UV-5 instrument with the Sprowl Scientific SS 20-2 circular dichroism modification. Samples were run in a 1-cm. path length cell at ambient temperature (29°). UV and visible light absorption were determined in a Cary model 15 or a Gilford model 240 spectrophotometer at ambient temperature. A Warner-Chilcott model 1205 D3 automatic fraction collector was used in conjunction with column chromatographic procedures.

The following materials were donated by Lederle Laboratories and used as standards: tetracycline hydrochloride (CL-13554; 4574B-1296), 4-epitetracycline ammonium salt (CL-16956; 705B-133-9), anhydrotetracycline hydrochloride (CL-17901; 8412 B97-A), and 4-epianhydrotetracycline (CL; 27212-7117B-93-5).

The several samples of commercial tetracycline capsules were acquired from the active stock of various retail and hospital pharmacies. They were collected at random without conscious regard for expiration date; however, none of the samples had expired.

Sephadex G-25, Medium (Pharmacia), was used in the chromatographic procedure. All other chemicals were of analytical grade quality.

is 1 cm. Although it is possible to use a second equation involving ellipticity at another wavelength to calculate the content of tetracycline and epitetracycline in a sample, the greater precision that can be achieved (Table I) by using absorbance measurements to determine total tetracyclines led to the use of a second equation based on UV analysis. As discussed later, a UV analysis of a sample should be made to determine the content of anhydrotetracyclines since they can interfere with the precision of the circular dichroism measurements if they are present in significant amounts. Absorbance at 356 nm., where both tetracycline and epitetracycline show an absorption peak, is proportional to the total tetracycline content. The solutions used to measure Ψ are usually too concentrated for direct UV measurement; hence, they are diluted by a factor, n, prior to analysis. Thus, the absorbance of the solution used in determining ψ is related to the molar concentration, C, of tetracycline and epitetracycline by:

$$nA_{MIX} = a_{TC}C_{TC} + a_{ETC}C_{ETC} \qquad \text{(Eq. 2)}$$

where nA_{MIX} is the absorbance of the circular dichroism solution, diluted n-fold, using a cell with a 1-cm. path length, and a_{TC} and a_{ETC} are the molar absorbances for each species. Applying Cramer's rule (21) to Eqs. 1 and 2 gives:

$$C_{TC} = \frac{a_{ETC}\psi_{MIX} - nA_{MIX}k_{ETC}}{k_{TC}a_{ETC} - k_{ETC}a_{TC}} \qquad \text{(Eq. 3)}$$

and:

$$C_{ETC} = \frac{nA_{MIX}k_{TC} - a_{TC}\psi_{MIX}}{k_{TC}a_{ETC} - k_{ETC}a_{TC}} \qquad \text{(Eq. 4)}$$

The various constants involved in Eqs. 3 and 4 were determined from known concentrations of pure materials and are listed in Table I. In this study, we found that the constants generated for tetracycline may depend on the source of tetracycline and vary slightly from time to time; thus, they should be verified periodically to ensure the highest accuracy. Substitution of the constants from Table I into Eqs. 3 and 4 leads to:

$$C_{TC} = (103.7\psi_{MIX} - A_{MIX})(-1.340 \times 10^{-6}) \qquad \text{(Eq. 5)}$$

$$C_{ETC} = (-A_{MIX} - 25.0\psi_{MIX})(-5.824 \times 10^{-6}) \qquad \text{(Eq. 6)}$$

Analysis of known mixtures of tetracycline and epitetracycline using Eqs. 5 and 6 gave the results listed in Table II. Recovery of tetracycline averaged 101.6% with an average error of 2.0%, while epitetracycline gave a recovery of 98.7% with an average error of 3.3%. A comparison of these results with a spectrophotometric assay was made. Absorbance of these same mixtures at 267 and 254 nm. was used and the fraction of tetracycline, F_{TC}, present was calculated using the mathematical form of the equation used by Pernarowski *et al.* (22):

$$F_{TC} = \frac{a_{ETC}^{254}Q_0 - a_{ETC}^{267}}{(a_{TC}^{267} - a_{ETC}^{267}) - (a_{TC}^{254} - a_{ETC}^{254})Q_0} \qquad \text{(Eq. 7)}$$

where Q_0 is the absorbance ratio A_{267}/A_{254}; and a_{TC} and a_{ETC} are the absorbances of tetracycline and epitetracycline, respectively, at wavelengths designated by the superscripts. The values for these constants are given in Table I and their substitution into Eq. 7 gives:

$$F_{TC} = \frac{15{,}467Q_0 - 14{,}477}{3890 - 104Q_0} \qquad \text{(Eq. 8)}$$

By using the mixtures listed in Table II, the fraction of tetracycline in each was determined using Eq. 8. The results of the analysis (Table III) show that an average recovery of 102.2% with an average error of 3.4% was obtained. This compares favorably with the results using the circular dichroism method.

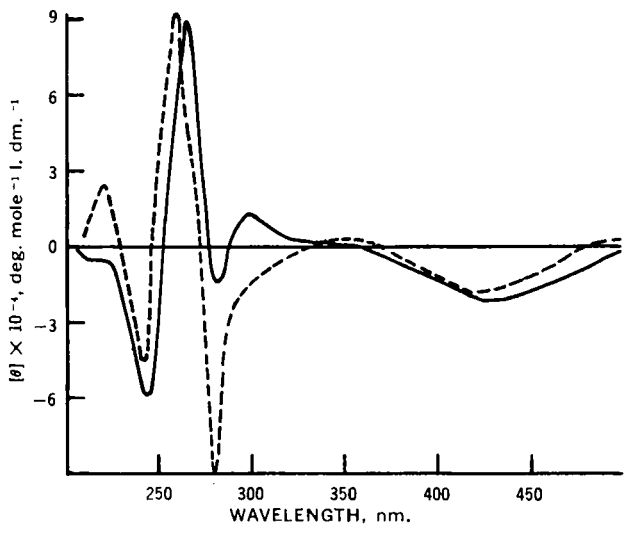

Figure 2—*Molar ellipticity [θ] of anhydrotetracycline hydrochloride (——) and 4-epianhydrotetracycline (- - -) as a function of wavelength in 0.03* N *HCl.*

Eight commercial samples of tetracycline hydrochloride capsules were then analyzed using the circular dichroism method *without* prior separation of anhydro compounds. The circular dichroism spectra of epianhydrotetracycline and anhydrotetracycline (Fig. 2) show that these compounds may interfere with the circular dichroism assay if present in significant amounts. When using the circular dichroism and UV constants for epianhydrotetracycline and anhydrotetracycline listed in Table I, it is possible to calculate the error that would be introduced in this assay if a solution of 1×10^{-4} *M* tetracyclines contained 90% tetracycline and 10% anhydrotetracycline. [Pernarowski *et al.* (9) reported that the maximum amount of anhydrotetracycline present in six commercial samples tested by them was 10%; in the present study the maximum percentage of anhydrotetracyclines in eight samples was 5.3%.] The theoretical ellipticity that would be observed at 262 nm. would be −0.0513°, and the absorbance of the solution at 356 nm. would be 1.314 for the tetracycline–anhydrotetracycline mixture. Using the new assay, Eqs. 5 and 6 would predict 88.9% tetracycline and 1.69% epitetracycline (rather than 90% tetracycline and 0% epitetracycline). Thus, the method would be low with respect to tetracycline recovery and predict the presence of a small amount of epitetracycline even though none were present. Analysis of the eight commercial products studied showed that the products contained from 2 to 5% anhydro species. This amount would not appreciably affect the tetracycline and epitetracycline calculation. Determination of the anhydro content was based on the FDA screening procedure using the formula:

$$\text{percent anhydrotetracyclines} = \frac{(A_{430} - A_{356} \times 0.0019)100}{180} \qquad \text{(Eq. 9)}$$

where A_{430} is the absorbance of the 0.04% solution at 430 nm. times 25, A_{356} is the absorbance of the 0.001% solution at 356 nm. times 1000, 0.0019 is the absorbance ratio (430 nm./356 nm.) for tetracycline, and 180 is the absorptivity (1%, 1 cm.) of anhydrotetracycline at 430 nm. The first column of Table IV lists the total percent of anhydrotetracyclines present in each product as determined by Eq. 9. Columns 2 and 3 (Table IV) give the percentage of tetracycline and epitetracycline in each product using the new assay. All samples contain tetracycline within accepted limits but also contain amounts of epitetracycline which vary from 3 to 17%. The values were not corrected for the small amount of anhydrotetracycline present. Column 5 of Table IV gives the fraction of tetracycline hydrochloride determined by the absorbance ratio assay (Eq. 7) where anhydrotetracyclines were first removed by resin column chromatography. The fraction of tetracycline present determined by the absorbance ratio method compares quite well with that obtained by the new technique (Table IV, Column 6).

Since limits have not been set on permissible levels of epitetracycline in commercial products, it is difficult to discuss the significance of the amounts found. Perhaps the most significant result of this analysis of commercial samples is the prevalence of capsule overfilling (in seven of eight products). Sample 8 would pass certification, showing 95–97% tetracycline, but it constitutes a poorer grade of drug because of the amounts of epitetracycline and anhydro compounds present. There is no specified upper limit on the amount of tetracycline that may be present in the standards set forth in the "Code of Federal Regulations," nor is any limit set for anhydrotetracycline and epianhydrotetracycline.

When Pernarowski *et al.* (9) examined six commercial tetracycline products, using absorbance ratios at 357 and 391 nm., they reported the samples as having 90–94% of the labeled tetracycline content, the remainder being only anhydro compounds as seen by TLC. Results of the present study indicate small amounts of anhydrotetracyclines and from 3 to 17% epitetracycline. There is no reason to expect that the samples used previously (9) were the same as those used in the present study, nor is it reasonable to expect large errors in epitetracycline content in the present method even in the presence of 5% anhydrotetracycline.

To determine further the accuracy with which epitetracycline could reasonably be estimated when present at low concentrations, eight known mixtures containing 4–17% epitetracycline in the presence of tetracycline were analyzed using the circular dichroism method and Eqs. 5 and 6. In this study, the concentration of epitetracycline in the samples varies from 3.82×10^{-6} to 1.58×10^{-5} *M* while the tetracycline was held constant at approximately 8×10^{-5} *M* (Table V). When the absolute difference between the percent found and the percent added is taken, the average error in detecting percent tetracycline is found to be 1.5%. Similar analyses of the results show that the percent of epitetracycline relative to the percent added was low by an average of 2.9% in all mixtures studied. Be-

Table III—Results of Known Mixtures of Tetracycline and Epitetracycline by the Spectrophotometric Method

95.4	4.6	96.0	1.3

[a] Calculated as: C_{TC} added or C_{ETC} added/C_{TC} added + C_{ETC} added × 100. [b] Calculated as: C_{TC} found or C_{ETC} found/C_{TC} added + C_{ETC} added × 100.

cause of the small amounts of epitetracycline present and the concomitant small changes in the ellipticity of mixtures of it and tetracycline, the assay for epitetracycline was predictably subject to error, but the error involved would not explain the amounts of epitetracycline found in commercial products in this study.

It appears that no presently existing assay will by itself completely quantify a mixture of tetracycline, epitetracycline, anhydrotetracycline, and epianhydrotetracycline. Absorbance ratios at 357 and 391 nm. permit the calculation of the fraction of total tetracycline (tetracycline and epitetracycline). Absorbance ratios at 254 and 267 nm. will predict tetracycline content providing anhydro compounds are not present. The new technique will predict tetracycline and epitetracycline levels if large amounts of anhydrotetracyclines are not present. Thus, it would appear that a recommended procedure for the analysis of tetracycline products would be to determine the total anhydro content by the FDA screening method. If more than 5% anhydrotetracyclines are present, the anhydro compounds should be separated by the described resin chromatography and the tetracycline–epitetracycline fraction should be analyzed using this method. Alternatively, mathematical corrections for the increase in epitetracycline can be made without prior chromatographic separation.

Application of Ion-Pairing to Separation of Selected Sulfonamides by Partition Chromatography

BOBBY R. RADER

Abstract □ Methods are presented for the separation and determination of individual sulfonamides in mixtures. These procedures are based on the ion-pair formation of the sulfonamides with the tetrabutylammonium ion, followed by separation on partition chromatographic columns. One procedure separates the trisulfapyrimidines (sulfamethazine, sulfamerazine, and sulfadiazine) and a second procedure separates sulfamethizole, sulfadiazine, and phenazopyridine hydrochloride. The separated sulfonamides are then determined by UV spectrophotometry and phenazopyridine hydrochloride by visible spectrophotometry. Ten commercial and five synthetic preparations were assayed by the procedures. Recoveries from the synthetic preparations ranged from 99 to 101%.

Keyphrases □ Sulfonamide mixtures—application of ion-pairing to separation by partition chromatography, commercial samples □ Ion-pairs—used in analysis of mixtures of sulfonamides, partition chromatography, commercial samples □ Tetrabutylammonium ion—ion-pair formation with sulfonamides, separation by partition chromatography, commercial samples □ Partition chromatography—use of ion-pairs for separation of sulfonamide mixtures, commercial samples

Sulfonamide combinations are found in a number of pharmaceutical preparations. Quantitation of the individual sulfonamides in these mixtures presents a difficult analytical problem. In the USP XVIII and NF XIII procedures (1, 2), the sulfonamides are separated by paper chromatography and determined colorimetrically by the Bratton–Marshall reaction. These procedures are time consuming and require an experienced analyst to obtain consistent results.

Other procedures used for the separation of sulfonamides include TLC (3, 4), partition chromatography (5), and GLC (6). Banes and Riggleman (7) summarized problems encountered in most of these techniques. They presented a procedure for the trisulfapyrimidines in which total sulfonamides are determined colorimetrically by the Bratton–Marshall procedure. Sulfadiazine is quantitated by its specific reaction with thiobarbituric acid, and sulfamethazine is separated by column partition chromatography and determined by UV spectroscopy.

The use of partition chromatography to separate sulfonamides has been hindered by the low solubility of the sulfonamides in many water-immiscible solvents. Solubility of the sulfonamides in chloroform and methylene chloride can be greatly increased by formation of ion-pairs with the tetrabutylammonium ion. Several workers (8–10) discussed the use of ion-pairs with quaternary ammonium ions in the extraction of acidic compounds. Ion-pair extraction in conjunction with partition chromatography was presented previously by Doyle and Levine (11, 12).

In the present report, methods are given for the analysis of two drug mixtures which are commonly encountered in this laboratory. One procedure (Method I) separates sulfamethazine, sulfamerazine, and sulfadiazine. Another procedure (Method II) separates sulfamethizole, sulfadiazine, and phenazopyridine. In both procedures, the sulfonamides are eluted from the partition column as ion-pairs with tetrabutylammonium ions. Separated sulfonamides are determined by UV spectrophotometry, and phenazopyridine hydrochloride is determined by visible spectrophotometry. Ten commercial and five synthetic drug preparations were assayed.

EXPERIMENTAL

Apparatus—A recording UV–visible spectrophotometer with 1-cm. cells was used.

Solvents—Chloroform, ether, hexane, and methylene chloride (all reagent grade) were used. Wash each solvent twice with equal volumes of water. Prepare 50% chloroform in hexane by mixing 500 ml. of chloroform with 500 ml. of hexane, and filter through filter paper.

Ten Percent Tetrabutylammonium Hydroxide in Water[1] (Reagent A)—Pipet 3.0 ml. of the solution into a flask and add about 20 ml. of water. Titrate the solution with 0.1 *N* HCl, using methyl red indicator. One milliliter of 0.1 *N* acid = 25.95 mg. of tetrabutylammonium hydroxide.

Sodium Hydroxide–Tetrabutylammonium Hydroxide Solution (Reagent B)—Pipet (with a 10-ml. measuring pipet) an aliquot of Reagent A, equivalent to 800 mg. of tetrabutylammonium hydroxide, into a 25-ml. graduated cylinder. Add 10.0 ml. of 0.2 *N* NaOH to the cylinder from a pipet. Dilute to 20.0 ml. with water and mix.

Standard Preparation—USP reference standards or NF grade standards of sulfadiazine, sulfamerazine, sulfamethazine, sulfamethizole, and phenazopyridine hydrochloride were used. For each sulfonamide to be assayed, prepare a standard solution of 1 mg./ml. in 1% ammonia in methanol; pipet exactly 1.0 ml. of this solution into a 100-ml. volumetric flask and dilute to volume with 0.12 *N* HCl. Prepare a phenazopyridine hydrochloride standard solution containing 5 mcg./ml. in 1% ammonia in ethanol.

Sample Preparations—*Tablets*—Weigh a portion of finely ground sample containing about 100 mg. of each sulfonamide and transfer with methanol to a 100-ml. volumetric flask containing 1 ml. of ammonium hydroxide. Shake occasionally during 15 min., dilute to volume with methanol, and mix.

Suspensions—With a "to contain" pipet, transfer a quantity of sample containing about 100 mg. of each sulfonamide to a 100-ml. volumetric flask containing 1 ml. of ammonium hydroxide. Add about 60 ml. of methanol and shake occasionally during 15 min., dilute to volume with methanol, and mix.

Method I: Sulfamethazine, Sulfamerazine, and Sulfadiazine—Mix 5.0 g. of diatomaceous earth[2] with 3.0 ml. of Reagent B, transfer to a chromatographic column[3] in two equal portions, and tamp after each portion. Pipet 3.00 ml. of the sample solution into a 100-ml. beaker and evaporate to dryness on a steam bath, using a gentle current of air. Pipet 1.0 ml. of Reagent A into the beaker and dissolve the residue. Add 2.0 g. of diatomaceous earth, mix until uniform, quantitatively transfer to the column, and tamp. Wipe the beaker, tamping rod, and spatula with a small piece of glass wool, add it to the column, and tamp.

Chloroform	100	100	95	90	85
Methylene chloride	100	100	100	100	90

[a] One milligram of sulfamethazine was mixed with 2 g. of diatomaceous earth and 1 ml. of 4% tetrabutylammonium hydroxide in the respective sodium hydroxide solutions and packed in the column. [b] Dashes indicate no detectable drug in 100 ml. of eluate.

Table II—Effect of Varying Sodium Hydroxide Concentration on Column Chromatographic Elution of Sulfadiazine by Various Solvents[a]

Solvent	Percent Eluted with 100 ml. of Solvent				
	1 *N* NaOH	0.5 *N* NaOH	0.25 *N* NaOH	0.1 *N* NaOH	0.05 *N* NaOH
Ether	—[b]	—	—	—	—
10% Chloroform in hexane	—	—	—	—	—
30% Chloroform in hexane	—	—	—	—	—
50% Chloroform in hexane	85	65	35	30	25
Chloroform	100	100	100	100	100
Methylene chloride	100	100	100	100	100

[a] One milligram of sulfadiazine was mixed with 2 g. of diatomaceous earth and 1 ml. of 4% tetrabutylammonium hydroxide in the respective sodium hydroxide solutions and packed in the column. [b] Dashes indicate no detectable drug in 100 ml. of eluate.

Wash the column with 50 ml. of 50% chloroform in hexane and discard the eluate. Place a 400-ml. beaker under the column and elute with an additional 250 ml. of 50% chloroform in hexane. This fraction contains sulfamethazine. Replace the receiver with a 600-ml. beaker and elute the column with 400 ml. of 50% chloroform in hexane. This fraction contains sulfamerazine.

Place a 250-ml. beaker under the column and elute with 100 ml. of methylene chloride. This fraction contains sulfadiazine.

Evaporate each fraction on a steam bath with an air stream. Dissolve the residues in 2 ml. of methanol, add 40 ml. of 0.12 *N* HCl, mix, transfer to separate 100-ml. volumetric flasks, and dilute to volume with 0.12 *N* HCl. Pipet a 15-ml. aliquot of each solution into separate 50-ml. volumetric flasks and dilute to volume with 0.12 *N* HCl. Record the UV spectrum from 400 to 220 nm., using 0.12 *N* HCl as the reference. Draw the baseline as a continuation of the curve between 400 and 360 nm., determine the corrected absorbance at the wavelength of maximum absorbance at about 242 nm., and calculate by comparison to standards.

Method II: Sulfadiazine, Sulfamethizole, and Phenazopyridine Hydrochloride—Mix 2.0 g. of diatomaceous earth with 1.0 ml. of Reagent B, transfer to the chromatographic column, and tamp. Pipet 3.00 ml. of sample solution into a 100-ml. beaker and evaporate to dryness on a steam bath, using a gentle current of air. Pipet 1.0 ml. of Reagent B into the beaker. Add 2.0 g. of diatomaceous earth, mix until uniform, quantitatively transfer to the column, and tamp. Wipe the beaker, tamping rod, and spatula with a small piece of glass wool, add it to the column, and tamp.

Place a 250-ml. beaker under the column. Wash the 100-ml. beaker with three 5-ml. portions of ether, adding each portion to the column. Elute the column with three 20-ml. portions of ether, allowing each to pass into the column before adding the next portion. Rinse the column tip with methanol. This fraction contains phenazopyridine. Replace the receiver with a second 250-ml. beaker and elute the column with 150 ml. of 50% chloroform in hexane. Rinse the column tip with methanol. This fraction contains sulfamethizole. Replace the receiver with a third 250-ml. beaker and elute the column with 100 ml. of methylene chloride. Rinse the tip with methanol. This fraction contains sulfadiazine.

For phenazopyridine hydrochloride, evaporate the first eluate on the steam bath with an air stream. Dissolve the residue in 40 ml. of ethanol, transfer the solution quantitatively to a 100-ml. volumetric flask containing 1 ml. of ammonium hydroxide, and dilute to volume with ethanol. Pipet a 15-ml. aliquot into a 50-ml. volumetric flask and dilute to volume with ethanol. Read the absorbance at 420 nm., using alcohol as the reference, and calculate by comparison to a standard.

For sulfamethizole and sulfadiazine, evaporate the respective eluates on a steam bath with an air stream. Dissolve the residues in 2 ml. of methanol, add 40 ml. of 0.12 *N* HCl, mix, transfer to separate 100-ml. volumetric flasks, and dilute to volume with 0.12 *N* HCl. Pipet a 15-ml. aliquot of each solution into separate 50-ml. volumetric flasks and dilute to volume with 0.12 *N* HCl. Record the UV spectrum from 400 to 220 nm., using 0.12 *N* HCl as the reference. Draw a baseline as a continuation of the curve between 400 and 360 nm. for sulfadiazine and between 360 and 340 nm. for sulfamethizole. Determine the corrected absorbance at the wavelength of maximum absorbance, about 242 nm. for sulfadiazine and about 268 nm. for sulfamethizole, and calculate by comparison to standards.

DISCUSSION

The extraction of the ion-pairs formed by tetrabutylammonium ions and sulfonamides from partition columns is controlled by the nature of the organic mobile solvent. Solvents with acidic protons, such as chloroform and methylene chloride, interact with the ion-pair to increase the extracting power of the organic phase. The effect of the concentration of such compounds on the partitioning of ion-pairs was studied by Higuchi and coworkers (13–15). They postulated a solvent cage of approximately two to five molecules of chloroform around the extracted ion-pair.

In the present study, the sulfonamides were readily extracted by chloroform and methylene chloride as ion-pairs with tetrabutylammonium ions from a basic partition column. The elution and separation of the ion-pairs from the partition column are influenced by the concentration of sodium hydroxide and tetrabutylammonium hydroxide in the column and the concentration of the chloroform or methylene chloride in the eluting solvent.

As the tetrabutylammonium hydroxide concentration is increased, the sulfonamides elute more rapidly. A tetrabutylammonium hydroxide concentration of about 4% was found to give the best elution times and separations for the sulfonamides studied.

Tables I and II illustrate the effect of the sodium hydroxide concentration and the solvent composition on the elution rate for the

Table III—Analysis of Sulfadiazine, Sulfamethazine, and Sulfamerazine in Commercial and Synthetic Drug Preparations by Method I

Sample	Percent of Declared			Total Sulfonamides (Bratton-Marshall), %
	Sulfamethazine	Sulfamerazine	Sulfadiazine	
Tablets 1	98.6	97.5	96.8	98.1
Tablets 2	103.0	101.3	101.0	99.6
Tablets 3	102.7	99.3	101.3	101.2

[a] Dashes indicate that these components are not present in these mixtures.

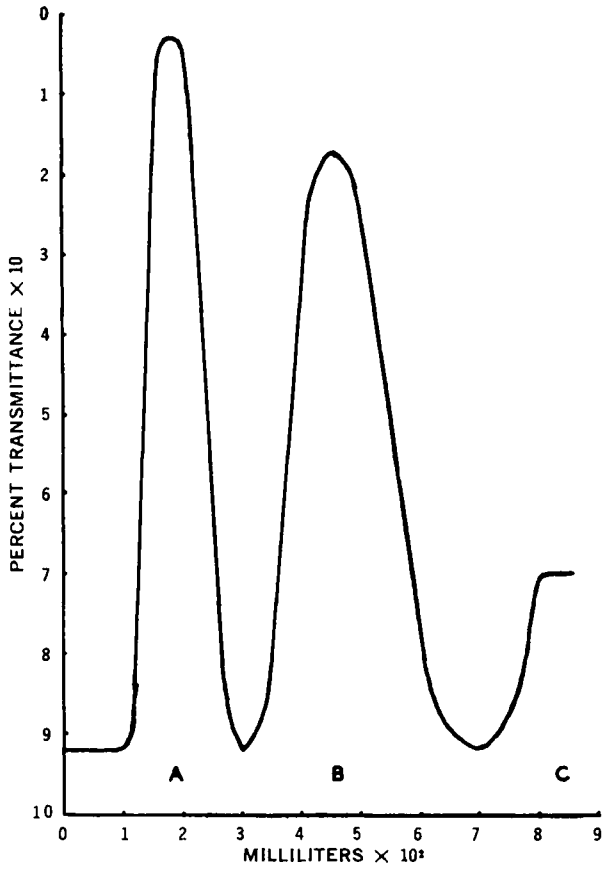

Figure 1—*Separation of sulfamethazine (A), sulfamerazine (B), and sulfadiazine (C) obtained by eluting the partition column with 50% chloroform–hexane.*

sulfamethazine and sulfadiazine ion-pairs. The increase in elution rate for the sodium hydroxide concentration range (0.05–0.2 *N*) is slight. However, the sodium hydroxide decreases the tailing of the eluting ion-pairs, resulting in a more complete separation.

In Method I, the sample is placed in a 10% tetrabutylammonium hydroxide layer. This enables the sulfonamides to reach the 0.1 *N* NaOH–tetrabutylammonium hydroxide separation layer in a narrower band and improves the separation. Figure 1 demonstrates the separation of the sulfamethazine, sulfamerazine, and sulfadiazine obtained by Method I. Also, methylene chloride is preferred to chloroform for the elution of sulfadiazine since there is less interference in the UV region.

RESULTS

Six commercial preparations of the trisulfapyrimidines and one sample containing sulfamerazine and sulfadiazine were assayed by Method I. Three commercial preparations of sulfamethizole, sulfadiazine, and phenazopyridine hydrochloride were assayed by Method II. Synthetic samples of these products were also analyzed. The results are reported in Tables III and IV. In addition, total sulfonamide content in the same commercial preparations was determined by the Bratton–Marshall procedure (7), with the results presented in Tables III and IV.

Synthetic 2	98.7	100.8	98.8	

SUMMARY

This investigation of the separation of four sulfonamides by ion-pair partition chromatography showed that the proposed procedures were rapid and gave good recoveries (99–101%). The analytical technique might well be extrapolated to include related acidic compounds.

Examination of Quinidine and Quinine and Their Pharmaceutical Preparations

EDWARD SMITH[▲], SUSAN BARKAN, BRUCE ROSS, MILLARD MAIENTHAL, and JOSEPH LEVINE

Abstract □ Methods for the detection and measurement of possible contaminants in quinidine and quinine and their pharmaceutical preparations were investigated to establish the actual composition of quinidine and quinine now on the market. Since no single TLC or GC procedure separated all of the compounds under consideration, multiple systems encompassing them were used to characterize the samples. Chromatographic and fluorometric techniques were applied to analysis of a wide variety of samples of quinidine and quinine and their pharmaceutical formulations. The dihydro analogs were found in all of the 75 samples examined, and the desmethoxy analogs (cinchonine or cinchonidine) were found in about half of the samples. The level of the dihydro alkaloids was higher in quinidine than in quinine (usually 5–9% in quinidine and 3–6% in quinine); the level of the desmethoxy analog was higher in quinine than in quinidine (usually 0–0.5% in quinidine compared to 1–2% in quinine). No epi-alkaloid, quininone, or quinotoxine was detected in any sample.

Keyphrases □ Quinidine, salts, and commercial formulations—composition, identification of dihydro and desmethoxy analogs as contaminants □ Quinine, salts, and commercial formulations—composition, identification of dihydro and desmethoxy analogs as contaminants □ Cinchona alkaloids—analysis of quinidine and quinine

Palmer *et al.* (1), in a recent study of the metabolites of quinidine, reported that congeneric alkaloids were present at levels of 10–30% in the quinidine samples used. They attributed the presence of these compounds to the current method of preparing quinidine (*via* base-catalyzed epimerization of quinine), which yields a complex mixture of epimers. Because of the lower therapeutic index of some epimers, a high epimer content might be undesirable. They recognized the possible presence of dihydroquinidine, which may be present in significant amounts in commercial quinidine (1, 2).

As a consequence, a study to establish the actual status of quinidine now on the market was initiated in these laboratories. Based on its source, the compounds most likely to be associated with quinidine are quinine, cinchonine, cinchonidine, epiquinidine, epiquinine, quininone, and quinotoxine, together with their dihydro analogs.

Several workers used paper chromatography for the qualitative analysis of the various cinchona alkaloids (3–5) and for study of the decomposition of quinidine solutions (6, 7). Palmer *et al.* (1) used GC but examined only the metabolites; many other workers using GC for cinchona alkaloid detection limited their studies to the four major vinyl alkaloids: quinine, quinidine, cinchonidine, and cinchonine. TLC was used first by many workers to separate these four vinyl bases and, more recently, to separate them from their dihydro analogs.

The USP XVIII monographs for quinidine and quinine salts (8) include a TLC test for "other cinchona alkaloids." This system differentiates quinine from quinidine and detects epiquinidine and epiquinine, but it does not separate dihydroquinidine from quinidine. Recently, Bohme and Bitsch (9, 10) applied two-dimensional TLC to separate quinine, quinidine, dihydroquinine, dihydroquinidine, cinchonine, and cinchonidine, but they did not investigate the presence of the epibases, quininone, and quinotoxine. They determined the quinine content of cinchona bark by measuring the UV absorbance of the material recovered from a TLC plate after a double development of the chromatogram.

Storck *et al.* (11) also separated the main alkaloids of cinchona bark by TLC and determined the quinine and cinchonidine content spectrophotometrically. Suszko-Purzycka and Trzebny (12) made a semiquantitative determination of the dihydro content of the individual alkaloids by visual comparison of the spots. Hartel and Korhonen (13) and Hartel and Harjanne (14) separated quinidine, dihydroquinidine, and quinidine metabolites isolated from biological fluids. They removed the separated zones from the TLC plate, extracted the alkaloid from each of them, and determined the fluorescence of the extracts. They reported that the quinidine preparations used in their study contained 12–13% dihydroquinidine. Gutzwiller and Uskokovic (15) used preparative TLC to isolate quinine and quinidine epibases. Vacha *et al.* (16) described TLC systems that separated epiquinidine or epiquinine from their respective analogs but did not separate the dihydro alkaloids from the parent alkaloids.

Recently, Roder *et al.* (17) reported the determination of the quinine, quinidine, cinchonidine, and cinchonine content of the extract of cinchona bark by densitometry of the fluorescent compounds on thin-layer chromatograms. They treated the developed chromatogram with a mixture of ether and concentrated sulfuric acid to activate cinchonidine and cinchonine. Although the four alkaloids were not completely resolved, the two pairs of alkaloids could be quantitated by the use of selective activation and emission wavelengths.

The scope of the present study included quinine in order to obtain a complete picture of the quality of the cinchona alkaloids now marketed as pharmaceuticals. Since no single TLC or GLC system would separate all of the compounds under consideration, multiple systems that encompassed all of them were used to characterize the samples.

EXPERIMENTAL

Materials—Cinchonine, cinchonidine, quinine, and quinidine free of their respective dihydro analogs were prepared from the commercial products *via* their mercury addition compound, essentially by the method of Thron and Dirscherl (18). Typically, a solution of 5 g. of quinidine sulfate in 50 ml. of 10% sulfuric acid is added to a solution of 7.5 g. of mercuric acetate in 75 ml. of 5%

Table I—Purified Cinchona Alkaloids

Compound	Solvent for Recrystallization	Melting Point, Observed[a]	Melting Point, Reported	Reference
Cinchonine	Alcohol	258–260°	264°	20, 21

[a] SG = silica gel G or GF, 0.25 mm. SH = silica gel H, 0.25 mm. [b] Solvent 1 (8) = chloroform–acetone–diethylamine (50:40:10). Solvent 2 = chloroform–acetone–methanol–ammonium hydroxide (60:20:20:1). Solvent 3 = methanol–ammonium hydroxide (100:1).

acetic acid. The solution is heated 4 hr. at 40–50°, cooled to room temperature, and made basic with ammonium hydroxide. The dihydroquinidine is extracted with ether. The aqueous layer is acidified with dilute sulfuric acid, and the mercury addition compound is reduced by adding sodium sulfite portionwise until no more mercury is precipitated. After mercury is removed by repeated filtration, the filtrate is made basic with ammonium hydroxide and the free base is extracted with ether. The ether is evaporated under vacuum, and the quinidine is recrystallized from alcohol. The other vinyl alkaloids were prepared in an analogous manner and recrystallized with the solvent noted in Table I.

The dihydro alkaloids were prepared by catalytic hydrogenation of the corresponding vinyl alkaloid over platinum oxide in ethanol. The isolated alkaloid was then recrystallized with the solvent noted in Table I. Quininone was prepared by oxidizing quinine with benzophenone in the presence of potassium *tert*-butoxide by the procedure of Woodward *et al.* (19). It was recrystallized twice from ether.

All of the isolated recrystallized alkaloids were dried under vacuum in a drying pistol at the temperature of refluxing xylene. The solvent of crystallization is removed in this process.

Sample Preparation—*Capsules, Tablets, and Powdered Quinidine or Quinine Salts*—Dissolve a portion of the sample in enough 50% alcohol to provide a solution equivalent to about 5 mg. of alkaloid base/ml. (The dissolved excipients do not affect the subsequent procedures.) Filter if necessary.

Quinidine or Quinine Base—Prepare a solution of about 5 mg./ml. in alcohol.

Injections—Transfer an aliquot of the injection containing about 80 mg. of the alkaloid salt to a separator containing 25 ml. of water, acidify with a few drops of diluted sulfuric acid, and extract with 50 ml. of ether. Discard the ether. Make the aqueous layer alkaline with ammonia and extract with 50 ml. of ether. Wash the ether layer with 25 ml. of distilled water, transfer the ether solution to a conical flask, and evaporate just to dryness under a stream of air. Dissolve the residue in enough alcohol to make a solution of about 5 mg. of alkaloid base/ml.

Assay Preparation—Dilute an aliquot of the sample preparation with enough alcohol to make a final dilution of 0.5 mg. of alkaloid base/ml.

Preparation of Thin-Layer Plates—Spread a slurry of 30 g. of silica gel H and 70 ml. of water over five 20 × 20-cm. plates with a suitable spreader[1] to obtain a 0.25-mm. layer. Air dry the plates and store in a dust-free atmosphere. Prepare silica gel G or GF plates (0.25 mm. thick) in an analogous manner, using a slurry of 30 g. of substrate and 60 ml. of water. (Commercial silica gel G or GF plates are also suitable.)

TLC System 1 (8)—This system separates quinine, quinidine, epiquinidine, epiquinine, cinchonidine, cinchonine, and quininone. It does not separate the dihydro alkaloids from the parent alkaloids. The plates are 0.25-mm. silica gel G or GF, and the developing solvent is chloroform–acetone–diethylamine (50:40:10).

TLC System 2—This system gives the best separation of the dihydro alkaloids from their respective vinyl alkaloids. It does not separate the epi-alkaloids, nor quinine from quinidine. The plates are 0.25-mm. silica gel H, and the developing solvent is chloroform–acetone–methanol–ammonium hydroxide (60:20:20:1).

TLC System 3—This system separates the epi-alkaloids and the dihydro alkaloids from the parent alkaloids, but it does not separate quinine from quinidine. The plates are 0.25-mm. silica gel H, and the developing solvent is methanol–ammonium hydroxide (100:1).

Qualitative TLC Identification—(Use TLC Systems 1 and 3.) At a point about 2 cm. from the bottom edge of the plate, spot 2 μl. of the sample preparation and each of the standard solutions of the respective alkaloids. Add the developing solvent to a trough in the bottom of a tank, one side of which is lined with a sheet of filter paper (Whatman No. 1 or equivalent). Introduce the plate immediately after adding the developing solvent to prevent presaturation of the tank. Let the solvent migrate 10–14 cm. from the point of spotting, and air dry the developed plate. Observe the plate under long wavelength UV light to locate the quinine series. To visualize the desmethoxy series, spray the plate with either 50% sulfuric acid, which converts them into fluorescent compounds, or iodoplatinic acid, which produces colored spots with all of the alkaloids. (Because of the diethylamine used in TLC System 1, these plates must be sprayed with acid prior to visualization.)

Quantitative TLC Separation—At a point 2 cm. from the bottom of the edge of the silica gel H plate, spot three 2-μl. aliquots of each assay preparation. If the qualitative procedure shows the presence of epi-alkaloids, use TLC System 3; otherwise, use TLC System 2. Develop as described under *Qualitative TLC Identification.*

Direct Scanning Fluorescence Measurement—The following conditions were found to be optimal for the apparatus used[2]: excitation wavelength, 345 nm.; and emission barrier filter, 430 nm. Set the source slit so the maximum intensity of the observed fluorescence is obtained and the entire width of the spot is scanned. (These conditions were provided by an 8-mm. slit in the instrument.) Set the variable slit to give a maximum of 90% of the 5-mv. range of the recorder for the most intense spot when the following settings of the amplifier[3] are used: right-hand step switch on 10, sensitivity key on 1, high tension switch on 1, amplification selector switch on F, and precision setting control knob on 5.

Align the TLC plate so that the centers of the spots pass under the center of the scanning slit. Scan the plate at 50 mm./min. with a chart rate of 200 mm./min. Use baseline corrected disk integrations[4] or electronic integration to calculate the ratio of the al-

[1] Desaga standard adjustable applicator (Brinkmann Instruments Inc., Westbury, NY 11590) was used for the preparation of TLC plates.

Table III—Relative Retention Times of Trimethylsilyl Derivatives of Cinchona Alkaloids

Alkaloid	Relative Retention Time[a]
Cinchonidine	0.55
Cinchonine	0.55
Dihydrocinchonidine	0.50
Dihydrocinchonine	0.50
Epiquinidine	0.87
Epiquinine	0.95
Dihydroquinidine	0.93
Dihydroquinine	0.93
Quinidine	1.00
Quinine	1.00
Quininone	0.83
Quinotoxine (quinicine)	1.52
Thioglycerol adduct of quinidine	13.4

[a] The retention times are relative to the appearance of quinidine, with the use of a glass column 6.1 m. × 3 mm. (20 ft. × 0.125 in.) packed with 3% OV-225 on Gas Chrom Q. (Quinidine elutes at approximately 21 min. with the column at 225°.)

kaloids. The following settings on the electronic integrator[5] provided optimal background correction with the silica gel H plates (settings should be checked on each instrument with standard mixtures of alkaloids): baseline tracking up 600, down 2000 μv./min.; input noise rejection, 5; minimum peak rate, 30 sec.; slope sensitivity, 2; count rate, 4 kc./mv.; minimum peak counts, 2000/sec.; and threshold level, 100 μv./min.

Solution Fluorescence Method—View the dried chromatogram under long wavelength UV light, and mark off areas of the alkaloids on the TLC plate. Scrape off the area of the separated alkaloids and a blank area of the plate corresponding in R_f to the alkaloid spot. Quantitatively transfer each scraped portion to a 15-ml. glass-stoppered centrifuge tube, add 10.0 ml. of 0.1 *N* H_2SO_4 (prepared from fluorescent grade sulfuric acid) to each tube, stopper, shake for 30 sec., and centrifuge at 20,000 r.p.m. for 30 sec. Transfer a portion of the supernatant liquid to a 1-cm. fluorescence cell, and measure the fluorescence directly with the excitation at 350 nm. and the emission at 455 nm.[6]. Calculate the ratio of the alkaloids in each sample from the fluorescence readings corrected for the contribution of the blank.

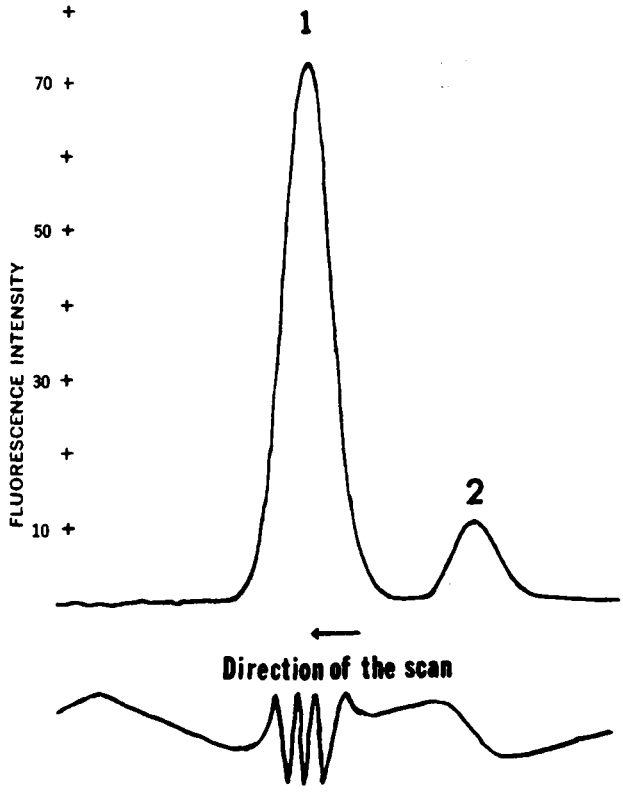

Figure 1—*TLC scan of a quinidine sample. Key: 1, quinidine; and 2, dihydroquinidine.*

Table IV—Direct Scanning Fluorescence Method: Comparison of Methods of Integration of Repetitive Scans[a]

Aliquot	Electronic Integration				Disk Integration		
1	9.1	8.9	9.0	9.2	8.8	8.9	8.5
2	8.6	8.6	8.8	8.6	8.4	9.1	8.2
3	8.4	8.5	8.6	8.5	8.8	8.7	8.4

[a] All results are given in percent of dihydroquinidine.

GLC Procedure—The system described separates the vinyl alkaloids from their dihydro analogs. It does not resolve the quinidine–quinine, dihydroquinidine–dihydroquinine, cinchonidine–cinchonine, and dihydrocinchonidine–dihydrocinchonine pairs, but it does resolve these pairs from each other. The following conditions are used: column, 6.1-m. × 3-mm. (20-ft. × 0.125-in.) glass, packed with 3% OV-225 on Gas Chrom Q; injector temperature, 235°; column temperature, 225°; and carrier gas, nitrogen at 30 ml./min. A suitable gas chromatograph[7] with a flame-ionization detector and an electronic integrator[5] is used. Evaporate 0.2 ml.of the assay preparation, containing the equivalent of 0.1 mg. of alkaloid under nitrogen, in a 0.3-ml. conical vial[8] and then dry under vacuum for 30 min. Add 0.1 ml. of *N*-methyl-*N*-trimethylsilyl-trifluoroacetamide or bistrimethylsilyl-trifluoroacetamide, cover with a Teflon-lined septum secured with a screw cap, and heat at 60° for 45 min. In-

ject 3 μl. of sample. Record the response and integrate the peak areas electronically. Calculate the ratio of the alkaloids in the samples from the integrated areas.

RESULTS AND DISCUSSION

Forty samples of quinidine and 35 samples of quinine in the form of the alkaloid, its salts, and pharmaceutical dosage forms were examined. The dihydro analogs were found in all samples, and the desmethoxy analogs (cinchonine or cinchonidine) were found in some samples. No epi-alkaloid, quininone, or quinotoxine was detected in any of the samples. The level of the dihydro alkaloids was higher in quinidine than in quinine; the level of the desmethoxy analogs was higher in quinine than in quinidine.

In preliminary work the alkaloids were extracted from the sample with methylene chloride. These solutions degraded rapidly to generate several additional TLC spots, one of which corresponded to quininone. The simple dissolution of the samples in alcohol gave stable sample preparations. No changes were observed in solutions standing in the dark for over a month.

Initial qualitative TLC is needed to verify the identity of the sample[9] and to select the quantitative TLC system to be used. TLC System 1 shows the presence of the epi-alkaloids. If they are present, TLC System 3, which resolves them from the natural bases, is used for quantitative measurement; if they are absent, TLC System 2, which gives a better resolution of the natural analogs, is preferred. The R_f values of the alkaloids are listed in Table II.

The GLC procedure permits the simultaneous quantitation of the desmethoxy alkaloids as well as the dihydro and vinyl alkaloids. The relative retention times of the trimethylsilyl derivatives of the alkaloids are listed in Table III. Since the GLC procedure does not separate the quinine series from the quinidine series, it is necessary to examine the sample by TLC, using TLC System 1 to verify the identity of the sample[9].

The most rapid and simple method for the examination of the chromatogram for the naturally fluorescent alkaloids uses the TLC scanner, preferably with a digital integrator for the quantitation. A typical scan is illustrated in Fig. 1. Since these instruments are probably not in widespread general use at this time, the method based on the fluorescence of the solution of the resolved alkaloids may be the most widely applicable procedure. The latter has greater specificity, since both the specific emission and the excitation wavelengths characteristic of these compounds can be set with the spectrophotofluorometer.

In scanning the thin-layer plates on the chromatogram spectrophotometer, occasional response was observed, indicating the presence of very minor spots not visible to the eye by their fluorescence nor after the chromatogram was sprayed with iodoplatinate reagent. These did not correspond to any of the alkaloids listed in Table II. If they were due to alkaloids having the same relative fluorescence as quinidine, they would amount to less than 0.2%.

Mixtures of known ratios of quinidine and dihydroquinidine were subjected to TLC by TLC Systems 2 and 3 and were quantitated by direct scanning and by solution fluorescence. They were also examined by the GLC procedure. Response was linear by all systems.

Table IV illustrates the results of repetitive scans of the same spot of a single sample by disk integration and electronic integration. Table V shows averages of scans of replicate chromatograms of individual solutions compared with results by the GLC procedure and the solution fluorescence of the same spot of the same chromatogram. With the disk integrator, graphic correction of the background is necessary. With the electronic integrator, accurate compensation of the background can be obtained by setting the baseline tracking characteristics with standards of known ratios of quinidine or quinine and its dihydro analog. In general, the closest agreement was found with the GLC and the solution fluorescent procedures, but on the average all methods of quantitation gave good agreement.

The amount of dihydroquinidine found in the various samples is summarized in Table VI. Dihydroquinidine was found in all samples, mostly in the 5–9% range with extremes of 3 and 22%. No epiquinidine, epiquinine, quinine, quininone, or quinotoxine was detected in any sample by the TLC systems that would detect them at 0.2%. The thioglycerol adduct of quinidine reported by Levine and Maienthal (24) was found in quinidine injections containing thioglycerol as a preservative.

Cinchonine and cinchonidine and their dihydro analogs may be detected by the qualitative TLC procedures; but because of their fluorescence properties, they do not interfere in the quantitative determination. Cinchonine was absent or was present at very low levels in the quinidine samples. It was quantitated by the GLC procedure. The results are shown in Table VI. An exception was one sample of quinidine sulfate powder which contained 7% cinchonine and 0.7% dihydrocinchonine. The GLC curve for this sample is illustrated in Fig. 2.

The examination of quinine samples showed dihydroquinine contents ranging from 0.2 to 9%, with the majority of the samples containing 3–6% (Table VII). The cinchonidine content ranged from none to 2%, with most of the samples containing about 1%. The level of cinchonidine found in quinine was much higher than that of cinchonine in quinidine.

The current USP monographs have no limit tests for the dihydro analog in the natural alkaloid. In the light of the findings, it has been recommended to the USP that the standards for quinidine and quinine and their salts should be redefined to reflect their actual composition.

Liquid and Solid Solution Interactions of Primary Certified Colorants with Pharmaceutical Gelatins

JAMES W. COOPER, Jr.▲, HOWARD C. ANSEL, and DONALD E. CADWALLADER

Abstract □ The liquid and solid solution interactions of eight FD&C dyes in 1% concentration with pharmaceutical gelatins and the effects of the dyes on the disintegration behavior of gelatins were observed. In liquid solution by visible region spectroscopy, all FD&C dyes interacted with a type A gelatin. The xanthene dye, FD&C Red No. 3 (erythrosine), interacted to the greatest extent by a combination of ionic, hydrogen, and hydrophobic types of bonds. The FD&C dyes did not appear to interact with a type B gelatin. A method for simulating a gelatin capsule shell wall was devised to examine solid-state interactions by visible and IR-attenuated total reflectance spectroscopy, dye release patterns, and the effect of the dyes on gelatin disintegration. FD&C Red No. 3 and Violet No. 1 in solid solution appeared to interact to a greater extent than the other FD&C dyes. Hydrogen bonding changes in the solid solution films of both gelatins were not observable by IR-attenuated total reflectance spectroscopy until very high (1:10 to 1:5) dye-protein ratios were attained. The same two dyes (FD&C Red No. 3 and Violet No. 1) that showed the greatest spectral changes exhibited the slowest release times from both gelatins at temperatures both below and within the temperature range at which gelatins disintegrate and go into colloidal solution. In simulated gastric fluid USP without pepsin, the FD&C Red No. 3 dye greatly diminished the average disintegration rate of both gelatins. The addition of pepsin essentially eliminated the effect of FD&C Red No. 3 on gelatin disintegration. In simulated intestinal fluid USP without pancreatin, both gelatins disintegrated slower than in simulated gastric fluid without pepsin. FD&C Red No. 3 also had a detrimental effect on gelatin disintegration in simulated intestinal fluid without pancreatin. Pancreatin was not added to the simulated intestinal fluid because of its interference with visualization of disintegration.

Keyphrases □ FD&C dyes—liquid and solid solution interactions with gelatins, effect on gelatin disintegration behavior, visible and IR-attenuated total reflectance spectroscopy □ Gelatins, pharmaceutical—effect of eight FD&C dyes on disintegration behavior, liquid and solid solution interactions with dyes, visible and IR-attenuated total reflectance spectroscopy □ Dye-protein interactions—effect on gelatin disintegration behavior □ Protein-dye interactions—effect on gelatin disintegration behavior □ Colorants, eight FD&C dyes—liquid and solid solution interactions with gelatins, effect on gelatin disintegration behavior, visible and IR-attenuated total reflectance spectroscopy □ Interactions—FD&C dyes-pharmaceutical gelatins

Gelatins used for the encapsulation of medication may be colored by the single or combined use of primary certified colorants. Several primary certified colorants were shown (1) to interact with pharmaceutical adjuvants with metallic or polyfunctional character in a chelation and/or chemisorption type of mechanism. Dyes were shown to inhibit the dissolution of sulfathiazole, sulfaguanidine, diethylstilbestrol, phenobarbital, riboflavin, and thymol (2–5) by a hypothesized preferential adsorption of dye at the primary dissolution faces in the various crystals (2–4). In addition, dyes were shown to affect the disintegration and solubility of cellulose polymers by mechanisms that vary with each dye–polymer combination (5).

While the capsule dosage form has been assumed to release its contents quickly upon administration, an article appeared that may question the reliability of capsule dosage forms (6). It stated that the use of dyes and/or opaquants in the capsule shell have no effect on disintegration rate. However, the article also stated that red-opaque and black capsules require 100–200 sec. longer to disintegrate than colorless or other colored or colored-opaque capsules which disintegrated or released their contents within 60–100 sec. All capsules were filled with sodium bicarbonate. An examination of the effects of colorants on the disintegration of gelatin was deemed necessary as the logical beginning toward a better understanding of the effects of intrinsic variables on gelatin disintegration.

The purposes of this investigation were to define the mechanisms of dye–protein binding in the liquid and solid solution states and to relate the dye–protein interaction to its effect on the disintegration of gelatin. The objectives of this study were:

1. To prepare a solid solution film system of dye and gelatin as a simplest simulation of a capsule shell wall.
2. To examine, by spectroscopic means, interactions of dyes with both cationic and anionic gelatins in both liquid and solid solutions.
3. To observe differences in binding of dyes to the two differently charged proteins by diffusion from the protein gel at temperatures within and below the point at which gelatin "melts" and disintegrates.
4. To compare the disintegration behavior of colored with uncolored gelatins in simulated gastric and intestinal fluid environments.

EXPERIMENTAL

Materials—The FD&C dyes (I–VIII) used in this study are listed in Table I[1], along with their synonym, color index number, and chemical class. All dyes were used as obtained. The pharmaceutical gelatins[2] utilized are presented in Table II. Gelatins were purified by the dialysis of a heterogeneous mixture of 5% gelatin and distilled water previously chilled to 5°. The gelatin served as its own dialyzing membrane. This mixture was allowed to stand overnight at 5° and was then filtered through a 20-mesh screen. The dialysis process

was repeated two more times. This method appeared in the literature with little attention to details (7–9) and reportedly removes inorganic ions and polypeptide fragments with a molecular weight range from 3000 to 20,000 (9). Following the third removal of supernate, the swollen gelatin particles were again combined with distilled water and the temperature was increased to 37° to dissolve the hydrated gelatin.

Stock Solution Preparation—A freshly prepared 5% gelatin stock solution was maintained at 37 ± 0.5° in a constant-temperature bath[3], and samples were pipeted from the immersed flask. Stock solutions of the various dyes were prepared to contain 0.01, 0.1, 1, and 10 mg./ml. A 5 *M* stock solution of sodium chloride was prepared by diluting 29.22 g. of sodium chloride to 100 ml. with distilled water. A 5 *M* urea solution was prepared by diluting 30.0 g. of urea to 100 ml. Simulated gastric fluid USP was prepared by diluting 2.0 g. sodium chloride, 3.2 g. pepsin, and 7.0 ml. hydrochloric acid to 1 l. with water. Simulated intestinal fluid USP without pancreatin was prepared by dissolving 6.8 g. of monobasic potassium phosphate in 250 ml. water and adding 190 ml. 0.2 *N* sodium hydroxide and 400 ml. water. The resulting solution was adjusted to pH 7.5 ± 0.1 with 0.2 *N* sodium hydroxide and diluted to 1 l. with water.

[3] Model MW 1172SSA, Blue M Scientific Co.

Pancreatin could not be added due to its interference with the visualization of gelatin disintegration.

Liquid Solution Procedures—In a preliminary investigation, the effects of pH, ionic strength, and urea and dye concentration changes on the λ_{max} and absorbance of aqueous 0.001% dye solutions (0.01 mg./ml.) were observed at 25 ± 2°. The various pH solutions were prepared by diluting 0.1 mg. of each dye to 10 ml. with constant ionic strength (μ = 0.2) buffer solutions (10). The sodium chloride–dye solutions were prepared by adding sufficient sodium chloride solution to make the final solution 1.0 *M*. Similarly, the urea–dye solutions were made 1.0 *M* with respect to urea. Each dye solution was scanned through the UV–visible range from 190 to 750 nm., utilizing a distilled water blank.

For each liquid-state solution in which changes in dye λ_{max} spectra were to be observed, the dye–protein sample, in a 1:100 dye–protein weight ratio, was run *versus* a blank with a similar quantity of protein. Each experiment consisted of a sample containing 0.10 mg. dye and 10 mg. protein in 10 ml. distilled water *versus* a blank of 10 mg. protein in 10 ml. solvent. The sample was incubated for 30 min. at 25 ± 2° prior to the observation of the spectra in all liquid-state experiments (7). The effects of sodium chloride and urea were observed separately by the addition of sufficient respective stock solutions to make the sample and blank solutions 1.0 *M* in urea or 0.154 *M* (0.9%) in sodium chloride. All dye–protein *versus* protein spectra were observed in the visible range only and were reproducible within 1 nm.

In those liquid-state experiments in which new bands were sought, the dye–protein samples, in a 1:10 dye–protein weight ratio, were run *versus* a similar quantity of dye in the blank solution. In these cases, 5 mg. dye was combined with 50 mg. protein in 10 ml. distilled water and run *versus* a blank containing 5 mg. dye/10 ml. The dye–protein *versus* dye experiments were repeated using the same ratio of dye to protein but diluted by a factor of 10 to observe the effect of dilution on the new bands obtained. Samples consisted of 0.5 mg. dye and 5 mg. protein in 10 ml. distilled water *versus* a blank of 0.5 mg. dye in 10 ml. of solvent. Sodium chloride and urea effects were also noted by making the sample and blank solutions 0.154 and 1.0 *M*, respectively, in concentration of each reagent for each separate experiment. New bands were sought in the range of 190–750 nm.

Solid Solution Procedures—All solid-state solutions were prepared by thoroughly mixing an appropriate amount of 5% gelatin stock solution at 37° with dye and other reagents (sodium chloride

or urea). All films were prepared in this manner in a 13-cm. diameter, Teflon-coated pan suspended on the surface of the constant-temperature bath at 37°. The final liquid-state volume was sufficient to fill the pan bottom with an even distribution of solution (50 ml. or more in total volume). The liquid solutions were allowed to evaporate at room temperature in a laminar flow hood[4]. The resulting solid solution films were lifted from the pan, placed in a desiccator over anhydrous calcium chloride, and allowed to equilibrate to a constant weight. Then they were cut into strips suitable for spectrophotometric analysis (approximately 1 × 4 cm.). The blank film contained all chemicals used in the sample for the respective experiments except the dye. Sample films were examined for shifts in λ_{max} in the visible range and for changes in the Amide I (1625 cm.$^{-1}$) and Amide II (1520 cm.$^{-1}$) bands of the proteins in the IR study.

Films to be examined by visible and IR spectroscopy were prepared using 500 mg. protein and 5–100 mg. dye. Average film thickness was 25 μ. The addition of any amount of sodium chloride or urea tended to inhibit film formation. Nevertheless, up to 135 mg. sodium chloride or 900 mg. urea was added with variable effects on film formation depending on the dye. Higher amounts of either reagent made lifting any portion of film a practical impossibility.

Films prepared for dye release disintegration studies were made using 2500 mg. protein and 25 mg. dye and were equilibrated over a saturated solution of calcium chloride in a desiccator. To assess the effect of pH change, the dye–protein solutions that were to be examined by visible spectroscopy as films were adjusted to pH 7 on a pH meter[5] with dilute sodium hydroxide solution before evaporation. All films for a particular experiment were prepared simultaneously. Average thickness of films prepared for dye release and disintegration studies was 130 μ.

Dye Release Study Procedure—Disks prepared for the dye release study were made by punching out portions, approximately 1.2 cm. in diameter and 20 mg. in weight, from the 2500-mg. protein–25 mg. dye films with a No. 6 cork borer attached to a drill press. For each dye release experiment at 37°, an accurately weighed disk was placed in an NF XIII dissolution basket, which was attached by a 30-cm. stainless steel rod of 0.6-cm. diameter to a variable speed, reversible, 1/40-hp. motor[6]. The basket rotation speed was 20 r.p.m. The rotating basket plus disk was centered on a 100-ml. beaker containing 50 ml. distilled water at a temperature of 37 ± 0.5°, and the bottom edge was placed approximately 2 cm. from the bottom of the beaker after allowing the hydrated film to adhere and flatten against the bottom of the basket. In the 27° experiments, the disk was placed in the same size beaker and volume of water, and a propeller of 3.0-cm. diameter replaced the basket. The agitation speed was 40 r.p.m. but did not appear to affect dye release in the range of 20–120 r.p.m. at 27 ± 0.5°, as long as the propeller did not physically tear the swollen, freely rotating film apart.

The vessel size and volume parameters were adjusted so that an approximately 1-ml. volume could be repeatedly withdrawn at the same location and read directly within Beer's law limits of 18–82% transmittance in a 0.5-cm. microcell with a solvent blank of distilled water. The withdrawn sample was returned to the experiment within 10–15 sec. after withdrawal; the solution loss due to this process and evaporation was 2–3% over 40 min. at 37° and 1–2% at 27° over 1–200 hr. Longer experiments at 27° were sealed in aluminum foil to prevent excess evaporation and to prevent photodecomposition of the dyes. A solution of similar protein weight per unit volume (20 mg. gelatin in 50 ml. water) was scanned through the visible region in which the λ_{max} occurs and did not absorb nor scatter any portion of that spectrum when run *versus* a distilled water blank.

The study at 27° was intended to determine the relative release times of 50% of the dyes from a gelatin film in distilled water that is not simultaneously dissolving, as a relative measure of protein binding of 1% dye within the film. Gelatin films have a "melt point" of 35 ± 5°, at which point the hydrated protein passes into colloidal solution (9). The purpose of the 37° study was to determine if the differences in dye release could also be observed when polymer dissolution is occurring simultaneously with dye diffusion and dissolution and if those differences have the same rank order as when the film is merely releasing dye. All dyes, when placed in similar conditions and concentrations without protein, dissolved within 1 min. The percent dye released at various specific time intervals for each dye–protein combination from at least three separate experiments was averaged, and the 50% release times were read directly from the graphs.

Disintegration Study Procedure—Gelatin disks were prepared by pressing out portions, approximately 2 cm. in diameter and 50 mg. in weight, of the 2500-mg. protein–25-mg. dye films with a No. 14 cork borer. Each disintegration experiment consisted of placing an accurately weighed disk in the center of a round-bottom 500-ml. beaker filled with 200 ml. of simulated gastric or intestinal fluid, with or without the respective enzyme (pepsin or pancreatin), equilibrated to 37 ± 0.5°, and covering the disk with a 2.54-cm. square of 8-mesh stainless steel screen. To allow sufficient time for the gelatin to adhere firmly to the bottom of the beaker, agitation was not begun for 1 min. At 1 min. from the start of the experiment, a three-

[a] D = decrease, I = increase, and NC = no change.

blade, 5.0-cm. diameter, polyethylene propeller attached to a hollow rod of the same material, with a concentric 0.3-cm. diameter stainless steel rod inside, was started at 40 r.p.m. by a variable-speed motor[7] controlled by a constant-speed and torque control unit[8]. The disintegration end-point was taken to be the complete visual disappearance of the gelatin disk. All various dye–protein combinations were observed in at least three separate experiments, and their disintegration rates (as milligrams per minute) were averaged.

UV–Visible Spectroscopy Method—The visible spectra for both liquid- and solid-state solutions and the UV spectra for some liquid dye–protein *versus* dye and all dye reference solutions were determined using a spectrophotometer[9]. Matched cells with a 1-cm. path length were employed for the liquid solutions, and the various film strips (approximately 1 × 4 cm.) were placed in liquid sample holders of the spectrophotometer and held in the beam path by the clip used to secure the liquid sample cells. A scan speed of 1.6 and 3.2 nm./sec. was used in the UV and the visible region, respectively. The spectrophotometer was calibrated using a holmium oxide standard. Where absorbance and/or scattering were high, appropriate filter screens were used.

For the diffusion study, a 0.5-cm. microcell was utilized[10].

IR–Attenuated Total Reflectance Method—The IR-attenuated spectra of the various films were observed in the 2000–625-cm.$^{-1}$ region, utilizing an IR spectrophotometer[11] equipped with a attenuated total reflectance attachment[12] and a 50 × 20 × 2-mm. thallous bromide–iodide internal-reflecting crystal[13]. Film strips cut to fit the crystal dimensions were placed on both sides of the crystal. An angle of incidence of 45° and minimal plate pressure were used to obtain the spectra at a scan speed of 1 cm.$^{-1}$/sec. Since only 30–40% of the expected transmission is obtained with the KRS-5 plate (11), a variable-slit filter[14] was placed in the reference beam for all experiments. The spectrophotometer was calibrated using a polystyrene standard.

RESULTS AND DISCUSSION

UV and Visible Maxima of FD&C Dyes—Table III lists the maxima of 0.001% unbuffered (pH 6.6–7.0) aqueous dye solutions at 25 ± 2°. By varying the pH from 1 to 13 at constant ionic strength (μ = 0.2), it was found that the dyes exhibited the same maxima at pH 6–7 as in unbuffered solution. At lower and higher pH values, the dyes exhibited changes in both maxima and absorbance. Sodium chloride had no effect on unbuffered dye maxima with the exception of FD&C Violet No. 1; this dye's visible maximum wavelength shifted hypsochromically to 540 nm. Urea had no effect on unbuffered dye maxima. Both sodium chloride and urea produced a variable effect on absorbance, from no effect to less than a 5% decrease in absorbance. The spectral effect of concentration changes from 0.001 to 20% dye can be summarized with the general statement that as concentration increases the visible region bands broaden and may shift their center in a random manner.

Liquid Solution Interaction—Spectrophotometric evidence of interaction between substances may take the form of a change in maximal wavelength, absorbance, or both. The results of liquid solution dye–protein *versus* protein spectra are summarized in Table IV. The pH value of all combinations of dye and protein ranged from 6.5 to 7.0. Figure 1 illustrates the spectral interaction effect with the two dyes that appeared to interact to the greatest extent with the gelatins. Since interactions between dyes and type B gelatin appeared to be minimal, sodium chloride and urea effects were not investigated.

The masking effect of sodium chloride and the lack of urea effect lend evidence that the observed liquid solution interactions were primarily electrostatic in nature. By reversal of the overall charge on the type B gelatin (to a positive sign) by changing the solution pH to 1, a type A gelatin shift occurred when the charge-reversed type B gelatin and Blue No. 1 were combined. This finding lends further support to the hypothesis that the liquid solution interactions of at least the three triphenylmethane dyes (Blue No. 1, Green No. 3, and Violet No. 1) are probably due to electrostatic considerations. However, in the case of the Red No. 3 interaction, the addition of sodium chloride did not return the wavelength to its original position (526 nm.). Even doubling the sodium chloride concentration (0.308 M) had no further effect; the wavelength remained at 529 nm. This may indicate a degree of irreversibility, binding other than hydrogen, hydrophobic, and/or electrostatic, or both. Anderson and Boyce (12) found that erythrosine (FD&C Red No. 3) interacts in equimolar aqueous solution with polyvinylpyrrolidone, a nonionic polymer, producing a greater shift (to 538 nm.). They postulated that electrostatic and van der Waals' bonds might be responsible, but they did not investigate the mechanism(s) of binding. Nevertheless, the fact that Red No. 3 does bind with a nonionic polymer does imply a capability to bind in other than an electrovalent manner. Otto (13) and Gustavson (14) considered the overlap of π-electron clouds of dye and polymer to be the primary force responsible for

dyestuff fixation. This could lead to a hypothesis that overlapping π cloud hydrophobic bonds play a major role in binding erythrosine to type A gelatin.

Table V summarizes the band search. The purposely high (1:10) ratio of dye to protein as well as overall solution concentration of dye (0.05%) and protein (0.5%), as compared with 0.001% dye and 0.1% protein in the dye-protein *versus* protein experiments, was employed to investigate the effect of excess dye and dye aggregation on dye-gelatin interactions. As can be seen from the effect of 10-fold dilution, all bands disappeared except those with erythrosine and type A gelatin. The bands of undiluted combinations are characteristic of the dye irrespective of the gelatin type, and this could be evidence of dye-dye aggregation. Figure 2 shows the new bands obtained with the erythrosine-type A gelatin dilution combination and the effects of both urea and sodium chloride on the absorbance of the new bands. The effect of urea or sodium chloride on the 547-nm. band led to the hypothesis that the interaction represented by this new band involves both electrostatic and hydrogen bonding. The enhancement of the absorption of the 500-nm. band by sodium chloride suggests an ionic mechanism for this band, which is intensified by an increase in ionic strength.

Visible Spectrum Solid Solution Maxima—The visible absorption bands obtained from dyed films are shown in Table VI. The similarity of shifts with either protein suggests that the shifts may be due to solid-state dye in solution characteristics rather than solely an interaction phenomenon. While the solid solution bands for the dye-protein films without buffer, sodium chloride, or urea are as sharp as liquid solution bands, the bands obtained from dye protein films that had buffer solution, sodium chloride, or urea added before evaporation to films show variable width in their band characteristics. In addition, it should be reemphasized that any additive to the dye-protein solution seriously affected film structural integrity. Figure 3 shows bands obtained from the erythrosine-protein series with and without additional reagents and the spectra obtained for solid-state erythrosine recrystallized on a cell face.

The range of total shift from liquid solution dye without protein to solid protein-dye solution showed wide variability between dyes. Sunset yellow exhibited the least shift (+3 nm.) and erythrosine the greatest shift with either protein (+16 nm. with type A and +15 nm. with type B gelatins).

Some investigators (1, 15–18) studied solid-solid interactions of dyes and various drugs with metallic and nonmetallic adjuvants using diffuse reflectance spectroscopy. Spectra are broader and less intense in diffuse reflectance spectroscopy than solution transmittance spectra. They stated that spectral changes in diffuse reflectance spectroscopy in the order of 5–10 nm. are usually associated with physical adsorption processes. Chemisorption changes are several times this range in magnitude (18). Although the authors (1, 15–18) refer to the spectral changes observed as solid-state surface interactions, most drug-adjuvant combinations are equilibrated in aqueous suspension to facilitate maximal interaction. However, the interactions appear to occur in the solid unequilibrated states in the presence of moisture (17). The bearing that these findings have on the dye-protein solid solution spectra is debatable due to differences in spectroscopic method, method of preparation, physical state (solid particle surface interaction *versus* solid solution in this study), and substances combined with the dyes or drugs. There is basis for the belief from the results (1, 15–18) that the shifts observed in this study on the transition of dye-protein from liquid to solid solution are

merely due to change in state. This is further substantiated in Table VI by the fact that individual bands of each dye with either protein (without added buffer, sodium chloride, or urea) are no more than 3 nm. apart.

Carroll (19), in a discussion of sensitizing dyes used in photography, stated that dye spectra in aqueous photographic gelatin-silver halide suspensions become more complex as a result of molecular interaction and dye aggregation in liquid solution, emulsion, and dried emulsion (film). Generally, the sensitizing dye absorption bands are shifted bathochromically in emulsion as compared to a solution of the dye by itself. Polymethine dyes commonly used as sensitizing dyes may shift from 0 to 190 nm. However, to be sensitized the dye has to be first adsorbed on the surface of silver halide crystals in an aqueous suspension. Furthermore, most polymethine dyes are cationic, whereas all FD&C dyes are anionic.

IR-Attenuated Total Reflectance Study—The effects of dye concentrations (on a gelatin weight basis) of from 1 to 20% on the Amide I and Amide II bands of the protein are summarized in Table VII. Changes in hydrogen bonding between molecules are usually indicated by shifts in the area of 3100–3600 cm.$^{-1}$ (8), but since many of the dyes absorb strongly in that area also due to O—H and N—H bonds present in their molecules, the Amide I (1625 cm.$^{-1}$) and Amide II (1520 cm.$^{-1}$) bands can be used to show hydrogen bonding changes. The Amide I band is characteristic of the C=O stretching vibrations, whereas the Amide II band is characteristic of the N—H deformation mode and may be coupled with the C—N stretching mode of the peptide group (8). The shifts observed in hydrogen bonding changes may be in either direction as is evidenced in Table VII (8). Figure 4 shows typical examples of shifts (or the

lack of same) observed with the 20% dye spectra. Noteworthy is the lack of effect of Red No. 3 on type A gelatin hydrogen bonding. This lends support to the hypothesis that the Red No. 3-type A gelatin interaction involves primarily ionic and possibly hydrophobic types of bonding.

Nelson (20) investigated the photoelectric properties of dyed gelatin films and stated that the addition of dye to gelatin greatly increases the yield of charge carriers in a gelatin film. Charge carriers are able to mediate redox processes, which may enhance gelatin cross-linking. Erythrosine enhanced the irreversible UV "hardening" effect on gelatin in Nelson's work, but only after heavy exposures to UV light. Furthermore, Nelson's films were dehydrated by immersion in isopropanol before photoemission was observed.

From the data presented in Table VII, it can be seen that some dyes affect hydrogen bonding between polypeptide chains, but the effect is detectable for the most part only at higher ratios of dye to protein. Films of 0.1 mg. dye to 100 mg. gelatin were also examined for hydrogen bonding changes, but none was detectable.

Artemova and Usova (21) found that indigotine, tartrazine, and amaranth in 0.02% concentration in 3 and 6% gelatin gels hinder structure formation in gelation. Idson and Braswell proposed (22) that hydrogen bonding is the primary force in gel formation. Iijima and Sekido (23) found that, in the dyeing of protein, all of the *p*-hydroxy dyes and those *o*-hydroxy azo dyes, in which the OH group is not involved in an intramolecular hydrogen bond are adsorbed to the protein by a hydrogen bonding mechanism in addition to the electrostatic attraction between the sulfonic acid groups and amino groups of the protein. This has bearing on the finding that the *o*-hydroxy azo dye, amaranth, showed no effect on either gelatin's intermolecular hydrogen bonding at all concentrations. In the case of the other *o*-hydroxy dyes, tartrazine and sunset yellow,

Each point represents the average of three experiments.*

effects on the hydrogen bonding of both proteins were seen. The *o*-hydroxy group of amaranth may be tied up in an intramolecular hydrogen bond, whereas the hydroxyls of the other two dyes apparently participate in intermolecular hydrogen bonding. Indigotine appeared to interact with hydrogen bonds of either type gelatin. The triphenylmethanes, with the exception of the Violet No. 1-type A gelatin combinations, appear to affect hydrogen bonding in either protein at primarily higher dye to protein ratios.

Other workers (7, 8) used IR-attenuated total reflectance to detect solid-state hydrogen bonding changes in gelatins combined with various carbohydrates.

Dye Release Results—Table VIII summarizes the times required for 50% dye release into distilled water from both proteins at 27 and 37°. Figures 5–7 illustrate representative examples of the release curves from which the data were obtained. The rank orders observed differed both between the two differently charged proteins and at the two different temperatures. Generally, the anionic FD&C dyes appeared to be more strongly bound to a cationic type A gelatin (Bloom No. 170, viscosity 25.6 millipoises) of lower Bloom strength and viscosity than to an anionic type B gelatin (Bloom No. 255, viscosity 49.2 millipoises) of higher Bloom strength and viscosity, at temperatures both within and below the "melt point" of gelatin.

At 27°, the FD&C Red No. 3 and FD&C Violet No. 1 appeared to be relatively tightly bound to both proteins. At 37°, the Red No. 3 appeared to be much more bound than any other dye. Reliable

spectrophotometric determination of FD&C Blue No. 2 at 37° was not possible. Others (24) found FD&C Blue No. 2 to be very unstable. Due to differences in method, revolutions per minute, and gelatin melting, comparison between the two temperatures should be approached with caution.

Disintegration Study Results—The effects of 1% dye concentrations, media, and the presence of pepsin on the average disintegration rates of both type gelatins are presented in Table IX. Although the end-point of these experiments was the disappearance of any trace of gelatin on the bottom of the beaker, the visual end-point can only be assumed to be the disintegration, dispersion, and beginning of the dissolution process or pseudodissolution rather than complete dissolution. That this was the case was confirmed by preliminary dissolution studies of undyed gelatin disks using a pH-stat[15] at pH values of 3 and 9 with a nitrogen flush to eliminate carbon dioxide alteration of the titration. Figure 8 shows that even after the gelatin had dispersed into the media, the titration of hydrated charged groups continued, indicating that the dissolution process was incomplete even though the disk was no longer visible. As a result, automation of the observation of the process would serve no useful purpose because the end-point would have to be observed visually in all experiments.

Overall, the gelatins disintegrated faster in simulated gastric fluid at pH 1.2 with or without pepsin than in simulated intestinal fluid without pancreatin at pH 7.5.

The xanthene dye FD&C Red No. 3, as might be expected from spectral and diffusion data previously given, had the most deleterious effect on average disintegration in the absence of pepsin in simulated gastric fluid or in simulated intestinal fluid. Even when pepsin was present, the type A–Red No. 3 disks in simulated gastric fluid did not disintegrate any faster than the undyed disks; *i.e.*, it appeared that pepsin did not accelerate the disintegration process as it had with other dyed disks. Xanthene dyes have been shown to inhibit the tryptic hydrolysis of casein (25). Perhaps erythrosine inhibited not only the intrinsic disintegration process by its presence in the gelatin matrix but, in addition, the diffused dye interfered with peptic action on the type A gelatin disk by complexation with enzyme. This did not appear to be the case with the type B gelatin–Red No. 3 disks in simulated gastric fluid with pepsin. However, a xanthene dye, rose bengal, has been shown to complex with trypsin (25).

The data indicate that pepsin appeared to have some effect on all disintegration rates in simulated gastric fluid with the exception of undyed type A gelatin. It was also observed that the inclusion of pepsin in simulated gastric fluid caused areas of the disk surface to be denuded within 2–5 min. into the experiment. These bare areas were irregularly shaped holes, which ranged from an estimated 20 to 50% of the disk surface. However, within several more minutes the hydrated protein reassumed a continuous circular surface with a slight convexity which increased as the experiment proceeded and the disk became smaller in diameter. Pepsin is an endopeptidase, *i.e.*, cleaves a polypeptide at peptide bonds within the chain (26). This would relieve restraints to hydration and swelling due to the intertwining of peptide chains. In addition, it would liberate progressively smaller and smaller peptide chains for the dissolution process. Results obtained in this investigation seem to agree with Czetsch-Lindenwald (27), who stated that pepsin accelerates gelatin capsule disintegration to the extent of only about 25%; type A gelatin–Red No. 2 disk disintegration rate was the most accelerated (35%) of all dye–protein combinations. On the other hand, pepsin seemed not to affect, or slightly decreased, the disintegration of undyed type A– or type B–Green No. 3 and type A gelatin–Violet No. 1 combinations.

The presence of dyes other than Red No. 3 in 1% concentration in type A gelatin in simulated gastric fluid with pepsin and both type A and type B gelatin in simulated intestinal fluid without pancreatin appeared to increase disintegration rates. This effect may be partially due to the number of microequivalents (μeq.) of sodium that are contained in the 0.5 mg. of dye in each 50-mg. disk. As can be seen in Table IX, the number of sodium microequivalents contained in each dye seems to divide the dyes into three distinct groups: those dyes with less than 1 μeq., those dyes with more than 1 and less than 2 μeq., and those dyes with greater than 2 μeq. of sodium/0.5 mg. While not absolutely correlatable, those dyes with higher microequivalent values may aid in the protein hydration process by not only pulling in water at a greater rate than those dyes with lower microequivalent values but also by diffusing outward at a greater rate (Table VII) and, in effect, allowing osmotic swelling to proceed at an increased rate. The effect may also be referred to as an internal "salting in" of the protein (28), whereby low concentrations of salts (0.05 *M* or less) solubilize the protein by breaking salt bridges and partially masking charges. The dye effect is particularly noteworthy in both type A and type B gelatins in simulated intestinal fluid. The type A gelatin disk disintegration is increased by as much as 57% by the presence of dyes; the type B gelatin disk disintegra-

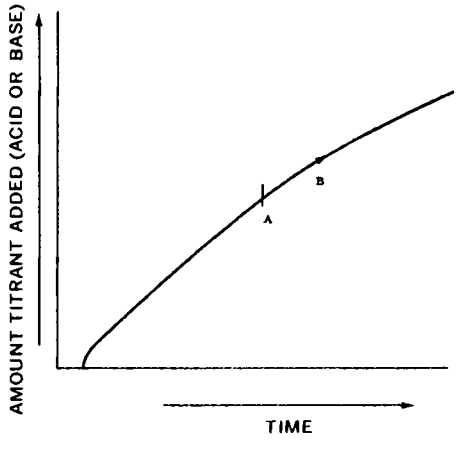

Figure 8—*Typical titration curve for type A or type B gelatin disks at pH-stat setting of 3 or 9 with acid or base titrant. Key: A, point at which disk disappeared completely and titrant continued to be added; and B, titrant may be added up to several hours beyond point A.*

[15] Radiometer, Copenhagen.

tion rate is increased by up to 31% by one dye. The pKa of sulfonic acid groups in most dyes is close to a value of 3; at a simulated intestinal fluid pH value of 7.5, the ionized form of the dyes would be predominant (23). At pH 1.2 in simulated gastric fluid, the dyes' sulfonic acid groups would be essentially (1%) unionized. In addition, the pKa of the carboxyl group of erythrosine is 4.95 (29). While approximately 1% of the dyes with sulfonic acid groups may be ionized at pH 1.2, only approximately 0.01% of the erythrosine could be ionized at pH 1.2. In addition, Red No. 3 is less soluble (9.0 g./100 ml. water, 25°) than the rest of the FD&C dyes (19.0–20.0 g./100 ml.), with the exception of Blue No. 2 (1.6 g./100 ml.) (30). At pH values of 5 or below, Red No. 3 is stated to be insoluble (30).

In summary, it appears that the effect of FD&C Red No. 3 on gelatin disk disintegration may be due to liquid and solid solution interaction with the gelatin, possible interaction with pepsin if present, and very low percent ionization and inherent insolubility at low pH values.

In vitro availability tests of capsule dosage forms, the shell of which is colored by erythrosine, may exhibit a delayed formulation release pattern as well as dye-hindered drug dissolution, particularly in acidic test media in which pepsin may have purposely been left out due to its interference with spectrophotometric determination of drug present in solution. *In vivo* effects would naturally depend on variables in stomach contents, emptying time, and drug absorption sites. Further studies on *in vitro* and *in vivo* effects with erythrosine and other xanthene dyes and dye classes are in progress.

SUMMARY AND CONCLUSIONS

1. A simple model of a gelatin shell wall was fabricated to examine dye–polymer interaction characteristics and disintegration behavior.

2. The model agreed to some extent with respect to previous findings of pepsin effect on disintegration of capsule shells.

3. In liquid solution, the anionic FD&C dyes tended to interact to a greater extent with a cationic type A gelatin than with an anionic type B gelatin.

4. All dyes interacted with both proteins in the solid state simply by virtue of the characteristics of the solid state; some dyes did affect the intermolecular hydrogen bonding of both proteins, but such effect was detectable only at relatively high concentrations.

5. The xanthene dye, FD&C Red No. 3 (erythrosine), interacted in both states of solution to the greatest extent of any FD&C class or type dye; the interaction may involve ionic, hydrogen, hydrophobic, and van der Waals' bonding, some of which may lead to a degree of irreversibility, even in the transition from solid to liquid solution state.

6. The triphenylmethane dye, FD&C Violet No. 1 (Wool Violet 5BN), interacted to some extent with the gelatins but primarily in an ionic manner that was reversible in liquid solution.

7. The FD&C dyes in 1% concentration were released at different rates from both types of proteins at temperatures both below and within the melt point of gelatins.

8. The dyes that exhibited the greatest spectral change activity (Red No. 3 and Violet No. 1) had the longest release times and adversely affected the disintegration of gelatin disks in either simulated gastric or simulated intestinal fluids; conversely, the dyes that exhibited the least spectral change activity generally appeared to be released quicker and actually may have enhanced disintegration, particularly those dyes with higher sodium microequivalent values when observed in simulated intestinal fluid.

9. It appears that, for a series of dye compounds, a spectral examination of their interactions with a polymer can yield some indication of their respective binding in liquid and solid solution. This observed indication coupled with a calculation of relative cation equivalents may lead to a presumptive hypothesis of an effect on both diffusion of the dye and the effect of the dye on the polymer's disintegration.

Computer Optimization of Pharmaceutical Formulations I: General Procedure

JOSEPH B. SCHWARTZ[▲], JOEL R. FLAMHOLZ, and ROBERT H. PRESS

Abstract □ A technique was developed whereby a formulation with optimum properties, according to predetermined criteria, can be selected *via* computer analysis. The results of a statistically designed set of experiments based on five independent variables were used as the data input to the computer. Regression analysis of these data resulted in a set of second-order polynomial predictor equations. Restrictions placed by the pharmacist on the characteristics of interest serve to eliminate undesirable formulations. Ultimately, the formulator can trade off properties to obtain an optimum formulation. Computer-generated graphs further aid the formulator in the understanding of the particular system. An example is presented of the selection of an optimum formulation by this procedure and of its preparation in the laboratory. Predictions and experimental results show excellent agreement.

Keyphrases □ Computer optimization of pharmaceutical formulations—general procedure, examples □ Formulation of pharmaceutical preparations—computer optimization, general procedure and examples □ Pharmaceutical technology—general procedure for computer optimization of pharmaceutical formulations

The development of a pharmaceutical formulation and the associated process involves a number of variables. Mathematically, they can be divided into two groups: (*a*) the independent or formulation and process variables that are controllable factors, and (*b*) the dependent variables that are the responses or characteristics of the resultant drug delivery system. Much of the work in pharmaceutics has been in the pursuit of relationships between the two.

Table I—Experimental Design for Five Factors

Trial	Factor Level in Experimental Units				
	X_1	X_2	X_3	X_4	X_5

Pharmaceutical research and development projects are often optimization problems. One experiments by a series of logical steps, carefully controlling the variables one at a time, until a satisfactory formulation results.

It may be necessary to trade off properties during such experimentation, to sacrifice one characteristic to improve another; *e.g.* to accept a softer tablet in order to improve the dissolution profile. Thus, the primary objective may not be to optimize absolutely but to compromise effectively and thereby to produce the best formulation under a given set of restrictions.

The techniques of optimization are well documented in the literature (1–7). Fonner *et al.* (8) demonstrated the applicability of mathematical optimization techniques to pharmaceutical systems. Their application of the Lagrangian method, while able to handle several responses or dependent variables, was generally limited to two independent variables. Experiences in these laboratories showed that a greater number of these variables are of general interest, but as the number of formulation factors is increased, the situation becomes more involved mathematically and graphically impossible. Although various multivariate techniques are available, computers are almost a necessity for their application.

The work reported here was undertaken to determine the feasibility of optimizing a pharmaceutical formulation with the aid of computers in a manner which could be used with relative ease by the development pharmacist. The procedure that resulted appears capable of being carried out by persons unfamiliar with the mathematics of optimization and with no previous computer experience.

This paper covers the general procedure followed to optimize formulations. Subsequent reports will discuss several other aspects of the optimization technique, its application to a practical situation, and the interpretation of the large quantity of data generated by this particular method.

THEORY

The type of project of concern here is one of selecting the most desirable level of ingredients or controllable process factors. That is, it is desired to *quantitate* a formulation that has been *qualitatively* determined.

The technique involves performing a set of statistically designed experiments as described by Box and Wilson (1, 2) and using the resulting data to derive a mathematical model which can be used for the optimization of a formulation. The experimental design is dependent on the number of variables involved in the study; for five independent or formulation variables, the modified half-factorial design shown in Table I requires a total of 27 experiments.

The first 16 experiments represent a half-factorial design for five factors at two levels resulting in $\frac{1}{2} \times 2^5 = 16$ trials. The two levels here are represented as +1 and −1. For the remainder of the study, three additional levels were selected: zero represented the base

Table II—Translation of Experimental Conditions into Physical Units[a]

Factor	−1.547 eu[b]	−1 eu	Base 0	+1 eu	+1.547 eu
X_1 = calcium phosphate–lactose ratio (1 eu = 10 mg.)	24.5/55.5	30/50	40/40	50/30	55.5/24.5
X_2 = compression pressure (1 eu = 0.5 ton)	0.25	0.5	1	1.5	1.75
X_3 = starch disintegrant (1 eu = 1 mg.)	2.5	3	4	5	5.5
X_4 = granulating gelatin (1 eu = 0.5 mg.)	0.2	0.5	1	1.5	1.8
X_5 = magnesium stearate (1 eu = 0.5 mg.)	0.2	0.5	1	1.5	1.8

[a] Physical quantities are rounded off only for convenience. [b] eu = experimental units.

level midway between the above-mentioned levels and the positive and negative 1.547 values represented the extreme values. The reader is referred to the literature for a discussion of the statistical design (1, 2, 5).

The proper name for this design is "a five-factor, orthogonal, central, composite, second-order design," and the type of predictor equation resulting from such a study is a second-order polynomial (with 21 terms) having the following form:

$$Y_i = a_0 + a_1X_1 \ldots + a_5X_5 + a_{11}X_1^2 \ldots + a_{55}X_5^2 + a_{12}X_1X_2 \ldots + a_{45}X_4X_5 \quad \text{(Eq. 1)}$$

where:

Y_i = level of a given response (dependent variable)
a = regression coefficients for second-order polynomial
X_j = level of independent variable

Such an equation is generated for each dependent variable relating it to the set of five independent variables.

EXPERIMENTAL

The formulation selected as a model system for the optimization program was a production formula already in existence. Briefly, the process involves a starch-paste–gelatin granulation of the drug with diluents. After drying and milling, the disintegrant, the glidant, and the lubricant are added.

The five independent formulation variables selected for this particular study were: X_1, diluent ratio; X_2, compressional force; X_3, disintegrant level; X_4, binder level; and X_5, lubricant level. With the exception of these five variables, everything else in the formulation and the processing steps remained constant throughout the study including: (*a*) the level of active ingredient; (*b*) the quantity of starch as paste; (*c*) the glidant level; (*d*) granulating, milling, drying, and blending conditions; and (*e*) the speed of the compressing machine. The translation of the statistical design (Table I) into physical units for the five variables is shown in Table II[1].

Each experiment consisted of a 30,000-tablet batch through the granulating, milling, dry mixing, and lubricating steps. From each batch, 3000 tablets were compressed on a rotary press[2] equipped with 35 sets of 0.6-cm. (0.25-in.) round, flat beveled-edge tooling run without precompression.

Table III—Values for Index of Determination from Regression Analysis

Response	R^2, %
Y_1 Disintegration time	98.08
Y_2 Hardness	98.90
Y_3 Dissolution	97.90
Y_4 Friability	75.38
Y_5 Weight	87.56
Y_6 Thickness	98.15
Y_7 Porosity	99.45
Y_8 Mean pore diameter	61.22

The responses measured on the resulting tablets were: Y_1, disintegration; Y_2, tablet hardness; Y_3, dissolution; Y_4, friability; Y_5, weight uniformity; Y_6, thickness uniformity; Y_7, tablet porosity (pore volume); and Y_8, mean pore diameter. Most of these response variables are properties of general interest to tablet formulators, but the list could be varied to fit the particular formulation.

Disintegration time was determined using the procedure and apparatus outlined in USP XVIII (9). Tablet hardness was determined using an electric hardness tester[3].

Dissolution measurements were made in 0.1 *N* HCl following the USP basket technique with a basket rotation at 100 r.p.m. The dissolution profile was followed by means of a servo-recorder[4], a spectrophotometer[5], and a flow cell.

Tablet friability was measured on a 60-tablet sample in a friabilator[6] using a 4-min. cycle (10).

Weight and thickness uniformity were calculated as the relative standard deviation of the given measurement. For tablet weight, 10 tablets were individually weighed on an analytical balance[7] and 20 tablet thicknesses were determined with a dial comparator[8].

Pore volume was determined[9], and a sample size of 10 tablets was necessary to obtain adequate readings of the mercury volume. Mean pore diameter was calculated from the porosimeter data.

RESULTS AND DISCUSSION

The responses from the 27 experiments were measured and tabulated. The large volume of data is unwieldy to report here and, for the most part, is irrelevant to the present discussion.

Statistical analysis was carried out which included the calculation of mean values for each of the eight responses in each of 27 experiments. Without repeated emphasis, it should be noted that values used for optimization must be statistically significant. The formulator must be confident that the results used as input are truly representative of the particular system.

The sets of data resulting from the statistical analysis were then subjected to computerized[10] regression analysis to determine the fit to a second-order model (Eq. 1). In most cases, the *R*-square value or the index of determination was satisfactory, as shown in Table III.

The ability of the system to predict accurately is only as good as the regression fit of the predictor equation used. The values for friability, weight, and mean pore diameter are less than desirable, and it may be that many pharmaceutical responses of interest do not follow a second-order model.

One advantage, however, of the digital type of system used is that it can be modified to accept other mathematical models, whether they be higher order polynomials, any other empirical relationships, or mathematical models based on first principles. For the present work, it was decided to restrict the model to the

[1] There are several places in the optimization procedure where the developmental pharmacist is indispensible. This is one of them, since only by formulation experience can one select reasonable ranges for those variables determined to be most important.

[10] The entire optimization system (series of programs) was written for use on a CDC 1700 (Control Data Corp., Minneapolis, Minn.).

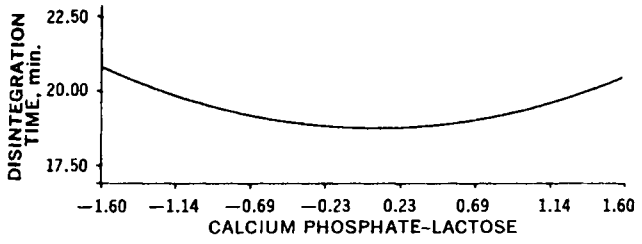

Figure 1—*Plot of disintegration time (minutes) as a function of diluent ratio generated from computer tapes and drawn by plotter. The abscissa represents the experimental range in terms of experimental units (see text).*

second-order polynomials, realizing that predictions for several variables might be inaccurate.

The remainder of the technique involves the analysis of the set of polynomial equations obtained *via* regression.

Optimization—In addition to the computerized statistical analysis and regression analysis already mentioned, programs were needed for the actual optimization. Two major steps were used: (*a*) the feasibility search, and (*b*) the grid search.

The feasibility program is used to locate a set of response constraints that is at the limit of possibilities. That is, given this particular set of restrictions, there *is* a solution (formulation), but if the constraints are tightened, there is no solution. The mechanics are to select several values for the responses of interest and slowly relax them until a possible solution is found. For example, the constraints in Table IV were fed into the computer and were relaxed one at a time until a solution was found. The first choice would have been a formulation with a disintegration time of <1 min., tablet hardness >12 kg., and dissolution >100% in 50 min.[11]. This set of constraints was expected to be unreasonable and, indeed, no solution was found until the values had been systematically relaxed to a disintegration time of 5 min., tablet hardness of 10 kg., and dissolution of 100% at 50 min. Any further relaxation of the constraints would, of course, also yield solutions.

The feasibility program is designed so that it stops after the first possibility; the formulation given may be one of many that could satisfy the constraints.

The second program, the grid search, is essentially a brute force method in which the experimental range is divided into a grid of arbitrary size and methodically searched. Based on an input of the most reasonable constraints (most likely resulting from the feasibility program), the grid search program prints out all points (formulations) in the grid that meet the criteria.

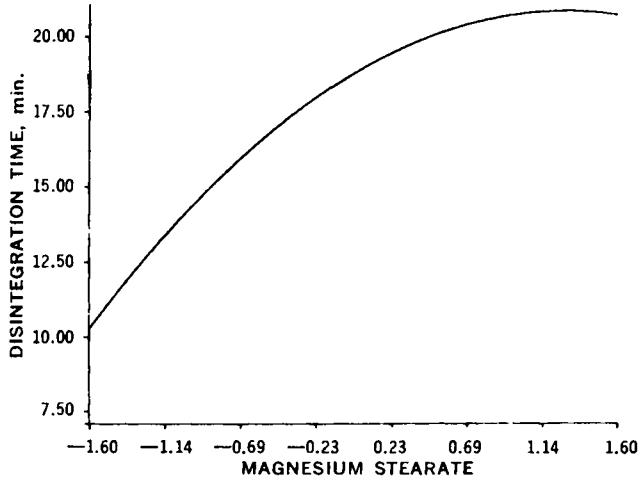

Figure 2—*Plot of disintegration time as a function of lubricant level drawn from computer tapes.*

[11] Values greater than 100%, as well as negative values, appear throughout this work. Because the second-order polynomials describe curves that may be parabolic, hyperbolic, ellipsoid, *etc.*, extrapolation may take one out of the realm of physical reality.

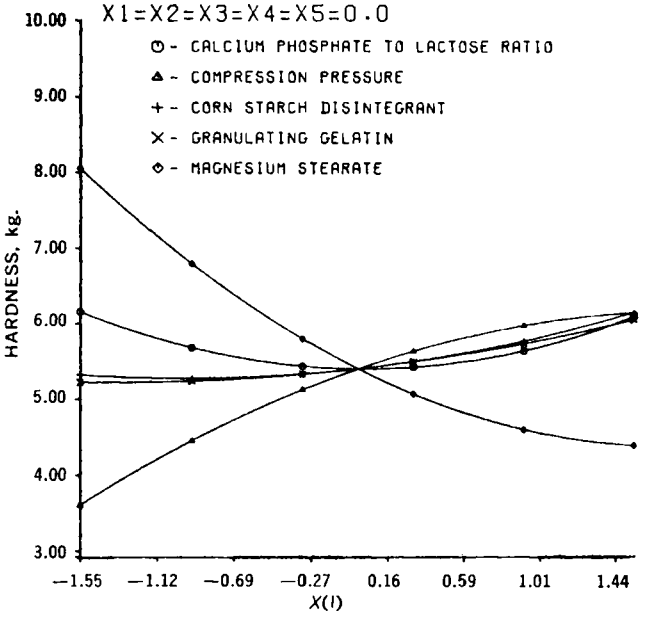

Figure 3—*Composite plot for tablet hardness as a function of each independent variable,* X_i (i = *1, 2, . . . , 5*).

The rationale for the feasibility program becomes apparent, for if one had arbitrarily selected suitable properties or constraints and made a grid search, the printout might contain hundreds of combinations that fit—or none. But, with the results of the feasibility study, it is known within reason the point at which tighter constraints yield no solutions. By running the grid search in this neighborhood, the printout will have only a few solutions from which the most suitable one can be selected.

For example, a grid search utilizing the above constraints (disintegration time ≤ 5 min., tablet hardness ≥ 10 kg., and dissolution ≥100% in 50 min.) produced eight solutions (formulations) that satisfied the requirements. A second grid search where the constraint on tablet hardness was relaxed to 8 kg. yielded 650 solutions. Of course, it is easier to choose one of eight solutions than one of 650 solutions.

In addition to providing a printout of each formulation, the grid search program also gives the corresponding values for the responses. This is the point where one can trade off one response for

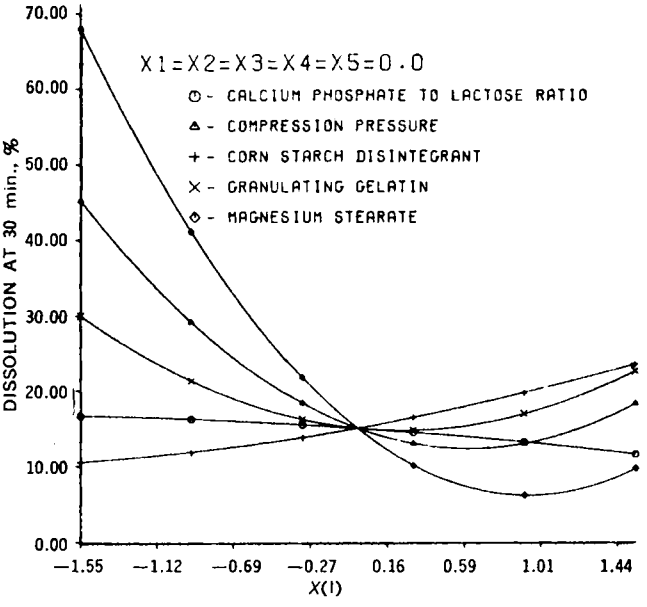

Figure 4—*Composite plot for dissolution response as a function of each independent variable,* X_i (i = *1, 2, . . . , 5*).

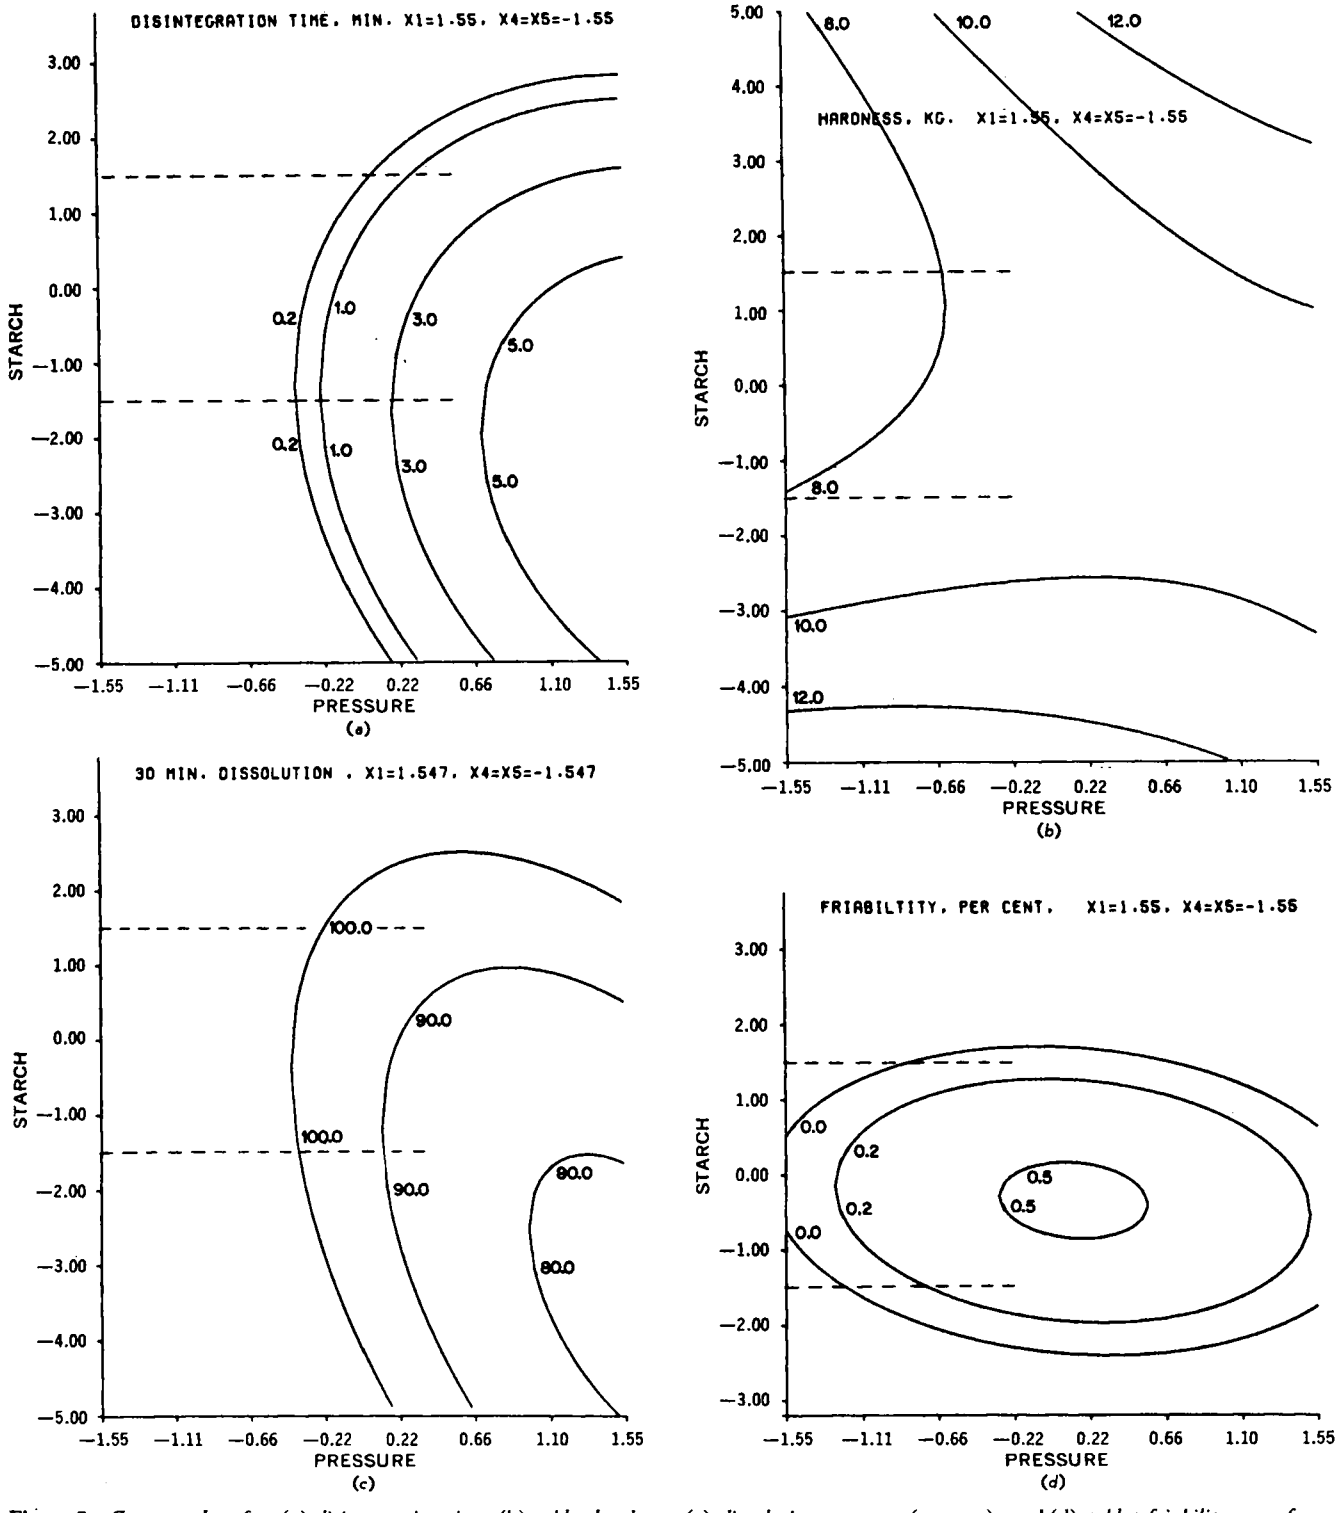

Figure 5—*Contour plots for:* (a) *disintegration time,* (b) *tablet hardness,* (c) *dissolution response (percent), and* (d) *tablet friability as a function of disintegrant level and compressional force. Dotted lines on ordinate denote limits of experimental range (−1.547 to +1.547 eu, see text).*

another or compromise as needed. Thus, the best or most acceptable formulation is selected from the grid search printout to complete the optimization.

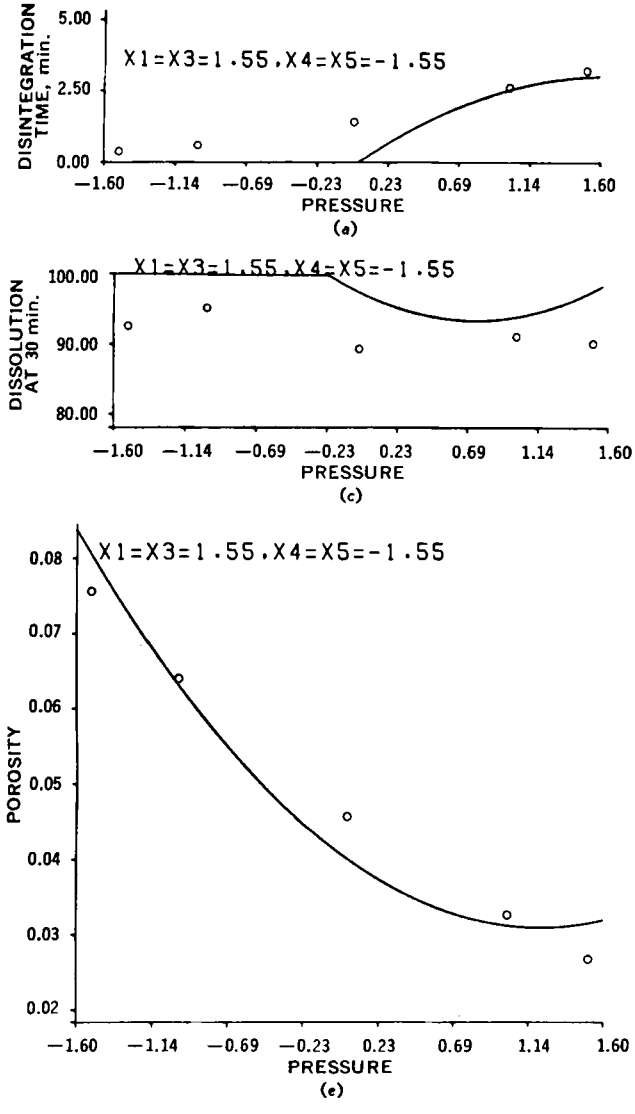
Graphical Approach—Although the computer programs discussed allow one to select the optimum formulation, certain refinements were desirable. Two graphical techniques have proven useful in the optimization procedure.

The first graphical procedure (Fig. 1) is a plot of a given response variable as a function of one of the independent variables. The responses are functions of the five independent variables and can be represented by Eq. 2:

$$Y_i = f(X_1, X_2, X_3, X_4, X_5) \qquad \text{(Eq. 2)}$$

with the full relationship given by Eq. 1. Thus, the relationship between the response and any one variable, *e.g.*, X_1, may be viewed as a partial derivative[12] of Y_i with respect to X_1 while holding all

[12] For convenience, this type of graph is called a "partial derivative" graph, although it is the slope that is actually the partial derivative.



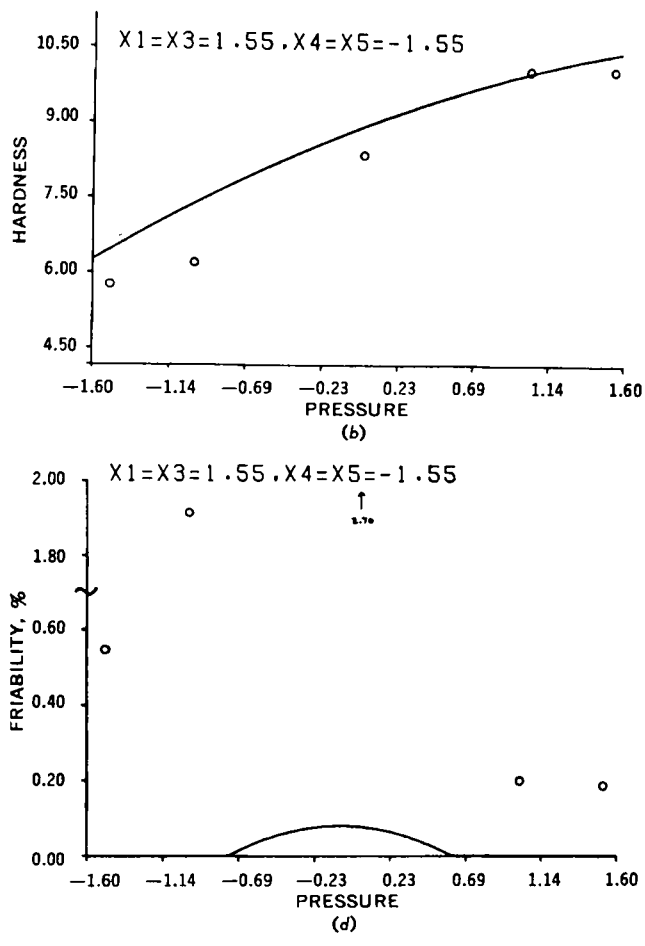


Figure 6—*Plots for several responses as a function of compressional force. The solid lines represent the computer predictions for:* (a) *disintegration time,* (b) *tablet hardness (kilograms),* (c) *dissolution response (percent),* (d) *friability, and* (e) *tablet pore volume; the circles represent experimental points.*

other X's constant. However, because Eq. 1 is a second-order equation with all possible cross-terms, the value of the partial derivatives is still a function of all the independent variables:

$$\left(\frac{\partial Y_i}{\partial X_1}\right)_{X_2X_3X_4X_5} = f(X_1,X_2,X_3,X_4,X_5) \qquad \text{(Eq. 3)}$$

For example, the full partial derivative with respect to X_1 is illustrated in Eq. 4:

$$\left(\frac{\partial Y_i}{\partial X_1}\right)_{X_2X_3X_4X_5} = a_1 + 2a_{11}X_1 + a_{12}X_2 + a_{13}X_3 + a_{14}X_4 + a_{15}X_5 \qquad \text{(Eq. 4)}$$

Thus, the values at which X_2, X_3, X_4, and X_5 are held constant are also important since a change in value will change the graph significantly.

Figure 1 is a plot of disintegration time, Y_1, as a function of the diluent ratio, X_1. In this case, X_2, X_3, X_4, and X_5 are all being held constant at zero or the base level. Note that the X axis is represented in statistical units rather than in physical units; *i.e.*, the experimental range extends from −1.547 to +1.547 experimental units (Table II). The ordinate is represented in the physical units corresponding to the dependent variable plotted. This graph, as well as the others in this series, was drawn from computer tapes[13], so that even the graphical analysis is computerized. The same type of plot can be made for each of the other independent variables, and Fig. 2 shows disintegration time as a function of X_5, the lubricant level.

In fact, one can generate five of these "partial derivative" plots for each of the responses or tablet properties. It is obvious that the paperwork could become overwhelming, so a "composite partial derivative" plot was generated (Figs. 3 and 4). This device enables one to get an overall view of any single response such as tablet hardness. Five of the previous *single* graphs were superimposed by the computer. Each of the five curves represents one of the independent variables, and the X axis represents the experimental field. Keeping the abscissa in terms of experimental units allows this superpositioning. The values at the top of the graph represent the

Table IV—Specifications for Feasibility Search

Variable	Constraint	Experimental Range[a]

Mean granule diameter, mm.	0.170	0.292
Weight uniformity, *RSD* %	0.74	0.54
Thickness uniformity, *RSD* %	1.14	2.00

[a] See *Footnote 11.*

level at which any variable is being held constant during the partial derivative operation. In this case, all are at zero or the base level.

One could generate an infinite number of these plots because the constant values noted at the top of the graphs can cover the entire experimental range for each variable; therefore, some thought must be given to the selection of the constant levels.

The second type of plot useful in optimizations is the contour plot (Fig. 5), again drawn by computer. Essentially, this allows the representation of a three-dimensional situation in two dimensions and is of special utility when the formulator knows, *a priori*, that two of the variables are of most import.

For the contour plots in Figs. 5*a*–5*d*, the specific response is noted on the graph, as are the fixed values of the three extra variables. Both axes are represented in experimental units this time.

Optimum Formula—Based on the printout of the grid search discussed in a previous section, one of the eight formulations was selected as most suitable. It was the formulation with every variable at its experimental extreme (Table V). Diluent ratio, pressure, and disintegrant were to be at high values; binder and lubricant were to be low.

One might have been able to guess these directions, but it would likely have taken many experiments to locate the exact combination of values. The particular formulation selected as the "optimum" is unlike any one of the 27 prepared as part of the experimental plan.

The formulation was prepared and tested in the same manner as the previous ones. Table VI shows the experimental results and the predicted values for the various responses. Between the initiation of this project and this experiment, several additional responses were added.

The agreement between experimental and predicted values is extremely good, especially for the responses of primary interest: disintegration, hardness, and dissolution.

Experimental *versus* Prediction—The optimum formulation was compressed at various pressures, *i.e.*, as a function of X_2. Some results are illustrated in Figs. 6*a*–6*e*, where the solid line is the computer prediction drawn by the plotter. In general, the agreement is excellent. As noted previously, the values for friability are not quantitative although qualitatively the same convex parabolic shape is present.

SUMMARY AND CONCLUSIONS

The optimization technique presented here has enabled the formulator to select a formulation exhibiting optimum properties. In addition, the large quantity of data generated by the required experimentation and the infinite possibilities of subsequent computerized experimentation and graphical analysis permit the investigator to gain an insight into his or her process.

No previous computer experience and no familiarity with computer languages are required.

The steps necessary for the developmental pharmacist to carry out the optimization program may be summarized as follows:

1. Select a system.
2. Select variables:
   a. Independent.
   b. Dependent.
3. Perform experiments and test product.
4. Submit data for statistical and regression analysis.
5. Set specifications for feasibility program.
6. Select constraints for grid search.
7. Evaluate grid search printout.
8. Request and evaluate:
   a. "Partial derivative" plots, single or composite.
   b. Contour plots.

The last step, which concerns the graphical techniques, may be requested at any time after the regression analysis has been performed and will probably be appropriate at several different stages of a project.

The choice of variables is in the hands of the formulator and there are no restrictions as long as the property can be quantitated. The ultimate goal, of course, would be to relate the formulation variables to responses of proven biological significance, *e.g.*, bioavailability, blood levels, or even therapeutic response.

It is recognized that the stability of a formulation is an important parameter. It is possible, in this method, to include the effects of time and storage conditions by using a stability-indicating property as a response variable.

The technique presented here is not meant to, and cannot, replace the developmental pharmacist. It is simply another tool which can aid in his or her search to further define the pharmaceutical system, and because it can be defined, it can be better controlled.

Semiautomated Method for Determining Diethylstilbestrol in Low Dosage Tablet Formulations

R. L. HUSSEY▲, J. L. HALE, and D. P. HOWARD

Abstract □ A semiautomated analytical system was developed for the assay of diethylstilbestrol in tablet preparations. The automated methods are similar in principle to the USP manual procedure. The heart of the assay lies in the use of a coiled quartz capillary tubing with reflectorized backing as the irradiation cell. This method is suitable for concentrations of 0.5 mg. or greater active ingredient per tablet.

Keyphrases □ Diethylstilbestrol—analysis in low dosage tablet formulations, semiautomated method □ Tablets, low dosage diethylstilbestrol formulations—semiautomated method □ Analysis—diethylstilbestrol in low dosage tablet formulations, semiautomated method

A semiautomated method was developed for the determination of diethylstilbestrol in low dosage tablets. The method is an extension of the manual assay procedure reported by Goodyear *et al.* (1) in 1954, with the inclusion of techniques described by Banes (2, 3) and Doyle *et al.* (4). The method is similar to the procedure found in USP XVIII (5) and has been demonstrated to yield the same assay results as the USP XVIII method for tablets and raw materials. The continuous flow irradiation technique is similar to that previously reported by Skeggs and Hochstrasser (6), Grasshoff (7), Heinicke *et al.* (8), Love and McCoy (9), and Dowd *et al.* (10).

EXPERIMENTAL

Equipment—The analytical train consisted of the following modules: Technicon Liquid Sampler II, Technicon Proportionating Pump III, a spectrophotometer[1] with 5-mm. flow cell, and a recorder[2]. A 435-w. lamp[3] served as the irradiation source of UV light. The irradiation cell[4] was a quartz capillary tubing of 2-mm. i.d. and 4-mm. o.d. The capillary tubing, of 6.0-ml. liquid capacity, was glass-blower bent into a compact grid 160 mm. long per turn [15.8 cm. (6.25 in.)] (Fig. 1). The capillary was backed with an aluminum reflector to intensify the illumination. The position of the capillary was then adjusted with the lamp on and a sample flowing at steady state. The final adjustment was made so that the yellow chromophore was essentially completely produced by the time the sample passed through the first 25% of the capillary tubing. A mere visual examination, using safety glasses to avoid eye injury, proved adequate for this adjustment. A hood was also employed. The hood served to remove ozone and helped to carry heat away from the irradiation cell.

Reagents—For the 50% ethanol–water reagent, add 500 ml. of SD 3A ethanol to 500 ml. of deionized water in a 1-l. volumetric flask. Mix well but do not dilute to volume.

For the pH 9.7–9.8 buffer (as measured in 50% ethanol), dissolve 5 g. of anhydrous dipotassium hydrogen phosphate in 500 ml. of deionized water in a 1-l. volumetric flask. Add 500 ml. of SD 3A ethanol slowly and with stirring. Do not dilute to volume.

Standards—Dissolve approximately 5 mg. of the reference standard *trans*-diethylstilbestrol, weighed accurately, in 100 ml. of 50% ethanol–water in a 100-ml. volumetric flask. Use ultrasonics for 15 sec. to aid dissolution. Approximately once a month, test the linearity of the assay system. For the linearity test, use approximate weights of 7, 5, 3, and 1 mg. weighed accurately. Dissolve these in the same manner as the 5-mg. reference standard.

Sample Preparation—The individual tablet or core of enteric tablet was weighed. The formulation was then thoroughly ground with a mortar and pestle. The ground formulation was then transferred to a suitable volumetric flask so that the final concentration in the flask would be 0.5 mg./10 ml. Deionized water equal to half the labeled capacity of the flask was added by pipet. Ultrasonic vibration for 15 sec. was employed. Pure alcohol equal to half the labeled capacity of the flask was then added by pipet. The flask was diluted to volume with 50% ethanol–water and allowed to stand for 30 min. prior to assay. The contents of the flask were then filtered through filter paper[5] (medium porosity), and the filtrate was placed into sampling cups of 5-ml. capacity.

Table I—Effect of Excipients on Assay when Added to Standard Diethylstilbestrol

Excipient	Milligrams	Assay, %
Talc	52	100.2
	102	100.2
	216	100.2
Magnesium stearate	20	100.0
	48	100.0
	106	100.2
Starch	62	100.8
	125	100.0
	260	100.0
Lactose	11	99.8
	27	100.2
	51	99.8
	99	100.0

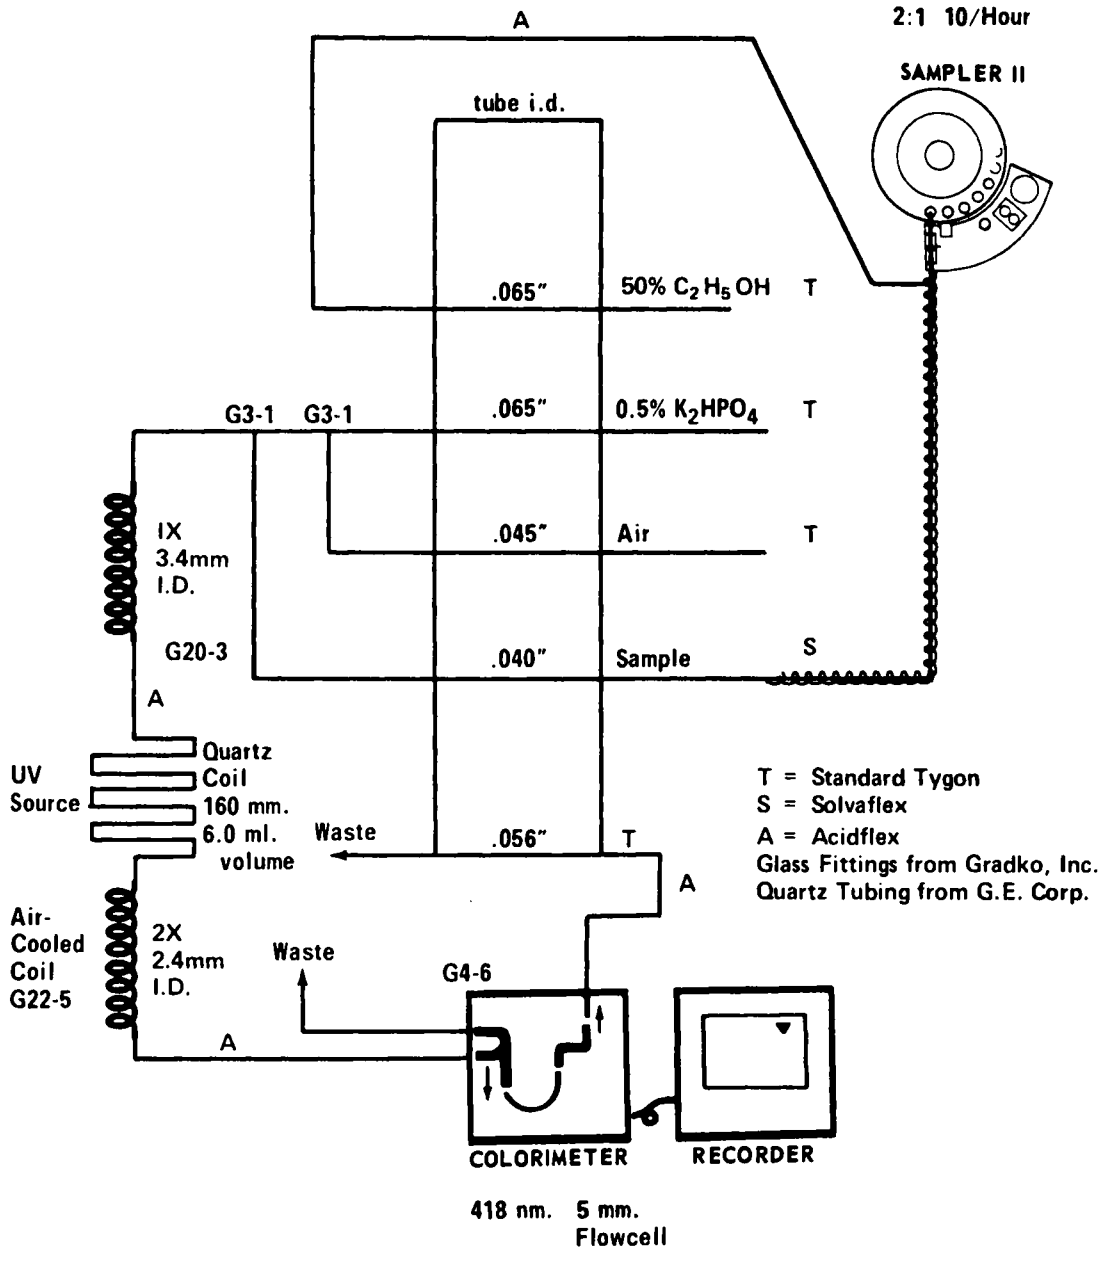

Figure 2—*Autoanalyzer schematic for determination of diethylstilbestrol.*

Procedure—A schematic diagram of the automated system is shown in Fig. 2. A typical assay run is shown in Fig. 3.

DISCUSSION

Two limitations were encountered in the development of this assay. First, tablets of dosage less than 0.25 mg. could not be assayed, owing to sample handling and volume considerations. Second, tablets containing visible dyes, such as core-coated (or finished) enterics, could not be assayed.

The introduction of water prior to alcohol in the tablet dissolution was necessary for complete diethylstilbestrol recovery. Lactose, magnesium stearate, talc, and starch were examined separately and together, both in the presence of diethylstilbestrol and alone, and were shown not to interfere (Table I).

Occasional noise found in the system was traced to aged acidflex tubing. The acidflex tubing (used for its opaqueness) was then changed every 2 weeks as a precaution.

The position of the UV radiation source was the most critical aspect of the analysis. The position needed to be arranged so that the yellow chromophore production occurred in the first 25% of the quartz irradiation coil. Hold time in the coil is approximately 3 min. Visual checking of the chromophore formation, using safety glasses, proved just as adequate as checking the rise-time to steady state and was easier.

Table II—Reproducibility of Assay, Composite Tablets[a]

Day of Assay	Formulation 1, mg./Tablet	Formulation 2, mg./Tablet
19	—	0.248
18	0.501	0.254
	—	0.254
17	—	0.254
15	0.496	—
	0.495	—
2	0.494	—
1	0.496	—
	0.495	—

[a] Relative standard deviation for Formulation 1 was 0.52%; for Formulation 2, 1.20%.

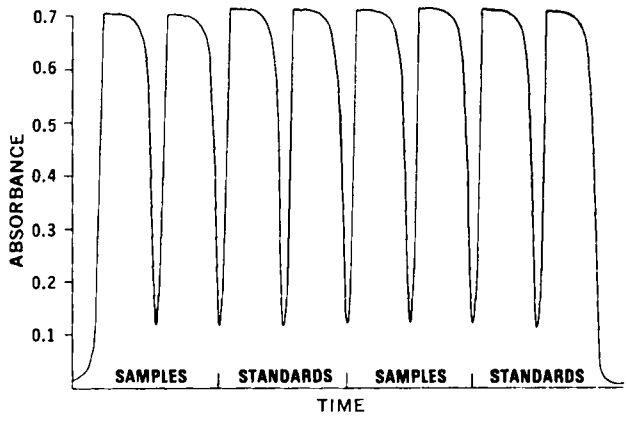

Figure 3—*Typical autoanalysis recording.*

Because of the time required for chromophore formation and wash in the assay, a sampling of 10/hr. was determined to be the maximum rate allowable.

RESULTS

Standard Curves—The absorbances, at 418 nm., of four solutions in the concentration range 0–60 mcg./ml. were measured. A plot of the four values gave a straight line passing through the origin.

Reproducibility of Standards—The reproducibility of the method was checked. The coefficient of variation was 0.005 on standards run as samples (or 0.5% expressed as relative standard deviation).

Reproducibility of Samples—Seven dosage forms, all containing magnesium stearate, starch (and/or paste), lactose, and talc, were automated. The standard deviation for all dosage forms was essentially the same. The method gave day-by-day reliability as well. Table II indicates the typical reproducibility of the assay over 19 days. Not all formulations were run on the same day. Table III compares the manual procedure of USP XVIII to the automated procedure. In this comparison, all samples equivalent to one tablet or core of enteric tablet were weighed from composite grinds to eliminate nonhomogeneity from the comparison. The method has since been employed on a unit dose basis for all seven dosage forms mentioned.

SUMMARY

A semiautomated method for the determination of diethylstilbestrol in tablet dosage forms was described. The automated procedure proved reliable and provided a threefold reduction in assay man-hours.

Table III—Correlation of Automated Method to Manual Method, Composite Tablets

Dosage Form	Strength, mg.	Lot	Manual	Automated
Tablet	0.250	1	0.250	0.242
		2	0.252	0.251
Tablet	0.500	1	0.490	0.482
		2	0.497	0.497
Tablet	1.0	—	1.00	1.04
Tablet	25.0	—	24.8	24.7
Enteric core	0.250	—	0.246	0.250
Enteric core	1.0	—	1.01	1.02
Enteric core	5.0	—	4.90	4.91

Automated, Simultaneous Determination of Dextromethorphan Hydrobromide, Glyceryl Guaiacolate, and Phenylpropanolamine Hydrochloride in Cough Syrups

O. W. A. WEBER and J. E. HEVERAN▲

Abstract □ An automated analytical method for the simultaneous colorimetric determination of dextromethorphan hydrobromide, glyceryl guaiacolate, and phenylpropanolamine hydrochloride in cough syrups was developed. The method significantly reduced the analysis time to 0.4 hr./sample and the relative standard deviations obtained were 1.36, 1.16, and 0.79%, respectively.

Keyphrases □ Dextromethorphan hydrobromide mixtures with glyceryl guaiacolate and phenylpropanolamine hydrochloride—automated, simultaneous colorimetric analysis □ Glyceryl guaiacolate mixtures with dextromethorphan hydrobromide and phenylpropanolamine hydrochloride—automated, simultaneous colorimetric analysis □ Phenylpropanolamine hydrochloride mixtures with dextromethorphan hydrobromide and glyceryl guaiacolate—automated, simultaneous colorimetric analysis □ Cough syrups—simultaneous analysis of dextromethorphan hydrobromide, glyceryl guaiacolate, and phenylpropanolamine hydrochloride □ Colorimetry -analysis, dextromethorphan hydrobromide, glyceryl guaiacolate, and phenylpropanolamine hydrochloride mixtures

With the wide use of an effective antitussive combined with an expectorant and a bronchodilator in cough syrups, the need for a rapid simultaneous method of analysis existed for the determination of dextromethorphan hydrobromide, glyceryl guaiacolate, and phenylpropanolamine hydrochloride. Several investigators reported on the simultaneous analysis of cough–cold preparations using GLC. Mario and Meehan (1) determined the three respective components and chlorpheniramine, Rader and Aranda (2) determined 50 compounds including the three components, and Goebbeler (3) determined dextromethorphan hydrobromide and phenylpropanolamine hydrochloride along with chlorpheniramine and salicylamide. However, the reported methods require manual sample preparation, *i.e.*, direct dilution, liquid–liquid extraction, or liquid–liquid partition chromatography, prior to injection of the sample into the gas chromatograph. An automated procedure[1] was developed by Ek *et al.* (4) for the simultaneous determination of total antihistamines by UV spectrophotometry, individual antihistamines by GC, and phenylpropanolamine hydrochloride by colorimetry using the dimethoxytetrahydrofuran reaction.

Although a wide variety of multicomponent pharmaceutical preparations have been analyzed using simultaneous automated procedures (5–7), the specific analysis of the three commonly used components in cough syrups has not been performed simultaneously using an automated system. This paper describes the simultaneous automated determination of the three active components, with initial sample dilution as the only manual step. Dextromethorphan hydrobromide is determined *via* ion-pair formation with bromcresol green, glyceryl guaiacolate is determined *via* reaction with formaldehyde in sulfuric acid–methanol, and phenylpropanolamine hydrochloride is determined *via* the ninhydrin reaction.

aldehyde solution[2] to 1 l. with absolute methanol.

pH 5 Citrate Buffer—Weigh 84.0 g. of citric acid monohydrate[5] into a 2-l. volumetric flask. Dissolve in 1 l. of water, add 32 g. of sodium hydroxide pellets[6], dissolve, and dilute to volume with water. Check the pH and adjust if necessary.

Ninhydrin Reagent—Dissolve 0.0261 g. of potassium cyanide[4] in 40 ml. of water and dilute to 1 l. with 2-methoxyethanol[7] (Solution I). Dissolve 10 g. of 1,2,3-indantrione monohydrate[7] in 200 ml. of 2-methoxyethanol (Solution II). Mix the total contents of both solutions and allow the reagent to stand overnight prior to use.

Apparatus—The automated system consisted of the following modules: Liquid Sampler II[8]; two Model III proportioning pumps[8]; two variable temperature heating baths[8], each equipped with two 2.4-mm. i.d. × 12.2-m. (40-ft.) coils[8]; three spectrophotometers[9]; and three recorders[10].

Procedure—*Standard Preparation*—Prepare accurately a standard solution in water containing 0.10–0.15 mg./ml. of dextromethorphan hydrobromide, 0.50-1.0 mg./ml. of glyceryl guaiacolate, and 0.15–0.26 mg./ml. of phenylpropanolamine hydrochloride.

Sample Preparation—Dilute accurately an aliquot of the cough syrup containing 10–15 mg. of dextromethorphan hydrobromide, 50–100 mg. of glyceryl guaiacolate, and 15–26 mg. of phenylpropanolamine hydrochloride to 100 ml. with water.

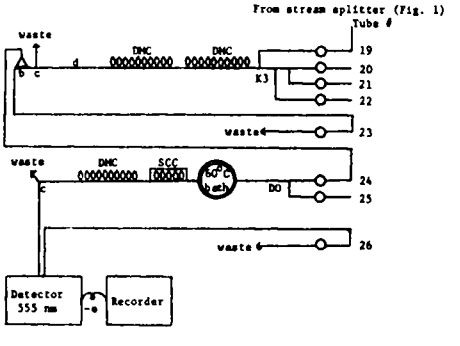

Figure 2—*Flow diagram for glyceryl guaiacolate determination. Key: 19, 1.19 ml./min. sample (Acidflex); 20, 2.03 ml./min. sulfuric acid–water–methanol reagent (Acidflex); 21, 0.6 ml./min. air (Standard); 22, 0.56 ml./min. formaldehyde–methanol reagent (Solvaflex); 23, 1.44 ml./min. waste (Acidflex); 24, 1.71 ml./min. sample (Acidflex); 25, 0.42 ml./min. air (Standard); 26, 1.19 ml./min. cell return (Acidflex); DMC, 28-turn coil; SCC, 14-turn jacketed cooling coil; a, C-1; b, B-0; c, C-3; and d, 15.2-cm. (6-in.) 0.110-i.d. Teflon tubing.*

[7] Matheson, Coleman and Bell.
[8] Technicon Instruments Corp., Tarrytown, N. Y.
[9] Hitachi-Perkin-Elmer model III, Coleman Instruments.
[10] Model SRL, E. H. Sargent and Co.

Sample Testing—Place portions of the samples and standards into the 8.5-ml. polystyrene Liquid Sampler II cups. Place the samples in the odd-numbered spaces in the Liquid Sampler II turntable, interspersing the standards at periodic intervals. Into the even-numbered spaces, place cups containing water. The simultaneous automated analysis is then performed using the schematic flow diagrams shown in Figs. 1–3. Record the absorbances of the samples and standards at 420 nm. for dextromethorphan hydrobromide, at 555 nm. for glyceryl guaiacolate, and at 570 nm. for phenylpropanolamine hydrochloride.

RESULTS

The precision and accuracy for the measurement of each of the components were established by analyzing individual standard aliquots and four marketed cough syrups. For a minimum of 20 determinations, the relative standard deviations for dextromethorphan hydrobromide, glyceryl guaiacolate, and phenylpropanolamine hydrochloride were 1.36, 1.16, and 0.79% at a concentration of 0.10, 1.00, and 0.25 mg./ml., respectively. Plots of the absorbance *versus* concentration for aliquots of dextromethorphan hydrobromide, glyceryl guaiacolate, and phenylpropanolamine hydrochloride are presented in Fig. 4.

Samples of the four marketed cough syrups were analyzed using the automated colorimetric methods. The results obtained for dextromethorphan hydrobromide and glyceryl guaiacolate in cough syrups, Samples A–D, and phenylpropanolamine hydrochloride in cough syrups, Samples C and D, along with the labeled components and manual assay values, are presented in Table I.

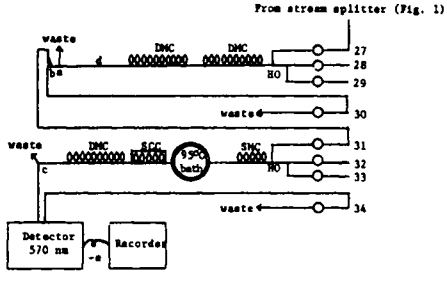

Figure 3—*Flow diagram for phenylpropanolamine hydrochloride determination. Key: 27, 1.19 ml./min. sample (Acidflex); 28, 2.50 ml./min. pH 5 citrate buffer (Standard); 29, 0.60 ml./min. air (Standard); 30, 1.44 ml./min. waste (Acidflex); 31, 2.03 ml./min. sample (Acidflex); 32, 1.44 ml./min. ninhydrin reagent (Acidflex); 33, 0.60 ml./min. air (Standard); 34, 2.42 ml./min. cell return (Solvaflex); DMC, 28-turn coil; SMC, 14-turn coil; SCC, 14-turn jacketed cooling coil; a, C-1; b, C-0; c, C-3; and d, 15.2-cm. (6-in.) 0.110-i.d. Teflon tubing.*

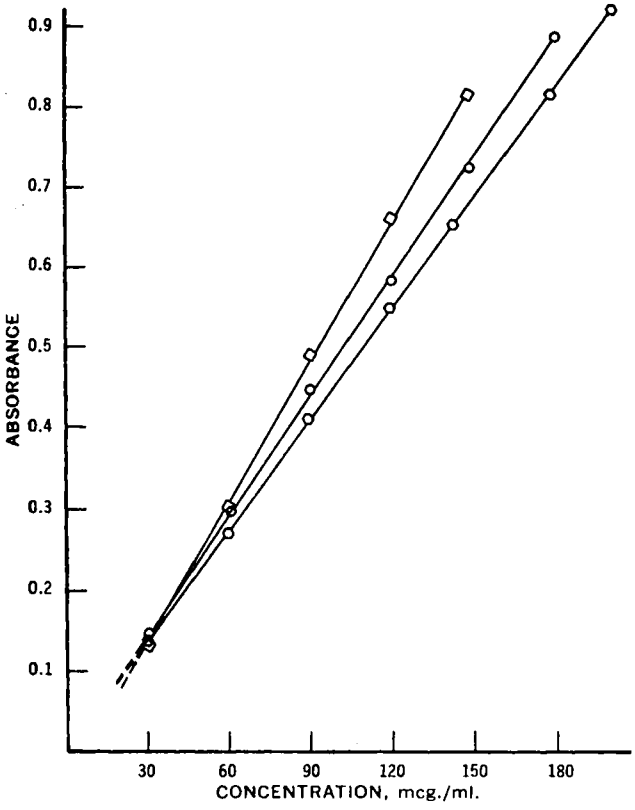

Figure 4—*Standard curves for dextromethorphan hydrobromide, glyceryl guaiacolate, and phenylpropanolamine hydrochloride. Key: O, dextromethorphan hydrobromide (micrograms per milliliter); □, glyceryl guaiacolate (micrograms per milliliter × 6.67); and ○, phenylpropanolamine hydrochloride (micrograms per milliliter × 1.67).*

Portions of the scans obtained for the sample analysis including standards are presented in Figs. 5–7.

DISCUSSION

The automated system was designed specifically for cough syrups containing only the following active components: dextromethorphan hydrobromide, glyceryl guaiacolate, and phenylpropanolamine hydrochloride. The system can be employed for the simultaneous determination of all three or any two components as well as the individual determination of any single component. The combined analytical methodologies cannot be completely applied to formulations containing other active ingredients, such as chlorpheniramine maleate, which would interfere with the colorimetric determination of dextromethorphan hydrobromide.

In the developed automated procedure, an aliquot of the sample was diluted with water and a portion was placed into the sample cups. An aliquot was automatically aspirated, acidified with 1 *N* hydrochloric acid, and extracted with petroleum ether, which was discarded after phase separation. A portion of the aqueous phase was then made alkaline with 1 *N* sodium hydroxide, and the three components were extracted into chloroform. After phase separation, the chloroform stream was divided into three segments by the stream-splitting technique.

One segment of the chloroform-extracted sample was used for formation of the dextromethorphan hydrobromide ion-pair with bromcresol green at pH 5.3, extraction of the complex into the chloroform phase, and measurement at 420 nm. The second segment was utilized for the colorimetric determination of glyceryl guaiacolate. After extraction and phase separation, the chloroform, lower phase, was discarded and the upper phase was passed through a heating bath (60°) for color development. The solution was cooled to room temperature and the resultant color was measured at 555 nm. An alternative extraction procedure was utilized instead of evaporating the chloroform extract to dryness with an in-line evaporator-digestor. Glyceryl guaiacolate was extracted into the sulfuric acid–methanol–water and formaldehyde–methanol reagents. A combination of sulfuric acid–methanol water (60:20:20) was found to yield an efficient phase separation. The third segment of the chloroform stream was used for the colorimetric determination of phenyl-

propanolamine hydrochloride. After extraction of the phenylpropanolamine from chloroform into pH 5 citrate buffer and separation of the phases, the chloroform was discarded and a portion of the aqueous phase was mixed with ninhydrin reagent. This mixed stream was passed through a heating bath (95°) for color development, cooled to room temperature, and measured at 570 nm.

The developed simultaneous automated system significantly reduced the analysis time. Previously, about 8 and 12 hr. were required to perform the comparable manual procedures for two-component and three-component preparations, respectively. Based on a single-lot determination with the automated procedure, the time required for analysis was 3 hr. This represented a time savings of 5–9 hr., depending on the number of components present. Since the automated system is capable of analyzing 20 samples/day in duplicate, a reduction in analytical time to 0.4 hr./sample can be realized.

Molecular-Scale Drug Entrapment as a Precise Method of Controlled Drug Release IV: Entrapment of Anionic Drugs by Polymeric Gelation

JAMES C. BOYLAN* and GILBERT S. BANKER▲

Abstract □ A physicochemical approach to the preparation of drug-containing matrix systems is described in which a soluble anionic drug may be entrapped on a molecular scale in coagulated (gelled) polymer emulsion systems. The resultant dried product (or drug–xerogel system) was designed to provide controlled, prolonged release. The phenomenon of gelation of the polymer emulsions by the addition of a divalent cation (Mg^{+2}) was utilized for the entrapment of various drug materials. A solid, highly reproducible entrapment compound of sodium phenobarbital, magnesium sulfate, and a styrene-acrylic copolymer latex was prepared and subjected to *in vitro* and *in vivo* prolonged-release studies. The physical factors influencing both entrapment and drug release were investigated. A significantly increased duration of therapeutic effectiveness was established by the *in vivo* results. Rats, fed dry polymer powder in their diet, exhibited no toxic effects in a 27-day study. The validity and reproducibility of the entrapment procedure were demonstrated.

Keyphrases □ Polymer emulsion systems—entrapment of anionic drugs by gelation, prolonged-release rates, methods, prepared with sodium phenobarbital, tested in rats □ Timed-release formulations—molecular-scale drug entrapment as a precise method of controlled drug release, anionic drugs by polymeric gelation, prepared with sodium phenobarbital, release rates, rats □ Gelations, polymeric—entrapment of anionic drugs (sodium phenobarbital), methods of preparation, release rates, tested in rats □ Phenobarbital—prolonged-release formulation prepared by molecular-scale drug entrapment, release rates, rats □ Anionic drugs—prolonged-release sodium phenobarbital formulation prepared by molecular-scale drug entrapment, release rates, rats □ Drug release—sodium phenobarbital from a prolonged-release formulation prepared by molecular-scale drug entrapment (polymeric gelation), rats

The inclusion of soluble drugs in insoluble matrixes is well known as a means of controlling drug release rates from solid dosage forms. Diffusional models describing drug release from such systems were thoroughly described by T. Higuchi (1) and W. Higuchi (2). Systems have been designed in which "channeling agents" are added to the matrix to attract fluid into the system as well as to facilitate drug diffusion from the matrix (3). Recently, others described (4) the use of dry gels of cross-linked polymer which are charged by immersion in solutions of the drug. Charging of drugs into cross-linked polymers offers a unique method of releasing drug into the eye for very long periods from soft lens systems or other ocular inserts (5). Other drug release systems from matrixes have obvious application for intrauterine and assorted implantable devices, which might range from being totally insoluble to completely soluble or biodegradable.

In previous papers in this series (6–10), it was demonstrated that cationic drug materials could be entrapped in the solid matrix of a flocculated (linear acrylic acid–methacrylic acid copolymer) polymer emulsion system[1] in such a manner as to exhibit reproducible control of drug release and prolongation of drug action from the resultant dried material. The advantages of polymer emulsion systems for this purpose include a high solids

propanolamine hydrochloride. After extraction of the phenylpropanolamine from chloroform into pH 5 citrate buffer and separation of the phases, the chloroform was discarded and a portion of the aqueous phase was mixed with ninhydrin reagent. This mixed stream was passed through a heating bath (95°) for color development, cooled to room temperature, and measured at 570 nm.

The developed simultaneous automated system significantly reduced the analysis time. Previously, about 8 and 12 hr. were required to perform the comparable manual procedures for two-component and three-component preparations, respectively. Based on a single-lot determination with the automated procedure, the time required for analysis was 3 hr. This represented a time savings of 5–9 hr., depending on the number of components present. Since the automated system is capable of analyzing 20 samples/day in duplicate, a reduction in analytical time to 0.4 hr./sample can be realized.

Molecular-Scale Drug Entrapment as a Precise Method of Controlled Drug Release IV: Entrapment of Anionic Drugs by Polymeric Gelation

JAMES C. BOYLAN* and GILBERT S. BANKER▲

Abstract □ A physicochemical approach to the preparation of drug-containing matrix systems is described in which a soluble anionic drug may be entrapped on a molecular scale in coagulated (gelled) polymer emulsion systems. The resultant dried product (or drug–xerogel system) was designed to provide controlled, prolonged release. The phenomenon of gelation of the polymer emulsions by the addition of a divalent cation (Mg^{+2}) was utilized for the entrapment of various drug materials. A solid, highly reproducible entrapment compound of sodium phenobarbital, magnesium sulfate, and a styrene-acrylic copolymer latex was prepared and subjected to *in vitro* and *in vivo* prolonged-release studies. The physical factors influencing both entrapment and drug release were investigated. A significantly increased duration of therapeutic effectiveness was established by the *in vivo* results. Rats, fed dry polymer powder in their diet, exhibited no toxic effects in a 27-day study. The validity and reproducibility of the entrapment procedure were demonstrated.

Keyphrases □ Polymer emulsion systems—entrapment of anionic drugs by gelation, prolonged-release rates, methods, prepared with sodium phenobarbital, tested in rats □ Timed-release formulations—molecular-scale drug entrapment as a precise method of controlled drug release, anionic drugs by polymeric gelation, prepared with sodium phenobarbital, release rates, rats □ Gelations, polymeric—entrapment of anionic drugs (sodium phenobarbital), methods of preparation, release rates, tested in rats □ Phenobarbital—prolonged-release formulation prepared by molecular-scale drug entrapment, release rates, rats □ Anionic drugs—prolonged-release sodium phenobarbital formulation prepared by molecular-scale drug entrapment, release rates, rats □ Drug release—sodium phenobarbital from a prolonged-release formulation prepared by molecular-scale drug entrapment (polymeric gelation), rats

The inclusion of soluble drugs in insoluble matrixes is well known as a means of controlling drug release rates from solid dosage forms. Diffusional models describing drug release from such systems were thoroughly described by T. Higuchi (1) and W. Higuchi (2). Systems have been designed in which "channeling agents" are added to the matrix to attract fluid into the system as well as to facilitate drug diffusion from the matrix (3). Recently, others described (4) the use of dry gels of cross-linked polymer which are charged by immersion in solutions of the drug. Charging of drugs into cross-linked polymers offers a unique method of releasing drug into the eye for very long periods from soft lens systems or other ocular inserts (5). Other drug release systems from matrixes have obvious application for intrauterine and assorted implantable devices, which might range from being totally insoluble to completely soluble or biodegradable.

In previous papers in this series (6–10), it was demonstrated that cationic drug materials could be entrapped in the solid matrix of a flocculated (linear acrylic acid–methacrylic acid copolymer) polymer emulsion system[1] in such a manner as to exhibit reproducible control of drug release and prolongation of drug action from the resultant dried material. content (usually 40–50%) and a very low viscosity (normally 100–200 cps.).

In the previous studies (6–8), all polymer emulsion systems were observed to flocculate on being coagulated. The flocculated products were dense and nonporous and required polymer hydration and dissolution to achieve satisfactory drug release. Polymers containing carboxyl functionality had appropriate solubility and were available as anionic polymer emulsions. These emulsions were effective in the entrapment of cationic drugs but were ineffective in the entrapment of anionic drugs. Some other type of system was obviously required to achieve molecular-scale entrapment of anionic drugs. In addition, a polymer latex that would gel on coagulation rather than flocculate would provide a less dense, more porous entrapment matrix and might permit the use of less soluble or insoluble polymers as the matrix or carrier.

The purposes of this investigation were to: (*a*) study the phenomenon of gelation of polymer emulsions, as induced by anionic drugs with and without added electrolytes; (*b*) elucidate the factors affecting drug entrapment by polymeric gelation, including polymer concentration, method of preparation, and added electrolytes; (*c*) study the factors affecting drug release rate, including particle size, method of drying, and drug concentration; and (*d*) evaluate these drug–polymer systems using recognized *in vitro* and *in vivo* techniques.

EXPERIMENTAL

Materials and Equipment—The medicinal agents used were either USP or NF quality. The purity of each was checked utilizing melting-point determinations. Table I summarizes the main properties of the polymer emulsions screened and their designation in this paper.

Particle-size reduction was accomplished using a comminutor[1].

Polymer Emulsion Screening—Coagulating of the polymer emulsions of Table I in the presence of various salts was performed using a test tube method outlined by Jirgensons and Straumanis (11). Uni/univalent or bi/bivalent electrolytes (sodium chloride and magnesium sulfate) were used to coagulate the anionic and nonionic polymer emulsions studied. Sodium phenobarbital was used as an anionic model drug substance throughout the study.

Sodium Phenobarbital Assay Procedure—A method of determining the sodium phenobarbital content in the presence of polymer was developed using a differential UV spectrophotometric procedure[2] first suggested by Walker *et al.* (12) and later by others (13–16). The procedure used routinely was as follows. An accurate aliquot of supernatant solution was removed and buffered to pH 10.5 in a volumetric flask. A second identical aliquot was removed and brought to volume with 0.2 *M* NaOH solution.

By using the pH 10.5 solution in the reference side and the 0.2 *M* NaOH solution in the sample side, the differential absorbance was measured at 260 nm. A plot of sodium phenobarbital concentration *versus* absorption was found to be linear and passed through the origin, allowing the accurate determination of the drug in the presence of polymer and magnesium sulfate.

The Entrapment Procedure—The following procedure illustrates the entrapment method commonly employed. The formulation used (Formula I) was: sodium phenobarbital, 1.20 g.; magnesium sulfate, 0.80 g.; distilled water, 20.00 ml.; and Polymer Emulsion 2, 25.00 ml. (11.75 g. of solids). (The USP cathartic dose of magnesium sulfate is 15 g. Calculations show that a dose of this sustained product will give a patient a negligible 73 mg. of magnesium sulfate.)

Procedure A—Fifty milliliters of a solution of magnesium sulfate and sodium phenobarbital was prepared and transferred to a volumetric flask. A 20.0-ml. aliquot of this solution was then transferred to a 100-ml. beaker. The polymer emulsion was added to the drug solution from a freely draining 25-ml. pipet with constant mixing;

[1] Fitzpatrick model M.

[2] A double-beam, UV visible, automatic recording spectrophotometer (Bausch & Lomb Spectronic 505) was used to develop the assay procedure. A Beckman model DU spectrophotometer was used for routine UV spectral analysis. All IR spectra were obtained using a double-beam IR spectrophotometer (Perkin-Elmer model 21).

Table II—pH Gradient for the *In Vitro* Release Rate Test

Hours	Amount of Fluid Removed[a], ml.	pH of Test Fluid
0	—	1.5
0.5	50.0[b]	1.5
1.5	30.0	2.2
2.5	50.0	7.5
4.5	50.0	7.5
6.5	50.0	7.5
8	50.0	—

[a] With one exception (see *Footnote b*), the fluid removed was replaced by an equal amount of pH 7.5 buffer solution (prewarmed to 37°). [b] This sample bottle was removed after 0.5 hr. and assayed. All of the remaining samples were taken from a second identical sample bottle.

the mixture was stirred for an additional 30 sec. and was then allowed to stand for 2 min. During this interval, a solid white gel of firm semisolid consistency formed. This material was transferred to an uncovered Petri dish by means of a spatula. During the next hour, the small amount of water (usually about 3–5 ml.) that leached out of the gel due to syneresis was carefully siphoned off. The gel was then allowed to air dry for 12 hr. At the end of this time, the material was broken into small pieces by hand, oven dried at 45° for 24 hr., and air dried for an additional 24 hr. The dried material was ground in a comminuter (previously cooled by passing dry ice through the machine). This served to prevent sticking of the polymer due to the heat produced by processing. The comminuted material was then sized. Particles that passed through a 40-mesh screen were used for *in vitro* testing.

Several alternative methods of preparing entrapment products were studied to evaluate their effects on the entrapment process and release of entrapped drug. These alternative procedures were as follows.

Procedure B—The solution containing the sodium phenobarbital and the magnesium sulfate was added to Polymer Emulsion 2 (the reverse was done in *Procedure A*).

Procedure C—An aqueous solution of magnesium sulfate was added to an aqueous mixture of the sodium phenobarbital and polymer emulsion.

Procedure D—The product was vacuum dried.

Procedure E—Alcohol USP was used as the drug solvent.

Solubility being a factor, magnesium sulfate was not used and phenobarbital replaced sodium phenobarbital.

Dialysis Procedure—Dialysis studies were used as an *in vitro* technique to ascertain whether or not the sodium phenobarbital and polymer were physically or chemically bound since permanent drug binding would be expected to reduce the therapeutic effectiveness of the sodium phenobarbital. The dialysis sacs were prepared from a semipermeable cellulosic membrane[4]. The closed sac, containing 20 ml. of sample solution, was placed in a 90-ml. (3-oz.) amber glass jar containing simulated gastric fluid USP (without pepsin). The jar was capped, sealed with a water-resistant tape, and

Table III—Oral Chronic Toxicity of Polymer Emulsion 2 Using Urine and Feces Analyses

Test[a]	Sensitivity
Proteinuria[b]	Detects less than 30 mg./100 ml. urine
Glucose[c]	Detects less than 0.5% in urine
Ketouria[d]	Detects 10 mg. of acetoacetic acid/100 ml. urine; reacts readily with acetoacetic acid but not with acetone
Bilirubin[e]	Detects 0.05 mg./100 urine
Occult blood[f]	Detects 1 part in 20,000

[a] All of the tests used are products of the Ames Division of Miles Laboratories, Elkhart, Ind. [b] Albustix test (urine). [c] Clinistix test (urine). [d] Ketostix (urine). [e] Ictotest (urine). [f] Hematest (feces).

allowed to tumble in the rotating-bottle apparatus for the specified time at 37°. Aliquot samples were taken both inside and outside the dialysis sac and assayed.

***In Vitro* Release Rate Procedure**—A rotating-bottle method (17, 18) was selected to evaluate the granular xerogel products. The comminuted samples were weighed in two individual 1.250-g. dosage units, and each sample was placed in a 90-ml. (3-oz.) amber glass jar. Fifty milliliters of simulated gastric fluid USP (without pepsin) was added, and the bottles were sealed as described earlier and were rotated at 41 r.p.m. at 37°. The first bottle was removed after 0.5 hr., the liquid was quantitatively filtered into a volumetric flask, and the solution (after proper dilutions) was assayed spectrophotometrically. The pH of the fluid in the second bottle was gradually changed from 1.5 to 7.5 over 2.5 hr. (Table II). Samples were assayed at each interval

The pH 7.5 intestinal buffer was not simulated intestinal fluid USP. The 0.2 *M* NaOH solution required in the sodium phenobarbital assay procedure precipitated the monobasic potassium phosphate of the USP fluid, but a pH 7.5 borate buffer was substituted with good results.

***In Vivo* Procedure**—*Activity Cages*—Williamson activity cages (19) located in an isolated, dark room were used to evaluate the degree and length of sedation of sodium phenobarbital administered in solution (as evidenced by a decrease in animal activity) *versus* a suspension of the sodium phenobarbital–magnesium sulfate–Polymer Emulsion 2 xerogel. The studies were performed on previously nondrugged, male, Holtzman strain, albino rats, weighing from 280 to 340 g. Male animals were selected because they demonstrate a shorter induction time as well as shorter duration of phenobarbital narcosis as compared to female rats (20). Four animals were randomly selected from the colony. Following 24 hr. of food deprivation (water was given *ad libitum*), the animals were weighed and placed in individual activity cages for a 0.5-hr. period of acclimatization. The animals were then briefly removed to a separate room for

Table IV—Coagulation of Polymer Emulsions

Polymer Emulsion Number[b]	Millimolar Coagulation Values[a]: Sodium Phenobarbital (Maximum Concentration 400 mmoles/l.)	Sodium Chloride (Maximum Concentration 1375 mmoles/l.)	Magnesium Sulfate (Maximum Concentration 325 mmoles/l.)
1	—	—	50–60[c]
2	—	—	50–60
4	180–200	350–400	65–80
5	180–200	1500	—
8	—	500	30–40
16	—	600–700	40–50
20	—	1000–1200	200–250

[a] Coagulation value is the concentration of the salt in millimoles per liter in the final system required to cause complete coagulation (gelation or flocculation) within 0.5 hr. A blank space indicates no coagulation occurred at the upper concentration stated for each salt. Coagulation, if it occurred, was usually immediate. If this rapid coagulation did not occur, the tubes were left undisturbed for 0.5 hr. and then reexamined for coagulation. [b] Polymer emulsion designations are given in Table I. [c] The concentration of the drug or electrolyte in millimoles per liter in the final coagulated system.

[a] Gels containing 22 mg./250 mg. were prepared by Formula I. [b] These values were obtained by dividing the total milligrams of drug found in solution after 72 hr. (inside and outside the sac) by the milligrams of xerogel entrapped drug and multiplying by 100.

oral dosing. All animals were dosed between 3:10 and 4:00 p.m. to eliminate diurnal activity variation (rats being more active at night).

The treatments were: (*a*) sodium phenobarbital, 50 mg./kg.; (*b*) sufficient suspended sodium phenobarbital–gel to release 50 mg./kg. of drug initially and a second 50 mg./kg. dose in sustained form (previously determined by the *in vitro* method already described); and (*c*) an equivalent volume of suspending agent alone (one part syrup USP and two parts water was found to be a good suspending agent for the drug-gel particles). The 50-mg./kg. dose of sodium phenobarbital was chosen from preliminary studies because of its ability to sedate the animals without inducing sleep. Malone *et al.* (20) reported that the volume of the vehicle influences the onset of sodium phenobarbital action. Consequently, fluid volume was maintained at 8 ml. After dosing, the rats were returned to the activity cages for a predetermined period.

Acute Toxicity—The purpose of this study was to determine any gross difference in acute toxicity between sodium phenobarbital and the drug-xerogel product. Since the action of sodium phenobarbital lasts much longer in the female rats as compared to the male (20), females were used. The oral LD_{50} of sodium phenobarbital in female rats reported from different laboratories was found to be quite variable (150–350 mg./kg.).

All animals used in the acute toxicity evaluation were fasted for 24 hr. prior to dosing. Starting with 150 mg./kg., rats were orally dosed with sodium phenobarbital in 25-mg. increments. The vehicle used was the same syrup–water combination previously mentioned. An approximate LD_{50} of 200 mg./kg. was established for the experimental conditions.

Twenty previously nondrugged, female, Holtzman strain, albino rats, weighing from 130 to 275 g., were used in the final acute toxicity evaluation. Ten rats received 200 mg./kg. of unmodified drug, and 10 were given an amount of drug–xerogel powder sufficient to release 200 mg./kg. of drug initially and a second 200-mg./kg. dose in sustained form (previously determined by the *in vitro* method).

Chronic Toxicity–Twenty 50-g. female rats were involved in this phase of the research. Ten animals were kept in a common cage and served as a control group, and the other 10 were kept in a separate, common cage. The control group was fed a daily measured quantity of powdered chow. The experimental group was fed in an identical manner except a quantity of solid, gelled, dried polymer (see Formula II) equivalent to 7.50 g./kg. of drug per rat was mixed daily with the rat chow powder. The rats were kept on their diets for 27 days.

The second formulation tested (Formula II) consisted of: Polymer Emulsion 2, 25.0 g.; and magnesium sulfate, 2.5 g. (The solid polymer was very tacky and difficult to work with. The presence of this small amount of magnesium sulfate made the solid polymer of Emulsion 2 much easier to handle.)

The animals were examined daily for gross physical changes. Twice weekly the animals were weighed. On these same days, they were placed in metabolism cages and their urine and feces were collected. Table III summarizes the tests run on the collected material.

At the conclusion of the 27 days, the animals were sacrificed. The kidneys, liver, and spleen were grossly examined and removed, and the net weight of each was determined. The organs were then placed in an oven (overnight) and weighed again to obtain a measure of the dry weight. In this manner, any differences in tissue weights between the control and experimental groups could be attributed to a change in either water content or tissue content.

Table VI—Reproducibility of *In Vitro* Release Rates of Sodium Phenobarbital–Magnesium Sulfate–Polymer Emulsion 2 Xerogels

RESULTS AND DISCUSSION

Polymer Screening—The results of the test tube emulsion coagulation procedure are shown in Table IV. Only those polymer emulsions that were coagulated by the drug system are shown. Four of the seven polymer emulsions were eliminated[b] because they appeared to flocculate rather than gel on coagulation and were listed only as "modified acrylics" in company literature. It was felt that the structures were too indefinite and probably very similar to the structure of the acrylic copolymer used by Goodman and Banker (6) to warrant extensive study in this project. Of the polymer emulsions left, all of which were styrene–acrylic latexes, Polymer Emulsion 2 was chosen for further investigation. The solid polymeric material precipitated from Polymer Emulsion 2 using 0.1 *N* HCl was insoluble in aqueous media over a wide pH range (from pH 1.0 to 0.2 *M* NaOH).

Dialysis Procedure—It was clearly established by spectrophotometric and gravimetric analyses that the drug could indeed pass freely through the porous membrane whereas the polymer could not cross this barrier.

[b] Polymer Emulsions 4, 5, 8, and 20 (Table I).

Table VII—Effect of Polymer–Drug Ratio on Release Rate Pattern of Sodium Phenobarbital (Cumulative Milligrams Released)[a]

[a] In all cases, a 1.250-g. sample of the drug–polymer gel was evaluated.

Drug Release from Polymer Gels—Table V summarizes the dialysis data obtained for a series of five drug–polymer xerogels. The concentration of materials in these gels and the method by which each was made are also given. Gels were prepared in at least two replicates, permitting comparison of the reproducibility of drug entrapment for a given method of preparation and concentration of drug. The effect of drug concentration on gels made by an identical method and the effect of the method of preparation on the reproducibility of gel entrapment and equilibrium dialysis for gels prepared utilizing the same concentration of drug are also shown in Table V.

Gel Series 1, 2, and 3 (Table V) contained the same initial concentration of drug. Three different methods were used to prepare the various gel products. The sodium phenobarbital available after 72 hr. ranged from 46 to 74% of the amount of drug originally entrapped (22 mg.). Gel Series 4 and 5, containing a greater amount of sodium phenobarbital but prepared by different methods, exhibited drug release varying from 62 to 82% of the original amount enclosed in the gel matrix (28 mg.). Despite this wide variance among the series (the five series in Table V), there is good agreement within each series.

***In Vitro* Release Rate Procedure**—*Rate of Release*—The *in vitro* release rate pattern was obtained initially with gels prepared using Formula I and Procedure A. Figure 1 represents a composite release curve drawn from four identically prepared gels (Gel Series 1) as shown in Tables V and VI. Except for a tailing-off between the 5th and 8th hr., the experimental data follow the "idealized" curve very closely. The idealized curve was constructed on the premise that in an oral sustained-action product involving phenobarbital, the patient should receive a dose of the drug material immediately (*i.e.*, within 0.5 hr.) and a second dose uniformly over the next 7.5-hr. period (for a total of 8 hr.). Ultimately, of course, the therapeutic response of the drug in man is the final criterion of the preparation (21).

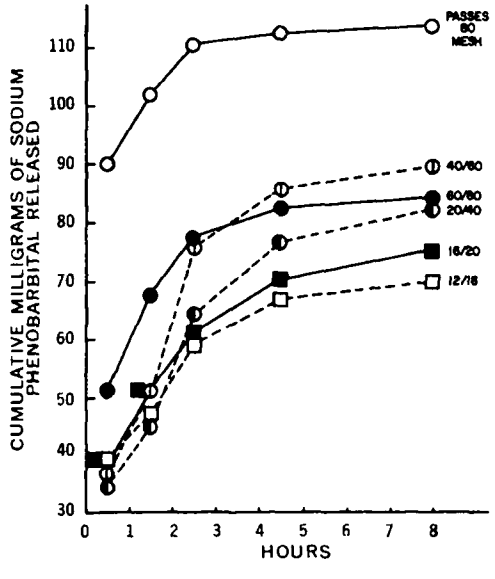

Figure 2—*Effect of particle size on release rate (Formula I and Procedure A).*

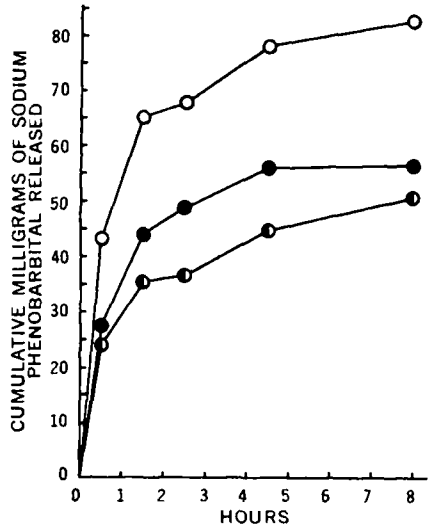

Figure 3—*Effect of method of preparation on the* in vitro *release rate of sodium phenobarbital. Key:* ◐, *Procedure A;* ●, *Procedure B; and* ○, *Procedure C. All samples contained 109 mg. of drug.*

Reproducibility—In this portion of the study, four gels[6] were prepared using Formula I and Procedure A. These gels were then subjected to *in vitro* analysis (Table VI), and excellent reproducibility of *in vitro* drug release was achieved.

Effect of Drug Concentration—This phase of the study was designed to establish limits of satisfactory drug concentrations in the Polymer Emulsion 2–magnesium sulfate gel system prepared using Procedure A. The results illustrating the effect of drug entrapment concentration on release rate are shown in Table VII.

The xerogels containing 5.9 and 8.7% sodium phenobarbital exhibited a desirable 2:1 release ratio (twice as much drug released after 8 hr. as after 0.5 hr.). The xerogel containing 3.1% drug had a 3:1 release ratio. Hence, at this concentration, the initial dose of drug might not be sufficient. At the highest drug concentration studied (11.3% entrapped), most of the drug was released initially (a 1:1.5 ratio), producing a poor release pattern. The limits of sodium phenobarbital concentration for good sustained action appear to be between 5.9 and 8.7% for this polymer system.

Effect of Particle Size—It would be reasonable to assume that the size of the final gel particles would influence the rate of drug release from the insoluble matrix. A smaller granule should release more drug and probably release it more rapidly due to greater surface exposure and a higher relative drug concentration at the xerogel surface.

The release rates of selected particle-size fractions were determined using the rotating-bottle technique. The results are summarized in Fig. 2. With minor exceptions, it can readily be seen that the smaller the particles, the more rapidly and completely the drug is released. Figure 2 also suggests the possibility of using mixed particle-size fractions to achieve a desired release rate.

Effect of Method of Preparation—In the section concerning dialysis, it was shown that, all other factors remaining constant, the method of preparing the sodium phenobarbital–magnesium sulfate–Polymer Emulsion 2 xerogel significantly altered the percent drug entrapment. As a result, an *in vitro* analysis was conducted using gels containing identical amounts of the three ingredients and varying only in the method of preparation (Fig. 3).

In Fig. 3, the shapes of curves A and C are nearly identical. However, Procedure C permits the release of approximately 30% more drug. This could result in greater economy in the manufacturing process through a savings in the amount of drug required and would produce a preparation having greater pharmacological reliability by virtue of more drug being accounted for as available drug. A possible explanation of this difference is that in Procedure A the polymer emulsion is added to a concentrated solution of the salts. As each emulsion drop enters the system, it comes into contact with a large excess of electrolyte solution, thereby gelling immediately. In Pro-

[6] These xerogels are listed as Gels 1, 1_1, 1_2, and 1_3 in Table V.

Table VIII—Effect of Drying on *In Vitro* Release Rate of Sodium Phenobarbital from Polymer Emulsion 2 Xerogels

Method of Drying	Milligrams Released after— 0.5 hr.	8 hr.	Percent Released after— 0.5 hr.	8 hr.
Air 12 hr., oven (45°) 24 hr.	24.2	50.6	22.2	46.5
Vacuum oven 24 hr., no heat	43.5	62.5	39.9	57.3
Air 1 hr., vacuum oven (60°) 12 hr.	60.0	62.5	55.0	57.3

Table IX—Effect of Polymer Concentration on Release of Sodium Phenobarbital from Polymer Emulsion 2 Xerogels

Percent Solids In Emulsion	Drug in System, mg.	Drug Released after 72 hr., mg.	Percent Drug Released
56–48	109	62.4	57
35–36	109	72.0	66
23–24	109	102.0	93

cedure C, however, the magnesium sulfate solution is slowly added to an aqueous mixture of the sodium phenobarbital and the polymer emulsion. Gelation does not occur until a sufficient concentration of electrolyte is present in the system. When this concentration is reached, the entire emulsion tends to gel simultaneously and more slowly. Consequently, the two processes result in a completely different rate of matrix formation. Of the three methods, Procedure C would be expected to produce a more porous xerogel and, in fact, resulted in the most rapid and complete dissolution release.

Another change in the method of preparing the gel involved the use of a vacuum oven to dry the product rather than conventional air and oven drying (Table VIII). Conventional drying produced a gel with the the best release rate of drug by far. One vacuum-dried product released nearly all of its unbound sodium phenobarbital within the first 0.5 hr. This was probably due to the fact that most of the water normally entrapped in the gel was rapidly drawn out of the matrix by the combination of vacuum and heat, thereby promoting drug migration to the gel surface. Sodium phenobarbital, being very water soluble, would have a greater tendency to migrate under these drying conditions. After comminution, probably very little of the unbound drug remained in the interstices of the xerogel.

When alcohol was used as the solvent in place of water, the polymer was precipitated as a solid mass. The alcohol simply "broke" the emulsion, causing the polymer to coagulate. *In vitro* analysis showed that this drug-polymer system released nearly all of its drug in the first 0.5 hr. Therefore, this product was unsuitable for sustaining the release of sodium phenobarbital.

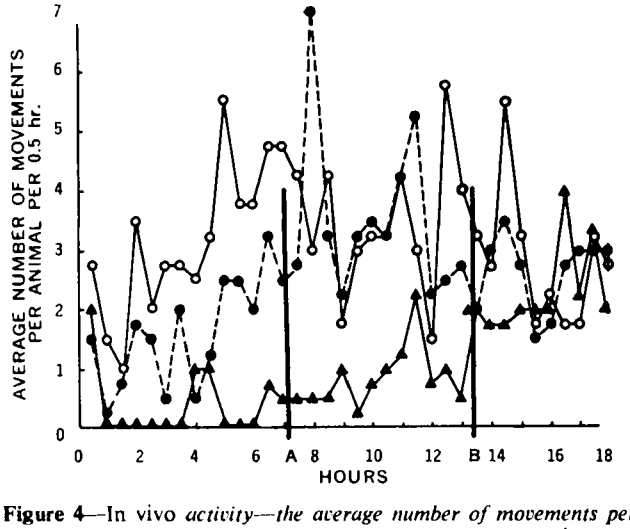

Figure 4—In vivo *activity—the average number of movements per animal per 0.5-hr. interval* versus *time. Key:* O—, *control group;* ●- - -, *sodium phenobarbital group, 50 mg./kg.; and* ▲—, *sodium phenobarbital-polymer group, 50 mg./kg.*

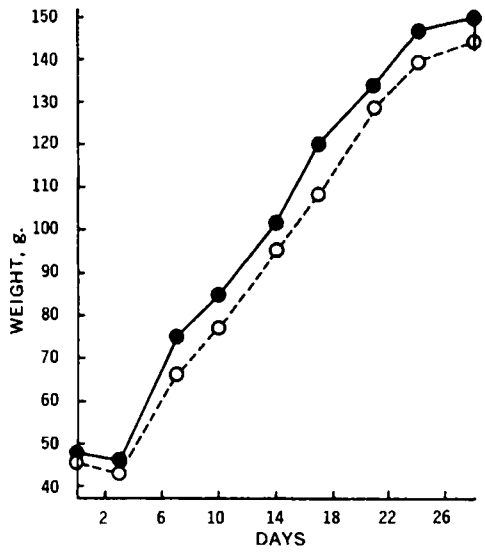

Figure 5—*Growth rate of rats on polymer feed diet* versus *control group. Key:* O- - -, *control group; and* ●—— *polymer group.*

Effect of Polymer Concentration—One potentially undesirable feature of the gel system was the "permanent" entrapment of 25–50% of the drug (depending on the procedure used). It was theorized that if the polymer emulsion were diluted and the drug-xerogel system prepared as before, the resulting matrix would be a looser and more open network. If this were the case, more drug should then be released from the interstices of the matrix.

To test this theory, the aqueous emulsion was diluted with varying amounts of distilled water. Gels were then prepared using Procedure A. The most dilute system that produced a satisfactory gel was prepared from an emulsion containing 23–24% solids (reduced from the original 46–48% solids). Table IX shows that dilution of the emulsion did, indeed, permit a substantially greater amount of the entrapped drug material to be released. This gives the formulator still another method of controlling the release of drugs from the polymer matrix.

***In Vivo* Procedures**—*Activity Cages*—The Williamson activity cages, utilized as previously described, yielded the data shown in Fig. 4. Each point represents an average value for four animals. The results clearly show a lengthening of the therapeutic effectiveness of sodium phenobarbital in the drug-polymer gel group. Furthermore, the *in vivo* drug effect observed permitted analysis of the general intensity (degree of central motor depression) of drug response throughout the test period. Over the entire period of prolonged action of the drug entrapped system, a consistent and continuous drug effect was seen. In Fig. 4, line A represents the sample

Table X—Wet Weights and Dry Weights of Various Organs of the Female Rat

Organ, g.	Polymer Group[a]	Control Group
Spleen		
Wet weight	0.502	0.569
Dry weight	0.113	0.138
Difference	0.389	0.431
Kidney		
Wet weight	1.59	1.56
Dry weight	0.42	0.41
Difference	1.17	1.15
Liver		
Wet weight	6.93	6.59
Dry weight	1.99	2.10
Difference	4.94	4.49

[a] The figures represent an average value for 10 animals (hence, a total of 20 animals was involved in this study).

Table XI—Coagulation of Polymer Emulsion 2 by Various Medicinal Agents[a]

Compound	Chemical	pH of Solution	Coagulation Type
Sodium phenobarbital	Cyclic	9.8	Gelation
Sodium citrate	Salt of an aliphatic acid	5.8	None[b]
Sodium salicylate	Salt of an aromatic acid	5.35	Gelation
Chloral hydrate	Aldehyde	4.5	Gelation
Caffeine alkaloid	Xanthine derivative	6.25	Gelation
Ephedrine sulfate	Secondary amine	5.6	Gelation
Ephedrine hydrochloride	Secondary amine	5.45	Gelation
Methapyrilene hydrochloride	Tertiary amine	6.2	Flocculation
Dextroamphetamine sulfate	Primary amine	5.9	Flocculation
Dihydrocodeinone bitartrate	Tertiary amine	1.75	Flocculation
Pyrilamine maleate	Tertiary amine	4.2	Flocculation

[a] All solutions (20 ml.) contained 1.20 g. of drug and 0.80 g. of magnesium sulfate, except the caffeine solution. This solution contained 0.80 g. of magnesium sulfate, but solubility limited the amount of caffeine to 0.40 g. [b] Gelation did occur when the concentration of magnesium sulfate was increased to 1.60 g.

mean of duration of effect for the group receiving drug alone and line B indicates the sample mean for the rats dosed with the drug–xerogel. For free drug:

$$\bar{x}_f = 7.1 \text{ hr.}$$
$$s^2 = 1.17$$
$$s = 1.08 \text{ hr.}$$
$$90\% \text{ confidence interval} = \pm 1.3 \text{ hr.}$$

where $\bar{x}_f$ is the sample mean, s^2 is the sample variance, and s is the standard deviation.

For drug xerogel:

$$\bar{x}_g = 13.4 \text{ hr.}$$
$$s^2 = 4.94$$
$$s = 2.2 \text{ hr.}$$
$$90\% \text{ confidence interval} = \pm 2.6 \text{ hr. (22)}$$

A sustained therapeutic effect was clearly achieved in that the free drug exhibited a duration of action of 7.1 ± 1.3 hr. whereas the drug–xerogel showed an effectiveness of 13.4 ± 2.6 hr. This portion of the *in vivo* work also served to substantiate the *in vitro* rotating-bottle procedure as a reliable method of predicting drug release for the systems of this study under the test conditions.

Acute Toxicity—Preliminary work suggested that, under the conditions previously described, an oral dose of 200 mg./kg. of sodium phenobarbital represented an approximate LD_{50} for female rats. Accordingly, 10 female rats were given this dose of free drug. Five of the animals died and an equal number lived. A second group of 10 animals were given the drug–polymer gel in an amount sufficient to release 200 mg./kg. of drug initially and an additional 200 mg./kg. of drug gradually. In this group, four animals died and six animals lived.

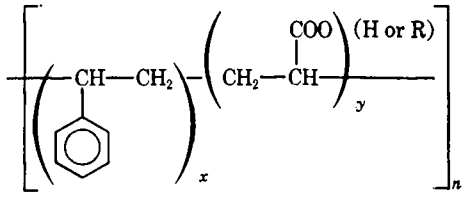
Many sustained-action preparations lower the acute toxicity of the modified drug product (23, 24). This also appeared to be true for sodium phenobarbital in the system used. The xerogel group received twice as much drug in the 8-hr. period as did the group that received unaltered sodium phenobarbital, yet one less animal receiving the sustained-release form died.

Chronic Toxicity—It was believed that the solid polymer material used in this study would not be toxic because of its apparent complete insolubility in aqueous media. It was feared, however, that contaminants (*e.g.*, catalysts, monomers, and surfactants) could be present and might themselves be toxic. Based on preliminary testing conducted in one animal species, the rat, no toxicity was noted. The growth curves of the two groups parallel each other closely (Fig. 5). Frequent urinalysis revealed no sign of any internal damage or structural malfunction (see Table III for the test procedures used). The only material detected in measurable quantity in the urine was a constant 30 mg./100 ml. of albumin in both the control and experimental groups.

The terminal study on the sacrificed animals revealed no visual abnormalities in any rats. Selected portions of the GI tract of several animals from each group revealed no visible irritation. The wet weight *versus* dry weight data of the various test organs are summarized in Table X. Considering the relatively small number of animals used, the organ weights show good experimental agreement.

Gelation Phenomenon—Physical examination and centrifugal testing established that the sodium phenobarbital–magnesium sulfate–Polymer Emulsion 2 product was a gel. It was clearly established that the magnesium ion (present as magnesium sulfate) was the coagulating ion in the system.

The best estimated structure of the copolymer latex as obtained from information from the manufacturer and an IR spectrum of a film of the emulsion is shown below. The ratio of styrene monomer



to acrylic monomer is probably not 1 to 1 (as shown), but rather 1 part styrene to between 0.5 to 0.7 part of acrylic monomer (25). Latex gels are normally highly cross-linked (11), which would contribute to their insolubility.

The gelation of selected polymer emulsions (colloidal suspensions prepared by emulsion polymerization) provides a unique physicochemical method of preparing drug–matrix and drug–xerogel systems. The xerogel entrapment technique utilizing polymer emulsions, as well as flocculation entrapment in such systems (6–8), offers physicochemical approaches to drug dispersion and entrapment with numerous applications in controlled release and drug delivery.

NOTES

Stability of Aspirin in Liquid and Semisolid Bases I: Substituted and Nonsubstituted Polyethylene Glycols

C. W. WHITWORTH▲, H. W. JUN, and L. A. LUZZI

Abstract □ The stability of aspirin in methoxypolyethylene glycol, polyethylene glycol acetate, or a mixture of polyethylene glycols was studied at three temperatures. Degradation proceeded to the highest extent in a mixture of polyethylene glycols and to a lesser extent in methoxypolyethylene glycol. Degradation in polyethylene glycol acetate for 30 days at 45° was insignificant. The data confirm that decomposition of aspirin in polyethylene glycol is due primarily to a transesterification reaction.

Keyphrases □ Aspirin—stability in liquid and semisolid bases, polyethylene glycols □ Polyethylene glycols—stability of aspirin, liquid and semisolid bases □ Stability, aspirin—in polyethylene glycols, liquid and semisolid bases

In a previous paper (1) on the decomposition of aspirin in polyethylene glycols, these laboratories provided data showing that degradation was due at least in part to a transesterification reaction between aspirin and the polyethylene glycols. This conclusion was reached when it was found that acetic acid was not among the degradation products when a mixture of aspirin and polyethylene glycols was stored at different temperatures. Further evidence of a transesterification reaction was the degradation of aspirin in various polyethylene glycols in the apparent absence of moisture and the resultant appearance of acetylated polyethylene glycol. Both the absence of acetic acid and the presence of acetylated polyethylene glycol were established using NMR techniques (1).

The implications of these findings are far reaching and, more specifically, may be applied to cases where polyethylene glycols may be desirable as a vehicle (either liquid, semisolid, or solid) for aspirin preparation. This being the case then, the next logical step was to establish the stability of aspirin when the transesterification pathway is inhibited. It was thought that inhibition of the transesterification mechanism could be brought about by reducing the number of sites available for this reaction, namely, by blocking free hydroxyl groups on the polyethylene glycols.

Methoxypolyethylene glycol has the formula CH_3—O—CH_2—$(CH_2$—O—$CH_2)_nCH_2OH$, which has a methoxy radical at one terminal and only one remaining hydroxyl group that may enter into the reaction. Acetylation of polyethylene glycol also reduces the number of hydroxyl groups and likewise was expected to retard the decomposition of aspirin.

EXPERIMENTAL

Materials—Aspirin USP[1] and polyethylene glycols[2] 400, 1540, and 6000 were used as received. Chloroform[3] was spectroscopic grade. Monosubstituted methoxypolyethylene glycol 550[4] was purchased, and polyethylene glycol 400 acetate was prepared in these laboratories.

Analytical Method—UV spectrophotometric techniques[5] were employed to measure aspirin and salicylic acid (2). Samples were taken at specific time intervals, dissolved in 1% acetic acid–chloroform, and read at 278 nm. for aspirin and 308 nm. for salicylic acid after appropriate dilutions. Standard curves were prepared for aspirin and salicylic acid. A correction factor was obtained to account for the overlapping of absorbance at absorption maxima of each drug. The quantification was based on the standard method of simultaneous spectrophotometric determinations (3).

Procedure—The samples were prepared by the incorporation of 12% of aspirin in methoxypolyethylene glycol 550, polyethylene glycol 400 acetate, and a mixture of polyethylene glycols [polyethylene glycol 400–1540–6000 (27:31:42)] at the melting points of the individual bases. Preparations were kept in airtight amber containers and stored in a desiccator at 4, 26, and 45°. At various time intervals a weighed amount (2.5 g.) of samples was dissolved in 1% acetic acid–chloroform. Spectrophotometric readings were taken immediately after dilutions for aspirin and salicylic acid.

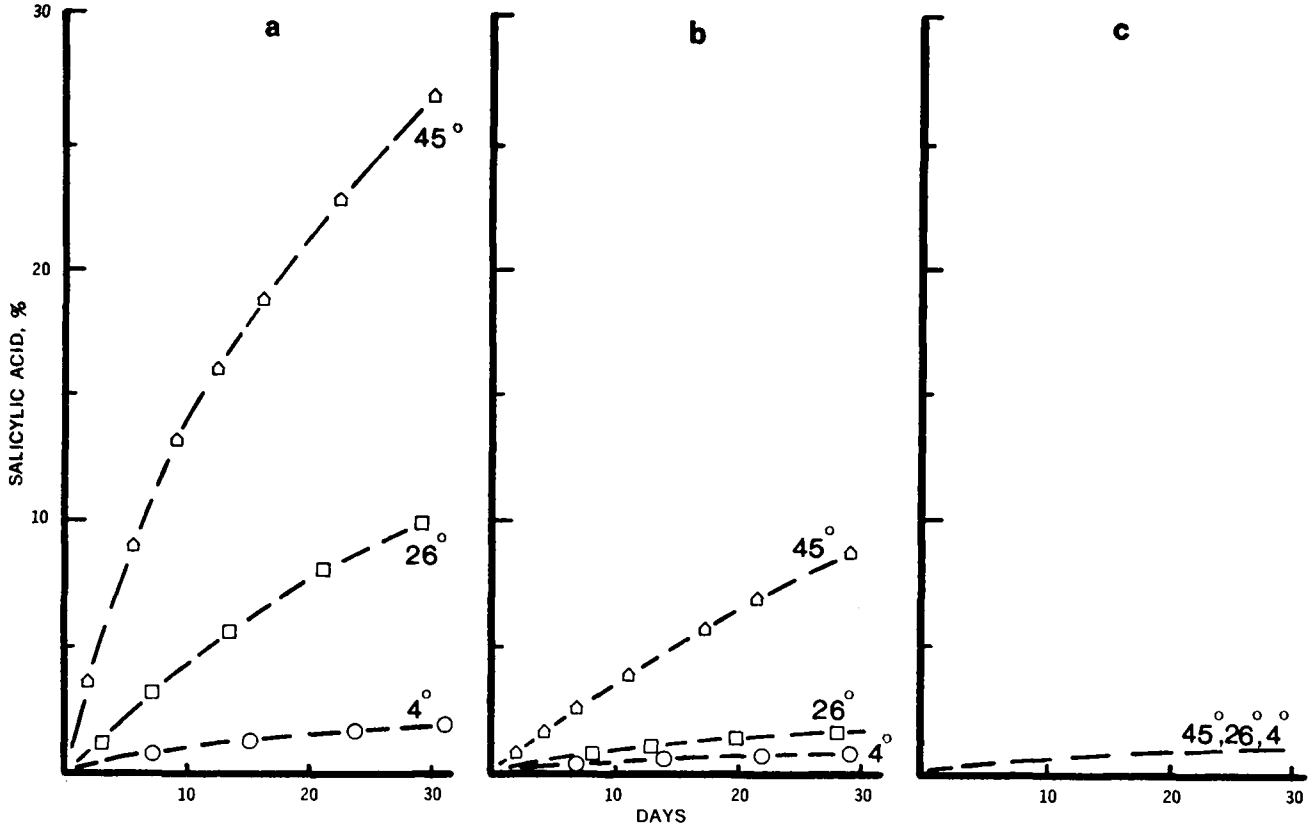

Figure 1—*Rate of appearance of salicylic acid* versus *time in a mixture of polyethylene glycols (a), in methoxypolyethylene glycol 550 (b), and in polyethylene glycol 400 acetate (c) at three temperatures.*

Acetylation of Polyethylene Glycol 400—Polyethylene glycol 400 acetate was prepared by refluxing a mixture of polyethylene glycol 400 and acetic anhydride (1:12 w/w ratio) at 139° for 4 hr. (4). Unreacted acetic anhydride and by-product were removed by vacuum evaporation.

RESULTS AND DISCUSSION

Earlier results (1) showed that degradation of aspirin in polyethylene glycols was due at least in part to transesterification (5). The present report deals with the comparison of the stability of aspirin in formulations of unsubstituted and substituted polyethylene glycols. The objectives were to investigate the possibility of blocking the transesterification route of degradation and to determine the effects on the stability of aspirin when this route is at least partially inhibited.

Table I shows the amount of aspirin remaining in three different formulations at three storage temperatures for 30 days. The percent as aspirin remaining varied widely at the three temperatures when unsubstituted polyethylene glycol was used as the base. The stability of aspirin was enhanced considerably when the monosubstituted glycol (Fig. 1b) was used. The acetylated glycol, prepared in these laboratories, was considerably more effective in preserving the stability of aspirin than the monosubstituted methoxyglycol.

Table I—Percent of Aspirin Remaining after 30 Days of Storage at Three Temperatures

Temperature	Mixture of Polyethylene Glycols (Unsubsituted)	Methoxy-polyethylene Glycol 550	Polyethylene Glycol 400 Acetate
4°	98.3	99.5	99.0
26°	90.0	98.5	99.0
45°	73.5	91.3	99.0

Figure 1 shows the overall profiles of degradation of aspirin in the three preparations at 4, 26, and 45° as indicated by the rate of the appearance of salicylic acid. A significant difference in the rate of formation of salicylic acid was seen between the substituted and unsubstituted glycols.

As shown in Fig. 1c, the stability of aspirin in the acetylated base was not temperature dependent during the 30 days of the test. From these results, it may be concluded that a transesterification reaction between aspirin and the polyethylene glycols is the predominating route for the degradation of aspirin in these bases. Speculation, at this stage, strongly favors the possibility of formulating stable preparations of aspirin in substituted polyethylene glycol bases.

Leucine and Its Derivatives as Potential Elicitors of Insulin Secretion in Rats

VICTOR D. WARNER*▲, ANN M. WARNER*, JOSEPH R. VASSELLI†, ELISABETH DECKE†, F. XAVIER PI-SUNYER†‡, and STEPHEN C. WOODS†

Abstract □ This report describes the testing of a number of leucine derivatives for their ability to increase serum levels of glucose and immunoreactive insulin. Insulin levels increased in rats when L-leucine, DL-leucine, and L-leucineamide were administered. Esters of L-leucine caused no significant effect on glucose or insulin levels.

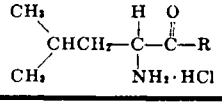
Keyphrases □ Leucine and derivatives—role in eliciting insulin secretion, rats, serum levels of glucose and immunoreactive insulin □ Insulin secretion, rats—effect of leucine and derivatives, glucose and immunoreactive insulin serum levels □ Immunoreactive insulin—role of leucine and derivatives in eliciting secretion, serum levels, rats

The amino acid, leucine, has been shown to cause hypoglycemia in normal subjects by increasing plasma levels of insulin (1, 2). Furthermore, an infusion of 10 essential amino acids, including leucine, results in a marked increase in insulin secretion, although the release of insulin by leucine appears to be *via* a different mechanism than that due to other amino acids (3, 4). In the present experiment, a number of derivatives of leucine were administered to rats, and glucose and immunoreactive insulin levels were obtained at subsequent intervals. It was found that only L-leucine (and DL-leucine to a lesser extent) had the ability to elicit insulin secretion in this preparation. Administration of L-leucineamide also caused an elevation in insulin levels, but it was secondary to a rise in blood glucose.

PROCEDURE

The compounds tested in this study are indicated in Table I. The methyl and ethyl esters of L-leucine were synthesized in the manner of Schneider and Schaeg (5), and the L-leucineamide hydrochloride and DL-leucineamide hydrochloride were synthesized from the corresponding methyl esters in the manner of Smith and Spackman (6). The drugs were all dissolved in distilled water to give a final concentration of 37.5 mg./ml. (w/v). The solutions were then coded according to Table I so that the persons injecting the rats, collecting and preparing the blood samples, and performing the biochemical determinations were unaware of the experimental conditions.

Table I—Compounds Studied



Name	R	Code on Figs. 1 and 2 and Tables II and III
—	—	A: Control solution (distilled water)
L-Leucineamide hydrochloride	NH_2	B
L-Leucine ethyl ester hydrochloride	OCH_2CH_3	C
L-Leucine methyl ester hydrochloride	OCH_3	D
DL-Leucine hydrochloride	OH	E
L-Leucine hydrochloride	OH	F
DL-Leucineamide hydrochloride	NH_2	G

A total of 118 mature albino rats of both sexes was used. All had had continuous access to both food[1] and water for at least a week prior to the experiment. For the experiment itself, all rats were deprived of food (but not water) for 24 hr. Each rat was then given an intraperitoneal injection of one of the seven solutions and returned to its individual home cage. The dose was always 150 mg./kg. of the appropriate drug or the equivalent volume of distilled water (Group A). The rats were removed from the home cage and decapitated by a guillotine at 2.5, 5, 10, or 20 min. after the injections. Uninjected rats (n = 5) were decapitated to provide baseline values for this population. Carotid blood was collected over ice and subsequently centrifuged. The serum portion was then frozen until the determinations were made.

Serum glucose determinations were done by the glucose oxidase method of O'Brien *et al.* (7), and serum insulin determinations were done by a modification (8) of the double antibody method of Morgan and Lazarow (9).

RESULTS

The results of the glucose and immunoreactive insulin determinations are summarized in Figs. 1 and 2 and Tables II and III, respectively. Baseline glucose and insulin values were 100.8 mg./100 ml. and 12.8 microunits/ml. serum, respectively. The placebo injection (Group A) caused a slight increase in glucose and a slight decrease in insulin, the magnitude and duration of which were previously observed in this laboratory (10, 11).

The administration of L-leucine hydrochloride (Group F) caused a large spike of insulin at 2.5 min., which then stabilized at a high level for the duration of the 20-min. test period. There was also a slight (nonsignificant) increase in glucose at that time. Although the small increase in glucose might have accounted for part of the initial rise in insulin in Group F, glucose levels in that group tended to

decrease over the 20-min. test period while insulin values remained elevated. A similar but greatly attenuated insulin pattern was observed after the administration of DL-leucine hydrochloride (Group E); in this instance, the significant increase in insulin after 2.5 min. could not be attributed to an increase in glucose since that group showed a nonsignificant decrease in glucose at that interval.

The administration of L-leucineamide hydrochloride (Group B) also resulted in an elevation of insulin levels, although no early spike (2.5 min.) was observed. In this instance, the increased insulin levels can be attributed to a glucose level that continued to rise throughout the 20-min. period. Administration of DL-leucineamide hydrochloride (Group G) caused a similar pattern, which was again attenuated and which did not appear until 10 min. following the injection.

Administration of the methyl (Group D) and ethyl (Group C) esters had no reliable effect on either glucose or insulin values.

DISCUSSION

L-Leucine was previously shown to cause a biphasic insulin response in man (12). In that experiment, the initial peak occurred at 5 min. and the secondary peak occurred at 20 min. after the injection. The present results in rats are similar, although the initial peak appeared somewhat sooner (2.5 min.). The biphasic insulin response corresponds to the two-pool system of insulin postulated by Porte and Pupo (13) and Porte and Bagdade (14).

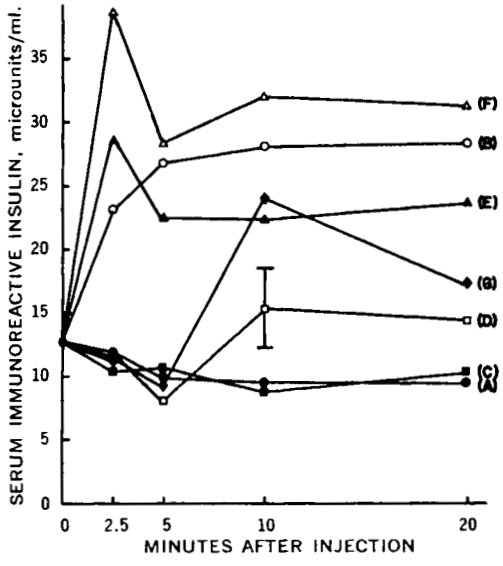

Figure 2—*Mean values of serum insulin for the different groups at the different intervals.*

The attenuated response to the DL-isomer of leucine was also reported previously (15). In that same paper, it was shown that the metabolic products of leucine have no effect in eliciting insulin secretion or hypoglycemia.

The delayed increase in insulin levels following the administration of L- and DL-leucineamide hydrochloride must be attributed to the elevated glucose levels in those rats. The mechanism for this increase in glucose is not known, although it probably is not secondary to a release of epinephrine because any epinephrine would be expected to prevent the observed increase in insulin output (16).

In summary, modification of the leucine molecule by addition of either an amide group or a methyl or ethyl ester eliminated the ability of the molecule to elicit insulin secretion. Furthermore, only the L-isomer of leucine appears to be effective because a DL-mixture responds in a manner predictable by simple dilution of the L-isomer.

Selective Blockade of Muricidal Activity in the Rat by Anorectic Agents

S. E. BOCKNIK▲ and A. S. KULKARNI

Abstract □ The ability of several anorectics to block selectively mouse killing in the rat was examined. A significant ratio between the muricide ED_{50} and the ED_{50} of a drug to produce debilitation in rotarod performance is a measure of selectivity. The mouse-killing behavior of a rat can be blocked with certain drugs at doses that do not render the animal debilitated. This selectivity, determined by the ratio of ED_{50}'s, was found in the four anorectics examined as follows: diethylpropion > dextroamphetamine > aminorex > fenfluramine.

Keyphrases □ Anorectic agents—ability to block mouse killing in rats, determination of selectivity, correlated with decreased rotarod performance □ Muricidal activity—selective blockade by anorectic agents, rat □ Mouse-killing behavior—killer rats, effect of four anorectic agents, determination of selective blockade

Horovitz *et al.* (1) demonstrated that several stimulants, antidepressants, and antihistamines block mouse-killing (muricide) behavior in rats. Barnes *et al.* (2) and Gogerty *et al.* (3) found that stimulants which possess anorectic activity abolish mouse-killing behavior. The stimulant-anorectic dextroamphetamine was shown by Horovitz's group and later by Sofia (4) to block selectively muricide behavior in the rat. Selectivity was observed when the dose of a drug causing muricidal blockade was significantly smaller than that resulting in debilitation of the animal. Selectivity was measured by the ratio between the ED_{50} (MKD_{50}) dose for mouse-killing blockade and the ED_{50} (NTD_{50}) for neurotoxicity (4), as found by the inability of the rat to perform on the rotarod *via* the method of Dunham and Miya (5).

Table I—Effects of Anorexigenic Compounds on Rat Rotarod Performance and Muricide Behavior

Drug	Muricide Blockade, MKD_{50}, mg./kg.[a]	Rotarod Debilitation, NTD_{50}, mg./kg.[a]	NTD_{50}/ MKD_{50}
Aminorex	1.67 (0.97–2.86)	12.1 (6.74–21.8)	7.25
Dextro-amphetamine	0.46 (0.30–0.72)	4.64 (1.82–11.8)	10.09
Diethylpropion	3.83 (2.13–6.89)	68.1 (no limits)	17.78
Fenfluramine	3.16 (1.69–5.92)	14.7 (8.5–25.3)	4.65

[a] MKD_{50} and NTD_{50} are given with fiducial limits in parentheses.

In the present experiment, the mouse-killing selectivity of other anorectic compounds was investigated. Rotarod performance was again used as a measure of neurotoxicity.

EXPERIMENTAL

The anorexigenics, aminorex, dextroamphetamine, diethylpropion, and fenfluramine, were tested in rats for their muricide-blocking ability and debilitation of performance on the rotarod as described in the following procedures.

Mouse Killing—Male Wistar rats[1], weighing 150–200 g. at the start of the experiment, were used. Food and water were freely available to each individually caged rat. To determine mouse-killing ability, a mouse was placed in each rat's cage for 10 min. This 10-min. period for the kill was gradually reduced to 5 sec. Eventually, only those rats that killed consistently and instantly upon confrontation with the mouse were saved for future drug studies. These animals, approximately 15% of the original group, were termed "killer rats."

Saline was administered intraperitoneally to condition the rats to the injection procedure and to eliminate any rats that did not kill after placebo administration. Mice were placed in the rats' cages 30, 60, and 120 min. after the saline injection. The same procedure was followed during the ensuing drug studies.

For a drug session, a single dose of one of the four drugs dissolved in saline was injected. A mouse was introduced to the rat at the three time intervals for a maximum of 30 sec. to test for muricide behavior. At the end of the 30 sec., all mice were removed from the cages. If a mouse was not killed at any of the three time intervals, muricidal behavior was considered blocked.

Killer rats were used for several drug injections. Therefore, at least 2 weeks elapsed between drug administrations. Between drugs, saline was given several times following the same procedure. Four rats were used for each dose of a drug, and the data were analyzed for an ED_{50} for mouse-killing behavior (MKD_{50}) by Horn's (6) method.

Rotarod Test—Wistar rats were also used for rotarod testing. Housing and food conditions were the same as in the mouse-killing experiments. Each rat was placed on a rotarod moving at a rate of approximately 4 r.p.m. and trained to maintain himself for 120 sec. Approximately 10% of the rats had difficulty in this conditioning and were discarded from the experiment. The rats were then intraperitoneally administered one dose of the four drugs to be examined. Thirty, 60, and 120 min. later, each animal was tested for its ability to remain on the rotarod for a 30-sec. period. If a rat fell off the rotating rod during any of the three testing sessions, he

Selective Blockade of Muricidal Activity in the Rat by Anorectic Agents

S. E. BOCKNIK▲ and A. S. KULKARNI

Abstract □ The ability of several anorectics to block selectively mouse killing in the rat was examined. A significant ratio between the muricide ED_{50} and the ED_{50} of a drug to produce debilitation in rotarod performance is a measure of selectivity. The mouse-killing behavior of a rat can be blocked with certain drugs at doses that do not render the animal debilitated. This selectivity, determined by the ratio of ED_{50}'s, was found in the four anorectics examined as follows: diethylpropion > dextroamphetamine > aminorex > fenfluramine.

Keyphrases □ Anorectic agents—ability to block mouse killing in rats, determination of selectivity, correlated with decreased rotarod performance □ Muricidal activity—selective blockade by anorectic agents, rat □ Mouse-killing behavior—killer rats, effect of four anorectic agents, determination of selective blockade

Horovitz *et al.* (1) demonstrated that several stimulants, antidepressants, and antihistamines block mouse-killing (muricide) behavior in rats. Barnes *et al.* (2) and Gogerty *et al.* (3) found that stimulants which possess anorectic activity abolish mouse-killing behavior. The stimulant-anorectic dextroamphetamine was shown by Horovitz's group and later by Sofia (4) to block selectively muricide behavior in the rat. Selectivity was observed when the dose of a drug causing muricidal blockade was significantly smaller than that resulting in debilitation of the animal. Selectivity was measured by the ratio between the ED_{50} (MKD_{50}) dose for mouse-killing blockade and the ED_{50} (NTD_{50}) for neurotoxicity (4), as found by the inability of the rat to perform on the rotarod *via* the method of Dunham and Miya (5).

Table I—Effects of Anorexigenic Compounds on Rat Rotarod Performance and Muricide Behavior

Drug	Muricide Blockade, MKD_{50}, mg./kg.[a]	Rotarod Debilitation, NTD_{50}, mg./kg.[a]	NTD_{50}/ MKD_{50}
Aminorex	1.67 (0.97–2.86)	12.1 (6.74–21.8)	7.25
Dextro-amphetamine	0.46 (0.30–0.72)	4.64 (1.82–11.8)	10.09
Diethylpropion	3.83 (2.13–6.89)	68.1 (no limits)	17.78
Fenfluramine	3.16 (1.69–5.92)	14.7 (8.5–25.3)	4.65

[a] MKD_{50} and NTD_{50} are given with fiducial limits in parentheses.

In the present experiment, the mouse-killing selectivity of other anorectic compounds was investigated. Rotarod performance was again used as a measure of neurotoxicity.

EXPERIMENTAL

The anorexigenics, aminorex, dextroamphetamine, diethylpropion, and fenfluramine, were tested in rats for their muricide-blocking ability and debilitation of performance on the rotarod as described in the following procedures.

Mouse Killing—Male Wistar rats[1], weighing 150–200 g. at the start of the experiment, were used. Food and water were freely available to each individually caged rat. To determine mouse-killing ability, a mouse was placed in each rat's cage for 10 min. This 10-min. period for the kill was gradually reduced to 5 sec. Eventually, only those rats that killed consistently and instantly upon confrontation with the mouse were saved for future drug studies. These animals, approximately 15% of the original group, were termed "killer rats."

Saline was administered intraperitoneally to condition the rats to the injection procedure and to eliminate any rats that did not kill after placebo administration. Mice were placed in the rats' cages 30, 60, and 120 min. after the saline injection. The same procedure was followed during the ensuing drug studies.

For a drug session, a single dose of one of the four drugs dissolved in saline was injected. A mouse was introduced to the rat at the three time intervals for a maximum of 30 sec. to test for muricide behavior. At the end of the 30 sec., all mice were removed from the cages. If a mouse was not killed at any of the three time intervals, muricidal behavior was considered blocked.

Killer rats were used for several drug injections. Therefore, at least 2 weeks elapsed between drug administrations. Between drugs, saline was given several times following the same procedure. Four rats were used for each dose of a drug, and the data were analyzed for an ED_{50} for mouse-killing behavior (MKD_{50}) by Horn's (6) method.

Rotarod Test—Wistar rats were also used for rotarod testing. Housing and food conditions were the same as in the mouse-killing experiments. Each rat was placed on a rotarod moving at a rate of approximately 4 r.p.m. and trained to maintain himself for 120 sec. Approximately 10% of the rats had difficulty in this conditioning and were discarded from the experiment. The rats were then intraperitoneally administered one dose of the four drugs to be examined. Thirty, 60, and 120 min. later, each animal was tested for its ability to remain on the rotarod for a 30-sec. period. If a rat fell off the rotating rod during any of the three testing sessions, he

[1] Harlan Industries, Cumberland, Ind.

was said to be debilitated. Four rats were used for each dose of drug, and the data were analyzed for NTD_{50} in rotarod performance by Horn's (6) method.

RESULTS

The selectivity of mouse-killing behavior can be calculated by dividing the rotarod NTD_{50} dose by the muricide MKD_{50} dose. A ratio close to or below 1.00 indicates a nonspecific blockade of mouse killing, the muricidal block being indistinguishable from debilitation or depression of the animal. A ratio significantly greater than 1.00 indicates selectivity of a drug, mouse-killing blockade at a nonneurotoxic dose.

The effects of the four anorectic compounds examined for muricide blockade and rotarod performance are given in Table I. With dextroamphetamine, the smallest dose (0.46 mg./kg.) of all the anorectics tested was needed to produce mouse-killing blockade in 50% of the rats and also the smallest dose was needed for rotarod debilitation. However, the separation between those two doses was great enough to produce a ratio of NTD_{50}/MKD_{50} of 10.09. Only the ratio for diethylpropion was larger (17.78) than that of amphetamine. Aminorex (7.25) and fenfluramine (4.65) also demonstrated ratios well above 1.00.

DISCUSSION

Of the four anorexigenic agents tested, only the dextroamphetamine data can be compared with results of other investigators. Even though different methods of calculation of the MKD_{50} and the NTD_{50} were used, Sofia (4) and Horovitz *et al.* (1) demonstrated a ratio significantly separating the antimuricide and neurotoxic doses for dextroamphetamine. Our data confirm this separation.

All of the anorexigenic drugs examined in this study illustrated selectivity determined by the NTD_{50}/MKD_{50} ratio in mouse killing in the rat. Muricide behavior was blocked at doses that did not render the rat physically debilitated. The relative selectivity of the anorectics studied is as follows: diethylpropion > dextroamphetamine > aminorex > fenfluramine.

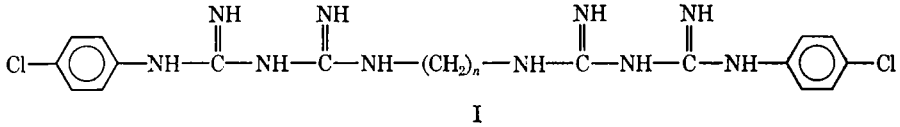
Synthesis and *In Vitro* Antiplaque Activity of Methylene Homologs of Chlorhexidine

VICTOR D. WARNER*▲, DALE B. MIRTH*, SAMUEL S. TURESKY†, and IRVING GLICKMAN†

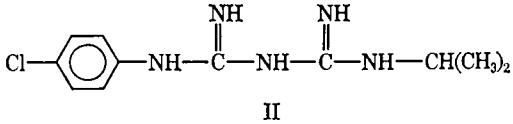
Abstract □ Five straight-chain homologs of chlorhexidine, containing from two to 12 methylene groups, were synthesized and evaluated along with chlorhexidine for *in vitro* antiplaque activity. Maximum antiplaque activity was exhibited by the compounds containing six (chlorhexidine) and 12 methylene groups.

Keyphrases □ Chlorhexidine methylene homologs—synthesized and tested *in vitro* for antiplaque activity □ Antiplaque activity—synthesis and *in vitro* testing of chlorhexidine methylene homologs □ Plaque inhibitors—synthesis and *in vitro* testing of chlorhexidine methylene homologs

Dental plaque is a soft, tenacious, bacterial deposit which forms on the surface of teeth. A close correlation exists between dental plaque and the principal diseases of the mouth: caries and periodontal disease (1). The high incidence of these diseases among the general population (2) is ample evidence that the current approaches to plaque control based on the use of mechanical aids are not effective. In this report, some efforts to develop long-acting chemical inhibitors of plaque formation are described. Recent *in vitro* and clinical studies (2–5) have shown that chlorhexidine [1,6-bis-(N^5-*p*-chlorophenyl-N^1-biguanido)hexane, I, $n = 6$], an antibacterial bisbiguanide, is an effective inhibitor of dental plaque. Three factors are apparently responsible for the antiplaque activity of chlorhexidine: (*a*) the antibacterial activity of chlorhexidine (6), (*b*) the ability of chlorhexidine to bind to the tooth surface (7), and (*c*) the largely bacterial nature of plaque (8).



I



II

was said to be debilitated. Four rats were used for each dose of drug, and the data were analyzed for NTD_{50} in rotarod performance by Horn's (6) method.

RESULTS

The selectivity of mouse-killing behavior can be calculated by dividing the rotarod NTD_{50} dose by the muricide MKD_{50} dose. A ratio close to or below 1.00 indicates a nonspecific blockade of mouse killing, the muricidal block being indistinguishable from debilitation or depression of the animal. A ratio significantly greater than 1.00 indicates selectivity of a drug, mouse-killing blockade at a nonneurotoxic dose.

The effects of the four anorectic compounds examined for muricide blockade and rotarod performance are given in Table I. With dextroamphetamine, the smallest dose (0.46 mg./kg.) of all the anorectics tested was needed to produce mouse-killing blockade in 50% of the rats and also the smallest dose was needed for rotarod debilitation. However, the separation between those two doses was great enough to produce a ratio of NTD_{50}/MKD_{50} of 10.09. Only the ratio for diethylpropion was larger (17.78) than that of amphetamine. Aminorex (7.25) and fenfluramine (4.65) also demonstrated ratios well above 1.00.

DISCUSSION

Of the four anorexigenic agents tested, only the dextroamphetamine data can be compared with results of other investigators. Even though different methods of calculation of the MKD_{50} and the NTD_{50} were used, Sofia (4) and Horovitz *et al.* (1) demonstrated a ratio significantly separating the antimuricide and neurotoxic doses for dextroamphetamine. Our data confirm this separation.

All of the anorexigenic drugs examined in this study illustrated selectivity determined by the NTD_{50}/MKD_{50} ratio in mouse killing in the rat. Muricide behavior was blocked at doses that did not render the rat physically debilitated. The relative selectivity of the anorectics studied is as follows: diethylpropion > dextroamphetamine > aminorex > fenfluramine.

Synthesis and *In Vitro* Antiplaque Activity of Methylene Homologs of Chlorhexidine

VICTOR D. WARNER*▲, DALE B. MIRTH*, SAMUEL S. TURESKY†, and IRVING GLICKMAN†

Abstract □ Five straight-chain homologs of chlorhexidine, containing from two to 12 methylene groups, were synthesized and evaluated along with chlorhexidine for *in vitro* antiplaque activity. Maximum antiplaque activity was exhibited by the compounds containing six (chlorhexidine) and 12 methylene groups.

Keyphrases □ Chlorhexidine methylene homologs—synthesized and tested *in vitro* for antiplaque activity □ Antiplaque activity—synthesis and *in vitro* testing of chlorhexidine methylene homologs □ Plaque inhibitors—synthesis and *in vitro* testing of chlorhexidine methylene homologs

Dental plaque is a soft, tenacious, bacterial deposit which forms on the surface of teeth. A close correlation exists between dental plaque and the principal diseases of the mouth: caries and periodontal disease (1). The high incidence of these diseases among the general population (2) is ample evidence that the current approaches to plaque control based on the use of mechanical aids are not effective. In this report, some efforts to develop long-acting chemical inhibitors of plaque formation are described. Recent *in vitro* and clinical studies (2–5) have shown that chlorhexidine [1,6-bis-(N^5-*p*-chlorophenyl-N^1-biguanido)hexane, I, $n = 6$], an antibacterial bisbiguanide, is an effective inhibitor of dental plaque. Three factors are apparently responsible for the antiplaque activity of chlorhexidine: (*a*) the antibacterial activity of chlorhexidine (6), (*b*) the ability of chlorhexidine to bind to the tooth surface (7), and (*c*) the largely bacterial nature of plaque (8).

[a] A = water and B = ethanol.

Structure–activity studies with biguanides have shown that molecules containing only one biguanide residue, *e.g.*, proguanil (II), do not inhibit plaque formation (4) and that the nature of the substituents attached to the biguanide groups in bisbiguanides has a marked effect on antiplaque (9, 10) and antibacterial activity (6). In addition, the distance between the biguanide residues in bisbiguanides affects antibacterial activity (6). These findings support the hypothesis that two properly substituted biguanide residues separated by a specific distance must be present in this type of molecule for optimal antiplaque activity.

To determine the optimal separation of the two biguanide groups, a series of chlorhexidine methylene homologs (I, n = 2, 4, 8, 10, 12) was synthesized and evaluated for *in vitro* plaque inhibition relative to chlorhexidine.

EXPERIMENTAL[1]

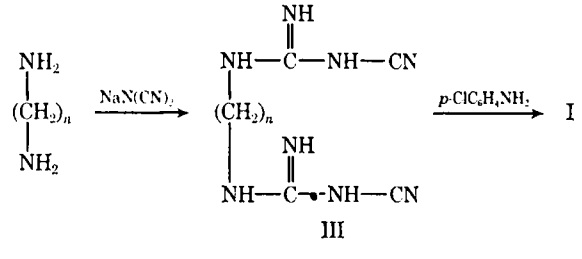
The homologs were synthesized using the method developed by Rose and Swain (11) as outlined in Scheme I. Treatment of the appropriate diaminoalkane with sodium dicyanamide gave the corresponding intermediate bis(N^3-cyano-N^1-guanidino)alkanes (III) (Table I) which, on treatment with *p*-chloroaniline, gave the desired bisbiguanides (I) (Table II).

Bis(N^3-cyano-N^1-guanidino)alkanes (III)—An intimate mixture of the appropriate diaminoalkane dihydrochloride (1.0 mole) and sodium dicyanamide (2.0 moles) was stirred in refluxing 1-butanol (15 ml./0.01 mole) for 12–18 hr. The cooled reaction mixture was filtered and, where the product was soluble (III, n = 2, 4), the filtrate was concentrated *in vacuo* and recrystallized to give the crude biscyanoguanidine which was used without further purification. Where the product was insoluble, the solid on the filter was washed with water to remove sodium chloride and recrystallized (Table I).

Bis(N^5-*p*-chlorophenyl-N^1-biguanido)alkanes (I)—A mixture of the appropriate bis(N^3-cyano-N^1-guanidino)alkane (1.0 mole) and *p*-chloroaniline hydrochloride (2.0 moles) was stirred in refluxing 2-ethoxyethanol (20 ml./0.01 mole) for 3–8 hr. Concentration *in vacuo* followed by recrystallization gave the pure bis(N^5-*p*-chlorophenyl-N^1-biguanido)alkane dihydrochlorides (Table II).

Antibacterial Activity—Antiplaque activity as displayed by chlorhexidine requires that a compound be an antibacterial agent. Therefore, the homologs were first evaluated for their *in vitro* antibacterial activity against *Streptococcus mutans* No. 6715, a pure strain of plaque-forming bacteria[2]. Chlorhexidine[3] and a solvent control were tested concurrently. One milliliter of a solution of the test compound was added to a tube containing 7.85 ml. of trypticase broth, 1 ml. of 50% sterile sucrose solution, and 0.15 ml. of a 24-hr. culture of *S. mutans* No. 6715, and this mixture was incubated under anaerobic conditions[4] for 48 hr.

Antiplaque Activity—The *in vitro* antiplaque activity of these same compounds was evaluated using the method of Turesky *et al.*



Scheme I

10	20	0
12	100	20

[a] All compounds were evaluated as their hydrochloride salts in dimethyl sulfoxide solution. Solvent controls exhibited 0% inhibition. Each compound was tested on five teeth. [b] Percentage of teeth that did not show plaque formation after stated incubation period.

(12). Sterilized extracted human teeth were immersed in solutions of the test compounds for two 1-min. periods, each of which was followed by a 1-min. exposure to air. These treated teeth were washed with 250 ml. of distilled water for 5 min. and then incubated with *S. mutans* No. 6715 under anaerobic conditions. The teeth were suspended in test tubes on orthodontic wire[5] (0.71-mm. diameter) threaded through a hole in the root so that the entire tooth was completely immersed. Subjective estimates were made of adherent microbial growth on the test tube walls, wires, and the teeth and of nonadherent growth in the broth using a scale from 0 (no growth) to 4 (maximum growth). Because in an overwhelming number of tests, growth ratings were either 0 or 4 both in the broth and on the hard surfaces, the findings were expressed as either + (growth) or − (no growth). The total microbial accumulation was considered as *in vitro* plaque.

RESULTS AND CONCLUSIONS

The five homologs and chlorhexidine all inhibited bacterial growth at a concentration of 10^{-5} *M* but not at 10^{-6} *M*. As shown in Table III, antiplaque activity was greatest when the biguanide groups were separated by either six or 12 methylene groups. Since all six compounds were comparable in antibacterial activity at the concentrations tested, the observed differences in antiplaque activity may reflect better binding to the tooth surface by the more active compounds.

Bioavailability of Dicumarol from Different Commercial Tablets in Dogs

M. J. AKERS*‡, J. L. LACH*, and L. J. FISCHER†▲

Abstract □ The availability of dicumarol from three different commercial tablets was determined by measuring plasma levels in dogs and by an *in vitro* dissolution rate test. The products showed significant differences in plasma levels, areas under plasma level curves, peak prothrombin time responses, and rates of dissolution even though they contained the labeled amount of dicumarol.

Keyphrases □ Dicumarol—bioavailability from three different commercial tablets, dogs □ Bioavailability—dicumarol from three different commercial tablets, dogs □ Anticoagulants—bioavailability of dicumarol from three different commercial tablets, dogs

In 1960, Losinski (1) reported that different formulations of dicumarol (bishydroxycoumarin) tablets, although chemically equivalent, exhibited large differences in therapeutic response after administration to patients requiring anticoagulation therapy. On the basis of that report, speculation has arisen that dicumarol tablets from different manufacturers may not be equivalent in terms of drug bioavailability. The availability of dicumarol from three different commercial tablets is reported here. *In vivo* studies, performed by measuring plasma levels of dicumarol in dogs, and *in vitro* dissolution rate tests indicated that significant differences in the bioavailability of the anticoagulant from commercial products do exist.

EXPERIMENTAL

Products Tested—Three commercial tablets, designated Products A, B, and C[1], were purchased in June 1971 from local pharmacies. Each was labeled to contain 25 mg. of dicumarol.

Animals—Four healthy mongrel dogs, weighing between 10 and 21 kg., were used. They were housed in stainless steel cages under controlled temperature and lighting. The animals were fed[2] daily between 8 and 11 a.m. and allowed water *ad libitum*.

Protocol—Large interanimal differences have been observed in the plasma levels of dicumarol after oral administration to dogs on a milligram per kilogram basis. The plasma levels, however, are reproducible in an individual animal (2). Similar results have been observed in humans (2). In the clinical use of the drug, the dosage is adjusted in each patient to provide the desired therapeutic response.

Similar to the clinical use of dicumarol, the dosage used in this study was adjusted in each individual animal to give a desired response. The dosage required to provide a peak plasma level of 21–25 mcg./ml. and a doubling of normal prothrombin time was determined in preliminary experiments. This was accomplished by administering different dosages of dicumarol powder to each dog and measuring drug plasma levels and prothrombin times. After the desired dosage had been determined in an animal (either 4, 5, or 7 mg./kg.), the drug was administered in tablet form. Individual dogs received the same dose of whole 25-mg. dicumarol tablets throughout the study. The animals were given Products A, B, and C on a randomized basis in a crossover design, and each dog received all three products using this procedure. At least a 2-week interval was allowed between doses of dicumarol to the same animal. During this period, the plasma levels of the drug fell to undetectable levels and prothrombin times returned to normal.

The animals were fasted from food for 8 hr. before and 24 hr. after drug administration. Blood samples were obtained from the external jugular vein at various times after the dose. The one-stage prothrombin time was determined on fresh, oxylated plasma. Plasma for dicumarol analysis was stored at −5°.

Analysis of Dicumarol—The spectrophotometric method of Weiner *et al.* (2) as revised by Nagashima *et al.* (3) was used for plasma. Tablets were analyzed for dicumarol by grinding a single tablet in a mortar and adding 25 ml. of 1 *N* NaOH. The solution was filtered and 0.1 ml. of the filtrate was added to 1.4 ml. of the citrate–phosphate buffer employed in the plasma assay for dicumarol. This solution was assayed for dicumarol by the same method used for plasma.

Rate of Dissolution—The USP XVIII method was used. One 25-mg. tablet was placed in a stainless steel basket immersed in 900 ml. of simulated intestinal fluid, pH 7.5 (without pancreatin), at 37°. The basket was about 4 cm. from the bottom of the beaker and rotated at 60 r.p.m. At appropriate times, a 5-ml. sample was withdrawn from the beaker by means of a sintered-glass filter pipet. An equal volume of fluid was added to the beaker. The sample was read directly at 373 nm. to determine dicumarol concentration.

Analysis of Data—Plasma concentrations of dicumarol, areas under plasma level curves, and peak prothrombin times were subjected to an analysis of variance randomized complete block design. Statistical differences between means were computed using the least significant difference method (4). The level of significance was chosen at $p < 0.05$.

[a] Doses used were: Dog 1 (10 kg.), 50 mg.; Dog 2 (18 kg.), 125 mg.; Dog 3 (21 kg.), 100 mg.; and Dog 4 (20 kg.), 100 mg. [b] Significantly different from Products A and C. [c] Significantly different from Products B and C. [d] In all cases the peak prothrombin response occurred at 48 hr. after the dose. Normal prothrombin times of 7–8 sec. were not subtracted from the values presented.

RESULTS AND DISCUSSION

Significant differences were observed among the mean plasma levels of dicumarol produced by the three different products. As shown in Table I, Product B produced significantly higher plasma levels than Product A at all time points. Product C produced the lowest mean plasma levels among the three products tested. Peak plasma levels after oral administration of Product B were almost three times higher than those produced by Product C.

The mean areas under the plasma level curves from 0 to 96 hr. also reflected product differences: Product B produced a significantly larger area than Product A or C. A semilogarithmic plot of the mean values for the 48-, 72-, and 96-hr. plasma levels showed that the mean plasma half-life for dicumarol was approximately the same after each product. The observed differences in plasma levels were probably due to differences in the availability of the drug for absorption.

Also shown on Table I are the mean peak prothrombin time responses attained after a single dose of each product. These values are directly related to the dicumarol plasma level attained with each product. Product B produced a 60% greater anticoagulant response than Product C, with the response from Product A occupying an intermediate position.

A characteristic of the dicumarol plasma concentrations observed in these experiments was the rather constant level produced between 4 and 24 hr. after the dose. The plasma levels could not be adequately fit by simple one- or two-compartment models using single zero- or first-order absorption rate constants. The absorption process was undoubtedly more complex. Since all products contained the labeled amount of drug (Table I), the different plasma concentrations but similarly shaped plasma level curves suggest that incomplete absorption may be primarily responsible for the observed inequivalency among products.

The USP dissolution rate test correlated well with the plasma level results. At the end of 1 hr., Product B allowed the dissolution of five times more dicumarol than was observed with Product C. Product A occupied an intermediate position in its availability for *in vitro* dissolution. The USP dissolution rate test, using simulated intestinal fluid, may be of use to the formulation scientist in predicting the relative bioavailabilities of experimental products.

Large differences existed in the bioavailability of the three commercial products. Only one lot of each product was tested so the reliability of the products cannot be assessed. The highly insoluble dicumarol undoubtedly represents a challenge to the formulation scientist. One would have to conclude from both the *in vivo* and *in vitro* data that the challenge had not been met for at least two of the products.

O'Reilly *et al.* (5) showed that dicumarol tablets are often poorly absorbed from the GI tract of humans. If it can be assumed that similar differences in absorption of dicumarol from the tablets studied here could occur in human patients undergoing anticoagulant therapy, then consideration of these products as biologically equivalent could lead to potentially dangerous clinical situations. It should be emphasized, however, that the present study is limited in scope and that the clinical use of dicumarol tablets should not be based on these results alone. The reporting of this data is meant to alert pharmaceutical and clinical scientists to possible differences in the commercial brands of dicumarol and to serve as an impetus for further studies in man.

Mesomorphic Behavior of Dioctyl Sodium Sulfosuccinate in Hydrocarbon Solvents

RENEE E. ROSENFELD* and SYLVAN G. FRANK▲

Abstract □ The formation of mesomorphic (liquid crystalline) systems by highly concentrated solutions of dioctyl sodium sulfosuccinate in an homologous series of five even-numbered chain length *n*-aliphatic hydrocarbon solvents was studied. It was determined that dioctyl sodium sulfosuccinate concentration, solvent chain length, and temperature significantly affect the formation of a mesomorphic phase. At constant temperature, the concentration of dioctyl sodium sulfosuccinate required to produce a mesomorphic phase increased as the solvent chain length increased from octane to dodecane and then decreased to hexadecane. At constant dioctyl sodium sulfosuccinate concentration in each of the five solvents, the mesomorphic-to-isotropic phase transition temperature reached a minimum at dodecane; however, the phase transition temperatures for dioctyl sodium sulfosuccinate systems in tetradecane and hexadecane were higher than those for decane and octane, respectively.

Keyphrases □ Dioctyl sodium sulfosuccinate—mesomorphic behavior in five hydrocarbon solvents, effects of concentration, solvent chain length, and temperature □ Mesomorphic phases—dioctyl sodium sulfosuccinate in five hydrocarbon solvents, phase transition temperatures, effects of concentration, solvent chain length, and temperature □ Phase transition, mesomorphic—dioctyl sodium sulfosuccinate in five hydrocarbon solvents

Under suitable conditions, certain solid organic compounds can exist in intermediate anisotropic states between true crystals and true isotropic liquids (1). The term mesomorphic or liquid crystal is used to describe the intermediate phase, which is a birefringent fluid of rheological properties ranging from viscous liquids to wax-like semisolids. As a result of their birefringence, mesomorphic phases may be characterized and identified by observation between crossed polarizers in an optical microscope (2). Rosevear (3) identified characteristic textures and birefringence that are related to the molecular arrangement within the phase.

Thermotropic mesomorphic phases are produced by heating a solid to a particular temperature, whereas lyotropic mesomorphic phases occur upon the addition of a solvent to a solid. Lyotropic systems can also be thermotropic in behavior, depending on the amount of solvent added and the temperature. The optical properties and sharp X-ray diffraction patterns indicate a degree of structural order in both types of mesomorphic systems (4, 5).

A number of concentrated solutions of viruses, lipids, polymers, and surfactants form lyotropic mesomorphic phases (6). Balmbra *et al.* (7) indicated that dioctyl sodium sulfosuccinate[1], a surface-active compound, is mesomorphic in the anhydrous state and in high concentration, forms lyotropic mesomorphic phases with water and toluene. At constant temperature, as the dioctyl sodium sulfosuccinate concentration in aqueous systems was increased, the systems underwent phase changes in the order: isotropic → neat phase → viscous isotropic → middle phase. The neat and middle phases were in reversed order from that seen with most other compounds except the phospholipids. The dioctyl sodium sulfosuccinate–toluene systems existed only as middle phase at high dioctyl sodium sulfosuccinate concentrations and were isotropic at lower concentrations. The middle and neat phases are both associated with the smectic mesomorphic phase, one of the three major mesomorphic structural arrangements, the others being nematic and cholesteric. The neat phase consists of a lamellar arrangement of bimolecular layers of surfactant with layers of solvent; the middle phase has an hexagonal structure of long cylindrical micelles (4). There is evidence for additional fine structure in the middle phase, indicating that the hexagonally arranged units may be linear chains of spherical micelles (5).

The purpose of this study was to investigate the formation of lyotropic mesomorphic phases in dioctyl sodium sulfosuccinate–*n*-aliphatic hydrocarbon solvent systems. The parameters evaluated included the influence of surfactant concentration, hydrocarbon solvent chain length, and temperature on the behavior of the lyotropic phases.

EXPERIMENTAL

Materials—Dioctyl sodium sulfosuccinate was synthesized and purified according to the procedure of Balmbra *et al.* (7). The final product, obtained as a hygroscopic waxy solid, gave the correct elemental analysis. Surface tension measurements indicated no minima at the CMC in water, and the CMC value was in good agreement with previously reported values (8, 9).

The hydrocarbon solvents *n*-octane[2], *n*-dodecane[2], *n*-hexadecane[2], *n*-decane[3], and *n*-tetradecane[3] were treated according to the method of Gillap *et al.* (10). Specific gravities determined for all solvents were in excellent agreement with previously reported values (11, 12).

Instrumentation—Microscopic observations were made with a polarizing microscope[4] equipped for photomicroscopy. Sample temperature was maintained on a microscope hot stage[5] regulated with a variable transformer to an approximately 2° rise in temperature per minute. Observations were made at 100×.

Procedure—The binary dioctyl sodium sulfosuccinate–hydrocarbon solvent systems were prepared on a weight/weight percentage basis. The samples, contained in Teflon-lined screw-capped culture tubes, were gently heated with agitation until they fused. The tubes were then slowly cooled to room temperature and allowed to stand for 24–48 hr. prior to observation. This latter step was necessary to ensure equilibration of the samples and thus avoid irreproducibility of the microscopic observations due to possible effects of prior thermal history.

A small portion of the sample was then placed on a microscope slide and formed into a wedge with a cover glass. The slide was

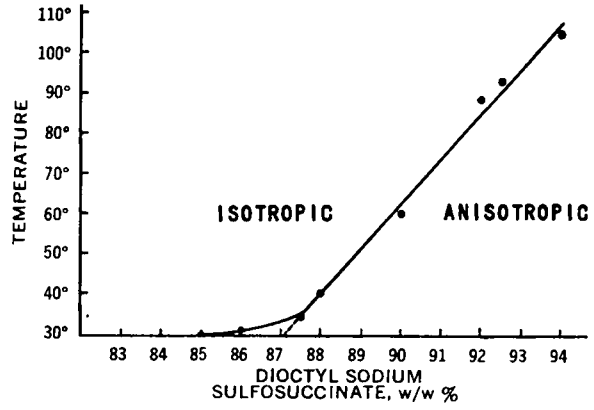

Figure 1—*Anisotropic- (liquid crystalline) to-isotropic transition temperatures for dioctyl sodium sulfosuccinate–dodecane systems.*

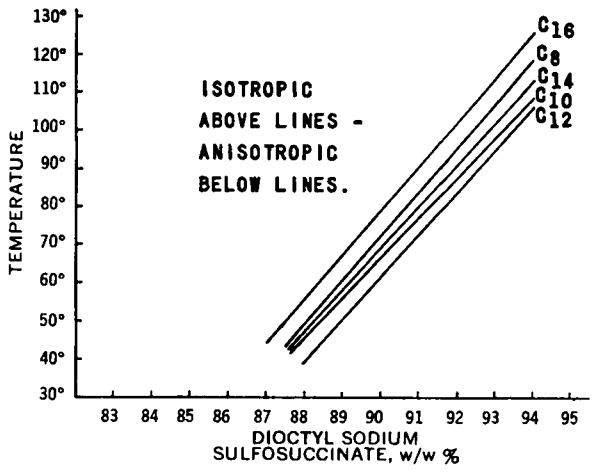

Figure 2—*Anisotropic- (liquid crystalline) to-isotropic transition temperatures for dioctyl sodium sulfosuccinate–n-aliphatic hydrocarbon solvent systems.*

placed on the hot stage at about 30°, and the center portion of the sample was observed as the stage temperature increased. The liquid crystalline systems were anisotropic and showed various birefringent colors and characteristic liquid crystal textures (9). The isotropic samples were dark with no birefringence when observed through the crossed polarizers. The anisotropic-to-isotropic transition temperature was determined to be the first significant darkening of the sample. Three samples for microscopy were taken from different portions of each mixture. Agreement between these runs was good (±0.2°), indicating good mixture homogeneity. Duplicate mixtures agreed within ±1°.

RESULTS AND DISCUSSION

In the absence of solvent, dioctyl sodium sulfosuccinate is a white, waxy, mesomorphic solid at room temperature. When observed between crossed polarizers in a microscope, it is birefringent and has a tightly packed mosaic texture. With increasing concentration of an *n*-aliphatic hydrocarbon solvent, at constant temperature, the system gradually changes to a mesomorphic, turbid, gray-white viscous liquid and finally to a clear, colorless, viscous liquid at the anisotropic-to-isotropic phase transition.

The mesomorphic behavior of dioctyl sodium sulfosuccinate–dodecane systems (Fig. 1) is typical of that of the other dioctyl sodium sulfosuccinate–*n*-aliphatic hydrocarbon solvent systems studied. In Fig. 1, anisotropic-to-isotropic phase transition temperatures are plotted as functions of the weight/weight percentage of dioctyl sodium sulfosuccinate in dodecane. The transition temperature increased as the dioctyl sodium sulfosuccinate concentration increased, consistent with the work of others (7). The lyotropic mesomorphic phase existed at higher temperatures with each increase in dioctyl sodium sulfosuccinate concentration. Below 40°, the data are nonlinear, an apparent result of the instability of the microscope hot stage at temperatures close to ambient. For this reason, the linear portion of the curve was extrapolated to the concentration axis to determine the dioctyl sodium sulfosuccinate concentration at the anisotropic-to-isotropic transition at 30°. Concentrations above 94% weight/weight were not included due to difficulty encountered in achieving adequate homogeneity of the fused binary mixtures. Due to the small amount of solvent present, it was not possible to ensure uniform solvent distribution.

The data for the five *n*-aliphatic hydrocarbon solvents are summarized in Fig. 2. As the *n*-aliphatic solvent chain length increased from octane to dodecane, the anisotropic-to-isotropic transition curves migrated to higher dioctyl sodium sulfosuccinate concentrations at a given constant temperature. For tetradecane and hexadecane, however, this trend was reversed, and at a constant temperature the transition occurred at a lower dioctyl sodium sulfosuccinate concentration with each increment in solvent chain length. Solvent chain length appears to have a significant effect on the formation of the lyotropic liquid crystalline phases in these binary surfactant–solvent mixtures.

When the anisotropic-to-isotropic transition temperature is plotted as a function of increasing *n*-aliphatic hydrocarbon solvent chain length at constant dioctyl sodium sulfosuccinate concentration (Fig. 3), the transition temperature reaches an apparent minimum at dodecane and then rises as the solvent chain length is increased to hexadecane. At constant dioctyl sodium sulfosuccinate concentration, the transition temperature for tetradecane and for hexadecane was higher than that for decane and octane, respectively. This behavior was observed for all of the surfactant concentrations studied. An alternative method of presenting these data is to plot isotherms of dioctyl sodium sulfosuccinate concentration as a function of *n*-aliphatic hydrocarbon chain length (Fig. 4). In interpreting the data in Fig. 4, it is important to remember that the systems are anisotropic above the curves and isotropic below. This is the reverse situation from that in Fig. 3. As shown in Fig. 4, at a constant temperature the dioctyl sodium sulfosuccinate concentration required to give an anisotropic liquid crystalline system increases as the solvent chain length is increased to dodecane and then decreases to hexadecane. The anisotropic system occurs at a lower dioctyl sodium sulfosuccinate concentration in hexadecane than in octane and similarly in tetradecane as compared to decane.

Balmbra *et al.* (7) determined that molecules of dioctyl sodium sulfosuccinate in the absence of solvent exist in hexagonally arranged elongated cylindrical structures. The two-dimensional hexagonal array of cylindrical structural units were generally similar to the inverse middle phase (M_2) proposed by Winsor (13) and the hexagonal II phase of Luzzati and Husson (4). The cylinders resembled elongated micelles, with the surfactant molecules oriented to give a polar core and a hydrocarbon exterior.

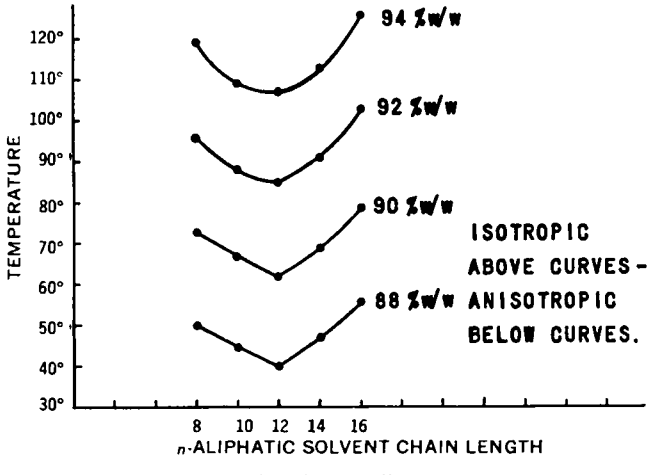

Figure 3—*Anisotropic- (liquid crystalline) to-isotropic transition temperatures for dioctyl sodium sulfosuccinate–n-aliphatic hydrocarbon solvent systems at constant dioctyl sodium sulfosuccinate concentration.*

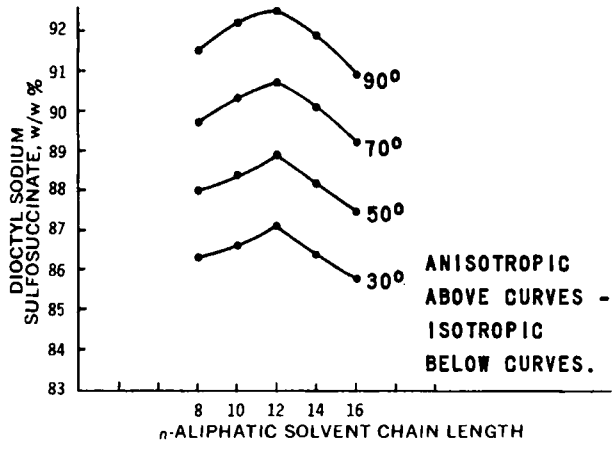

Figure 4—*Isothermal effect of dioctyl sodium sulfosuccinrte concentration on the anisotropic- (liquid crystalline) to-isotropic phase transition of dioctyl sodium sulfosuccinate*-n-*aliphatic hydrocarbon solvent systems.*

Additional fine structure was found (7), suggesting a structural unit consisting of linear chains of aggregated spherical micelles arranged in an hexagonal array. Regardless of the model selected for the structure of the elongated units, it appears that upon addition of solvent the structural arrangement is loosened by solvent orientation at the interface between the structural units (4, 5, 13). Such solvent orientation would, in effect, separate the structural units, decreasing the short-range order but maintaining a degree of long-range ordering dependent on the distance of separation of the units. If the units are composed of linearly aggregated micelles, such solvent penetration would be expected to occur between the micelles and, perhaps to a greater extent, between the linear aggregates themselves. Either of these effects, or both, would produce a weakening of the structural order of the liquid crystalline phase.

At solvent concentrations below the critical amount at a given temperature, deaggregation may be produced by elevating the temperature to the anisotropic-to-isotropic phase transition for the particular system.

Comparison of the octane and hexadecane systems indicates that the anisotropic-to-isotropic phase transition occurs at a higher temperature in hexadecane than in octane (Fig. 3). The lack of significant solvation of dioctyl sodium sulfosuccinate micelles in the longer chain *n*-aliphatic hydrocarbon solvents along with the higher cohesive energy of these solvents resulted in an increase in the micelle weight as the chain length of the solvent was increased (14). It is, therefore, reasonable to expect the dioctyl sodium sulfosuccinate micellar structural units to be more strongly bound in the longer chain *n*-aliphatic hydrocarbon solvents; hence, deaggregation occurs at a higher temperature in hexadecane than in octane. This explanation, however, does not account for the behavior of the dioctyl sodium sulfosuccinate systems in decane, dodecane, and tetradecane. As indicated earlier, the anisotropic-to-isotropic phase transition temperature decreased from octane to dodecane and then increased to hexadecane (Fig. 3). The decrease in thermal stability of the mesomorphic phase, resulting in the minimum at dodecane, indicates that the dioctyl sodium sulfosuccinate structural units are more loosely bound in this solvent than in the other solvents studied.

The "transitional" behavior of dodecane has been reported in studies of the micelle weight of dioctyl sodium sulfosuccinate in the same *n*-aliphatic hydrocarbon solvents. It was found that the micelle weight of anhydrous and hydrous dioctyl sodium sulfosuccinate–dodecane systems was larger than that expected by extrapolation of the corresponding micellar weights in the other solvents (14). In addition, studies of the solubilization of water by solutions of dioctyl sodium sulfosuccinate in the *n*-aliphatic hydrocarbon solvents also indicated the transitional behavior of dodecane systems (15). The relatively low water solubilization and phase properties resembled that of the longer chain solvents, whereas the temperature dependency of the phase transitions was similar to that of the shorter chain solvents. It is not clear at this point what interrelation may exist between these studies; however, it appears that the dioctyl sodium sulfosuccinate–dodecane systems are extremely interesting and worthy of additional study. Work is in progress to elucidate the mechanism of the transitional behavior of dodecane.

Prototropic Reactivity in Salicylamide and Salicylanilide by Molecular Electronic Spectroscopy

STEPHEN G. SCHULMAN▲, PETER J. KOVI, and JOHN F. YOUNG

Abstract □ The acidity dependences of the electronic absorption and fluorescence spectra of salicylamide and salicylanilide were employed to demonstrate the presence of an intramolecular hydrogen bond in the ground states of the neutral molecules. Upon excitation to the lowest excited singlet state, intramolecular proton transfer from the phenolic groups to the carboxamide and phenyl carboxamide groups is observed. Hydrogen bonding and protonation of the carboxamide groups are shown to occur at the nitrogen atoms rather than at the oxygen atoms.

Keyphrases □ Salicylamide—prototropic reactivity, molecular electronic spectroscopy, presence of intramolecular hydrogen bond □ Salicylanilide—prototropic reactivity, molecular electronic spectroscopy, presence of intramolecular hydrogen bond □ Molecular electronic spectroscopy—prototropic reactivity in salicylamide and salicylanilide □ Hydrogen bonding—salicylamide and salicylanilide, prototropic reactivity, molecular electronic spectroscopy

In recent years, salicylamide and salicylanilide have become among the more notorious members of the pharmaceuticals related to salicylic acid. Nonlegend sleeping pills containing salicylamide frequently have been involved in suicide attempts, while several substituted derivatives of salicylanilide have been identified as photosensitizers. Sensitive fluorometric methods for the analysis of salicylamide are available (1–3). However, because of the similarities in the emission frequencies between the species derived from salicylamide and salicylic acid in the basic solutions on which fluorometry is carried out, there is little selectivity in fluorometric analysis and contamination by salicylate is always a problem. Little or no information about the the electronic absorption or fluorescence of salicylanilide appears to be available. As a result of our interests in the electronic structure, analytical toxicology, photochemistry, and photobiology of these compounds, the present study of the acidity dependences of the electronic spectra of salicylamide and salicylanilide was undertaken.

EXPERIMENTAL[1]

Salicylamide[2] and salicylanilide[2] were recrystallized from chloroform.

Chloroform[3] (spectroquality) and sulfuric acid[4] were used without further purification. Distilled deionized water was used to make dilutions of the sulfuric acid and to prepare acetate, phosphate, and borate buffers as well as sodium hydroxide solutions for absorption and fluorescence titrimetric studies.

[1] Absorption spectra were taken on a Beckman DB-GT spectrophotometer. Fluorescence spectra were taken on a Perkin-Elmer MPF-2A fluorescence spectrophotometer whose monochromators were calibrated against the xenon line emission spectrum and whose output was corrected for instrumental response by means of a rhodamine-B quantum counter. The pH measurements were made on an Orion model 801 pH meter with a Beckman silver–silver chloride–glass combination electrode.

[a] Spectral maxima are reported in nanometers.

RESULTS

The long wavelength absorption maxima and fluoresence maxima of salicylamide and salicylanilide in representative regions of the Hammett acidity and pH scales are presented in Table I. The electronic absorption spectra of these compounds are shown in Figs. 1 and 2.

The ground-state dissociation constants for the prototropic equilibria between the protonated and neutral molecules (pKa_1) and between the neutral molecules and anions (pKa_2) derived from salicylamide and salicylanilide were estimated from the midpoints of the variations of the absorption spectra with pH and Hammett acidity (absorptiometric titrations). The excited state dissociation constants (pKa_1^* and pKa_2^*) were determined from the midpoints of the variations of relative fluorescence quantum yields with Hammett acidity and pH (fluorometric titration curves). These data are presented in Table II.

DISCUSSION

Agren (4) previously reported the pKa for the equilibrium between the neutral molecule and anion derived from salicylamide to be 8.9. However, the current spectrophotometric studies yielded a value of 8.3. Dissociation of the neutral molecule results in a shift of the long wavelength absorption maximum to longer wavelength, indicating that dissociation of the neutral salicylamide takes place from the phenolic group in the ground electronic state (5). The magnitude of the ground-state pKa for dissociation from the phenolic group of salicylamide is comparable to that of methyl salicylate (6), the only other simple derivative of salicylic acid in which the phenolic group is free to dissociate while the functional group derived from the carboxyl group of salicylic acid is uncharged.

The shift to longer wavelength of the absorption spectrum of salicylamide, accompanying protonation, is qualitatively similar to that of methyl salicylate (6) and indicates that, in the ground state, protonation of salicylamide occurs in the carboxamido group. However, while methyl salicylate can only be protonated at the carboxyl-type oxygen in concentrated acid, salicylamide can con-

pKa_1^*	−5.3	−6.6
pKa_2	8.3	6.9
pKa_2^*	2.1	—[c]

[a] The pKa values were determined by absorptiometric titrations. [b] The pKa* values were taken from the midpoints of the fluorometric titrations. [c] Equilibrium was not attained during the lifetime of the excited state of the salicylanilide zwitterion.

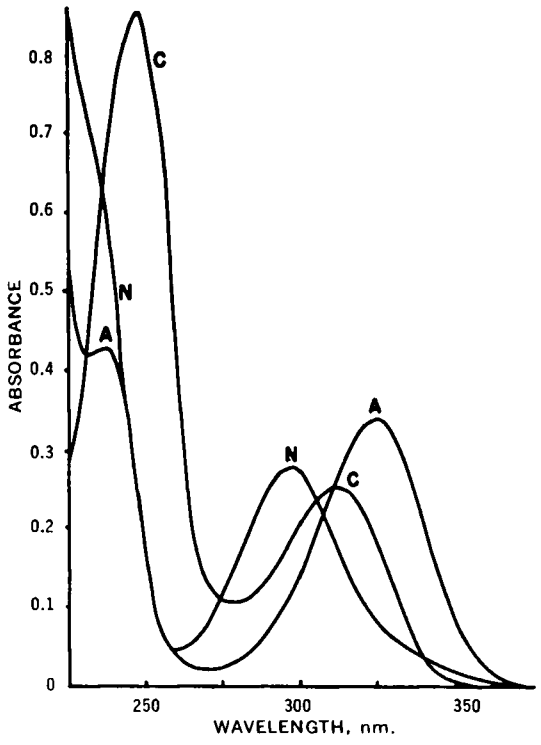

Figure 1—*Absorption spectra of the prototropic species derived from salicylamide (C) cation, $H_0 = -10$; neutral molecule (N), pH 4; anion (A), pH 12.*

ceivably be protonated at either the carbonyl oxygen atom or the amido nitrogen atom of the carbamido group. A recent study (7) showed that, in benzamide, protonation takes place in the ground state, the lowest excited singlet state, and the lowest triplet state at the amido nitrogen atom. The magnitude of the shift of the absorption spectrum of salicylamide upon protonation, which is smaller than that of methyl salicylate, and the pKa for protonation of salicylamide, which is only slightly more acidic than that of benzamide (7) and considerably less acidic than that of methyl salicylate, suggest that protonation occurs at the nitrogen atom in salicylamide. The proposed sequence of protolytic dissociations of salicylamide, beginning with the cation, is shown in Scheme I.

Upon going from concentrated acid to more dilute acid media, the fluorescence of salicylamide shifts to a longer wavelength. This indicates that the protonated molecule, present in concentrated acid,

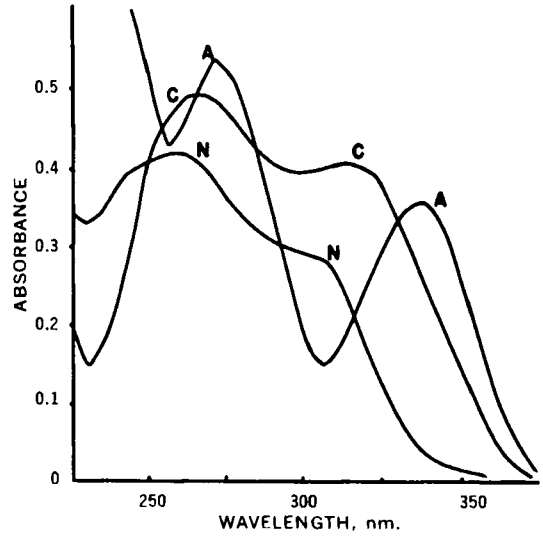

Figure 2—*Absorption spectra of the prototropic species derived from salicylanilide (C) cation, $H_0 = -10$; neutral molecule (N), pH 4; anion (A), pH 12.*

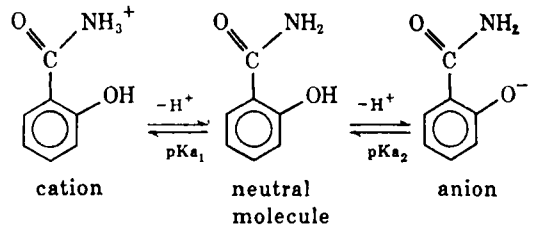


Scheme I—Protolytic reactions of salicylamide in the ground state

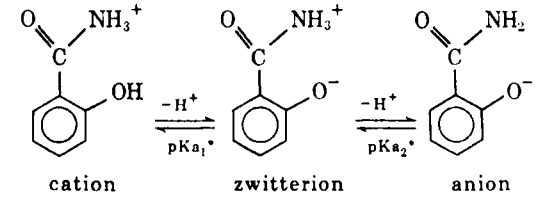
dissociates in the lowest excited singlet state from the phenolic group. In near neutral media, the fluorescence shifts to a shorter wavelength, signaling dissociation from the carboxamido group. The proposed sequence of dissociations of salicylamide in the lowest excited singlet state is represented in Scheme II.

In the lowest excited singlet state, the uncharged salicylamide is a zwitterion, while in the ground state it is a neutral molecule. As a result, no straightforward comparison between the successive ground and excited state equilibrium constants is possible.

In the region between pH 2.1 and $H_0 = -2.6$, the formation of the excited zwitterion of salicylamide must proceed entirely by phototautomerization of the neutral molecule. The pKa_1 of salicylamide is about 0.5 log unit more acidic than that of benzamide, even though the *O*-hydroxyl group might be expected to enhance the basicity of the carboxamido group. This is very much like the diminution of the basicity of the carboxyl group in salicylic acid by the presence of the hydroxyl group and suggests the presence of an intramolecular hydrogen bond between the hydroxyl group and the carboxamido group in the ground state. Presumably, the phototautomerism of salicylamide is intramolecular, consisting of readjustment of the position of the hydroxylic proton in the hydrogen bond so that the proton is essentially lost from the phenolic group and gained by the carboxamido group.

The arguments that were developed for salicylamide are all qualitatively applicable to the prototropic reactivity of salicylanilide, as seen from the similarities between the spectral shifts of the two compounds produced by protolytic dissociation. However, the presence of the phenyl group on the carboxamido nitrogen atom of salicylanilide has a substantial effect on the acid and base strengths of the various ground and excited state prototropic species derived from salicylanilide. All measurable equilibrium constants of salicylanilide are about 1.5 orders of magnitude more acidic than those of salicylamide. This observation can be rationalized in terms of the electromeric electron-withdrawing effect the phenyl group has on the lone pair of the carboxamido nitrogen atom of salicylanilide. This effect reduces the basicity of the carboxamido nitrogen, making it more difficult to protonate and thereby accounting for the lower value of pKa_1 for salicylanilide. The reduction in basicity of the carboxamido nitrogen atom also weakens the hydrogen bond between the phenolic proton and the phenyl-substituted carboxamido group. The weakening of this hydrogen bond, which stabilizes the phenolic proton in the neutral salicylamide molecule, makes the phenolic proton easier to remove. In addition, the electron-withdrawing effect of the phenyl group makes the phenyl-substituted carboxamido group more electron withdrawing than the unsubstituted carboxamido group. The combined effects of the weakening of the internal hydrogen bond and the stronger electromeric and field effects upon the hydroxyl group make pKa_2 more acidic in salicylanilide than in salicylamide.

Finally, in the lowest excited singlet state, only pKa_1^* could be measured for both compounds. Because pKa_1^* represents dissocia-



Scheme II—Protolytic reactions of salicylamide in the lowest excited singlet state

tion of the cations from the phenolic groups to form the zwitterions, hydrogen bonding is not important in this equilibrium. However, the electron-withdrawing enhancement of the carboxamido group by the phenyl group is even stronger in the lowest excited singlet state than in the ground state, as evidenced by the reduction in basicity of arylamines in the lowest excited singlet state (8). Thus, the lower pK_{a_2} of salicylanilide relative to salicylamide is attributed entirely to the greater electromeric and field effects of the phenyl-substituted carboxamido group in the lowest excited singlet state.

Alkaloid Studies VIII: Isolation and Characterization of Alkaloids of *Tabernaemontana heyneana* Wall and Antifertility Properties of Coronaridine

WALTER E. MEYER, JOHN A. COPPOLA*, and LEON GOLDMAN▲

Abstract □ Extraction of the roots of *Tabernaemontana heyneana* Wall yielded the alkaloids coronaridine, voacangine, ibogamine, 19-oxocoronaridine, and the pseudoindoxyl of voacangine. Coronaridine was demonstrated to prevent pregnancies in adult female rats when administered orally.

Keyphrases □ *Tabernaemontana heyneana* Wall—isolation and characterization of alkaloids, antifertility properties of coronaridine □ Alkaloids—isolation and identification from *Tabernaemontana heyneana*, antifertility properties of coronaridine □ Antifertility agents, potential—isolation, characterization, and screening of coronaridine from *Tabernaemontana heyneana* □ Coronaridine—isolation from *Tabernaemontana heyneana*, screened for antifertility properties in rats

Investigation of the alkaloids of the Tabernaemontanoideae tribe of the Apocynaceae family has received considerable attention because of the interest aroused in the alkaloids isolated from *Tabernanthe iboga* of the same family.

The roots and bark of *Tabernaemontana heyneana* Wall were previously shown to contain the indole alkaloid coronaridine (I) (1) and its 20-hydroxy derivative heyneanine (II) (2). In this study, the roots of this botanical were examined, and the isolation and identification of additional indole alkaloids and some pharmacological properties of coronaridine are described.

DISCUSSION

An aqueous ethanolic extract of the roots of *T. heyneana* Wall was found to prevent fertilization of adult female rats when administered orally. The residue from this extract was treated with aqueous acetic acid, and the soluble components were then extracted into methylene chloride. Removal of the acidic components from the methylene chloride extract by washing with aqueous base gave, after evaporation of the solvent, a brown amorphous crude material (Fraction A), which retained all of the antifertility activity of the original extract. Chromatographic fractionation of a portion of Fraction A on silica gel yielded the alkaloid coronaridine and a closely associated alkaloid which was not obtained pure.

The alkaloids in Fraction A were precipitated as their hydrochloride salts, and the free bases were regenerated to afford a tan amorphous mixture of alkaloids (Fraction B). Sequential chromatography of Fraction B on silica gel, Grade I neutral alumina, and Grade III neutral alumina yielded additional coronaridine and the second alkaloid, which was identified as voacangine (III) by comparison with an authentic sample[1].

The syrup obtained from a methanol wash of the Grade III neutral alumina column was separated further by partition chromatography on diatomaceous earth to give a chromatographically pure, noncrystalline alkaloid. This alkaloid, which appeared on thin-layer chromatograms of solutions of coronaridine that had been exposed to air, was identical with the iodine–sodium bicarbonate oxidation [the procedure for conversion of ibogaine (IV) to 19-oxoibogaine (V) (3)] product of coronaridine. The appearance of a second carbonyl absorption band in the IR spectrum (6.06 μ) and a molecular-ion peak (m/e 352.1780) in the mass spectrum, which appeared 14 mass units higher than the molecular-ion peak for coronaridine, indicated this alkaloid to be 19-oxocoronaridine (VI), previously isolated from the bark of *Conopharyngia jollyana* Stapf. (4). [In *Reference 5*, this compound was characterized only by mass spectral analysis (m/e 352) and R_f values.]

Column chromatography of Fraction B on Grade II neutral alumina yielded a noncrystalline alkaloid fraction, which was further separated by partition chromatography on diatomaceous earth. A fraction containing 19-oxocoronaridine, contaminated with a highly fluorescent yellow material, was rechromatographed on silica gel to provide a crystalline yellow-green fluorescent alkaloid. The distinctive UV spectrum and mass spectrum indicated this material to be the pseudoindoxyl (VIII) (6) of voacangine (III).

Those fractions collected before the pseudoindoxyl (VIII) was

[1] The authors thank Dr. M. Gorman, Lilly Research Laboratories, for a sample of voacangine.

tion of the cations from the phenolic groups to form the zwitterions, hydrogen bonding is not important in this equilibrium. However, the electron-withdrawing enhancement of the carboxamido group by the phenyl group is even stronger in the lowest excited singlet state than in the ground state, as evidenced by the reduction in basicity of arylamines in the lowest excited singlet state (8). Thus, the lower pK_{a_2} of salicylanilide relative to salicylamide is attributed entirely to the greater electromeric and field effects of the phenyl-substituted carboxamido group in the lowest excited singlet state.

Alkaloid Studies VIII: Isolation and Characterization of Alkaloids of *Tabernaemontana heyneana* Wall and Antifertility Properties of Coronaridine

WALTER E. MEYER, JOHN A. COPPOLA*, and LEON GOLDMAN▲

Abstract □ Extraction of the roots of *Tabernaemontana heyneana* Wall yielded the alkaloids coronaridine, voacangine, ibogamine, 19-oxocoronaridine, and the pseudoindoxyl of voacangine. Coronaridine was demonstrated to prevent pregnancies in adult female rats when administered orally.

Keyphrases □ *Tabernaemontana heyneana* Wall—isolation and characterization of alkaloids, antifertility properties of coronaridine □ Alkaloids—isolation and identification from *Tabernaemontana heyneana*, antifertility properties of coronaridine □ Antifertility agents, potential—isolation, characterization, and screening of coronaridine from *Tabernaemontana heyneana* □ Coronaridine—isolation from *Tabernaemontana heyneana*, screened for antifertility properties in rats

Investigation of the alkaloids of the Tabernaemontanoideae tribe of the Apocynaceae family has received considerable attention because of the interest aroused in the alkaloids isolated from *Tabernanthe iboga* of the same family.

The roots and bark of *Tabernaemontana heyneana* Wall were previously shown to contain the indole alkaloid coronaridine (I) (1) and its 20-hydroxy derivative heyneanine (II) (2). In this study, the roots of this botanical were examined, and the isolation and identification of additional indole alkaloids and some pharmacological properties of coronaridine are described.

DISCUSSION

An aqueous ethanolic extract of the roots of *T. heyneana* Wall was found to prevent fertilization of adult female rats when administered orally. The residue from this extract was treated with aqueous acetic acid, and the soluble components were then extracted into methylene chloride. Removal of the acidic components from the methylene chloride extract by washing with aqueous base gave, after evaporation of the solvent, a brown amorphous crude material (Fraction A), which retained all of the antifertility activity of the original extract. Chromatographic fractionation of a portion of Fraction A on silica gel yielded the alkaloid coronaridine and a closely associated alkaloid which was not obtained pure.

The alkaloids in Fraction A were precipitated as their hydrochloride salts, and the free bases were regenerated to afford a tan amorphous mixture of alkaloids (Fraction B). Sequential chromatography of Fraction B on silica gel, Grade I neutral alumina, and Grade III neutral alumina yielded additional coronaridine and the second alkaloid, which was identified as voacangine (III) by comparison with an authentic sample[1].

The syrup obtained from a methanol wash of the Grade III neutral alumina column was separated further by partition chromatography on diatomaceous earth to give a chromatographically pure, noncrystalline alkaloid. This alkaloid, which appeared on thin-layer chromatograms of solutions of coronaridine that had been exposed to air, was identical with the iodine–sodium bicarbonate oxidation [the procedure for conversion of ibogaine (IV) to 19-oxoibogaine (V) (3)] product of coronaridine. The appearance of a second carbonyl absorption band in the IR spectrum (6.06 μ) and a molecular-ion peak (m/e 352.1780) in the mass spectrum, which appeared 14 mass units higher than the molecular-ion peak for coronaridine, indicated this alkaloid to be 19-oxocoronaridine (VI), previously isolated from the bark of *Conopharyngia jollyana* Stapf. (4). [In *Reference 5*, this compound was characterized only by mass spectral analysis (m/e 352) and R_f values.]

Column chromatography of Fraction B on Grade II neutral alumina yielded a noncrystalline alkaloid fraction, which was further separated by partition chromatography on diatomaceous earth. A fraction containing 19-oxocoronaridine, contaminated with a highly fluorescent yellow material, was rechromatographed on silica gel to provide a crystalline yellow-green fluorescent alkaloid. The distinctive UV spectrum and mass spectrum indicated this material to be the pseudoindoxyl (VIII) (6) of voacangine (III).

Those fractions collected before the pseudoindoxyl (VIII) was

eluted were combined and subjected to partition chromatography utilizing a less polar solvent system. One fraction yielded a crystalline alkaloid which was identified as ibogamine (VII) (7–9).

Although 19-oxocoronaridine and the pseudoindoxyl of voacangine may occur naturally, the susceptibility of the iboga alkaloids to oxidation under mild conditions (10) suggests that these alkaloids may be formed by the autoxidation of the parent alkaloid. Hootele and Pecher (5) suggested the possibility of a similar origin for several 19-oxo iboga alkaloids isolated from *C. jollyana*. The possibility of the pseudoindoxyl derivatives isolated from *T. rupicola* being artifacts was suggested by Niemann and Kessel (11).

EXPERIMENTAL[2]

Extraction Procedure—Dried ground roots of *T. heyneana* Wall[3] (7.5 kg.) were extracted by percolation for 18 hr. with 67.5 l. of 5% 3A ethanol. The percolate was evaporated under reduced pressure at 25°, and the residue was stirred for 18 hr. with 3.3 l. of 10% aqueous acetic acid. The suspension was filtered and the filter cake was washed with 10% acetic acid. The combined extract and wash was extracted three times with 1-l. portions of methylene chloride. The combined extracts were washed two times with 250-ml. portions of 1 *N* sodium hydroxide and then the methylene chloride layer was dried (magnesium sulfate). Evaporation of the solution *in vacuo* yielded 26.4 g. of a brown frothy residue (Fraction A).

A 5.0-g. sample of Fraction A was dissolved in 100 ml. of ether. A solution of dry hydrogen chloride in ether was added, and the pale-yellow precipitate which formed was removed by filtration. The precipitate was distributed between chloroform and 1 *N* sodium hydroxide, and the chloroform layer was dried (magnesium sulfate) and evaporated *in vacuo* to give 3.4 g. of a tan amorphous residue (Fraction B).

Isolation of Coronaridine (I) and Voacangine (III)—Fraction A (2 g.) was chromatographed on a silica gel column (200 g.) by developing with 1 l. of benzene, followed by 200-ml. portions of benzene containing 5, 10, 20, and 40% chloroform. When a yellow band appeared at the column front, collection of 20-ml. cuts was begun. Cuts 75–150 contained 2.1 g. of a mixture of two alkaloids, a 1-g. portion of which was chromatographed on a column[4] using a mixture of chloroform and methanol (200:1); 5-ml. cuts were collected. Pure noncrystalline I (353 mg.) was obtained from the residue of cuts 30–62; $[\alpha]_D^{25}$ −35.2° (c 1.1, $CHCl_3$) [lit. (12) $[\alpha]_D^{25}$ −34° (c 1.0, $CHCl_3$)]; $\lambda_{max}^{CHCl_3}$: 2.89, 5.80, 6.84, and 7.99 nm. The hydrochloride salt was prepared in the usual manner, m.p. 213–214° dec. [lit. (12) m.p. 210–211° dec.].

Fraction B (3.4 g.) was chromatographed on 120 g. of silica gel, and the material eluted with chloroform–methanol (200:1) was purified further on a column of 200 g. of Grade I alumina which was developed with benzene–chloroform (1:1). The first fraction (125 ml.) yielded 395 mg. of coronaridine. The following fractions, which contained a mixture of coronaridine and voacangine, were rechromatographed on a column of 100 g. of Grade III alumina. The column was developed with benzene and, after collecting 17 125-ml. cuts, was washed with chloroform and methanol. The residue (245 mg. Fraction C) from the wash was reserved for further purification. Evaporation of the first cut yielded an additional 429 mg. of coronaridine, whereas the residue from the third cut yielded 122 mg. of voacangine (III), obtained as a pale-yellow syrup. The mass spectrum of this syrup was identical with that of an authentic sample of III[1]. The PMR (13), IR (14), and UV spectra (14) were in accord with published data.

Isolation of 19-Oxocoronaridine (VI)—Fraction C (245 mg.) was subjected to partition chromatography, and the effluent was monitored at 285 nm. 19-Oxocoronaridine (VI) (23 mg.) was obtained in the fourth holdback volume as a pale-yellow syrup, $\lambda_{max}^{C_2H_5OH}$: 222 (28,500), 276 (sh) (6500), 284 (7110), and 292 (6000) nm.; λ_{max}^{KBr}: 5.81, 6.06, 6.92, 8.00, 8.85, and 13.51 μ; PMR ($CDCl_3$): δ 8.20 (s, 1H, exchangeable NH), 7.15 (m, 4H, substituted aromatic), 4.51 (s, 1H, $\diagdown$C—H$\diagup$), 3.70 (s, 3H, CO_2CH_3), and 0.97 (t, 3H, CH_2CH_3); mass spectrum, molecular ion at *m/e* 352.1780 ($C_{21}H_{24}N_2O_3$, calc. 352.1786).

Oxidation of Coronaridine (I) to 19-Oxocoronaridine (VI)—Coronaridine hydrochloride (260 mg., 0.7 mmole) was dissolved in 8 ml. of 50% aqueous tetrahydrofuran containing 500 mg. of sodium bicarbonate. A solution of 360 mg. (1.4 mmoles) of iodine in 10 ml. of tetrahydrofuran was added dropwise and, after an additional 30 min. at 25°, the reaction was cooled in an ice bath and 10 ml. of water and 20 ml. of methylene chloride were added. The layers were separated and the aqueous phase was washed with 10 ml. of methylene chloride. The combined methylene chloride solutions were washed consecutively with 20 ml. of 5% sodium thiosulfate, 2 *N* sulfuric acid, and water. After drying (magnesium sulfate), the solution was evaporated to give 240 mg. of a pale-yellow syrup, which was chromatographed on a silica gel column[5] using ethyl acetate for development; 0.75-ml. cuts were collected. Coronaridine (27 mg.) was recovered by evaporation of cuts 2–8, and 19-oxocoronaridine (86 mg.) was obtained after evaporation of cuts 15–30. This material was found to be identical with the 19-oxocoronaridine isolated from *T. heyneana* by comparisons of IR and mass spectra.

Isolation of the Pseudoindoxyl VIII of Voacangine—Fraction B (12.7 g.), obtained from a 16-g. portion of Fraction A, was chromatographed on 400 g. of alumina (Grade II). After elution with 3 l. of benzene, a chloroform–methanol (4:1) wash yielded a fraction (2 l.) which, upon evaporation, gave 6.9 g. of a yellow syrup. Partition chromatography of 6.0 g. of this syrup yielded a yellow syrup (Fraction D) from the first two holdback volumes and 553 mg. of a

yellow syrup (Fraction E) from the fourth holdback volume. Final purification of Fraction E was effected by chromatography on 15 g. of silica gel and eluting with ethyl acetate, followed by preparative TLC on silica gel plates[6] using ethyl acetate for development. A bright-yellow band (R_f 0.7) was eluted with methanol, and the solution was evaporated *in vacuo* to yield 175 mg. of a yellow froth. Two crystallizations from methanol gave 20 mg. of VIII as yellow-green fluorescent needles, m.p. 201–203° [lit. (6) m.p. 205–208°]; PMR ($CDCl_3$): δ 3.77 (s, 3 H, OCH_3) and 3.55 (s, 3 H, CO_2CH_3). The mass, IR, and UV spectra were in accord with published data (6).

Isolation of Ibogamine (VII)—Fraction D was fractionated by partition chromatography using a 2-methoxyethanol–heptane system. Evaporation *in vacuo* of the third holdback volume and crystallization of the residue from ethanol yielded colorless crystals of VII, m.p. 160–161° [lit. (7) m.p. 162–163°]; $[\alpha]_D^{25}$ −31.3° (c 1.1, $CHCl_3$) [lit. (7) $[\alpha]_D^{26}$ −36.4° ($CHCl_3$)]. The IR (8) and mass (9) spectra were in agreement with published data.

PHARMACOLOGY

Coronaridine was tested previously in a variety of pharmacological systems (12). Although a relatively broad spectrum of biological activity was reported, no antifertility properties were described. In the present study, the oral administration of coronaridine hydrochloride to adult female rats at levels of 5 mg./kg./day or above prevented pregnancies. Voacangine, assayed by the same procedure, did not prevent pregnancies.

Graded doses of coronaridine hydrochloride were administered orally once daily for 10 days to adult female rats (225–250 g.), which were maintained on a standard diet of laboratory rat pellets and water *ad libitum*. The dose was composed of propylene glycol and an appropriate amount of coronaridine hydrochloride, so that the desired dose was administered in a 0.25-ml. volume. Control rats were given propylene glycol without the alkaloid. From the 1st day of treatment, the females were placed with fertile males. Four days after the last dose, the females were sacrificed and uterine fetal implantation sites were counted. Estrone was used as a standard. Under these conditions, simultaneously performed vehicle control groups yielded pregnancy rates of approximately 90%, and the ED_{100} of estrone was consistently 0.5 mg./kg./day.

The results of this study are summarized in Table I.

[6] Quanta-Gram PLQ1-F.

In the uterotropic assay, which measured estrogenic activity, immature female rats (50–60 g.) received single daily oral doses in 0.25 ml. of propylene glycol for 3 days. The uteri were removed and weighed 24 hr. after the last dose. A minimum of five rats was tested at each dose level and, here also, estrone was used as reference standard. The average uterine weights of estrone- or test compound-treated rats were divided by the average uterine weight of simultaneously performed vehicle controls to estimate the degree of uterine hypertrophy. Thus, for example, a ratio of 1.25 indicated a 25% increase in uterine weight above control values. The results of this assay are summarized in Table II. The data indicated that coronaridine was weakly estrogenic in that it was only about 3×10^{-4} times as potent as estrone in eliciting uterine growth. Nevertheless, doses approximately one-third the minimally effective antifertility dose produced a 35% increase in uterine weight, and the antifertility ED_{100} was associated with an 85% increase. Therefore, the contraceptive action of coronaridine was ostensibly related to its inherent estrogenicity since the two effects were apparently inseparable.

Influence of Lecithins on Autoxidation of Cholesterol from Aqueous Dispersions at 85°

NORMAN D. WEINER*▲, WERNER C. BRUNING*, and ALVIN FELMEISTER†

Abstract □ The autoxidative formation of 7-ketocholesterol and 7-hydroxycholesterol from aqueous cholesterol dispersions was studied in the absence and in the presence of various lecithins at 85 ± 2°. Whereas more than one-half of the cholesterol is oxidized within 8 hr. in the absence of phospholipids, less than 10% oxidation occurs in the presence of the lecithins. The *in vivo* significance of these data is discussed.

Keyphrases □ Lecithins—influence on autoxidation of aqueous cholesterol dispersions □ Cholesterol dispersions, aqueous—influence of various lecithins on autoxidation at 85°, *in vivo* significance □ Autoxidation—aqueous cholesterol dispersions, influence of various lecithins, *in vivo* significance □ Phospholipids—influence of lecithins on autoxidation of aqueous cholesterol dispersions

Cholesterol is relatively stable toward air oxidation in the macrocrystalline state, but when finely divided and exposed to excess oxygen, oxidation takes place. These conditions are met, in particular, when cholesterol, in colloidal dispersion stabilized with sodium stearate, is aerated (1–3). The reaction is rapid at 85°, and the chief products are 7-ketocholesterol and diols, principally 7α- and 7β-hydroxycholesterol (3). Oxidation also occurs when cholesterol in thin films is exposed to air and irradiated with UV light (4).

It was found that the oxidation of cholesterol under physiological conditions of pH and temperature takes place, although at a slower rate. Bergström and Wintersteiner (2, 3) suggested that a conversion of cholesterol to the 7-oxygenated sterols might occur *in vivo* and that an attack on the sensitive 7-position of the cholesterol molecule might be involved in the biological degradation of this sterol. It has also been suggested that the oxidation of cholesterol *in vivo* may be related to the development of a variety of pathological conditions such as carcinoma (5), cholelithiasis, and atherosclerosis (6). In addition, MacDougall *et al.* (7) showed a number of oxidation products of cholesterol to be toxic to organ cultures of rabbit aorta.

In a recent series of papers (8–10), the autoxidation of cholesterol in aqueous dispersions and in monomolecular films was reported. The rate of oxidation of cholesterol was much faster at the surface than in the bulk. Although more than one-half of the cholesterol was oxidized at the surface within 8 hr. at room temperature, no noticeable reaction was observed for the oxidation of cholesterol from aqueous dispersions at room temperature during this time. However, similar rates of oxidation were observed when the dispersions were maintained at 85°.

Although it is conceivable that some cholesterol oxidation does occur *in vivo* (2, 3), these reaction rates must be significantly slower than those reported for *in vitro* systems. Surface pressure–surface area data for mixed cholesterol–phospholipid films (8) did indicate that the phospholipids present in the film protected the cholesterol from attack by oxygen. The mechanism of this protection appears to be physical rather than chemical in nature. Apparently, it involves intermolecular interactions between the phospholipids and cholesterol which serve to protect the reactive groups on the cholesterol molecule from attack by oxygen. Since membrane associated cholesterol is always associated with phospholipids, it appears likely that this association could be a significant factor in the *in vivo* protection of cholesterol oxidation.

It was, therefore, of interest to quantitate the effects of phospholipids on the air oxidation of cholesterol in aqueous dispersions.

EXPERIMENTAL

Two and one-half grams of cholesterol[1] was dissolved in 100 ml. of absolute alcohol with the aid of heat. The purity of cholesterol was verified by TLC (a 250-mcg. sample yielded a single spot). Sodium stearate, 0.5 g. (purified powder), was dissolved in 500 ml.

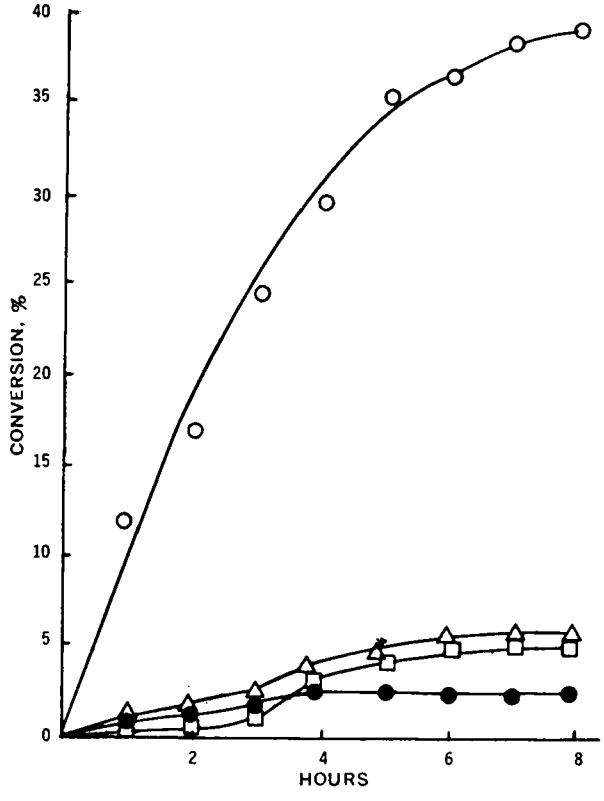

Figure 1—*Percentage conversion of cholesterol to 7-ketocholesterol for dispersions exposed to flowing air at 85 ± 2°. Key: ○, no lecithin; ●, vegetable lecithin; □, egg lecithin; and △, dipalmitoyl lecithin.*

[1] Pierce Chemical Co., Rockford, Ill.

of distilled water, which was preheated to 70°. The cholesterol solution in absolute alcohol was then poured into the sodium stearate solution with constant stirring to obtain a colloidal dispersion. Dry air was allowed to pass through a flowmeter at a rate of 100 ml./min. and was directed into the cholesterol dispersion, which was maintained at a temperature of 85 ± 2°. The air was allowed to flow for 8 hr., during which time samples of the cholesterol dispersion were removed with the aid of a micrometer syringe[2] at hourly intervals.

The amount of diols, expressed as 7-hydroxycholesterol, was determined by the method described by Bergström and Wintersteiner (3). Cholesterol dispersion, 0.03 ml., was mixed with 1 ml. of chloroform and 2 ml. of Lifschütz reagent. This color reagent was prepared by dissolving 0.1 g. of ferric chloride hexahydrate in 90 ml. of glacial acetic acid and then adding 10 ml. of concentrated sulfuric acid. After 5 min., a bluish-green color developed which remained stable for about 15 min. The absorbance was read at a wavelength of 590 nm. with a spectrophotometer[3], and the concentration of the diols was determined from the standard curve. The preparation of 7-hydroxycholesterol for use in obtaining the standard curve was described previously (9).

The amount of 7-ketocholesterol formed was determined by mixing 0.03 ml. of cholesterol dispersion and 3 ml. of ethanol. The absorbance was read at a wavelength of 256 nm. with the spectrophotometer[3]. The concentration was then determined from the standard curve of 7-ketocholesterol[4]. The purity of this standard was verified by TLC. The use of standard mixtures demonstrated that 7-hydroxycholesterol did not interfere with the analysis of 7-ketocholesterol and that the presence of 7-ketocholesterol did not interfere with the analysis of 7-hydroxycholesterol.

Similar experiments were performed for systems in which vegetable lecithin[5], egg lecithin[6], or dipalmitoyl lecithin[7] was added. In each case, the lecithin was dissolved with the cholesterol in 100 ml. of absolute alcohol to yield 1:1 cholesterol–lecithin molar ratios.

To correct for the presence of lecithins in the assays of 7-ketocholesterol and 7-hydroxycholesterol, standard curves for mixtures of the steroids and lecithins were used.

RESULTS AND DISCUSSION

Figures 1 and 2 show the percentage conversion–time curves for the conversion of cholesterol to 7-ketocholesterol and 7-hydroxycholesterol, respectively, in the absence and in the presence of the lecithins.

As can be seen, all lecithins studied are very effective inhibitors of cholesterol oxidation. Although the mechanism of inhibition cannot be stated with certainty, it appears to be physical rather than chemical in nature since: (*a*) the intermolecular interactions between cholesterol and lecithins are strong and involve the sensitive

3-hydroxy group of cholesterol, and (*b*) dipalmitoyl lecithin, a fully saturated phospholipid, is very effective in inhibiting oxidation.

Although the systems studied here certainly cannot be easily extrapolated to *in vivo* systems, the data indicate that a possible mechanism for the protection of membrane-bound cholesterol from oxidation may be the interactions with phospholipids.

Synthesis and MAO Inhibitory Activity of 6-(2-Propynyl)-6,7-dihydro-5*H*-dibenz[*c*,*e*]azepine

J. RICHARD GRUNDER, LUKE SAN, and PUSHKAR N. KAUL▲

Abstract □ A propynyl dibenzazepine was synthesized with a view to design a compound that would possess the structural features essential for biological activity present in the antiadrenergic compound azapetine and in the MAO inhibitor pargyline, both of which have been used as antihypertensives. The new compound possesses MAO-inhibiting activity weaker than that of pargyline.

Keyphrases □ 6-(2-Propynyl)-6,7-dihydro-5*H*-dibenz[*c*,*e*]azepine—synthesized and screened as potential MAO inhibitor □ MAO inhibitors, potential—synthesis and screening of 6-(2-propynyl)-6,7-dihydro-5*H*-dibenz[*c*,*e*]azepine □ Dibenzazepines—synthesis and screening of 6-(2-propynyl)-6,7-dihydro-5*H*-dibenz[*c*,*e*]azepine as MAO inhibitor

Various dibenzazepine derivatives were described by Randall and Smith (1), of which azapetine[1] (I) was the most potent antiadrenergic compound. It was subsequently marketed for clinical use in hypertensive and vascular disorders. Both the allyl group and the dibenzazepine tricyclic arrangement in azapetine appear to be essential for its biological activity.

Another series of compounds that possesses strong MAO-inhibiting activity led to the clinically used antihypertensive pargyline[2] (II), the inhibiting property being not necessarily related to the hypotensive property (2). The synthesis and evaluation of several MAO inhibitors structurally related to pargyline have indicated the importance of the propargyl or 2-propynyl group to the activity of these compounds (3, 4).

The 2-propynyl or propargyl derivative of the dibenz[*c*,*e*]azepine ring system may provide a compound with desirable or even more potent antihypertensive activity than either of the two clinically tried agents, I and II. Synthesis of such a compound, 6-(2-propynyl)-6,7-dihydro-5*H*-dibenz[*c*,*e*]azepine (III), and its MAO-inhibiting activity are reported in this paper while the antiadrenergic and antihypertensive properties of the compound will be reported later.

[a] S_1 (2.0×10^{-3} *M*) and S_2 (8.9×10^{-4} *M*) are the two concentrations of tyramine used as substrate.

Compound III was prepared by the lithium aluminum hydride reduction of *N*-(2-propynyl)diphenimide. The latter was obtained by the alkylation of potassium diphenimide with 2-propynyl bromide. Diphenimide was prepared from diphenic acid by methods reported in the literature (5, 6), involving diphenic anhydride and diphenamic acid as intermediates.

EXPERIMENTAL[3]

The following were used: diphenic acid[4]; diphenic anhydride, prepared according to the method of Roberts and Johnson (5); and diphenimide, prepared according to the method of Underwood and Kochmann (6).

***N*-(2-Propynyldiphenimide)**—A solution of alcoholic potassium hydroxide (1.5 g. potassium hydroxide in 1.5 ml. water, *q.s.* to 5 ml. with absolute ethanol) was added with stirring to a hot (65–70°) solution of diphenimide (5.0 g., 22.4 mmoles) in 130 ml. of absolute ethanol. After removing the solvent *in vacuo*, the residue was triturated with anhydrous ether–acetone to yield a white solid potassium salt, which was collected by filtration and used without further purification. A solution of 2-propynyl bromide (2.7 g., 22.5 mmoles) in 10 ml. of dimethylformamide was added slowly with stirring to a solution of potassium diphenimide in 50 ml. of dimethylformamide. The mixture was heated for 4 hr. under gentle reflux and poured into water. The gray-white precipitate (5.0 g., 85%) was collected, m.p. 169–171°. Decolorization[5] and recrystallization from ethanol–water gave a colorless product, m.p. 175–176°.

[3] All melting points were determined with a Fisher melting-point apparatus and are uncorrected. IR spectra were recorded with a Perkin-Elmer model 700 grating spectrophotometer and were as expected. Microanalyses were performed by Galbraith Laboratories, Knoxville, Tenn.

Table II—*In Vivo* Inhibition of Hepatic MAO in Mice by III and Iproniazid

Treatment	Inhibition of MAO at 10 min. after Incubation, %: Acute (0.1 mmole/kg. i.p., 2 hr. before Assay)	Chronic (0.01 mmole/kg. i.p., Daily for 7 days)
Dibenzazepine derivative (III)	25	10
Iproniazid	64	28

Anal.—Calc. for $C_{17}H_{11}NO_2$: C, 78.14; H, 4.24; N, 5.36. Found: C, 78.25; H, 4.34; N, 5.12.

6-(2-Propynyl)-6,7-dihydro-5*H*-dibenz[*c*,*e*]azepine (III)—*N*-(2-Propynyl)diphenimide (7.0 g., 27 mmoles) was placed in a soxhlet extraction apparatus above a stirred suspension of lithium aluminum hydride (5.5 g., 146 mmoles) in 300 ml. of anhydrous ether. Extraction was continued for 72 hr., after which time only a slight residue remained in the thimble. The excess hydride was decomposed by the cautious addition of water followed by 5 ml. of 20% sodium hydroxide. The resulting mixture was filtered and the ethereal layer was separated and dried over anhydrous sodium sulfate. The hydrochloride salt of III (5.5 g., 75%) was precipitated by mixing the dried ether layer with ethereal hydrogen chloride. The salt was recrystallized from 2-butanone, m.p. 201–203°.

Anal.—Calc. for $C_{17}H_{16}ClN$: C, 75.68; H, 5.97; N, 5.19. Found: C, 75.23; H, 6.13; N, 5.25.

MAO Inhibition—Inhibition of MAO was determined by a modification of the method of Snyder and Hendley (7), which employs tyramine as the substrate and homovanillic acid as the fluorescence generating reagent. Mouse liver was homogenized in ice-cold 0.1 *M* phosphate buffer, pH 7.8 (1:20 dilution) and centrifuged at 14,500×*g* and −5° in a refrigerated centrifuge[6] to obtain a cell-free supernate which served as the source of enzyme. Iproniazid[7] and pargyline[2] were used as standard inhibitors for comparison.

The inhibition constants (K_i) were determined by the method of Dixon (8). For *in vitro* inhibition studies, the drugs were incubated with the mouse liver enzyme prior to addition of the substrate. For acute *in vivo* inhibition studies, mice were given single intraperitoneal doses of the drugs 2 hr. prior to the removal of liver for determination of enzyme activity. In the case of chronic *in vivo* studies, however, the drugs were given once daily for 7 days and the livers were removed for the enzyme determination 4–6 hr. following the administration on the last day.

[6] Sorvall, RC2-B.
[7] Roche.

RESULTS AND DISCUSSION

Table I includes the data on the *in vitro* inhibition of the mouse liver MAO produced by varying concentrations of III and two known inhibitors, iproniazid and pargyline. Both the data and the K_i values show that III is a much weaker inhibitor of MAO than is pargyline.

The results of *in vivo* inhibition studies in both acute and chronically treated animals are shown in Table II. In these studies also, III appears to be a weaker MAO inhibitor.

Antitumor Agents from *Jatropha macrorhiza* (Euphorbiaceae) I: Isolation and Characterization of Jatropham

R. M. WIEDHOPF, E. R. TRUMBULL, and J. R. COLE▲

Abstract □ A new lactam has been isolated from *Jatropha macrorhiza* (Euphorbiaceae) and has shown tumor-inhibitory properties against the P-388 lymphocytic leukemia test system. The compound was identified by means of NMR, UV, IR, rotary dispersion, mass spectrometry, and classical chemical procedures. It has the structure 5-hydroxy-4-methyl-3-pyrrolin-2-one and has been named jatropham.

Keyphrases □ *Jatropha macrorhiza* (Euphorbiaceae)—isolation and characterization of jatropham (5-hydroxy-4-methyl-3-pyrrolin-2-one), antitumor activity □ 5-Hydroxy-4-methyl-3-pyrrolin-2-one (jatropham)—isolation from *Jatropha macrorhiza*, characterization, antitumor activity □ Antitumor agents—isolation and characterization of jatropham (5-hydroxy-4-methyl-3-pyrrolin-2-one) from *Jatropha macrorhiza*

As a result of the continuing search for plants having tumor-inhibiting constituents, it was found that the chloroform extract of the leaves, stems, flowers, and fruits of *Jatropha macrorhiza* Benth. (Euphorbiaceae)[1] showed inhibitory activity toward the P-388 lymphocytic leukemia test system (3PS)[2]. The plant was collected in Cochise County, Ariz., in June 1968.

DISCUSSION

Solvent extractions of the chloroform extract with hexane followed by acetonitrile yielded a crystalline compound from the acetonitrile solution. This compound demonstrated activity of 125% test/control (T/C) at 45 mg./kg. in the 3PS test system. Activity in the 3PS system is defined as an increase in the survival of treated animals over that of controls resulting in a T/C $\geq$ 125% (1).

The compound was soluble in water, alcohol, and acetone but insoluble in less polar organic solvents. Elemental analysis and molecular weight (mass spectrum) indicated that the molecular formula was $C_5H_7NO_2$. The IR spectrum showed broad absorption at 3400–3450 (OH and NH) as well as 1725 (carbonyl) and 1640 cm.$^{-1}$ (double bond). The NMR spectrum showed a methyl group (δ 1.7, 3H, singlet), and the remaining four protons appeared individually at δ 4.9 (doublet), 5.4 (doublet), 6.5 (singlet), and 7.6 (singlet). When deuterium oxide was added to the solution, the doublet at δ 4.9 and the singlet at δ 7.6 disappeared and the doublet at δ 5.4 was reduced to a singlet. Apparently, in deuteroacetone, used as the solvent here, the hydrogen of the hydroxyl group does not exchange rapidly and couples with the adjacent proton. The UV spectrum showed strong end absorption and a shoulder at 230 nm.

The spectra are consistent with several pyrrolin-2-one structures with a secondary alcohol and a methyl group on the ring. In particular, they are similar to the spectra reported for a series of alkyl 5-hydroxy-3-pyrrolin-2-one derivatives (2). The location of the methyl group with respect to the carbonyl was demonstrated by reduction of the compound over platinum oxide to the known 4-methyl-2-pyrrolidone (II, Scheme I). The positions of the hydroxyl group and double bond were established by oxidation of the jatropha lactam (which was given the trivial name jatropham) with chromic acid in acetone to citraconic acid imide (III). The reactions show the structure of jatropham to be 5-hydroxy-4-methyl-3-pyrrolin-2-one (I).

Jatropham is optically active, levorotatory in the visible region, thus indicating that there is no ring tautomerism with the open-chain aldehyde-amide. This fact is consistent with the work of Scheffold and Dubs (2) who did not find evidence for ring opening with their 5-hydroxy-3-pyrrolin-2-ones, although corresponding lactones were in equilibrium with open-chain acids. The optical rotatory dispersion (ORD) curve has one peak (at 260 nm.) and two troughs (300 and 215 nm.) in the 600–200-nm. region. The higher inversion, molecular amplitude $\alpha = -22$, is centered near 270 nm. where there is no peak in the UV spectrum. The second inversion, molecular amplitude $\alpha = +208$, is centered near 235 nm. where there is a shoulder in the UV spectrum.

EXPERIMENTAL[3]

Isolation Procedure—Fresh-frozen leaves, stems, flowers, and fruits were placed in a lyophilizer and dried for 24 hr. The dried material (2 kg.) was ground in a Wiley mill and macerated with 12 l. of chloroform for 24 hr. The material was filtered and air dried, yielding an extract weighing 70 g. The chloroform extract was repeatedly extracted with hexane (technical) in 2-l. portions until the hexane was clear. The residue was then extracted with acetonitrile (technical) in 1-l. portions until the acetonitrile portion was clear. Evaporation of the acetonitrile solution yielded a crystalline solid material (1.3 g.).

A sample recrystallized from acetonitrile for analysis had m.p. 131–132°; $[\alpha]_{549}^{25}$ −62°; ORD data (c, 1.6 × 10^{-2}, water), $[\phi]_{589}$ −67°, $[\phi]_{300}$ −560°, $[\phi]_{260}$ +1700°, and $[\phi]_{215}$ −19,100°; IR (acetonitrile): 3550 (s), 1725 (s), 1600 (m), 1050 (s), and 870 (m) cm.$^{-1}$; UV (methanol): strong end absorption with a shoulder at 230 nm.; log ϵ 3.06.

Anal.—Calc. for $C_5H_7NO_2$: C, 53.09; H, 6.24; N, 12.38; mol. wt. 113. Found: C, 52.63; H, 6.21; N, 12.56; *m/e* 113.

Hydrogenation of Jatropham—A sample of lactam weighing 0.910 g. (8.0 mmoles) was dissolved in 70 ml. of ethanol, 0.110 g. of plat-

[1] Identification was confirmed by Robert J. Barr, College of Pharmacy, and Dr. Charles T. Mason, Botany Department, University of Arizona, Tucson. A reference specimen was deposited in the University of Arizona Herbarium.

[2] Drug Evaluation Branch, Drug Research and Development, Chemotherapy, National Cancer Institute.

[3] Carbon, hydrogen, and nitrogen analyses were performed by Huffman Laboratories, Inc., Wheatridge, Colo., and Chemalytics, Inc., Tempe, Ariz. Mass, NMR, UV, and IR spectra were determined using a Hitachi Perkin-Elmer double-focusing spectrometer (model RMU-6E), a Varian T-60 spectrometer, a Beckman DB-G spectrophotometer, and a Beckman IR-33, respectively. ORD measurement was obtained from a Cary 60, and melting points were determined on a Kofler hot-stage apparatus and are uncorrected.

inum oxide was added, and hydrogen was admitted to the system at atmospheric pressure. The solution absorbed 400 ml. (13.6 mmoles) of hydrogen in 30 min., after which no further uptake was observed. The reaction mixture was filtered to remove platinum and evaporated to dryness, leaving 0.851 g. of residual oil.

The crude product was separated by chromatography on 20 g. of silica gel into two main fractions, which were eluted from the column with acetone. The first of these weighed 0.451 g. and crystallized as long needles. Recrystallization from hexane gave material melting at 53–56° [lit. (4) m.p. 54–56°] and having the properties expected of 4-methyl-2-pyrrolidinone; mass spectrometry: M^+, *m/e* 99; ν_{max}^{CHF}: 3460 (m), 3240 (s), 3020 (s), and 1700 (s) cm.$^{-1}$; NMR (60 MHz.): δ 1.3 (3H, doublet), 1.8 (1H, multiplet), 2.4 (2H, unresolved), 3.4 (2H, two doublets), and 7.4 (1H, broad).

Anal.—Calc. for C_5H_9NO: C, 60.61; H, 9.09; N, 14.14; mol. wt. 99. Found: C, 60.79; H, 8.84; N, 14.33; *m/e* 99.

The second fraction, 0.364 g., did not crystallize. The IR spectrum differed from that described for the first fraction in having strong, broad absorption near 3300 cm.$^{-1}$. The NMR spectrum had a peak at δ 5.3 (1H) that was removed when deuterium oxide was added to the solution. This material, presumably a mixture of 5-hydroxy-4-methyl-2-pyrrolidinones, was not investigated further.

Oxidation of Jatropham—A solution of 0.815 g. (7.2 mmoles) of lactam in 40 ml. of acetone was cooled to 5°, and a solution of chromic acid (5) was added slowly with occasional addition of portions of anhydrous magnesium sulfate until the red-orange color of the oxidizing agent persisted. The mixture was filtered, the insoluble portion was washed thoroughly with acetone, and the solution was evaporated to dryness. The residue weighed 0.62 g. (78%). The material was recrystallized from carbon tetrachloride, giving a sample melting at 99–102°. This sample was further purified by sublimation, yielding long needles, m.p. 103–105°. The purified material was identical in IR spectrum (chloroform solution), TLC behavior, and mixed melting point (103–105°) with a sample of citraconic acid imide, m.p. 104–105°, synthesized by heating citraconic anhydride with ammonium hydroxide (6).

Anal.—Calc. for $C_5H_6NO_2$: C, 54.05; H, 4.50; N, 12.61; mol. wt. 111. Found: C, 54.35; H, 4.54; N; 12.32; *m/e* 111.

Dissolution Rates of Cholesterol Monohydrate Crystals and Human Cholesterol Gallstones in Bile Acid–Lecithin Solutions: Enhancing Effect of Added Alkyl Quaternary Ammonium Salts

Keyphrases □ Cholesterol monohydrate crystals and human cholesterol gallstones—dissolution in bile acid–lecithin solutions, effect of alkyl quaternary ammonium salts □ Cholate–lecithin dissolution media for cholesterol dissolution—effect of alkyl quaternary ammonium salts on interfacial barriers □ Benzalkonium chloride—effect on cholesterol dissolution in cholate–lecithin solutions □ Quaternary ammonium compounds—effect on cholesterol dissolution in cholate–lecithin solutions □ Bile acid–lecithin solutions—cholesterol dissolution, effect of alkyl quaternary ammonium salts □ Gallstone dissolution in bile acid–lecithin solutions—effect of quaternary ammonium salts

Sir:

Recent experiments on cholesterol dissolution in micellar bile salt solutions showed that added lecithin decreases the dissolution rates even though it increases the solubility of cholesterol monohydrate crystals in the solvent media (1, 2). From these data, effective crystal–solution interfacial barriers for the dissolution process were deduced, assuming a model based upon the interfacial barrier in series with a Nernst diffusion layer. Table I shows: (*a*) the dissolution rates of a compressed cholesterol monohydrate pellet (J/A), and (*b*) the solubilities (C_s) and diffusivities (D) of cholesterol molecules in various media determined by reported methods (2). The total transfer resistance (R) was calculated as the sum of diffusional resistance (h/D) and interfacial resistance ($1/P$). For example, in 2% cholate–1% lecithin solution, the interfacial resistance for cholesterol dissolution is nearly 20 times the diffusional resistance based upon the benzoic acid dissolution experiment. These findings are important in view of the recent clinical studies showing that *in vivo* diminution of cholesterol gallstones may be controlled by dissolution kinetics. This communication reports findings with benzalkonium chloride and other quaternary ammonium compounds in counteracting or eliminating the interfacial barriers present in the cholate–lecithin media for cholesterol dissolution.

As shown in Table I, in 2% cholate–1% lecithin and in 5% cholate–2.5% lecithin, added benzalkonium chloride significantly reduced the large R values to

inum oxide was added, and hydrogen was admitted to the system at atmospheric pressure. The solution absorbed 400 ml. (13.6 mmoles) of hydrogen in 30 min., after which no further uptake was observed. nearly that found with benzoic acid dissolution. Similar effects with benzalkonium chloride were also found in 2 and 5% cholate. Other dissolution studies in 2% cholate–1% lecithin showed that 0.5% cetylpyridinium chloride may have the same effect as benzalkonium chloride, giving $R = 4.85 \times 10^3$ sec. cm.$^{-1}$; 0.5% cetrimonium bromide was around 80% as effective as benzalkonium chloride, giving $R = 10.3 \times 10^3$ sec. cm.$^{-1}$. Experiments with human cholesterol gallstones were conducted by reported methods (2) in 2% cholate–1% lecithin solutions, with or without 0.5% benzalkonium chloride. Similar results as those shown in Table I for cholesterol monohydrate pellets were obtained: $R = 1.57 \times 10^3$ sec. cm.$^{-1}$ and $R = 61.76 \times 10^3$ sec. cm.$^{-1}$ with and without benzalkonium chloride, respectively.

The clinical implications of these findings with the quaternary ammonium compounds may be important in the medical treatment of the gallstone disease. Recent clinical studies of Danzinger *et al.* (3) showed that oral administration of chenodeoxycholic acid to patients with gallstones can lead to the undersaturation of the bile with respect to cholesterol and the dissolution of the stones. They found that, in six of the seven patients studied, gallstones progressively diminished in size during the 14–30 months of chenodeoxycholic acid treatment. In a different kind of study by Admirand[1] involving the dissolution of cholesterol gallstones retained in the common bile duct postoperatively *via* T-tube perfusion of 5% cholate, small stones of millimeter diameter were dissolved in 3–14 days while larger stones did not appear to diminish significantly. These studies support the idea that increasing the *in situ* gallstone dissolution rate should yield material patient benefits through reduced medical treatment times. The results and methodology reported with benzalkonium chloride and other quaternary ammonium compounds may prove valuable in finding or designing safe and efficacious agents or therapeutic regimens for the medical treatment of the gallstone disease.

[a] Panmycin. [b] Indicates that these values are estimated using Eq. 7 of *Reference 1*.

taining preliminary estimates of the rate constants for a two-term exponential model. These estimates may then be used as initial starting values in a digital computer program, providing more assurance that the computer program will converge at the global minimum within a few iteration steps.

Let us suppose that we are able to observe C_t, the serum concentration of an investigational drug at time t. Furthermore, let the two-term exponential model be of the form:

$$E(C_t) = \beta_1 e^{\alpha_1 t} + \beta_2 e^{\alpha_2 t} \qquad t = 0, 1, \ldots, n \qquad \text{(Eq. 1)}$$

where E is the mathematical expectation, and α's and β's are the population parameters of the model for the drug under investigation. In clinical practice, a subject is selected at random and the values of C_t are assayed at equal intervals of time. Thus, the two-term exponential equation in the sample situation can be written as:

$$C_t = b_1 e^{\alpha_1 t} + b_2 e^{\alpha_2 t} = b_1 d_1^t + b_2 d_2^t \qquad t = 0, 1, \ldots, n \qquad \text{(Eq. 2)}$$

Because of the algebraic structure of Eq. 2, it is possible to rewrite the model in the form of a difference equation:

$$(C_{t+2} - C_{t+1}) - (C_{t+1} - C_t) = r_2 C_{t+2} - r_1 C_{t+1} \qquad \text{(Eq. 3)}$$

where:

$$d_1 + d_2 = (2 - r_1)/(1 - r_2) \qquad \text{(Eq. 4a)}$$

$$d_1 d_2 = 1/(1 - r_2) \qquad \text{(Eq. 4b)}$$

Summing Eq. 3 over the values of i from 0 to $i - 2$, we have:

$$C_i - C_{i-1} = (r_2 - r_1)S_{1i} + r_1 C_i + f \qquad \text{(Eq. 5)}$$

where $S_{1i} = \Sigma_0^i C_k$ and $f = C_0(r_1 - r_2) - r_2 C_1$.

Again, summing Eq. 5 over the values of i from 1 to i, we have:

$$C_i = (r_2 - r_1)S_{2i} + r_1 S_{1i} + if + g \qquad \text{(Eq. 6)}$$

where $S_{2i} = \Sigma_0^i S_{1k}$ and $g = C_0(1 - r_2)$.

Equation 6 is known as the internal regression (3) of Eq. 2; the values of constants, namely, $(r_2 - r_1)$, r_1, f, and g, can be obtained[1] by regressing C_i on S_{2i}, S_{1i}, and i. Having obtained these values from the data, we can then estimate d_1 and d_2 from the following equation:

$$(\hat{d_1}, \hat{d_2}) = \{1 - r_1/2 \pm \sqrt{(r_2 - r_1) + r_1^2/4}\}/(1 - r_2) \qquad \text{(Eq. 7)}$$

Theoretically, it is possible that the roots may be complex. However, if this situation does arise, then Eq. 2 can be mathematically expressed as sine, cosine functions, indicating that the two-term exponential model may not be appropriate. To illustrate the methodology, certain values of serum levels of tetracycline hydrochloride activity (Table I) from Eq. 7 (1) were interpolated to make the data equally spaced.

Using the linear regression set up by considering S_{1i}, S_{2i}, and i as independent variables and C_i as a dependent variable, we find the following regression coefficients (Eq. 6): $\hat{r}_2 - \hat{r}_1 = -0.1733$, $\hat{r}_1 = -1.2486$, $\hat{f} = 2.4522$, and $\hat{g} = 1.6671$. Now, using Eq. 7 or 4, we find $(\hat{d}_1, \hat{d}_2) = (0.862, 0.479)$ or:

$$\hat{a}_1 = \ln \hat{d}_1 = -0.14761 \qquad \text{(Eq. 8a)}$$

$$\hat{a}_2 = \ln \hat{d}_2 = -0.73697 \qquad \text{(Eq. 8b)}$$

Having obtained $\hat{a}_1$ and $\hat{a}_2$, we can obtain $\hat{b}_1$ and $\hat{b}_2$ by regressing C_t on $\exp(\hat{a}_1 t)$ and $\exp(\hat{a}_2 t)$:

$$\hat{b}_1 = 2.75726 \qquad \text{(Eq. 9a)}$$

$$\hat{b}_2 = -3.54831 \qquad \text{(Eq. 9b)}$$

Thus, the two-term exponential model (2) can be written as:

$$C_t = 2.75726e^{-0.14761t} - 3.54831e^{-0.73697t} \qquad \text{(Eq. 10)}$$

indicating that the rate constants $\hat{a}_1$ and $\hat{a}_2$ are very near to the least-squares estimates of -0.149 and -0.716.

The method does provide good starting values for a computer program. Convergence is achieved within one or two steps of iteration, indicating that the method of obtaining the estimates is nearly 100% efficient with respect to the least-squares method. The analytical comparison of efficiencies of the estimates with the standard least-squares estimate is currently under investigation.

[1] To obtain approximation to the parameters, we may consider S_{1i} and S_{2i} as independent variables in the linear regression equation (6).

Coacervate Formation by Sodium Salicylate with Benzalkonium Chloride

Keyphrases ☐ Coacervate formation—sodium salicylate with benzalkonium chloride, density variations ☐ Sodium salicylate—coacervate formation with benzalkonium chloride ☐ Benzalkonium chloride—coacervate formation with sodium salicylate

Sir:

Colloidal solutions undergo phase transformations when subjected to changes in temperature, pH, concentration, and other factors. These phase transformations include crystallization, flocculation, and gel formation. One of the least studied of these changes is coacervation. From the definition by Bungenberg de Jong (1) and as used in this report, coacervation is the phenomenon of separation of colloidal aqueous solutions into two or more immiscible aqueous layers. One of the aqueous layers contains most of the colloid and is termed the coacervate, while the second aqueous layer is colloid poor and is termed the equilibrium liquid (2, 3).

These coacervate systems are of growing general scientific (4, 5) and biological (6) interest.

This communication reports the preparation of a new coacervate system. Also reported is a unique phenomenon of this system which occurs with changes in either temperature or composition of the system.

The coacervate system is obtained by mixing various concentrations of sodium salicylate and benzalkonium chloride in water. Figure 1 shows a diagram of this system obtained by plotting mixing concentrations at the points of coacervate formation. This diagram illustrates two main regions: (*a*) biphasic coacervate system, and (*b*) monophasic solution. The biphasic coacervate system shows two distinct regions; in one region (B), the coacervate phase has a higher density than the equilibrium liquid and settles to the bottom of the container. In the second region (T) the coacervate phase is lighter than the equilibrium liquid and floats on the top of the liquid. The transition from the biphasic to the monophasic system by increasing concentrations of benzalkonium chloride was observed to be a sharp one.

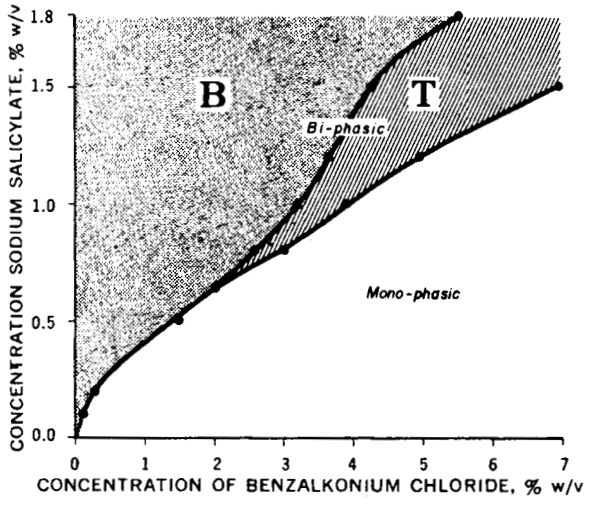

Figure 1—*Mixing concentrations of sodium salicylate and benzalkonium chloride to give coacervate systems at 24°. Dark area represents the region of coacervate formation and light area represents region of no coacervate formation. Key: B, system with coacervate at the bottom; and T, system with coacervate at the top.*

Table I—Mixing Concentrations and Relative Coacervate Density *versus* Temperature

Concentration of Sodium Salicylate, % w/v	Concentration of Benzalkonium Chloride, % w/v	Temperature	Location of Coacervate Phase in System
0.64	2.0	<26°	Bottom
		26–29°	Top
0.80	3.0	<16°	Bottom
		16–19°	Top
1.00	3.9	−2–0°	Bottom
		>0°	Top
1.12	4.0	<19°	Bottom
		19–23°	Top

Some biphasic systems at the transition line of the diagram were studied for the effect of temperature (Table I). It was observed that it is possible to change the density of a coacervate enough to make it lighter or denser than the equilibrium liquid by changing the temperature of the whole system; *i.e.*, both the equilibrium liquid and the coacervate phase change their relative densities to different degrees when undergoing the same change in temperature.

In Table I, the range in temperature for this change in relative density is reported. A more precise temperature could not be obtained, because the coacervate phase is viscous and also tends to stick to the wall of the container so an excess change in energy (temperature) is required to break it loose and make it begin to move.

The coacervate phase was observed to be isotropic when observed under a polarizing microscope.

Picogram Analysis of Tetrahydrocannabinol and Application to Biological Fluids

Keyphrases □ Tetrahydrocannabinol in biological fluids—GLC–electron-capture analysis, picogram quantities □ GLC–electron-capture detection—analysis, tetrahydrocannabinol in biological fluids

Sir:

A major goal in marijuana research is to quantify those compounds and metabolites in biological fluids responsible for psychoactive effects (1). Clinical investigations of Δ^9-tetrahydrocannabinol (2, 3), a major active component of marijuana, and 11-hydroxy-Δ^9-tetrahydrocannabinol (4), an active metabolite, have relied on analysis by radioactive labeling. However, the study of distribution, metabolism, and excretion of the drug and its metabolites under chronic or "street" conditions demands nonradioactive analytical procedures suitable for analysis in biological fluids of the picogram quantities of Δ^9-tetrahydrocannabinol typically found under clinical conditions (2, 3).

Detection of larger amounts of tetrahydrocannabinol is possible using several procedures (5) including GLC with flame-ionization detection, but the sensitivity for the underivatized tetrahydrocannabinols does not exceed 0.8 ng. (Fig. 1). An antibody detection method was recently developed (6), and submicrogram amounts of Δ^9-tetrahydrocannabinol and metabolites may be quantified by mass fragmentography (7) or fluorometry (8).

The procedures described herein permit the quantitative analysis of the total Δ^9- and Δ^8-tetrahydrocannabinols in picogram amounts by preparing the pentafluorobenzoate ester for analysis by GLC with electron-capture detection. A gas chromatograph[1], fitted with both ^{63}Ni and flame detectors, was used. Detectors were maintained at 285°. The ^{63}Ni detector had a separate nitrogen gas flow of 35 ml./min., and the glass columns were 30 cm. long (2.0 mm. i.d.). The conditions were: column 210–230°; injection port, 245°; 3% OV-225 on Gas Chrom Q, 100–200 mesh; nitrogen gas flow, 35 ml./min.; standing current (^{63}Ni), 60–90% at 2×10^{-9}; and background noise, 2–3% at 1×10^{-10}. The minimum detectable quantity of tetrahydrocannabinol was 1.65×10^{-14} mole. The minimum detectable quantity is defined as that amount giving a signal three times the background noise at maximum sensitivity (1×10^{-10}). When tetrahydrocannabinol was extracted from various solutions prior to derivatization, the minimum detectable quantity was a function of the efficiency of the extraction processes and the nature and magnitude of the nonionizable contaminants present and ranged between 40 and 125 pg./ml. of plasma for a 5-ml. blood sample.

To extract tetrahydrocannabinol from blood, a 5-ml. blood sample was centrifuged and a 2.5-ml. aliquot of plasma was transferred into a 50-ml. glass centrifuge tube. One milliliter of 5% trichloroacetic acid was added dropwise while shaking to denature proteins. Ten

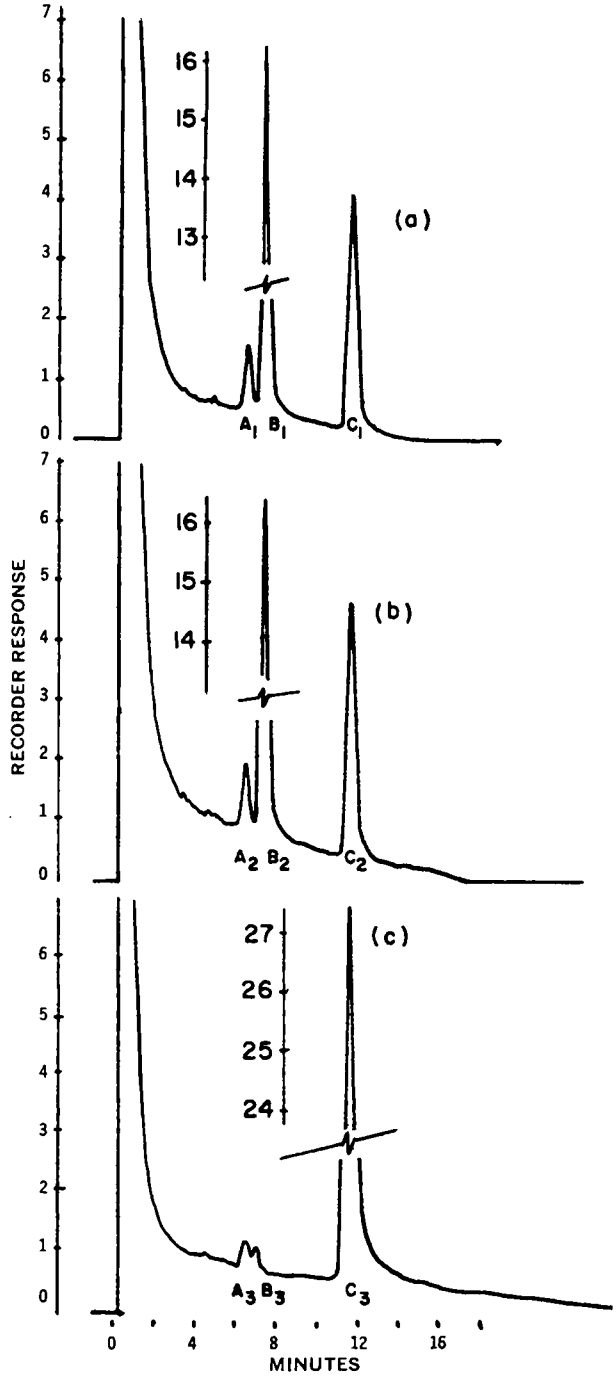

Figure 1—*(a) GLC analysis by flame-ionization detection of 1.3 μl. of a toluene solution containing 5 mg./ml. tetrahydrocannabinol and 1 mg./ml. cannabinol. Key: A_1, Δ^8-tetrahydrocannabinol (0.4 mcg.); B_1, Δ^9-tetrahydrocannabinol (6.5 mcg.); and C_1, cannabinol (1.3 mcg.). The tetrahydrocannabinols were from the same stock solution (see text), and A_1 accounted for 6.2% of the total tetrahydrocannabinols. (b) Tetrahydrocannabinol, 50 mcg., from the stock solution was added to 50 ml. water and treated as described in the text for extraction of tetrahydrocannabinol from blood. Cannabinol was added after the last step (prior to derivatization). After these various treatments, A_2 accounted for 7.0% of the total tetrahydrocannabinols. (c) GLC analysis (using flame-ionization detection) of the cannabinol used as internal standard. The amount of Δ^8- and Δ^9-tetrahydrocannabinols (A_3 and B_3, respectively) present as contaminants was approximately 1%. C_3 represents 5.2 mcg. cannabinol.*

The peak height ratios are plotted as the mean of three replicate extractions, and the vertical lines represent the standard deviations.*

quantitatively to a third 50-ml. test tube containing 25 ml. of 0.1 *N* HCl. This mixture was shaken for 5 min. and centrifuged. The organic layer was transferred quantitatively to another 50-ml. test tube. The tetrahydrocannabinol solution was then ready to be derivatized.

These procedures neither isomerized Δ⁹-tetrahydrocannabinol to Δ⁸-tetrahydrocannabinol nor the converse. This was shown by adding 50 mcg. of Δ⁹-tetrahydrocannabinol [from a 5-ml. sample[3] containing 1.0 g. of (−)-Δ⁹-*trans*-tetrahydrocannabinol in 99% ethanol, assayed as 93%] to 50 ml. of water and treating in the exact manner already described. This included the addition of trichloroacetic acid and the various treatments with acid and buffer. The relative amounts of Δ⁹- and Δ⁸-tetrahydrocannabinols were compared for the material before and after these treatments.

The assay was performed by GLC analysis with flame-ionization detection in a system capable of quantifying both the Δ⁸ and Δ⁹ species. The GLC system and conditions were the same as given for the electron-capture detection, except that a 1.8-m. (6-ft.) column was used and the nonderivatized material was chromatographed and detected by flame ionization. Cannabinol (from a 1-ml. sample[4] containing 10 mg. of cannabinol in 99% ethanol, assayed as 99%) was used as the internal

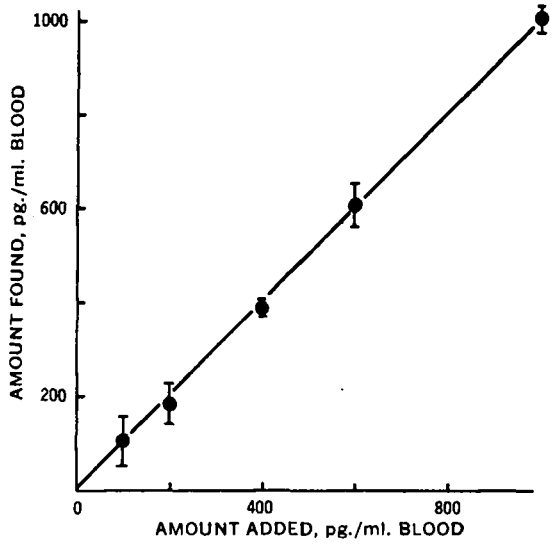

Figure 4—*Demonstration of the validity of the calibration curve and dilution technique. Sixty milliliters of fresh heparinized dog blood (same blood as used in Fig. 1) was divided into five 12-ml. samples, and one of each set was spiked with 100, 200, 400, 600, and 1000 pg./ml. with tetrahydrocannabinol (30 mcg./ml. in ethanol). The points represent the mean of three replicate extractions from 4-ml. aliquots. The vertical lines represent the standard deviations for the values shown, and the standard deviations ranged from 14.0 to 51.3 pg./ml. The slope and intercept of this plot were not statistically different from the expected values of 1.0 and zero, respectively.*

standard. The chromatograms of the Δ^9-tetrahydrocannabinol are given in Figs. 1*a* and 1*b* before and after the extraction processes, respectively. The original sample showed 6.2% Δ^8 (Fig. 1*a*); after the various treatments, there was 7.0% Δ^8, which demonstrated negligible conversion of Δ^9 to Δ^8 in the procedures. Although the cannabinol had about 1% of Δ^8- and of Δ^9-tetrahydrocannabinol impurities (Fig. 1*c*), this contribution to the peaks in Figs. 1*a* and 1*b* was below the sensitivity for these compounds at the level and conditions used with cannabinol as an internal standard.

The extractions of the tetrahydrocannabinols were made from dog blood, and the calibration curves obtained for known amounts of tetrahydrocannabinol in the blood from different dogs were significantly different. Significant differences among individuals should be assumed until shown otherwise. If electron-capture detector analysis of a derivatized blank plasma sample shows significant amounts of nonionizable compounds (steroids, *etc.*), a TLC or liquid chromatography cleanup step may be required. This was not necessary with the dog plasma used.

The solution of tetrahydrocannabinol in dichloromethane in the 50-ml. glass centrifuge tube was reduced to dryness under nitrogen and reconstituted in 0.2 ml. of dry dichloromethane containing 50 μl. of triethylamine. Ten micrograms (at least a 10-meq. excess) of pentafluorobenzoyl chloride[5] in 0.2 ml. of dry dichloromethane was added dropwise over 1 min. The solution was constantly stirred and allowed to react for 5 min. After the reaction was complete, 10 ml. of 0.1 *N* NaOH was added and the mixture was shaken for 5 min. The solution was centrifuged and the dichloromethane layer was transferred quantitatively to another 50-ml. test tube containing 10 ml. of 0.1 *N* HCl.

This mixture was shaken for 5 min. and centrifuged, and the dichloromethane layer was transferred quantitatively to a 3-ml. glass-stoppered test tube and stored overnight at 0° until time for GLC analysis.

The sodium hydroxide and hydrochloric acid washings were designed to hydrolyze and remove unreacted acid chloride and triethylamine catalyst. These removals were imperative for successful quantitative analysis.

At the time of GLC analysis, the final dichloromethane solution was dried under a stream of nitrogen and redissolved in at least 25 μl. of toluene containing the derivatized internal standard, cannabinol pentafluorobenzoate.

Although the cannabinol used had about 1% of tetrahydrocannabinol as an impurity (Fig. 1*c*), at the levels used for the addition of the derivatized cannabinol as cannabinol pentafluorobenzoate internal standard, no peaks assignable to these impurities were observable on electron-capture detection (Fig. 2*b*). Figure 2*b* shows the chromatogram for the internal standard obtained from 200 pg. of cannabinol. The chromatogram of derivatized Δ^9- and Δ^8-tetrahydrocannabinols appeared as one peak under our conditions (Fig. 2*a*) and was well separated from the peak assigned to the internal standard, cannabinol pentafluorobenzoate. This chromatogram was for the derivatized tetrahydrocannabinol obtained from 200 pg. of the original material.

Calibration curves over small concentration ranges were preferred since the ^{63}Ni detector has a small linear detectable range. Whole blood samples with known amounts of tetrahydrocannabinol added (*e.g.*, 150–550 pg./ml. plasma) were extracted and derivatized as already described. At the same time, 1 mcg. (or more) of cannabinol (internal standard) was derivatized and reconstituted in clean, dry toluene such that 1 μl. of the cannabinol pentafluorobenzoate solution contained about 10 times the minimum detectable amount, 1.65×10^{-14} mole. A volume of this internal standard solution, 25–500 μl., was added to each of the dried tetrahydrocannabinol pentafluorobenzoate samples such that the midpoint concentration of the tetrahydrocannabinol samples gave a peak height ratio of about one when 1–3 μl. of the final solution of derivatized tetrahydrocannabinol was injected. The calibration curve in Fig. 3 was obtained in this manner. A zero intercept for the linear range of the calibration curve was not necessarily expected or needed.

Once the calibration curve was obtained, a known volume of the internal standard solution (starting with 25 μl.) was added to each dried, unknown tetrahydrocannabinol pentafluorobenzoate sample prepared as described. If, on injection of 1–3 μl. of this solution the peak height ratio did not fall within the calibration curve, an additional volume of the internal standard solution was added until the peak height ratio did. The actual blood level concentration was obtained by correcting the value obtained from the calibration curve for the excess internal standard used. If a peak height ratio of 1.0 corresponded to 375 pg./ml. (X_1) on the calibration curve when 75 μl. (Y_1) of internal standard solution

[5] PCR, Inc., Gainesville, FL 32601

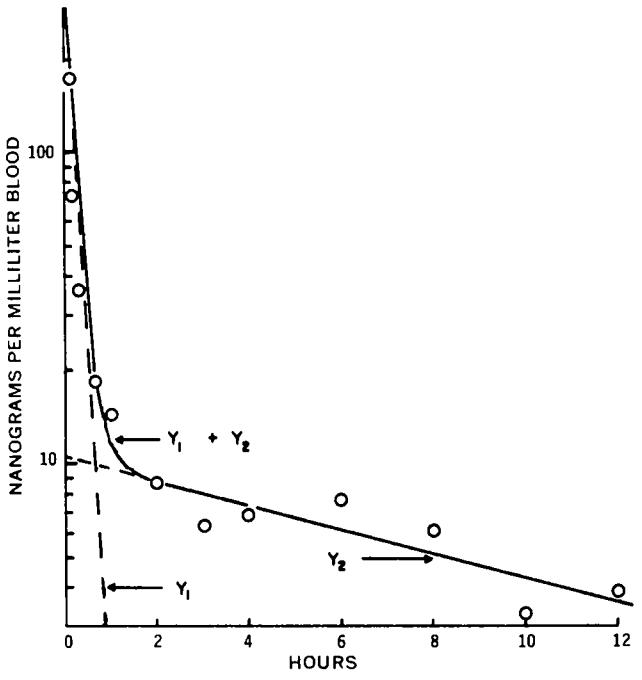

Figure 5—*Pharmacokinetic profile of tetrahydrocannabinol (0.1 mg./kg.) in blood from an 18.0-kg. dog. The calibration curve used is shown in Fig. 2. Five-milliliter blood samples were taken at 5, 10, 20, 40, and 60 min. and 2, 4, 6, 8, 10, and 12 hr. Urine was collected for 28 hr. but only a trace amount of tetrahydrocannabinol was found. The time course of this curve is fitted with the sum of two first-order exponential components,* Y_1 *and* Y_2, *where* $Y_1 = 300\ (ng./ml.)\ e^{-0.17t}$ *and* $Y_2 = 10.05\ (ng./ml.)\ e^{-1.05t}$. *The slower component,* Y_2, *has a* $t_{1/2}$ *of 8.0 hr. and the faster component,* Y_1, *has a* $t_{1/2}$ *of 7.5 min. The volume of distribution associated with* Y_2 *(equilibrated tissues) referenced to total drug in blood is 171 l. and the volume of distribution associated with* Y_1 *(central compartment) is 6.0 l.*

was used for all calibration curve values and a peak height ratio of 1.0 was obtained for an unknown amount of tetrahydrocannabinol (X_2) in blood when 25 μl. (Y_2) of internal standard was used, $X_2 = (X_1/Y_1)Y_2$. In this case, X_2 = 125 pg./ml. Figure 4 demonstrates this procedure and verifies its validity.

A number of critical variables affected the reliability and error of this procedure. Tetrahydrocannabinol bound extensively (15–40%) to glass from aqueous and organic solutions at low concentrations, and the degree of adsorption was time dependent. In the case of organic solutions, the tetrahydrocannabinol could be reincorporated from the glass into the solution on vigorous shaking. Thus, it was imperative to use vigorous shaking prior to any sampling. The degree of adsorption may be reduced if glassware is treated with an organic solution of a silyl reagent[6], followed by a solvent rinse of dichloromethane and drying. Storage times in aqueous or plasma solutions should be minimized and standardized since adsorption on storage in these media is unavoidable. Loss of tetrahydrocannabinol or a derivative from such solutions should not be assigned to instability until adsorption has been ruled out. Reagents of maximum purity must be used. Known amounts of tetrahydrocannabinol should be analyzed periodically to ensure reagent quality.

To demonstrate the applicability of this analytical technique, we determined the blood levels of tetrahydrocannabinol in a dog as a function of time. An 18.0-kg. dog was given a 1.8-mg. i.v. dose of tetrahydrocannabinol (0.1 mg./kg.) in 5 ml. of 50% aqueous ethanol. Blood samples were taken as a function of time over 24 hr. and urine was collected for 28 hr. The results are shown in Fig. 5 for tetrahydrocannabinol concentrations in blood as a function of time. Only a trace amount of unchanged tetrahydrocannabinol was found in the total urine collected when the urine was analyzed in the same manner as blood, and appropriate calibration curves were prepared. The calibration curves of Figs. 3 and 4 were prepared using blood from this dog and were used in this study. The apparent volumes of distribution of the central compartment referenced to the total concentration of the drug in blood was 6.0 l., whereas that of the rapidly equilibrated fluids was 171 l.

This pharmacokinetic profile shows an initial rapid distribution and metabolism phase (apparent half-life 7.5 min.) followed by a slow loss of tetrahydrocannabinol from blood (apparent half-life 8.0 hr.) and is consistent with the similar results reported for humans based on radiotracer studies (2).

Figure 5 demonstrates that this analytical procedure may be used to analyze blood levels of tetrahydrocannabinol. Although this procedure does not allow the separate quantitative analysis of Δ^8- and Δ^9-tetrahydrocannabinols at this sensitivity, preliminary results indicated that a similar procedure may be used to separate and quantify picogram amounts of other metabolites of tetrahydrocannabinol in blood and urine.

[6] Rinsing glass for 30 min. with a 1% (v/v) solution of Sil-Prep (Applied Science Labs., State College, PA 16801) in dichloromethane reduces adsorption to less than 5%.

Keyphrases ☐ Moisture content of granulations—relationship to particle size ☐ Granulations—moisture content as function of particle size

Sir:

In theoretical considerations relative to the drying of granulations, whether by stationary or fluid-bed techniques, it is customary to consider: (*a*) the granulate as uniform, and (*b*) a pooled, average moisture content as the experimental variable. However, granulations have a range of granule sizes and, in the strictest sense, it is not permissible to assume that the moisture is evenly distributed during and after drying. If a granule-sieve fraction has a particle diameter a, then the following relation can be obtained (1):

$$\frac{W - W_\infty}{W_0 - W_\infty} = \frac{6}{\pi^2} \sum_{j=1}^{\infty} \frac{1}{j^2} \exp[-j^2 t/\kappa] \sim \frac{6}{\pi^2} \exp[-t/\kappa] \quad \text{(Eq. 1)}$$

where W is moisture content; the subscripts zero and infinity denote initial and final conditions, respectively; j is a running index; t is time; and $\kappa = a^2/(4\pi^2 D)$, where D is a diffusion coefficient. Hence, W depends exponentially on a^{-2}, and the smaller granules are (as is intuitively obvious) drier than the larger ones after a certain drying time, t'.

In an experimental study of a continuous process, presently being conducted, sucrose granulations originally containing 7.0 ± 0.2% moisture were subjected to countercurrent drying[1]. The original moisture quoted is composite and theoretical and is not related to any sieve fraction, since wet sieving would be distortive at this point. In the case cited, a granulation was dried for 1 hr. The air inlet temperature was 149° (300° F.), the air outlet temperature was 45° (113° F.), and the dryer was operating at 3.5 r.p.m.

The dried granulation was sieved, and the various sieve fractions were subjected to toluene moisture analysis. The percent moisture was then plotted as a function of particle size (Fig. 1). Separate experimentation showed that $W_\infty = 0.42$, and plotting of $\ln[(W - 0.42)/6.58)]$ as a function of a^{-2} then produced a straight line (Fig. 2) with a slope of $-t'4\pi^2 D$ cm.^{2} [*i.e.*, the diffusion coefficient for the particular situation would be $-(\text{slope})/(4\pi^2 t')$ cm.^{2}/sec.] and an intercept of $\ln(6/\pi^2) = -0.5$; here t' is 3600 sec. It is seen from Fig. 2 that: (*a*) the data adhere fairly well to linearity and (*b*) the intercept is −0.56, in good agreement with the theoretical. These two facts substantiate the view that granules dry by a diffusional process and that, therefore, moisture content is a function of particle size. In cases where granules are not case hardened, the moisture levels equilibrate and the granulation is uniform when it reaches the tablet press. Most wet granulations, however, exhibit case hardening to a greater or lesser degree, and the above phenomena must be accounted for in processing.

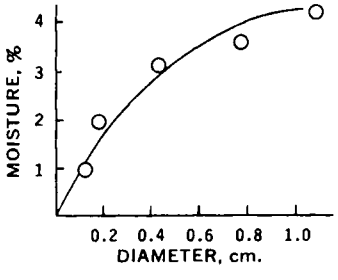

Figure 1—*Moisture content (percent) as a function of particle diameter. Diameters represent the average of the sieve fraction in question.*

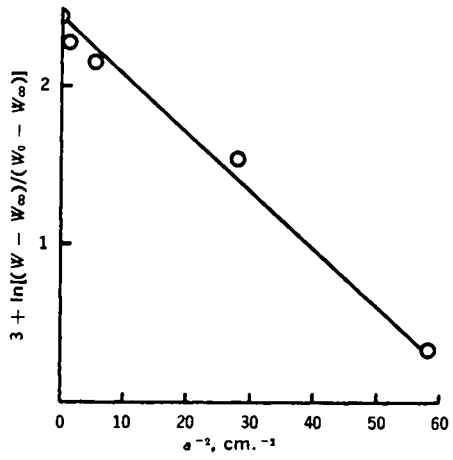

Figure 2—*Data from Fig. 1 plotted as shown in Eq. 1. The slope is -3.68×10^{-2} cm.^{2}, and the intercept is −0.56, i.e., 2.44 − 3.*

The diffusion coefficient for the curve in Fig. 2 is $(3.68\ 10^{-2})/(4\pi^2 3600) = 3 \times 10^{-7}$ cm.^{2}/sec., which is of the right order of magnitude for diffusion through capillary void space (2, 3).

REVIEWS

Structure and Function of Oxidation–Reduction Enzymes. Volume 18 (Proceedings of the International Symposium held in Stockholm, August 1970). Edited by Å. ÅKESON and A. EHRENBERG, Pergamon Press, Inc., Maxwell House, Fairview Park, Elmsford, NY 10523, 1973. 777 pp. 17 × 25 cm. Price $55.50.

Hugo Theorell has had a tremendous influence on biochemistry due to his fertile imagination, a possession of a sense for critical accuracy, and great technical skills. Theorell's achievements have been acknowledged by the scientific community in many ways, including the award of the Nobel prize. To mark his retirement, a conference was held in Stockholm in 1970, which was attended by many of his colleagues and students. Publication of the proceedings of this conference are presented in this volume. That the contributors are themselves a very distinguished company is an indication of Theorell's contribution to biochemistry. The scientific contributions of Theorell are considered by B. Chance in the first chapter of this impressive volume. However, the reader can obtain a rapid impression of Theorell's influence just by purusing the table of contents. The volume consists of some 80 papers, which are short pertinent reviews of a broad range of subjects pertaining to enzymology. These include the primary structures of various enzymes, *e.g.*, bovine liver glutamate dehydrogenase, soybean leghemoglobin, and horse liver alcohol dehydrogenase, as well as the chemical synthesis of horse heart cytochrome *c* and some of its analogs. Other sections deal with the X-ray structural studies of whole enzymes and some coenzymes, allosteric transitions in enzymes, physicochemical studies of various enzymes in solution, kinetics of enzyme action, and excitation transfer between chromophores in enzymes. Enzyme interactions in integrated structures such as mitochondria and chloroplasts are also covered.

Krantz and Carr's Pharmacologic Principles of Medical Practice. By DOMINGO M. AVIADO. Williams & Wilkins, 428 E. Preston St., Baltimore, MD 21202, 1972. xx + 1345 pp. 17.5 × 26 cm. Price $22.50.

Incorrectly labeled as the eighth edition, this is actually the first edition of an entirely new book—completely rewritten and reorganized. The resemblance to the "parent" text is negligible. Professors of pharmacology in schools of pharmacy will be especially pleased with this book since the author appears to have taken seriously the recommendations of the 1964–1967 A.A.C.P. Committee on Curriculum that the ideal course sequence in pharmacology should be built around organ systems (rather than chemical structure) and should concentrate in-depth upon the pharmacology of carefully selected prototype drugs (*cf.* pp. 16-17; "Studies of a Core Curriculum," Melvin R. Gibson, Ed., American Association of Colleges of Pharmacy, Silver Spring, MD 20910, 1967). However, all medical scientists and practitioners will find the book to be a valuable and unique reference since it is the first text to rate drug efficacy using the Drug Efficacy Study Implementation (DESI) ratings resulting from the deliberations of the expert panels appointed by the National Academy of Science–National Research Council. These ratings otherwise must be searched for in the *Federal Register*. The prototype drugs have been chosen with obvious care and the supporting references cited in the bibliographies at the ends of the chapters are both selective and current. After the five inadequate chapters of introductory material, the remaining 71 chapters are efficiently sequenced into 19 sections: Drugs Acting on the Central Nervous System and Used in the General Practice of Medicine; Pharmacology of the Central Nervous System Relating to the Practice of Neuropsychiatry; Pharmacology of the Central and Peripheral Nervous Systems Relating to the Practice of Anesthesiology; Pharmacology of the Sympathetic Nervous System; Pharmacology of the Parasympathetic Nervous System and Cholinergic Areas; Pharmacology of the Respiratory System; Pharmacology of the Cardiovascular System: Heart and Coronary Blood Vessels; Pharmacology of the Cardiovascular System: Systemic Blood Vessels; Pharmacology of Blood Cells and Blood Plasma; Pharmacology of Fluids, Electrolytes, and Renal Drugs; Pharmacology of the Reproductive System; Pharmacology of the Endocrine System; Drug Suppression of Allergic, Immunologic, and Inflammatory Responses; Drugs Used in the Practice of Ophthalmology, Otorhinolaryngology, and Dermatology; Gastrointestinal Tract, Digestion and Nutrition; Cancer Chemotherapy; Chemotherapy of Infections; Chemotherapy of Parasites; and Special Topics in Pharmacology. Appendixes A, B, and C compare the teaching of pharmacology in medical, pharmacy, and dental schools, respectively, and are well worth study by academicians. Appendix D categorizes 100 prototype drugs and 100 alternative agents. It is questionable as to whether Appendix E is really appropriate for a textbook in pharmacology since the primary *raison d'etre* for this section seems to be to facilitate comparison of prescription prices per unit; this is, of course, useful information but more current data can be obtained from other sources and this aspect is hardly pharmacologic. According to the text's preface, Appendix E was authored by Dr. Harry Salem.

Methods in Pharmacology, Volume 2 Physical Methods. Edited by C. F. CHIGNELL, Appleton-Century-Crofts, 440 Park Ave. S., New York, NY 10016, 1972. 499 pp. 16 × 23 cm. Price $29.95.

For those who see the pharmacologist as a tabulator of rat tail flicks, the topics covered in this text should be an eye opener: fluorescence and phosphorescence spectroscopy, circular dichroism and optical rotatory dispersion, Mössbauer effect spectrometry, nuclear magnetic and electron spin resonance, scattered light measurement, spectrophotometry of enzyme suspensions, flow and relaxation methods in the measurement of fast reactions, X-ray diffraction, mass spectrometry, oscillographic polarography, and heatburst microcalorimetry. Although aimed at the pharmacologist, this volume would be equally at home in the libraries of biochemists, physiologists, and medicinal chemists, illustrating that when disciplines converge, distinctions vanish.

Dr. Chignell's purpose in assembling (and substantially contributing to) this book was to acquaint the researcher with newer physical techniques in a way that would enable him or her to judge their applicability to his or her own problems. In this, the book succeeds. Each chapter is lucidly written, presumes a minimum of ignorance, and is well illustrated and referenced. There may be disagreement, in some instances, with the amount of detail included or omitted. In the chapter on mass spectrometry, for instance, those of us returning to the use of stable isotopes could wish for a more explicit treatment of the mass spectrometer as a quantitative analytical tool. But these are only matters of personal leaning and do not detract from the main aim of the book. If a serious complaint is to be raised against the book, it will come loudest from those quarters where the pharmacologist, physiologist, or biochemist works under tight budgets and without access to the costly instrumentation described. For those so deprived, agonizing over the good fortune of their plusher colleagues will be little assuaged by a theoretical knowledge of techniques which are passing them by.

Structure and Function of Oxidation–Reduction Enzymes. Volume 18 (Proceedings of the International Symposium held in Stockholm, August 1970). Edited by Å. ÅKESON and A. EHRENBERG, Pergamon Press, Inc., Maxwell House, Fairview Park, Elmsford, NY 10523, 1973. 777 pp. 17 × 25 cm. Price $55.50.

Hugo Theorell has had a tremendous influence on biochemistry due to his fertile imagination, a possession of a sense for critical accuracy, and great technical skills. Theorell's achievements have been acknowledged by the scientific community in many ways, including the award of the Nobel prize. To mark his retirement, a conference was held in Stockholm in 1970, which was attended by many of his colleagues and students. Publication of the proceedings of this conference are presented in this volume. That the contributors are themselves a very distinguished company is an indication of Theorell's contribution to biochemistry. The scientific contributions of Theorell are considered by B. Chance in the first chapter of this impressive volume. However, the reader can obtain a rapid impression of Theorell's influence just by purusing the table of contents. The volume consists of some 80 papers, which are short pertinent reviews of a broad range of subjects pertaining to enzymology. These include the primary structures of various enzymes, *e.g.*, bovine liver glutamate dehydrogenase, soybean leghemoglobin, and horse liver alcohol dehydrogenase, as well as the chemical synthesis of horse heart cytochrome *c* and some of its analogs. Other sections deal with the X-ray structural studies of whole enzymes and some coenzymes, allosteric transitions in enzymes, physicochemical studies of various enzymes in solution, kinetics of enzyme action, and excitation transfer between chromophores in enzymes. Enzyme interactions in integrated structures such as mitochondria and chloroplasts are also covered.

Krantz and Carr's Pharmacologic Principles of Medical Practice. By DOMINGO M. AVIADO. Williams & Wilkins, 428 E. Preston St., Baltimore, MD 21202, 1972. xx + 1345 pp. 17.5 × 26 cm. Price $22.50.

Incorrectly labeled as the eighth edition, this is actually the first edition of an entirely new book—completely rewritten and reorganized. The resemblance to the "parent" text is negligible. Professors of pharmacology in schools of pharmacy will be especially pleased with this book since the author appears to have taken seriously the recommendations of the 1964–1967 A.A.C.P. Committee on Curriculum that the ideal course sequence in pharmacology should be built around organ systems (rather than chemical structure) and should concentrate in-depth upon the pharmacology of carefully selected prototype drugs (*cf.* pp. 16-17; "Studies of a Core Curriculum," Melvin R. Gibson, Ed., American Association of Colleges of Pharmacy, Silver Spring, MD 20910, 1967). However, all medical scientists and practitioners will find the book to be a valuable and unique reference since it is the first text to rate drug efficacy using the Drug Efficacy Study Implementation (DESI) ratings resulting from the deliberations of the expert panels appointed by the National Academy of Science–National Research Council. These ratings otherwise must be searched for in the *Federal Register*. The prototype drugs have been chosen with obvious care and the supporting references cited in the bibliographies at the ends of the chapters are both selective and current. After the five inadequate chapters of introductory material, the remaining 71 chapters are efficiently sequenced into 19 sections: Drugs Acting on the Central Nervous System and Used in the General Practice of Medicine; Pharmacology of the Central Nervous System Relating to the Practice of Neuropsychiatry; Pharmacology of the Central and Peripheral Nervous Systems Relating to the Practice of Anesthesiology; Pharmacology of the Sympathetic Nervous System; Pharmacology of the Parasympathetic Nervous System and Cholinergic Areas; Pharmacology of the Respiratory System; Pharmacology of the Cardiovascular System: Heart and Coronary Blood Vessels; Pharmacology of the Cardiovascular System: Systemic Blood Vessels; Pharmacology of Blood Cells and Blood Plasma; Pharmacology of Fluids, Electrolytes, and Renal Drugs; Pharmacology of the Reproductive System; Pharmacology of the Endocrine System; Drug Suppression of Allergic, Immunologic, and Inflammatory Responses; Drugs Used in the Practice of Ophthalmology, Otorhinolaryngology, and Dermatology; Gastrointestinal Tract, Digestion and Nutrition; Cancer Chemotherapy; Chemotherapy of Infections; Chemotherapy of Parasites; and Special Topics in Pharmacology. Appendixes A, B, and C compare the teaching of pharmacology in medical, pharmacy, and dental schools, respectively, and are well worth study by academicians. Appendix D categorizes 100 prototype drugs and 100 alternative agents. It is questionable as to whether Appendix E is really appropriate for a textbook in pharmacology since the primary *raison d'etre* for this section seems to be to facilitate comparison of prescription prices per unit; this is, of course, useful information but more current data can be obtained from other sources and this aspect is hardly pharmacologic. According to the text's preface, Appendix E was authored by Dr. Harry Salem.

Methods in Pharmacology, Volume 2 Physical Methods. Edited by C. F. CHIGNELL, Appleton-Century-Crofts, 440 Park Ave. S., New York, NY 10016, 1972. 499 pp. 16 × 23 cm. Price $29.95.

For those who see the pharmacologist as a tabulator of rat tail flicks, the topics covered in this text should be an eye opener: fluorescence and phosphorescence spectroscopy, circular dichroism and optical rotatory dispersion, Mössbauer effect spectrometry, nuclear magnetic and electron spin resonance, scattered light measurement, spectrophotometry of enzyme suspensions, flow and relaxation methods in the measurement of fast reactions, X-ray diffraction, mass spectrometry, oscillographic polarography, and heatburst microcalorimetry. Although aimed at the pharmacologist, this volume would be equally at home in the libraries of biochemists, physiologists, and medicinal chemists, illustrating that when disciplines converge, distinctions vanish.

Dr. Chignell's purpose in assembling (and substantially contributing to) this book was to acquaint the researcher with newer physical techniques in a way that would enable him or her to judge their applicability to his or her own problems. In this, the book succeeds. Each chapter is lucidly written, presumes a minimum of ignorance, and is well illustrated and referenced. There may be disagreement, in some instances, with the amount of detail included or omitted. In the chapter on mass spectrometry, for instance, those of us returning to the use of stable isotopes could wish for a more explicit treatment of the mass spectrometer as a quantitative analytical tool. But these are only matters of personal leaning and do not detract from the main aim of the book. If a serious complaint is to be raised against the book, it will come loudest from those quarters where the pharmacologist, physiologist, or biochemist works under tight budgets and without access to the costly instrumentation described. For those so deprived, agonizing over the good fortune of their plusher colleagues will be little assuaged by a theoretical knowledge of techniques which are passing them by.

PHYSICAL PHARMACY (*continued*)

Membrane Permeation—Phenomena associated with membrane permeability are important pharmaceutically in drug transport modeling and in the design of effective drug delivery systems. Flynn and his coworkers studied the influence of solvent composition and permeant solubility on membrane transport (850) and the influence of alkyl chain length on flux-determining properties of the barrier and diffusant (851), and they derived equations describing the diffusion layer control flux of a permeant through a membrane sandwiched between two liquid phases (852). It was shown that, under certain conditions, the steady-state transfusion through dimethylpolysiloxane membranes by *p*-aminoacetophenone from binary solvent mixtures was essentially controlled by the thermodynamic activity of the compound in the applied phase (850). A theoretical expression was presented correlating the effect of alkyl chain length on partition coefficient, solubility, and maximum steady-state flux through a model membrane. This expression, predicting a parabolic dependency of the flux with respect to alkyl chain length, was experimentally verified by determining transport rates of an homologous series of esters across the dimethylpolysiloxane membrane (851). Equations derived for the diffusion layer control flux of a permeant through a membrane sandwiched between two liquid phases confirmed that the steady-state flux in such cases is only dependent on the applied phase concentration, the diffusivity within the diffusion layers, and the reciprocal of the sum of the diffusion layer thicknesses. Furthermore, a lag time expression was derived which relates the duration of the nonsteady state to the membrane and diffusion layer

thicknesses, the membrane–solvent partition coefficient, and the reciprocal of diffusivity within the solvent. The significance of the lag time effect as the limiting factor in the structure–activity profile for a series of organic homologs was discussed (852).

The changes in *in vitro* permeability rates of benzocaine through silicone rubber implants by introduction of copermeant plasticizers into the implant were investigated. Solubility, diffusivity, molecular volumes and mobilities of the copermeants, hydrogen-bonding capabilities, and potential for internal segmental motion of polymeric plasticizers were considered as the factors influencing drug transmission rates (853). Studies on permeation of aniline and substituted anilines (854), aromatic acids, alcohols, amines, esters, aldehydes, and ketones (855) were performed to ascertain the effect of chemical structure on the permeation of these agents through polyethylene. The permeability constants of these compounds were shown to correlate with their hexane–water partition coefficients by an empirical equation (855). A thermogravimetric analysis method was used to evaluate the diffusion and solubility of a series of aliphatic alcohols in a specific polyurethane film at several different temperatures. In general, the diffusion coefficients of the straight-chain alcohols increased with temperature and decreased with molecular weight. By knowing solubility and diffusion coefficients, the permeability constants were estimated (856).

The effects of changes in the polymer ratio and environmental conditions on the water vapor transmission properties of plasticized films containing combinations of hydroxypropyl methylcellulose and ethylcellulose were evaluated. The findings of this study demonstrated the presence of another mechanism of vapor transmission, in addition to diffusion, which is apparently related to the hydrophilic character of the film (857). Water vapor transmission through cellulose acetate phthalate and *n*-butyl methacrylate polymer films showed significant differences in permeability behavior with the cellulose acetate phthalate films, depending on whether moisture was present on one or both sides of the film during permeation; however, this effect did not occur with the *n*-butyl methacrylate films. The dehydration of the distal cellulose acetate phthalate film surface when moisture is present only on the proximal surface was provided as an explanation for the permeability behavior of the membrane (858). A method was described for the study of free unsupported polymer films; its applicability was demonstrated by testing effects of spray rate and film substrate on mechanical strength and water permeability of cellulose acetate films (859).

The hindrance of solute diffusion was measured through microporous membranes of known pore geometry with pore radii ranging from 2.5 to 300 Å. The membranes were prepared by bombardment of mica sheets with fission fragments from a ^{235}U source and subsequent etching with hydrofluoric acid. It was concluded that in most membrane operations there is a considerable resistance to diffusion due to the presence of a liquid film boundary layer along the surface of the membrane. However, this boundary layer resistance was not inversely proportional to the solute diffusivity, as has been often assumed in the unstirred layer theory,

but was proportional to the −0.6 power of the solute diffusivity (860). A new theory based on absolute reaction rates was proposed to explain diffusion of polystyrene spheres through a thin membrane with cylindrical pores (861). Two different models for the diffusion of a binary solution through a membrane were used to derive relations between the solute permeability coefficient and the reflection coefficient. The theoretical considerations were shown to agree with previously reported data for highly porous membranes (862).

The transport rates of sodium and potassium chlorides through the bovine eye-lens capsule, insoluble gelatin membrane, and collagen membrane were measured to estimate the permeability coefficient, the rate constant of permeation at the interface, the apparent membrane constant, and the interface constant. The permeability of the bovine eye-lens capsule was greater than the gelatin membrane but was comparable to the collagen membrane (863). In a subsequent study, ionic diffusion and permeability of potassium hydrogen aspartate and magnesium hydrogen aspartate across the vitreous bovine eye-lens capsule was investigated (864). The permeability of potassium chloride through two-component membranes, composed of gelatin and chondroitin sulfate C, was measured. The membrane permeability was decreased with an increase of total weight of the membrane and with an increase of the amount of chondroitin sulfate C (865).

The effect of salicylate on the relative cation permeability of a membrane was investigated in large, identified molluscan neurons. Salicylate caused a reversible, dose-dependent decrease in the permeability of rubidium, cesium, sodium, and lithium ions relative to

that of potassium ions, probably due to the adsorption of salicylate anions to the membrane with a subsequent increase in the density and field strength of anionic sites in the membrane (866). Salicylate, benzoate, and their analogs reversibly increased the membrane potential and conductance of identified molluscan neurons by increasing potassium conductance and decreasing chloride conductance. The relative potencies of these compound's were closely correlated with their octanol–water partition coefficients and their pKa values (867).

Additional membrane permeability studies are listed in Table XXV.

Complexation—The studies related to complexation phenomena are categorized into: (*a*) interactions of drugs with biological substances, and (*b*) interactions of drugs with nonbiological substances.

Interactions of Drugs with Biological Substances—Computer programs were used to compute and plot theoretical data in which the binding capacities, association constants, and level of protein were varied in a system of dicumarol (bishydroxycoumarin) and human serum albumin. In general, for any one drug level the amount of unbound drug was inversely proportional to the binding capacity, association constant, and protein content (879). The *in vitro* binding of a number of sulfa drugs to human serum albumin was studied as a function of pH, and the results were correlated with pKa, octanol–water partition coefficient, and electron distribution of the sulfa drug. It was concluded that the primary effect in sulfa drug binding with human serum albumin may be an electrostatic attraction between the anionic drug molecule and a cationic site of human serum albumin, while hydrogen bonding and attraction between the tryptophan residue of human serum albumin and the sulfa drug play a secondary role (880–882).

Interaction between 5-dimethylamino-1-naphthalenesulfonamide and human serum albumin suggested that the binding of the drug to the protein is hydrophobic in nature, and it occurs near the tryptophan residue of the protein (883). The binding constants of various sulfonamide drugs with bovine serum albumin determined as a function of pH were analyzed with five energy-related physicochemical parameters, taking into account the correction for ionization of the drugs. It was postulated that the binding equilibrium depends on the hydrophobicity of the drug and binding occurs between the neutral drug molecule and the hydrophobic fraction of the protein surface (884). The binding of 33 organic compounds to bovine serum albumin was studied at pH 7.4 and 37°. The binding affinity of these compounds correlated with their octanol–water partition coefficients when more than 50% of the compound existed as unionized molecules at pH 7.4. It was shown that the octanol–water and isobutanol–water reference systems for defining hydrophobic character yield comparable results (885).

The interaction of tritiated prostaglandin E_1 with various constituents of human blood was examined by equilibrium dialysis and incubation experiments. Prostaglandin E_1 apparently exhibited weak interactions with serum albumin but did not interact with blood cells and plasma globulins (886). Following incubation of tritiated digoxin with human blood, all the radioactivity was found associated with the plasma, with 25% bound to the serum albumin and the rest free in solution. Addition of cortisol, progesterone, or cholesterol to the serum decreased digoxin binding (887). However, analysis of the serum obtained from human subjects 2 hr. after receiving tritiated digoxin orally or by intravenous injection showed only 1–10% of the drug bound to serum protein (888). The plasma protein binding of diphenylhydantoin in adult patients with epilepsy, in normal subjects, and in hyperbilirubinemic newborn infants was investigated. Competition was indicated between the drug and bilirubin for albumin binding sites (889). The binding of estrone sulfate by human serum albumin appeared to involve one strong binding site and several weaker binding sites. Estradiol 3-sulfate, androsterone sulfate, and similar other compounds were shown to compete for estrone sulfate binding (890).

The binding of salicylic acid to human serum albumin was studied by equilibrium dialysis and frontal gel chromatography. The reproducibility of the data provided by chromatography was far superior to that obtained with equilibrium dialysis (891). An ultrafiltration method, using membranes that quantitatively separate small molecules from plasma proteins, was employed to measure plasma binding of salicylate. The results obtained by this method were comparable to those obtained by equilibrium dialysis (892). The proportion of salicylate bound to serum proteins of rats *in vitro* increased with the increasing age of the rats, from 30% at 7 days to 53.2% at 60 days, due to increased serum albumin concentrations in the older rats. These results may partially explain the greater drug sensitivity of newborn animals (893). Three sulfonylureas, acetohexamide, chlorpropamide, and tolbutamide, were investigated in terms of their affinity for the major human serum proteins. At pH 6.5, 7.4, and 8.4 and normal human serum protein concentrations, these drugs were primarily bound to albumin. Inhibition of sulfonylurea–albumin binding by drugs that are known to potentiate activity of these sulfonylureas was studied (894). The serum albumin binding capacity of doxycycline, metoclopramide, sulfaethylthiazole, and progesterone was increased approximately 40% in the presence of physiological concentrations of urea. Disorganization of the protein structures by a reduction of intramolecular hydrophobic forces was suggested as a probable reason for the urea-induced increase of the drug–protein binding (895). Antileprous drugs and thyroxine bind to human serum proteins at a common site. This was demonstrated by mutual interference between thyroid hormones and antileprous drugs in binding to human serum (896). On the basis of affinity for serum proteins, antileprous drugs were classified into: the albumin-affinitive type, the globulin-affinitive type, the nonadsorbing type, and those having moderate affinity to serum proteins (897).

In lecithin–water model membrane systems, polymyxin B interacted with the polar and nonpolar regions of the phospholipid, while gramicidin S interacted only with the polar region. The implication of these observations with respect to lipid–protein interactions and

antibiotic activity was discussed (898). At equimolar concentrations, chlorothricin formed a strong complex with lecithin and prevented the phospholipid from swelling in water. This was ascribed to nonpolar association of the antibiotic with the hydrocarbon chains of the phospholipid (899). Phospholipid, cholesterol, protein, and mixed lipid–protein monolayers were used as models to study interactions between 3,4-benzpyrene, a carcinogenic hydrocarbon, and cell membranes. The carcinogen was shown to interact strongly with phospholipid, protein films, and mixed lipid–protein films. The biological significance of these data was discussed (900). A similar study dealt with interactions between dimethyl sulfoxide and these monolayer model films. The results indicated that the remarkable penetration abilities of dimethyl sulfoxide may be due to some alteration of protein structure as a result of dehydration at the biomembrane (901). The interactions of some oral contraceptive steroids with cholesterol and lecithin monolayer films were studied to determine their role in platelet aggregation. The data support the hypothesis that steroids may adsorb at platelet surfaces and alter the surface properties or the penetrability of the platelet membrane to cause increased platelet aggregation (902).

Additional references pertaining to interactions of drugs with biological substances are given in Table XXVI.

Interactions of Drugs with Nonbiological Substances— A theoretical study dealt with the calculation of heats of complexation and the structures of charge-transfer complexes of chloranil, fluoranil, and tetrachlorophthalic anhydride with various methylbenzenes in carbon tetrachloride solvent. The theoretical interaction energies were calculated from the monopoles-bond polarizabilities approximation, and the ground-state charge distributions were taken from CNDO/2 calculations[1]. The solvent contribution to the heat of complexation was estimated using the cavity model (927). The effects of water on the charge-transfer transition energy and the equilibrium constant were investigated for complexation of chlorpromazine hydrochloride with *p*-xyloquinone and of sodium *N*,*N*-dimethyl-*p*-aminobenzoate with sodium anthraquinone-2-sulfonate (928). In a subsequent study, the influence of water on the rate of charge-transfer interaction between aniline and chloranil was reported. It was concluded that water promotes the charge-transfer complexation presumably due to the enhancement of the solvent polarity (929).

Metal complexes of thiouracils were studied by potentiometric titration and polarographic techniques in an attempt to determine stability constants and rationalize the mechanistic bases of the relative complex stabilities, thiouracil structures, and biological activities. The relative tendency of metal ions to complex with thiouracils, $Cu^{+2} \gg Pb^{+2} > Cd^{+2} \gg Ni^{+2} \sim Zn^{+2}$, was found consistent with the "natural order" of such transition metals, their relative ionic radii, their electronic structure, and the concept that "soft acids" prefer to complex with "soft bases" (930). Stability constants were determined for a series of imidazole, pyrimidine, and related heterocyclic thiones with Cu^{+2}, Al^{+3}, and Fe^{+3} ions. The relative magnitude of these constants indicated formation of four-membered chelate rings involving nitrogen and sulfur atoms (931). Metal complexes of *ortho*-, *meta*-, and *para*-aminobenzoic acids were examined by atomic absorption, IR, differential thermal analysis, and thermal gravimetric analysis techniques. These complexes consisted of 2:1 ratios of metal to ligand, with amino and carboxyl groups assumed to participate in the complex formation (932). Based on electron microscopy and gel chromatography studies of an iron–dextran complex, a structural model was presented for the complex, with dextran attached by the terminal metasaccharinic acid units to the FeOOH component (933).

The interactions of alkyl trimethylammonium bromides with amaranth were investigated by microscopy, microelectrophoresis, phase solubility, and other physi-

cal techniques. The dye–surfactant complexation was shown to be a coacervation phenomenon, and the results were interpreted using general coacervation theories (934). Crystalline 1:1 complexes of acetaminophen with caffeine and theophylline were isolated from aqueous solution. The caffeine–acetaminophen complex was found to exist in three forms, each differing only in the degree of solvation (935). Acetaminophen was shown to form a stable 1:1 complex with antipyrine; the complexation involved amino and hydroxyl groups of acetaminophen and the carbonyl group of antipyrine (936). The formation of a complex between phenylmercuric nitrate and sodium metabisulfite, which is more active in acidic media but less active in alkaline media than phenylmercuric nitrate alone, provided an explanation for the observed antibacterial activity of the drug–metabisulfite mixture (937). A series of six 2,6-diamino-8,9-disubstituted purines was shown to form cyclic 2:1 hydrogen-bonded complexes with phenobarbital in dilute chloroform solution at room temperature, whereas 9-phenbutyladenine formed a 1:1 complex with phenobarbital under similar conditions (938). The effects of the CNS active drugs pentobarbital, bemegride, and trimethadione on the NMR spectrum of formanilide showed that the *cis*-isomer of the amide forms a doubly hydrogen-bonded complex with the drugs, but the *trans*-isomer favors formation of a single hydrogen bond. Implications of results in terms of the mechanistic basis of CNS active drugs were discussed (939).

The formation of inclusion complexes of barbiturate drugs with cycloheptaamylose was examined by solubility analysis and by circular dichroism measurement. These complexes existed in 1:1 ratios with the relative strength of interaction in the order: phenobarbital > pentobarbital > amobarbital > barbital (940). The interactions of β-cyclodextrin with six barbituric acid derivatives and thiopental were studied by solubility analysis. Barbituric acid derivatives having a cyclic substituent at the 5-position formed a more stable complex than those having an acyclic substituent. The physical stability of aqueous solutions of sodium barbiturates was improved in the presence of β-cyclodextrin (941).

The interaction of sodium lauryl sulfate with polyvinylpyrrolidone and polyvinyl alcohol in aqueous solutions was studied by intrinsic viscosity and membrane equilibrium measurements. The intrinsic viscosity and membrane equilibrium yielded a bell-shaped profile with increasing concentration of sodium lauryl sulfate (942). It was shown that monolayers of polyvinylpyrrolidone copolymers interact more strongly with dissolved benzoic acid than with *p*-hydroxybenzoic acid. However, in bulk solutions of polyvinylpyrrolidone, the latter is more strongly bound. This difference was ascribed to the highly oriented structure which polymers assume at interfaces (943). Aqueous mixtures of papaverine hydrochloride and atropine sulfate with various surfactants and polymer excipients were examined by TLC. An interaction between the drugs and sodium lauryl sulfate, as well as a tendency toward complexation of the drugs with methylcellulose, was evidenced (944). Equilibrium constants and coordination numbers were determined for complexes obtained by coupling methacrylic acid and acrylic acid polymers with various ammonium salts of drugs. The experimental data were interpreted by a modified Bjerrum-Gregor theory (945). Complexation of aspirin, salicylic acid, and thimerosal with methacrylate copolymers was indicated by equilibrium dialysis measurements (946).

Additional references related to interactions of drugs with nonbiological substances are listed in Table XXVII.

Surface Phenomena—The publications dealing with surface phenomena are divided into four major categories: interface studies, adsorption studies, general properties of surfactants, and micelle studies. However, because of the obvious overlap among these categories, the reader with a special interest in this field is advised to consider the entire section.

Interface Studies—Equations correlating the free volume and zero energy of interaction with the surface tension of liquids are based upon the assumption that each particle moves independently in its potential well. Since this concept does not account for the interaction resulting from particle oscillation, the free volume term in these equations was replaced by the free phase space, which can be calculated from the free energy and entropy of interaction among particles (964). Surface tension calculation for simple liquids using the Kirk-

wood–Buff theory, assuming a smooth variation of density between liquid and vapor, and the estimation of the thickness of the interface were shown to be in fair agreement with experimental results (965). The surface energy, surface entropy, and latent heat of surface formation were calculated for water, benzene, *n*-butanol, and six other similar liquids from the information on surface tension as a linear function of temperature (966). The surface tensions of oleic acid, sodium oleate, and a mixture of both in aqueous media were determined as a function of temperature and concentration. Occurrence of intermolecular attraction between these compounds was indicated from the surface energies calculated for the mixture (967). A thermodynamic description of the interfacial layers was presented by treating interfacial layers as a collection of molecular planes (968). This model, at equilibrium, was shown to be in agreement with the Gibbs formula (969).

The thermodynamic properties of the film compression process were evaluated for a series of liquid-condensed and liquid-expanded lipid films. It was shown that, for the liquid-condensed and liquid-expanded monolayers, the hydrocarbon region is energetically similar to bulk hydrocarbon liquids. Entropies of compression for the polar groups suggested that characteristic changes in water structure are likely to occur in the formation of each condensed monolayer state (970). In a subsequent study with mixed lipid films, it was concluded that: (*a*) in the absence of specific interactions, the liquid-condensed films of octadecanol, stearic acid, and dipalmitoyl lecithin are immiscible with cholesterol; and (*b*) cholesterol forms nonideal mixtures with liquid-expanded lipid films (971). Surface pressure–area curves were obtained for mixed monolayers of myristic acid, an expanded film-forming acid, with condensed film-forming acids of chain lengths from C_{17} to C_{26}. The change in characteristics of the curves with chain length indicated the dominant effect of hydrophobic interactions (972). An empirical equation was given relating the average carbon chain length of a molecule in films spread at the air–water interface with the pH of the aqueous phase, and it was applied for films of palmitic acid, stearic acid, arachidic acid, and behenic acid (973). Measurements of equilibrium spreading pressure for various saturated fatty acid triglycerides revealed that the spreading pressure decreases while the collapse pressure increases with the increase in fatty acid chain length. Successive stages leading to collapse of the film were discussed (974). IR spectra of stearic acid films spread on aqueous aluminum chloride solutions were studied by the attenuated total reflectance (ATR) technique to correlate the molecular structure of the film with the film stability. The stability of this film was attributed to the formation of an adsorption layer of dihydroxoaluminum stearate (975).

The surface pressure–area and oxygen permeation behavior of stearic acid, dipalmitoyl lecithin, and lung alveolar surfactant films were investigated to elucidate the mechanism of surface hysteresis exhibited by the lung surfactant. Mechanisms for the hysteresis phenomenon were proposed based on surface relaxation and compression rates of these films. The results of oxygen permeation studies indicated that only the films with the abilities both to pack efficiently in the condensed state and to regenerate themselves from the collapsed state significantly reduce oxygen permeation (976). The interaction of cetyl sulfate and cetrimonium (cetyltrimethylammonium) ions with dipalmitoyl glycerol monolayers at the air–water interface was followed by variation of the surface pressure and surface potential. The kinetics and mechanism of these monolayer interactions and their implications to microstates of biomembranes were described (977). The free energy changes, activation energies, and activation entropies associated with material transfer through liquid–liquid interfaces were experimentally determined for propionic acid, *n*-butyric acid, and *n*-valeric acid in the benzene–water system. The increase in the interface resistance with increasing alkyl chain length was attributed to the change in activation entropy (978). Thermodynamic parameters for the transfer of *n*-alkanols at the air–solution interface were obtained from surface pressure measurements. In accordance with Traube's rule, free energy values decreased linearly with increasing alkyl chain length and the enthalpy values were independent of the chain length. Approximately a twofold difference was observed between the theoretical and experimental entropy values and was presumed to be due to hydrogen bonding between alcohol and water (979). Equations were derived characterizing diffusion and viscous-type propagation of a liquid on solids (980).

Additional references on interface studies are listed in Table XXVIII.

Adsorption Studies—Gibbsian thermodynamics of adsorption from liquid mixtures on solids were formulated in terms of excess properties. A general expression was derived for the temperature coefficient of the surface excess in terms of heat of immersion of the adsorbent. Experimental data on nonisothermal adsorption and the heats of immersion were reported for the benzene–cyclohexane system adsorbed on silica gel (1001). A new isotherm for adsorption of a monolayer on a smooth surface, which is reducible in limiting cases to the Langmuir, Freundlich, or Temkin isotherm, was proposed. Immobile and mobile adsorbed molecules were considered, the number of the latter being determined by a Boltzman expression (1002). The influence of counterion concentration on the thermodynamic parameters of dodecylpyridinium chloride at the free surface of solution was investigated. The free energy, enthalpy, and entropy of adsorption values were correlated with the temperature and counterion concentration of the solution (1003). Adsorption of five steroids was determined at the oil–water interface in an effort to test a localized and a nonlocalized model for the adsorbed layer. Since neither model provided an accurate description of the adsorption kinetics, it was concluded that both the energy barrier and diffusion play a role in adsorption kinetics (1004).

Carstensen and Su (1005) described the effect of solvent intercalation in adsorption isotherms of montmorillonite from solvents with a high dielectric constant. It was shown that the number of solvent layers in the interlaminar spacing is higher when the clay is equilibrated with liquid than with the solvent vapor. These

authors (1006) also presented data supporting the hypothesis that the adsorption of unionized organic compounds on montmorillonite is a surface adsorption phenomenon mediated *via* an ion–dipole interaction. Dissolution and dialysis studies were reported showing that cationic drugs and some nonionic drugs adsorb very strongly to montmorillonite clay. A two-step process involving a cation-exchange reaction followed by strong surface chemisorption was proposed as the mechanism for cationic drug–clay binding. The initial urine levels of amphetamine after oral administration of the drug–clay complex were significantly lower than those for the pure drug (1007). The adsorption of benzidine on montmorillonite suspended in aqueous solutions was studied as a function of pH and electrolyte concentration. The interaction between benzidine and the clay was considered to be a cation-exchange process (1008).

The liquid and vapor phase adsorption of primary aliphatic alcohols (C_1–C_{10}) on calcium and sodium montmorillonite was investigated by X-ray techniques. Molecular configurations of the adsorbed molecules consistent with the experimental data were suggested (1009). The adsorption of salicylic and gallic acids by sodium and calcium forms of kaolinite, montmorillonite, and other clays was determined in aqueous media. The results were discussed in terms of the differing crystal structures of the clays (1010). In aqueous solutions, Langmuir-type isotherms were observed for the adsorption of crystal violet on the H-forms of bentonite and kaolinite. Both clays sorbed crystal violet in amounts greater than their cation-exchange capacities, indicating that unionized molecules of the dye were adsorbed in the interlamellar spaces of the clay and that dimerization of the dye occurred on the clay surfaces (1011). Adsorption of benzoic acid by kaolin was studied as a function of pH. For effective preservative action, when both benzoic acid and kaolin are present in a formulation, the use of either high benzoic acid concentrations at pH > 5 or low concentrations at pH < 5 was recommended (1012).

Adsorption of tetracycline on calcium fluoride was investigated in an attempt to develop a physical–chemical model capable of describing the adsorption of specific tetracycline species from aqueous solution onto model adsorbents, both in the presence and absence of added electrolytes and over wide concentration and pH ranges. In the absence of other electrolyte species, Langmuirian-type adsorption isotherms were observed when the equilibrium concentrations of the adsorbate were calculated to reflect the activity of the negatively charged tetracycline species. The data obtained in the presence of fluoride or sulfate anions were explained on the basis of competitive binding by these anions for the same surface site. In the presence of calcium or magnesium cations, it was proposed that other drug species adsorb simultaneously with the negatively charged tetracycline species (1013). Determination of adsorption isotherms for four sulfanilamides on activated carbon, as a function of pH, showed an adsorption maximum between pH 4.5 and 5.5, corresponding to the isoelectric points of the molecules (1014). The influence of surface area of activated carbon upon the adsorption of coccinine and picric acid from granular and other forms was investigated. A mathematical interpretation of the data showed that the adsorbing power of the carbon can be represented by an exponential equation (1015, 1016).

Additional references on adsorption studies are listed in Table XXIX.

General Properties of Surfactants—Surface activity and emulsifying properties of quaternary ammonium salts were correlated with the structure of the surfactant molecule and its orientation at the toluene–water interface. Differences between the predicted and experimental values of adsorption energies suggested that about 40% of the methylene groups present in the surfactant molecule were submerged in the aqueous phase. The maximum emulsifying ability was observed for the alkyl trimethylammonium-type compounds containing 14–16 carbon atoms (1031). The surfactant properties of a water-soluble phosphated nonylphenol ethoxylate in aqueous media were examined as a function of pH, temperature, and surfactant concentration. From the measurements of the CMC in buffer solutions

over the 4.0–9.2 pH range, it was suggested that the surface-active properties of the compound were unaffected by the state of ionization of the polar phosphate group. The group interfacial cross-sectional area of the molecule varied from about 0.92 nm.^{2} at 15° to 0.82 nm.^{2} at 50°, which was consistent for the system having nonionic portions of the molecule oriented at the interface (1032). A thermodynamic treatment for the occurrence of a minimum on the surface tension isotherm suggested that the presence of an impurity that lowers the CMC causes a minimum on the isotherm, but an impurity that increases the CMC may not always yield a minimum (1033). The literature data for surface pressures of mixtures of anionic and cationic surfactants were found consistent with theoretical predictions based on the surface behavior of the separate constituents (1034). An ultrasound method was described for the determination of the degree of hydration of nonionic surfactant molecules in an aqueous solution (1035).

The association equilibrium and micelle formation by polyethylene glycol *n*-nonylphenyl ether (1036) and β-D-*n*-octyl glucoside (1037) were determined by vapor pressure, osmometric, light scattering, ultracentrifugation, and sedimentation methods. For both surfactants, the data agreed with the model of closed association, and a linear relationship existed between the enthalpy and entropy of association. A subsequent publication dealt with the theoretical estimation and experimental measurements of viscosity of the two surfactants (1038). The effects of a polymer interacting with a surfactant upon the solubilization of the surfactant, surface tension, and viscosity were discussed. Interactions of polymers were more pronounced with anionic surfactants than with nonionic and cationic surfactants (1039). In a similar study, viscometric and conductometric measurements showed that the interactions of polyvinyl alcohol with anionic surfactants occurs below the CMC's (1040).

The HLB values of fluorocarbon and ionic hydrocarbon surfactants were related to their CMC values. A modified equation, derived from Davies' theory, was employed for the estimation of cohesive free energy change per methylene group in the surfactant molecule (1041, 1042). Application of NMR as a direct measure for the determination of HLB values for nonionic surfactants was demonstrated. Estimation of the relative proportion of lipophilic and hydrophilic protons by this technique provided the basis for the calculation of the HLB characteristics of a surfactant (1043). The HLB values of surfactants were correlated with the ratio of the work of surfactant adsorption from two liquid phases at their interphase (1044) and with the spreading coefficient determined from surface and interfacial tension measurements (1045).

Additional studies on general properties of surfactants are listed in Table XXX.

Micelle Studies—The definition and phenomenological interpretation of the CMC in multicomponent systems were discussed. The CMC was considered as the transition point for a second-order phase transition in a multicomponent system. Expressions were given for the mutual dependencies of temperature, pressure, and composition of a system at its CMC (1059). Mukerjee (1060) applied procedures for dealing with multiple

equilibria in stepwise self-association when all species are in a rapid association-dissociation equilibrium to micellar systems. The possibility of determining the number average degree of association by utilizing experimental weight average values was demonstrated. The self-association model, along with some approximate nonideality corrections, was stated to reproduce the shapes of some observed reduced turbidity data showing minima (1060). A model describing the kinetics of micelle formation from chemical relaxation studies predicted a single relaxation time and a correlation between the relaxation time and overall surfactant concentration. The model, consisting of an associated state of micelles of various sizes and a nonassociated state of monomers, assumed that the enthalpy change for the micellization was independent of the size of the micelle (1061). Some consequences of the equilibrium model of closed association between monomeric and polymeric molecules for micellar systems were discussed. In some cases, the Debye method of determining monomer concentration suggested the existence of a premicellar equilibrium (1062).

The changes in molecular motion of ions and their hydration layers during adsorption from the bulk solution into the Stern layer of a detergent micelle were studied by NMR. The results suggested that the rate of rotation of hydrated sodium ions is unlikely to alter by >35% on adsorption from the bulk to the Stern layer of sodium lauryl sulfate micelles; however, the symmetry of the hydrated layer may be altered by the charged head groups of the micelle (1063). The kinetics of micelle dissociation determined by temperature-jump and NMR methods did not agree with the mechanism involving a single, slow step dissociation process. The results, when treated on the basis of many sequential steps for dissociation, were compatible with rate constants 10^5–10^6 $sec.^{-1}$ for micelles having aggregation numbers greater than 50 (1064).

Yalkowsky and Zografi (1065) calculated the partial molal volume of a large number of surfactants in the micellar state by adding partial atomic values and accounting for the hydrocarbon liquid-like nature of the micelle interior. This approach provides a means of determining relatively accurate values by simple calculation (1065). In response to a previous publication questioning the existence of spherical-shaped micelles of common single-chain surfactants, Zografi and Yalkowsky (1066) concluded that the exact shape of micelles is still an open question but, in general, previous arguments presented against the spherical micelle shape were considered invalid. The authors proposed that until more definitive evidence is available, a spherical or near-spherical micelle model can be considered useful in the estimation of molecular area and other micelle dimensions. Tanford (1067) concluded, on the basis of simple geometric considerations, that most of the common small soluble micelles must be ellipsoidal rather than spherical in shape. It was suggested that amphiphiles with a single hydrocarbon chain per polar head group form micelles with a distribution of sizes with spherical and ellipsoidal shapes, while those with two hydrocarbon chains per head group prefer extended bilayer or vesicle-shaped micelles.

The number average micellar molecular weight for a purified sample of polysorbate 80 in aqueous systems was determined by membrane osmometry. This method was also employed to study the effect of micellar solubilization on the molecular weight of the micelle (1068). The surface tension measurements of aqueous polysorbate 20 solutions from 0.001 to 10 mg./ml. concentrations suggested that the CMC of polysorbate 20 is in the vicinity of 0.06 mg./ml. surfactant concentration (1069). The CMC of homogeneous polyethylene glycol lauryl ethers was determined from the spectral change produced by the charge-transfer solubilization of 7,7,8,8-tetracyanoquinodimethan. The values obtained by this method were consistent with those obtained by surface tension measurements (1070). The aggregation of an uncharged surfactant in aqueous solution was described in terms of a multiple equilibrium model. Average aggregation numbers and diffusion coefficients for *n*-alkyl hexaoxyethylene glycol monoethers were calculated from light scattering and free boundary experiments (1071).

The temperature dependence of the CMC of several cationic surfactants in the presence of glucose or sucrose was reported. Thermodynamic parameters were calculated using the uncharged phase-change model. The changes in CMC values in glucose or sucrose solutions were interpreted as the effects of modifications in water structure and the reduction of dielectric constant (1072). Micellization behavior of four antihistamines in aqueous solutions was studied by light scattering to estimate the effective micellar charge, CMC, and degree of ionization. It was pointed out that since the effective charge refers to the equivalent charge under ideal conditions, which is generally lower than the true value at the shear surface, the value for the degree of ionization, therefore, is likely to be an underestimation of the extent of ionization of the micelles (1073). Aggregation numbers and effective charges of two cationic surfactant micelles were determined at various ionic strengths and temperatures. From the micellar parameters, the hydrophobic and electrostatic contributions to the free energy and enthalpy of micellization were calculated and the enthalpy values were compared with calorimetric values (1074).

Additional references on micelle studies are given in Table XXXI.

Dispersion Stabilization—The quantitative investigation of coalescence kinetics in dilute oil-in-water emulsions was presented. Experimental data were in agreement with the flocculation model, but they significantly deviated from the classical coalescence model. However, incorporation of the hydrodynamic effect into the coalescence model yielded reasonable agreement between the experimental coalescence data and the theoretical results (1089, 1090). The effect of nonlagging molecular forces on the coagulation and condensation growth of highly dispersed aerosol particles was studied as a function of the size of the impinging particles. It was shown that molecular forces have less effect on coagulation of particles of different sizes than of identical sizes (1091). The changes in interfacial tension, particle size, and stability of an oil–water–nonionic surfactant emulsion system were studied as

functions of temperature and ethylene oxide units of the surfactant. In systems containing surfactants with more than 10 ethylene oxide units, the particle size was decreased and the stability improved with increasing emulsification temperature (1092). The factors influencing coalescence in liquid–liquid dispersions, including the effect of mass transfer, shape of droplets, agitation, and coalescence at a liquid or solid surface, were discussed (1093).

Expressions for the work and heat of wetting were derived and applied to heptane–water–powdered glass systems containing variable amounts of a surface-active agent (1094, 1095). Addition of lauryl alcohol to a mineral oil (Nujol) oil-in-water emulsion had a stabilizing effect, while the stability of an olive oil-in-water emulsion was unaffected by the addition of lauryl alcohol. These observations were explained in terms of adsorption of lauryl alcohol at the mineral oil–water interface (1096). The effect of micelle formation and the nature of the oil phase on the distribution of a nonionic surfactant in three- and four-component emulsions was investigated. The results were related to mechanisms responsible for the formation and stability of emulsions (1097). The stability of a liquid petrolatum–water emulsion containing 0.2% sodium lauryl sulfate decreased upon storage up to 25 days and thereafter increased with time. This was rationalized in terms of an initial desorption of the surfactant upon increase in the droplet size, followed by readsorption of the surfactant at the oil–water interface (1098). The stability and phase dispersion of petrolatum emulsions were studied as functions of surfactant and water concentrations. The stability was enhanced by increasing the proportion of water, while the stability was not greatly influenced by the surfactant concentration (1099).

The role of adsorption in the interaction of water-soluble polyelectrolytes with colloids and highly dispersed systems was discussed. The reversible adsorption was considered as an important phenomenon governing stability of relatively dilute systems, while irreversible adsorption causing alteration of the solid surface was considered important in the stabilization of concentrated dispersions (1100). Theoretical calculations analyzing the effect of polydispersity of nonattracting spherical particles upon sedimentation volume were presented. In a polydisperse mixture, small particles occupy interspaces between large particles so that the sedimentation volume becomes smaller than for a monodisperse mixture (1101). The colloidal stability of polydisperse systems was calculated for particles differing in size and surface potential. According to these calculations, dispersions of particles with Gaussian distributions of radii or surface potential were shown to be less stable than the corresponding monodisperse systems with constant surface potential (1102). An asymptotic solution to a simplified equation for the kinetics of coagulation was applied to aerosol systems. The simplified coagulation model with a constant collision parameter was shown to approach a self-preserving form, which is independent of the initial distribution (1103).

Sedimentation kinetics of flocculated silica suspensions were studied to elucidate the role of ζ-potential in sedimentation mechanisms. In the initial time periods, the sedimentation rate constant was shown to be a function of both Stokes and aggregational forces; in the final phase, the reciprocal of the smaller of the two contraction rate constants was linearly related to the reciprocal of the ζ-potential (1104). The structural stability of montmorillonite and palygorskite suspensions in organic liquids was studied in relation to their electrokinetic properties. No direct correlation between the ζ-potential and stability of these suspensions was observed (1105). A kaolin suspension containing sodium caprylate was stabilized by the addition of caprylic acid. A phase diagram was presented for the water–sodium caprylate–caprylic acid liquid crystal system (1106). The effect of pH on the flocculation of bentonite sols by an acrylamide–acrylate copolymer was studied. The results demonstrated the existence of a flocculation threshold at the pH where the macromolecular chain exists in the completely extended form (1107).

Additional references on dispersion stabilization are given in Table XXXII.

Rheology—The structure and rheological properties of emulsions stabilized by the mixed emulsifier, polyethylene glycol 1000 monocetyl ether (cetomacrogol 1000) and cetostearyl alcohol, were investigated. The mixed emulsifier exhibited a self-bodying network phenomenon showing an increase in consistencies with increasing emulsifier concentration and with increasing temperature up to a maximum. At higher temperatures, consistency decreased as the network weakened and finally dissolved to form an isotropic solution. The mechanisms responsible for the formation of nonionic

networks were discussed and compared with mechanisms that function in gels formed by ionic surfactant–long-chain alcohol mixed emulsifiers (1124, 1125). The rheological behavior of 20% water-in-oil emulsions and dispersions of glyceryl tristearate crystals in oils was interpreted by the network model for a system of dispersed particles where particles tend to aggregate into random chains due to van der Waals' forces (1126). Rheological parameters were correlated with stability of liquid paraffin emulsions prepared with carboxymethylcellulose and with a mixture of gum acacia and gum tragacanth. The thixotropy of the carboxymethylcellulose preparation was practically constant during storage, while that of the gum emulsion increased and then decreased (1127). A similar study dealt with the rheological aspects of liquid paraffin, castor oil, and cod liver oil emulsions prepared with acacia and methylcellulose (1128).

The effect of wetting and surface-active agents on the rheological properties of various ointment gels was studied. Viscosity varied inversely with the degree of wetting, especially upon addition of surface-active agents (1129). Some rheological properties of hectorite dispersions such as viscosity, plastic flow, and static yield values were related to the particle shape, particle interactions, and addition of uni-univalent electrolytes (1130). Some anionic surfactants were found to increase the viscosity of the salicylic acid–cetrimide system to a maximum and then decrease it on further addition of the surfactant. The results were explained in terms of interaction between the anionic surfactant and free cetrimide molecules (1131). Quantitative measurements

1145	Influence of metallic soaps on the rheological properties of lipophilic bases

of thixotropic characteristics by a weight-actuated viscometer were demonstrated. This approach eliminated the problems involved in obtaining the classical hysteresis loop, since it provided data on the actual rates of breakdown and buildup of the systems (1132). Elastic, retarded elastic, and viscous components of the total deformation of gels were derived by plotting the penetration of a cone against the logarithm of time. The results were in agreement with those obtained from creep measurements with coaxial cylinders (1133). Rheological properties of Newtonian (silicone) fluids and a viscoelastic material (cetrimide cream BPC) were studied by a modified single-pan chemical balance method. Equations were given for the calculation of viscosities and compliances using this method (1134).

Additional references on rheology are provided in Table XXXIII.

PHARMACEUTICAL ASPECTS

Antibiotics—Water-soluble polymer derivatives of penicillin with vinylpyrrolidone copolymers were prepared. These derivatives retained their antimicrobial activity and were inactivated by penicillinase at a slower rate than penicillin (1146). Studies on combined precipitation of nystatin with polyvinylpyrrolidone from dimethylformamide solution included dynamics of precipitation, solvent effects, and the composition of the complexes (1147). Gramicidin was shown to aggregate in aqueous solution and form monolayer films at the air–water interface. The observed first-order rates of lecithin monolayer penetration by gramicidin were consistent with the proposed intramembrane dimerization of gramidicin to form ion-conducting channels (1148). Semipermeable membrane sacs containing *E. coli* were placed in the peritoneal cavity of rabbits to study the effects of proteins on the antibiotic activity of gentamicin. It was concluded that the serum protein inhibited, while immune serum enhanced, the action of gentamicin (1149).

Heman-Ackah and Garrett (1150) reported on the effect of erythromycin on the action of lincomycin (phase II) and the 7(*S*)-chloro analogs of lincomycin against *E. coli*. Combinations of erythromycin and the 7(*S*)-chloro analogs of lincomycin demonstrated *a priori* antagonism of effects because of possible allosteric interactions which decrease the effects of one drug in the presence of the other at their site of action. It was emphasized that the dose–response relationship over a wide concentration range, as well as the kinetics and mechanisms of the separate drug action, must be considered in the quantification and prediction of combined action of antibiotics (1150). Addition of sodium edetate (EDTA) to sodium penicillin G or potassium phenoxymethyl penicillin (penicillin V) failed to enhance *in vitro* the antibacterial activity of either antibiotic against several bacterial species. Oral administration of edetate (EDTA) in combination with potassium phenoxymethyl penicillin or tetracycline hydrochloride also failed to increase antibiotic absorption in pigs (1151). Combinations of disodium carbenicillin and gentamicin showed an additive effect on *E. coli* and prevented its regrowth. Clinical use of this and other antibiotic combinations and development of resistance to these combinations were discussed (1152). An ophthalmic preparation of chloramphenicol containing methylcellulose remained in the conjunctival sac of the eye for several hours due to a viscosity effect, while one without the methylcellulose remained in the sac for only 10 min. (1153).

Radiopharmaceuticals—The type of theoretical background and practical experience required by a pharmacist in the preparation of radiopharmaceuticals in hospitals was discussed (1154). Pharmacological, pathological, and radiation hazards associated with the use of radioactive pharmaceuticals were reviewed. These hazards were considered slight with the use of modern radiopharmaceuticals, especially in view of their diagnostic value (1155). Factors influencing the stability of radioiodinated insulin including pH, concentrations of insulin and ^{125}I, and the addition of bovine serum albumin were examined. Insulin-^{125}I retained its immunoreactivity and gel filtration characteristics best when stored at <0.2 mcg./ml., −20°, in borate buffer (pH 8.6) with the addition of 1% bovine serum albumin (1156). Metal chelate complexes of ^{153}Sm and ^{169}Yb were prepared by exchange reaction for use as radiopharmaceuticals. Electrophoresis provided the most suitable method for controlling the radiochemical purity of the complexes (1157). Values for the equilibrium absorbed dose constants of ^{111}In and ^{169}Yb were calculated, and the metabolic behavior of indium and ytterbium chelates was reviewed (1158).

Additional references on pharmaceutical aspects are listed in Table XXXIV.

BIOPHARMACEUTICS

The various publications dealing with biopharmaceutics were subdivided according to the areas of special interest. However, because of the obvious overlap in subject matter, the reader seeking a thorough review should consider the entire section.

Current concern over generic inequivalence among various drug products was discussed by several workers (1172–1175). Smith (1176) stressed an urgent need to pursue clinical and pharmacokinetic measurements of relative absorption efficiency of those drugs where consistent potency is essential. Official action to introduce better *in vitro* standards and to implement quality control that will monitor any batch-to-batch variation in bioavailability was also recommended. Wurster (1177) discussed the influence of drug particle size, polymorphism, tablet hardness, formulation composition, dissolution rate, and other factors upon the efficacy of drug delivery systems. Similar aspects of factors influencing drug bioavailability were reviewed in several other publications (1178–1182).

An *in vitro* diffusion model for the transport rates of solutes in a three-phase system was applied to theoretical and experimental exploration of the pH–partition theory of drug absorption. Experimental rates for a variety of conditions reasonably correlated with computer predictions obtained by independent evaluation of physicochemical parameters in the system (1183, 1184). A three-phase model cell, employing a liquid lipid barrier, was used to establish correlations between reported *in vivo* absorption data and experimentally determined *in vitro* transport rates for a series of *N*-substituted heterocyclic sulfanilamides. These correlations suggested utility of this model to simulate passive drug absorption (1185).

Physical models for the diffusional transport of drugs across membranes of cells in culture suspensions were introduced by Ho *et al.* (1186) to describe the nature of the principal transport barrier, the kind of drug species

being transported, solute binding, and the effect of pH and partition coefficients on the drug transport. Mathematical expressions were derived for the quasi-steady-state diffusion through the membrane followed by distribution of drug in the heterogeneous cell interior (1186). A subsequent study dealt with the development of some baseline procedures for cell culture–drug transport experiments, consisting of cholesterol uptake by Burkitt lymphoma cells, and the methods of quantitative mechanistic interpretation of the experimental results (1187). A physical model for the adsorption of drugs applicable to situations in which the diffusional flux of the drug may be influenced by the bulk fluid flow and surface pH was described. Theoretical computations were made for different cases in simulation of the *in situ* absorption of drugs in animals with varying tonicity of the drug solution (1188). Previously reported results on human buccal absorption were quantitatively analyzed by the physical model approach using a two-phase compartmental diffusion model. Theoretical estimations of the absorption rate–buffer pH profiles were in good agreement with experimental results (1189).

A two-phase series model for the permeability behavior of the fully hydrated stratum corneum was examined using previously reported data on steroids. In general, reasonable self-consistencies were found among the various experimental results and parameters of the model (1190). Penetration of drugs through skin and the dependence of penetration rate on various parameters subject to vehicle influence were reviewed by Poulsen (1191). A systematic approach in the design of a topical corticoid dosage form, which provides good physical stability, patient acceptability, and optimum drug absorption through the skin, was presented (1192). Drug absorption through the stratum corneum of humans and the effects of hydration, temperature, humidity, solvents, and racial variations in drug penetration were reviewed (1193). The properties of the stratum corneum as a reservoir for topically applied drugs in humans were discussed. Data showing the effects of temperature and humidity on the reservoir content of topically applied sodium fusidate and fusidic acid were presented (1194). Application of the attenuated total reflectance IR spectroscopy technique to study the uptake of dodecylbenzenesulfonate by human skin *in situ* was demonstrated. The reproducibility of the technique was better than 5% for the drug permeation systems that are not influenced by moisture and/or hydrogen bonding (1195). General test methods for measuring percutaneous absorption of drugs in rabbits and guinea pigs were described, along with a discussion of various factors that affect percutaneous absorption (1196).

Engineering control systems analysis and optimization techniques were described for the evaluation and control of the therapeutic performance of drugs, drug products, and interacting drug combinations; for the design of dosage forms with optimum drug release patterns; and for setting optimum dosage regimens for individual patients. The feasibility of the approach was demonstrated by computer simulation of an ideally sought level of therapeutic drug response intensity (1197). A detailed basis for the use of experimentally determined dose–effect curves to transform observed intensities of pharmacological response into biphasic drug levels at all times following dosing by any route was presented. These principles were graphically demonstrated through the construction of dose–response–time surfaces (1198). An electronic circuit, which simulates theoretical curves associated with multiple-dosing kinetics, was described. Plasma level–time curves can be generated by this circuit, assuming a one-compartment open-model system and rapid intravenous injection (1199). A digital computer program was developed to calculate safe and effective doses of kanamycin for individual patients with renal insufficiency. The validity of the program was demonstrated by its ability to predict serum concentrations of kanamycin measured by microbiological assay. The principles of the program were considered potentially applicable to many other drugs (1200). Computer estimations of dosage regimens for digitalis, kanamycin, gentamicin, and lidocaine were discussed in a review article (1201). Several other reviews considered the application of computers to simulate pharmacokinetic models and to determine various pharmacokinetic parameters (1202–1205). The use of dosage regimen calculations as a facet of drug evaluation that can be implemented by the pharmacist was exemplified by tetracycline and penicillin antibiotic dosage regimens (1206).

Additional references on biopharmaceutics are listed in Table XXXV.

Effects of Physicochemical Properties—Various physicochemical parameters including solubility, surface tension, partition coefficient, vapor pressure, activity parachor, R_f values, molecular orbital calculations, and Hammett and Taft constants were correlated with the biological activity of a number of sulfonamides (1241). Rational physicochemical approaches in drug design to modulate biological action were discussed for various types of drugs (1242, 1243). A comprehensive review by Hansch and Dunn (1244) dealt with the linear relationships between lipophilic character and biological activity of drugs, a linear free energy model for structure–activity relationships, and hydrophobically sensitive and insensitive free energy relationships (1244). Determination of hydrophobicity constants and their application to structure–activity correlations of systems such as penicillin serum binding, 2-haloalkylamine adrenergic blocking activity, and *m*-nitroaniline sweeteners were reviewed. Tables of hydrophobic, electronic, and steric constants for a number of biologically active compounds were presented (1245). An interactive searching program of a structure and biological activity file, coupled with a program that scans a file of herbicidal activity of compounds, was presented. These programs were considered useful in providing background knowledge for further testing and synthesis of active drugs (1246). Utilization of operational schemes for the stepwise approach in the design of a most potent drug analog was suggested. These schemes were based on the considerations of hydrophobic, electronic, and steric effects by a particular substituent upon biological activity of the molecule (1247).

The methylene group contribution to the thermodynamics of solutions of drug molecules was obtained

from activity coefficient, Henry's constant, and partition data. The free energy of transfer of the methylene group from water to nonpolar organic solvent was estimated as -850 cal. mole^{-1}, but for polar solvents values ranged from -712 to -452 cal. mole^{-1}. Application of these thermodynamic concepts to structure-activity relations was discussed (1248). Adoption of a thermodynamic standard state for comparing drug molecules in structure-activity studies was suggested. This standard state, acting as if it were infinitely dilute where the solvent is a suitable aliphatic hydrocarbon such as cyclohexane or isooctane, could be a 1 molal, 1 molar, or 1 mole-fraction solution (1249).

The two most frequently used regression models for structure-activity analyses, the additive and the linear multiple regression models, were shown to be fundamentally interrelated. Each approximation used in reducing the additive model to its linear multiple regression counterpart provided useful insight into how these regression methods can be best applied (1250). Statistical significance of structure-activity correlations using multiple regression analysis and the potential problems in obtaining chance correlations when many variable parameters are involved were examined. The data were presented to assess the probable degree of chance correlation as a function of the number of observations and the number of variables (1251). Suitability of the calculated electron population parameters for multiple regression analysis of biological activity was determined. It was concluded that both the CNDO/2 and *ab initio* methods of Pople *et al.*, but not extended Hückel theory, may be suitable for use in the multiple regression analysis (1252).

Quantitative relationships between physical properties and antibacterial activity of erythromycin esters were evaluated by the Free-Wilson and extrathermodynamic techniques. Both analyses indicated that esterification decreases activity; this decrease increases with increasing chain length of the ester. The extrathermodynamic equations suggested that the partition coefficient is an important determinant of activity (1253). Antibacterial activity of rifamycins was shown to correlate with the chromatographic substituent constant R_m (1254). The structure-activity relations of penicillins were discussed in several reviews (1255–1257). Analgesic activity of *p*-substituted acetanilides showed better correlation with the chromatographic substituent constant R_m than with the Hansch hydrophobic substituent constant π (1258). The structure-activity relationships in the anesthetic action of aliphatic ethers were found to be parabolic functions of their octanol-water partition coefficients. An optimum lipophilic character (log P_0) of about 2 was determined for general anesthetics, which is comparable to that obtained for barbiturates, ureas, alcohols, *etc.* (1259).

Correlations between steric, electronic, and hydrophobic parameters and biological activity were estab-

lished for 2-phenylquinoline-4-carbinol antimalarials (1260), 1,3-dioxolane cholinergics (1261), tricyclic neuroleptics and antidepressants (1262), anti-inflammatory 3-(5-aryl-2-tetrazolyl)alkanoic acid derivatives (1263), hemolytic activity of polyene antibiotics (1264), decahydroisoquinolines possessing antiarrhythmic activity (1265), veratrum alkaloids (1266), and a series of 2*H*-1,2,4-benzothiadiazine 1,1-dioxide antihypertensive compounds (1267, 1268). The steric and electronic parameters of styrylpyridine analogs were correlated with their choline acetyltransferase inhibitory activity in an effort to elucidate the nature of interactions of this type of inhibitor with the enzyme. Hydrophobic and electron-donor contributions by the aryl moiety and electron-acceptor characteristics of the pyridinium moiety were believed to be involved in the inhibitor–enzyme binding (1269). A similar approach to structure–activity correlation was applied to study interactions of acetylcholinesterase with substituted phenylammonium iodide inhibitors (1270). The parts of the inhibitor molecule that contribute to the hydrophobic bonding with the enzyme might only be the parts that are in contact with the enzyme. Such a directional nature of hydrophobic bonding was demonstrated in the case of phenylethanolamine *N*-methyltransferase inhibitors (1271). The lipophilicity of some hexamethonium analogs was compared with their ganglionic blocking activity. The compounds more lipophilic than hexamethonium were less active than hexamethonium, but the lipophilic character of a highly active analog was comparable to that of hexamethonium (1272, 1273).

Theoretical prediction of the influence of complex formation on the transport rate of a drug and computation methods were described by Vaidhyanathan (1274, 1275). It was shown that complexation of a drug with a substance of lower diffusion coefficient leads to enhancement of the transport rate of the drug; complexation with substances having similar diffusion coefficients, however, results in reduction of the transport rate (1274). Fluxes of drugs across membranes affected by the presence of a complexing agent in the membrane were represented by a generalized form of Fick's law, which accounts for the existence of coupling between fluxes of different species (1275). A series of publications by Hayton and coworkers (1276–1281) dealt with the subject of drug complexation and its effect on drug absorption. The effects of certain *N,N*-dialkyl propionamides on the permeability of the rat small intestine and of a synthetic lipoid barrier to prednisone and prednisolone were investigated. Enhancement in the intestinal absorption of these drugs by *N,N*-dibutyl- and *N,N*-dipropylpropionamide appeared to be due to the formation of a steroid–amide complex in the intestinal barriers. However, the intestinal absorption of several nonsteroid drugs which complex with the amides was not significantly affected by these amides. This indicated that the absorption-enhancing effect of the amides was relatively specific to a drug. Some structural features of the steroid molecule required for the enhancement of drug absorption by its complexation with an amide were considered (1276–1281). The transfer process of various acidic drugs from water into chloroform containing phospholipids was examined using a nonemulsifying system. The ionized forms of the drugs with little lipid solubility showed a marked increase in transfer to the chloroform phase containing lecithin at the physiological pH of the small intestines. These results indicated the possible role of phospholipids in the intestinal absorption of ionized acidic drugs (1282).

Relationships between surface activity and biological activity of drugs were reviewed for local anesthetics, sedatives and hypnotics, antibacterial agents, hormones, fat-soluble vitamins, and miscellaneous drugs (1283). Iso-branched fatty acids, with fungistatic and bacteriostatic properties, were found to enhance the effect of conventional antimicrobial agents acting inside the cell membrane. A molecular mechanism for this effect was proposed on the basis of surface film studies (1284). Molecular interactions between quaternary ammonium surfactant bactericides and bacterial cell wall constituents were studied by means of surface film balance and conductometric methods. The results suggested that in Gram-positive organisms, the bactericide first becomes associated with the protein in the cell wall; subsequent penetration leads to disruption of the cell membrane. In Gram-negative organisms, the phospholipid present in the cell wall affords the organism a degree of protection from the bactericide (1285, 1286).

Additional studies on the effects of physicochemical properties are listed in Table XXXVI.

Effects of Formulation—Two crystal forms of the drug sulfameter were orally administered to man. The absorption rate was about 1.4 times greater with the more energetic metastable crystal form than with the stable crystal form; the results were discussed in relation to the free energy differences between the two crystal forms and their *in vitro* dissolution rates (1316). The rate and extent of reserpine absorption in rats were significantly enhanced upon oral administration of reserpine–polyvinylpyrrolidone coprecipitates. The fraction of the oral dose absorbed was 2–3 times greater with the coprecipitate than with either the pure drug or physical mixtures of drug with polyvinylpyrrolidone. The *in vivo* absorption data were consistent with the *in vitro* dissolution characteristics of the tested drug forms (1317, 1318). Crystalline and amorphous preparation of asparaginase were found comparable with regard to toxicity and capacity to induce remission of acute leukemia in children (1319).

The absorption of orally administered riboflavin-5′-phosphate by healthy male subjects was increased significantly when it was given in 50 ml. of 2% sodium alginate solution rather than in the aqueous vehicle without sodium alginate. Retention of the vitamin at specialized absorption sites for prolonged time periods because of the slow movement of the highly viscous sodium alginate solution was proposed as the rationale for the absorption data (1320). Oral administration of sodium *p*-aminosalicylate with methylcellulose and gum arabic to rats produced higher but delayed absorption, probably due to a viscosity effect; administration with surface-active agents in concentrations below the CMC considerably increased the drug absorption (1321).

Partition coefficients of ionized and unionized salicylic acid molecules between water and the micelles of several nonionic surfactants were determined. The results were discussed in terms of their significance to the process of drug absorption from surfactant solutions (1322). The influence of macromolecular nonionic agents such as polyethylene glycol, methylcellulose, and polyvinyl alcohol on the enzymatic activity of pepsin, amylase, invertase, and lipase was investigated. Most of the high viscosity polymers tested decreased to a varying degree the activity of these enzymes (1323–1325). Samples of dicumarol (bishydroxycoumarin), equilibrated with various tablet excipients, were administered to dogs to determine the excipient effects on the drug absorption. Administration of the drug with talc, colloidal magnesium aluminum silicate (Veegum), aluminum hydroxide, or starch resulted in significantly lower plasma levels of the drug; but with magnesium oxide and hydroxide, plasma levels of the drug were higher than for the drug administered alone. In further work, *in vitro* dissolution characteristics of three commercial brands of dicumarol (bishydroxycoumarin) tablets were shown to correlate positively with the *in vivo* plasma levels of the drug. As a second phase of the study, application of diffuse reflectance spectroscopy in evaluating physical stability of simple emulsion bases and chemical stability of various drugs within an emulsion was demonstrated (1326).

Blood salicylate levels after administration of aspirin preparations of varying particle sizes to rabbits indicated that the absorption rate was inversely proportional to the particle size; however, the absorption rates of aspirin particles coated with 10% precirol were approximately the same regardless of particle size (1327). Four buffered aspirin tablets were tested for their *in vitro* dissolution rate, buffer capacity, absorption rate, and induced GI bleeding in normal human subjects. An inverse rank-order correlation was found between buffer capacity and GI bleeding (1328). In a comparative study with four commercial enteric-coated aspirin tablets, disintegration times in pH 6 buffer solution correlated with the drug absorption rates in humans (1329). Significant differences were observed in the absorption characteristics of three commercial tetracycline preparations. These differences were observed after both single-dose and multiple-dose administration (1330). The *in vitro* dissolution rates of tablet and capsule dosage forms of diazoxide in 0.1 *N* hydrochloric acid and of griseofulvin in simulated intestinal fluid were shown to correlate linearly with the blood levels of the respective drugs (1331). Tablet, capsule, and suspension formulations containing trimethoprim and sulfamethoxazole were considered bioequivalent in humans on the basis of blood level data (1332).

Timed-release tablet formulations of sulfamethizole consisting of a lipase–lipid system as the release-controlling vehicle were studied for their *in vitro* release rates and *in vivo* absorption patterns in dogs. Uniform blood levels over 12 hr. were observed following oral administration of the tablets. Lipolytic digestion of the lipid was considered as the primary factor in the timed-

release rates of the drug (1333). Three slow-release preparations of isoniazid were studied in man for their potential use as once-a-week dosage forms in the treatment of tuberculosis; a matrix-type formulation was considered therapeutically effective (1334). The cancer chemotherapeutic agents sodium methotrexate, vincristine sulfate, and cytosine arabinoside provided timed-release activity in mice when administered in multiple-emulsion injectable formulations (1335). A timed-release multiple emulsion was used to extend the radioprotective action of cysteamine in mice (1336). Determination of blood phenobarbital levels in minipigs or dogs, during long-term administration of the drug in conventional or three timed-release dosage forms, failed to show any advantage with the timed-release formulations (1337).

Pharmaceutical aspects of corticosteroids in dermatological preparations, such as uptake of steroids from ointments by the skin, physical and chemical modification of the steroids during manufacture, and modification of the carrier, were reviewed (1338). Selection of a particular base vehicle for topical formulation of each individual drug to obtain optimum therapeutic activity was demonstrated by comparing activities of fluocinonide and fluocinolone acetonide in the same vehicle with intrinsic activities of the drugs. Fluocinolone acetonide was readily released from the base and exhibited significant clinical effectiveness; however, fluocinonide activity was considerably reduced because of poor drug release from the base (1339). Ointment preparations of betamethasone 17-benzoate in white soft paraffin and propylene glycol or in white paraffin and isopropyl myristate showed higher vasoconstrictor activity in humans than five other ointments tested, including water-miscible ointments based on polyethylene glycols (macrogols) (1340).

The rate of water desorption of untreated and surfactant-treated depilated rabbit skin was determined to supplement previous data of surfactant-induced changes in biological membranes. The water desorption rate was always greater with the surfactant-treated than with the control skin. The results confirmed earlier findings that the tested nonionic surfactants affect membrane structure, thereby increasing skin permeability (1341). Various sunscreening, deodorant, antiperspirant, and insect repellent preparations were studied to determine the effect of formulation variables on the skin retention of the medicament and efficacy of the formulation. The retention of the drug on human skin was correlated with the solubility and partition coefficient of the drug (1342). The delayed rate of onset of erythema on the human skin induced by methyl nicotinate in aqueous glycerol solutions appeared to be related to the decreased partition coefficient and diffusivity of the drug in these solutions (1343). A correlation was established between the diffusion of ditetracycline from ointment bases of various chemical nature through agar and its permeation through rabbit conjunctiva (1344). Relative rates of percutaneous absorption from hydrophilic and lipophilic ointment bases were evaluated for 4-bromophenyl isothiocyanate-^{35}S (1345) and salts of 8-hydroxyquinoline and procaine (1346). The anti-inflammatory effect of ichthammol (Ichthyol) ointments was shown to correlate with the dielectric constant of the preparation (1347).

Properties of ophthalmic formulations, such as pH, isotonicity, hydrophilic and lipophilic bases, and medicament, that affect absorption through the cornea were discussed by Silverman (1348). The adjuvant effect on intramuscular drug absorption was investigated by *in vivo* absorption studies in rats and *in vitro* diffusion model experiments. The absorption rate correlated with the viscosity of the injectable preparation for adjuvants having relatively small molecular size such as propylene glycol, glycerin, and polyethylene glycol 400. From *in vitro* diffusion studies, it was concluded that the contribution of the diffusion process through the pores of the capillary wall was dominant compared with diffusion through muscle fiber space (1349). The degree of tissue lesion in rat quadriceps femoris muscles following intramuscular injections of aqueous formaldehyde was studied as a function of duration, concentration, solvent composition, and volume of the injected solution. The extent of tissue lesion was proportional to the concentration and postinjection time, and it was twofold larger with ethanol than with glycerol formaldehyde (1350, 1351). A method for clinically evaluating pain of injection for parenteral preparations was described (1352).

Additional references on the effects of formulation are listed in Table XXXVII.

Absorption Control and Alteration—This section of biopharmaceutics is comprised of studies related to control and alteration of drug absorption by coadministration of drugs or a drug with other chemical agents, disease, blood flow, food, route of administration, and age.

Parallel *in vitro* and *in vivo* determinations of adsorption characteristics of activated charcoal were carried out with drugs having different pKa's: aspirin, salicylamide, and phenylpropanolamine. Adsorption and desorption characteristics of these drugs, evaluated by *in vitro* tests, were predictive of the effect of dose and mode of charcoal administration on its antidotal effectiveness in humans (1387, 1388). Prompt administration of a sufficient quantity of activated charcoal had a significant inhibitory effect on the absorption of aspirin from solution, conventional tablets, enteric-coated tablets, and timed-release tablets. Aspirin absorption can be reduced even if activated charcoal is administered 3 hours after aspirin ingestion, provided that the drug is still in the GI tract at that time (1389). Drug adsorption efficacy of commercial activated charcoal tablets and activated charcoal powder was compared by *in vitro* tests and in man, using phenylpropanolamine as the test drug. The rate and extent of drug adsorption by charcoal tablets *in vitro* were much lower than by the powder. Equal doses of charcoal tablets and powder reduced phenylpropanolamine absorption in man by 48 and 73%, respectively (1390). Similar inhibitory effects of activated charcoal were also observed for the absorption of sulfamethazine (sulfadimidine) and sulfaguanidine (1391). The absorption of diazepam in man from a suspension formulation containing colloidal magnesium aluminum silicate (Veegum) was slower than from a solution preparation

without it. This was attributed to the desorption of diazepam from the emulsifier as a rate-limiting factor in the drug absorption process (1392).

Cholestyramine, an anion-exchange resin with hypocholesterolemic activity, was shown to interact strongly and rapidly with the antibiotic sodium fusidate. As suggested by the *in vitro* results, concurrent oral administration of the resin and sodium fusidate to rats yielded statistically significant reductions in serum antibiotic levels at all experimental time intervals. *In vitro* adsorption studies also demonstrated that physiological bile salt and fatty acid anions effectively compete with fusidate anions for the available binding positions on the resin (1393, 1394). Inhibition of iron and vitamin B_{12} absorption by cholestyramine was considered the reason for the observed iron and vitamin B_{12} deficiency in rats following prolonged administration of the resin (1395). Various factors influencing the absorption of vitamin B_{12} (*e.g.*, food, charcoal, and pentagastrin) were studied in healthy subjects and in patients with pernicious anemia. The drug absorption in patients was decreased by simultaneous administration of charcoal (1396). The oral absorption of ^{57}Co-labeled vitamin B_{12} at low doses in cats was enhanced by coadministration of dog or human pancreatic juice (1397). Effects of sugars, polyalcohols, and organic acids on hydrolytic polymerization of iron were examined. The results suggested that these compounds enhance the absorption of iron across the intestine by formation of low molecular polymers of iron (1398).

The effect of tetracyclines on the intestinal absorption of sulfonamides was investigated by the recirculation and loop methods in the rat. At pH 6 and 8, demeclocycline (demethylchlortetracycline) and methacycline (methyleneoxytetracycline) enhanced the absorption of sulfaguanidine, while tetracycline enhanced the sulfa drug absorption only at pH 8 (1399). In a subsequent study, the amount of intravenously administered sulfa drug exsorbed into the intestine was examined with the intestine either perfused with tetracycline solution or isotonic buffer. The effect of tetracycline on the absorption and exsorption of sulfa drugs was attributed to changes in the small intestinal tissue by tetracycline (1400). Specific inhibition of cholesterol absorption in rats and mice was shown to occur with sulfaguanidine but not with other structural analogs of the sulfa drug (1401). The influence of polybasic antibiotics and sulfaguanidine on the absorption and excretion of

cholesterol and bile salts was discussed in a review article (1402). Heparinic acid and its acid salts were readily absorbed from the intestine to provide systemic anticoagulant activity in rabbits, monkeys, and dogs. Increased absorbability, however, was accompanied by a decrease in stability. Weak nitrogenous bases such as nicotinamide were complexed with heparinic acid to give compounds with high absorbability coupled with good stability (1403). The absorption of streptomycin from uterine and salpingeal mucosa was significantly greater when the drug was applied with hyaluronidase; the absorption was further enhanced when galvanic current was introduced during intrauterine electrophoresis (1404).

Oral administration of the anticholinergic drug propantheline bromide to healthy adult males 30–60 min. before an oral dose of riboflavin phosphate delayed the absorption of the vitamin but caused a pronounced increase in total amount absorbed. This was attributed to delayed gastric emptying and slowed transit of riboflavin solution through the small intestinal lumen due to the anticholinergic effect of propantheline (1405). However, oral administration of aminopyrine with barbital produced significantly higher initial plasma levels of aminopyrine, which were attributed to the increased rate of gastric emptying induced by barbital (1406). Magnesium hydroxide and aluminum hydroxide given by gastric intubation to the rat prior to, or simultaneously with, sodium pentobarbital decreased GI absorption of pentobarbital and delayed the onset of sleep. Magnesium hydroxide, by raising the gastric pH, allowed the drug to remain in the ionized unabsorbable form while aluminum hydroxide acted by delaying gastric emptying time. Although these antacids decreased the absorption rate of pentobarbital, the total amount absorbed remained unaltered (1407). Enhanced absorption of pseudoephedrine by concurrent administration of aluminum hydroxide gel was ascribed to the increase in GI pH caused by the antacid (1408). Intestinal absorption of tritiated folic acid in human subjects with a triple lumen tube positioned in the proximal jejunum was decreased by about 44% after perfusion with diphenylhydantoin. This inhibition of folic acid absorption was considered as a likely reason for the folate deficiency that occurs with diphenylhydantoin therapy (1409).

Rapid penetration of gentamicin in the aqueous humor of rabbit eyes with corneal ulcers occurred when the antibiotic was administered by subconjunctival injection, topical drops, or continuous lavage. Concomitant serum levels of gentamicin were lowest when topical drops were used (1410). In a review paper, calculation of multiple-dosage schedules for maintenance of desired drug levels in anuric patients and elimination rate constants of several drugs in such patients were presented (1411). Acetaminophen (paracetamol), taken orally after overnight fasting, was absorbed up to five times faster but to the same extent as when it was taken after a high carbohydrate breakfast. Subjects taking the drug immediately before sleep excreted up to 36% less than after taking it in the morning (1412). The presence of food in the intestine decreased the *in vivo* uptake rate of anisotropine methylbromide in the rat but had no effect on the total uptake. The sum of drug bound to intestinal tissue and that taken into the circulation was 48% of the dose administered (1413). Absorption of ampicillin and nalidixic acid by infants and children with acute shigellosis was determined. Five of the 16 patients receiving nalidixic acid had a pronounced delay in absorption, while 10 of 21 ampicillin-treated patients showed depressed plasma levels and prolonged half-lives (1414). A mathematical model was described to explain the apparent difference in the rate of increase of alveolar halothane concentration between children and adults. Concentration of the anesthetic used, cardiac output, and metabolic rate were considered as reasons for the observed difference (1415). Since intestinal absorption of tritiated 25-hydroxycholecalciferol was about the same in both normal children and those with osteopathies, it was concluded that the resistance of osteopathies to the drug therapy is not because of malabsorption of the drug (1416).

Oral doses required for a drug are sometimes larger than are needed by the parenteral route of administration. This might be the case when a large fraction of the oral dose is eliminated on first passage through the liver. An equation derived based on these considerations provided an estimation of the availability of a completely absorbed, orally administered drug. The importance of clearance concepts in bioavailability studies, drug design, and enzyme induction studies was discussed (1417). The antagonism of isoproterenol-induced tachycardia by orally and intravenously administered propranolol was measured in five subjects and related to the plasma propranolol concentration. The degree of β-blockade at a given plasma drug concentration observed 2 hr. after oral administration of a single dose of propranolol was greater than with intravenous administration. This was explained by the formation of an active metabolite, 4-hydroxypropranolol, only after a single oral dose; this metabolite has a shorter half-life than the parent drug (1418).

Polyinosinic acid–polycytidylic acid was given to rabbits by intravenous, intraocular, and topical ocular routes. A pyrogenic response was achieved by all three routes. The minimum pyrogenic doses were 0.1, 1.0, and 1000 mcg./kg. for intravenous, intraocular, and topical ocular administrations, respectively. Ocular responses of the drug paralleled the pyrogenic responses (1419, 1420). Streptomycin concentration in lung tissue and bronchii of tuberculosis patients was three to four times higher for 12 hr. after intratracheal–bronchial administration than after intramuscular or intravenous injection. Clinical effectiveness of the drug administered by the intratracheal route was increased by simultaneous general antibacterial therapy (1421). Inhalation by asthma patients of beclomethasone dipropionate from a pressurized aerosol exerted a significant topical action on the airways, with the expected clinical response (1422). A more lasting and effective clearing of airways in asthmatic patients was obtained by administering rimiterol in aerosol form in frequent small inhalations rather than in a single larger dose (1423).

Absorption Mechanisms—Mucosal-to-serosal flux of a number of solutes across the rat everted small intestine was determined as a function of time. The transfer rates of certain solutes progressively increased during the experiment, which was attributed partially to a loss of functional integrity of the intestine with respect to passive transfer (1462). Histological changes in the rat small intestine induced by edetate (EDTA), tetracycline, and sodium lauryl sulfate were examined using light and scanning electron microscopes. The observations provided further insight into the possible mechanism for the facilitative absorption of poorly absorbed drugs by these agents (1463). Concurrent absorption of water from the *in situ* rat small intestine during drug absorption experiments indicated that approximately 4 ml. of water was lost from the intestine during 60 min. The importance of considering the rate of water absorption to estimate accurately a drug absorption rate constant was emphasized (1464). The influence of net water transfer on drug absorption in an *in situ* rat intestinal preparation was studied using hypotonic, hypertonic, and isotonic intestinal lumenal solutions. The results indicated that the intestinal water loss or gain which occurred with the different tonicity solutions did alter the apparent rate constant for sulfaethidole absorption. When the apparent rate constants were corrected for the liquid volume and relative available surface area, permeability constants of sulfaethidole were comparable for the isotonic and hypotonic solutions, but a reduced permeability constant was obtained with the hypertonic solution (1465). Intestinal absorption of drug was positively correlated with the blood flow by the determination of absorption rates from perfused rat jejunal loops at different levels of blood flow. A mathematical model for intestinal drug absorption was discussed (1466).

The principal mechanisms of drug transport through the skin, the respiratory tract, and the GI tract were discussed. Two kinds of absorption regions were described: (*a*) the lipid protein matrix for the penetration of lipophilic substances, and (*b*) intercellular pores for hydrophilic substances (1467). Permeation of ions through *Necturus* gallbladder epithelium was shown to occur mainly through the intercellular junctions, thus bypassing the epithelial cells (1468). The mechanism by which surfactants affect drug absorption was studied by

measuring the rate of permeation of chloramphenicol through model membranes in the presence of surfactants. The rate was related to the extent of drug binding to the bovine serum albumin transport barrier and was controlled by competitive binding of the surfactant molecules (1469). The diffusion of hydrocortisone across a cellulose acetate membrane and the effects of *n*-alkyl polyethylene surfactants on the drug transport were explained by the thermodynamics of the test system (1470). A protein of about 12,000 molecular weight, which binds long-chain fatty acids and certain other lipids, was identified in cytosol of intestinal mucosa, liver, myocardium, and other tissues. The presence of this protein was regarded as a possible reason for the previously observed differences in intestinal absorption among fatty acids (1471).

The absorption of quinine and chlorpheniramine through the rat rectum, small intestine, and stomach was enhanced in the presence of anionic agents. Although enhancement of absorption was related to partition behavior, organic solvent, and surface activity of ion-pair complexes, these properties alone failed to provide a complete explanation for the observed effect (1472). The intestinal absorption of two poorly absorbed quaternary ammonium drugs, hexamethonium chloride and pralidoxime chloride, in the presence of various organic and inorganic anions was investigated using a modified *in situ* gut technique. Enhanced absorption of these drugs by cholate and phoscholate ions was attributed to the effect of these anions on the structural integrity of the membrane tissue. A kinetic model was suggested for the possible mechanism of absorption of quaternary ammonium drugs (1473). Kakemi and coworkers (1474–1476) investigated the intestinal absorption of sulfapyridine, salicylamide, acetanilide, and methyl orange from oil solutions and oil-in-water emulsions in rats, using *in situ* recirculation and loop techniques. In the absorption of drugs having partition coefficients greater than one, the amount of drug in the aqueous phase of the emulsion was the critical factor in the absorption process. Two possible mechanisms for methyl orange transport were proposed: passive transport and an active-like process involving enzymatic reduction of methyl orange on the mucosal side of the membrane (1474–1476). Major pathways involved in the GI absorption of sodium nitrite and its concentration in the mouse stomach 10 min. after oral administration were determined. The major pathway for the nitrite absorption was directly from the stomach into the bloodstream (1477).

In a comparative study, percutaneous absorption of haloprogin, *N*-acetylcysteine, cortisone, testosterone, caffeine, and butter yellow was shown to occur at a decreasing rate in the order: rabbit, rat, miniature swine, and man, with the swine having the closest permeability characteristics to human skin (1478). Absorption profiles of intramuscularly administered cationic drugs, protonated at physiological pH, were studied using the rat thigh muscle clearance method and *in vitro* uptake experiments. The storage or affinity of these drugs for the muscle tissue was proposed as one factor responsible for the low absorptive nature of cationic drugs (1479).

Subcutaneous absorption of a series of local anesthetics, chemically related to lidocaine, was investigated in anesthetized rats using the system of Ballard and Menczel. The results concurred with the proposed mechanism for subcutaneous absorption involving two processes: (*a*) spreading into surrounding connective tissue, and (*b*) absorption through capillaries (1480, 1481). Absorption of saccharides and urea from the rat lung appeared to be mainly by the process of diffusion (1482). A subsequent study dealt with the absorption of various drugs (*e.g.*, antipyrine, pentobarbital, and salicylic acid) from the rat lung. Comparison of absorption rate constants with chloroform–water partition coefficients and aqueous diffusion coefficients of the drugs suggested that these drugs are absorbed by diffusion across a lipoid–pore membrane. Absorption of drugs was significantly faster from the lungs than from the small intestine (1483). Solubilization as a mechanism of gas transport in biological systems by aggregation through associated micelle formation was investigated. Halothane, ether (ethyl), trichloroethylene, and nitrous oxide were used with surfactant systems of polysorbate 80, dioctyl sodium sulfosuccinate, and bovine albumin; a modified tonometer was used as an absorption chamber (1484).

Additional references on absorption mechanisms are listed in Table XXXIX.

Drug Absorption—Oral absorption characteristics of a systemic anti-inflammatory agent, naproxen, was studied in beagle dogs. Complete absorption of the drug was observed, with the absorption occurring at a significantly faster rate from the sodium salt and calcium salt of the drug than from the unmicronized form of the drug. No significant differences were noticed in the rate and extent of drug absorption in man between tablet and capsule formulations of this drug (1510). The absorption, distribution, metabolism, and excretion of naproxen were studied in rats, dogs, monkeys, and human subjects after either oral or intravenous administration. The drug administered orally was rapidly absorbed in all species; all except the dog excreted naproxen plus its metabolites predominantly in the urine (1511). When propantheline labeled with ^{14}C in its xanthene carboxylic moiety was administered orally or intrajejunally to healthy subjects, the absorption of the intact drug after oral administration was estimated to be less than 50% (1512). Transformation of 1-β-D-arabinofuranosylcytosine to 1-β-D-arabinofuranosyluracil by the intestinal microflora of the rat seemed to be partially responsible for the poor absorption of the orally administered drug. This was further evidenced by a twofold increase in the drug absorption by coadministration with antibiotics (1513). Salicylazosulfapyridine was also extensively metabolized in the human digestive tract, presumably by the action of the gut flora (1514).

The oral absorption of mepenzolate bromide in humans was studied by administration of the drug in solution or capsule dosage forms. In either case, an average of 14% of the total administered drug was eliminated in the urine, thus indicating substantial oral absorption of this quaternary onium-type drug (1515). Kinetics of absorption and elimination of pralidoxime

chloride, a quaternary ammonium drug, were investigated in the dog. Apparent absorption rate constants from the isolated jejunum and ileum were found to be 7.89×10^{-3} and 1.75×10^{-2} min.$^{-1}$, respectively. After oral administration of the drug in solution, detectable plasma levels were obtained in unanesthetized dogs but not in anesthetized dogs. A three-compartment model was employed to describe plasma levels of the drug after intravenous administration (1516).

Methods commonly employed to calculate absorption rate constants from the time course of drug in the blood were shown to yield "apparent" rate constant values when the drug at the site of administration is simultaneously lost to an extravascular compartment(s). It was demonstrated that the true rate constant for absorption in such a case can be calculated by determining the fraction of the dose actually absorbed, provided that all of the initial dose can be accounted for by other simultaneous rate processes (1517). A biokinetic method for the analysis of temporal pharmacological data was described, which permits the computation of the amount of drug absorbed from a site of administration at any time following dosing by any route. This pharmacological approach obviates the need for the periodic sampling of body fluids to determine drug absorption rates (1518). Application of the pharmacological method was demonstrated for two mydriatically active drugs, tropicamide and tridihexethyl chloride, administered ophthalmically, intravenously, intramuscularly, and orally to rabbits (1519). The time course of indomethacin plasma levels in rabbits after intravenous or intraduodenal administration followed a two-compartment model system, but the rate constants estimated by this system increased as the dose was increased, which was ascribed to the saturable binding of the drug to protein (1520). In a subsequent study, the mechanism of intestinal absorption in the rat and drug bioavailability in man after oral administration of micronized indomethacin powder were investigated. Major conclusions derived from the study were: (*a*) indomethacin was bound strongly to the intestinal tissue, (*b*) both the ionized and unionized forms of the drug were absorbed, and (*c*) 96.2% of the drug dose was absorbed in man from capsules containing micronized drug powder (1521).

The absorption of iron was not influenced by concurrent oral administration of ascorbate, succinate, dioctyl sulfosuccinate, fumarate, aspartate, or folate in normal humans or subjects with iron deficiency. Slow-release preparations of ferrous sulfate were only half as active compared to conventional rapid-release dosage forms (1522). Following oral administration of 1–10 mg. sodium fluoride to humans, the peak salivary fluoride concentrations occurred about 45 min. later, with the rate of the subsequent decline being a function of the dose (1523). Copper sulfate has been regarded as a rapidly acting emetic for use in the immediate treatment of poisoning by ingestion. However, in view of the significant oral absorption of copper sulfate observed in rats, its use as an emetic was not recommended (1524). The peak serum levels of lithium in human subjects, after oral administration of a single standard dose of lithium acetate or timed-release tablets of lithium carbonate or lithium sulfate, were attained after 1, 2, and 3 hr., respectively (1525).

The kinetics and equilibrium of hexachlorophene sorption and desorption by human epidermis were studied *in vivo*, utilizing a bioelectrometric technique and direct drug analysis. An average of 41.6% of hexachlorophene was recovered by elutriation from the contents of three apparent kinetic compartments (1526). The *in vitro* penetration of methotrexate through human and hairless mouse skin was determined by scintillation counting and by determining the inhibition of dihydrofolate reductase. Significant absorption of the drug through the skin evidenced by both methods suggested efficacy of methotrexate in dermatology (1527). The fate of disodium cromoglycate in asthmatic patients was examined after oral, inhaled, and intravenous administration. Although maximum plasma concentrations

were obtained within 15 min. of inhaling the drug, which suggests rapid drug absorption from the lung, most inhaled drug was swallowed and excreted in the feces (1528, 1529). In a similar study, absorption and excretion characteristics after oral and inhaled administration of salbutamol to asthmatic patients were investigated (1530).

Additional studies on drug absorption are listed in Table XL.

Pharmacokinetics—General principles of pharmacokinetics, mathematical aspects of single- and multicompartmental models, and application of these concepts to absorption, distribution, metabolism, and excretion studies of a drug as well as to establishment of an optimal dosage scheme were discussed in a number of review articles (1558–1567). In addition, many other reviews focused on pharmacokinetics of specific drugs—*viz.*, niacin (nicotinic acid) and its derivatives (1568); morphine and morphine-like analgesics (1569); hydrochlorothiazide, ioglycamate, and antibiotics (1570); magnesium, plutonium, and iodine (1571); aspirin (1572); penicillin (1573); pentobarbital and penicillin G (1574); and antibiotics (1575). Quantitative and qualitative aspects of pharmacokinetics in relation to biological membrane permeability (1576) and the skin as an organ of absorption from a pharmacokinetic viewpoint (1577) were discussed in two separate reviews.

Earlier pharmacokinetic methods generally assumed the body as a single compartment, with drug absorption and other kinetic processes occurring at first-order rates. A two-compartment model has been proposed, which assumes a central and a peripheral body compartment. An equation for the two-compartment model was derived, which provides interrelationships among absorption, distribution, and elimination processes following oral administration of a drug. These concepts were further applied to study the effect of a solid drug dispersion on the absorption of highly water-insoluble steroids (1578). The two-compartment model assumes that the amount transferred to the peripheral compartment is directly proportional to the dose. A nonlinear model was considered in which the amount of drug transferred to the peripheral compartment is a curvilinear function of dose due to limited drug storage capacity of the peripheral compartment. It was emphasized that several different doses of a drug need to be administered intravenously to elaborate the appropriate pharmacokinetic model (1579). General treatments were presented by which linear mammillary models with elimination from any compartment can be described, utilizing the method of partial fractions for solving Laplace transforms and a multiple-dosing function. The approach was considered relatively simple and applicable in deriving equations for any linear mammillary compartment model with any first-order, zero-order, or impulse input process (1580). A statistical program for the calculation of pharmacokinetic parameters was described. The results of intravenous injection and drug retention experiments were analyzed by this program according to monoexponential or biexponential relationships (1581).

Many therapeutic agents can be applied more predictably and effectively if a constant plasma concentration can be maintained. With the use of a two-compartment open-system model, a method of combining intravenous bolus and continuous infusion was described to calculate the regimen required to reach a predetermined plateau concentration. Application of the method was demonstrated by administration of selected bolus and continuous infusion of theophylline dose regimens to humans (1582). Attainment of desired peak tissue levels of griseofulvin and aspirin required significantly higher peak plasma levels with a multiple intravenous

dosing regimen than with continuous infusion. Thus, infusion therapy was preferred, especially with relatively toxic drugs, when appearance of the drug in a peripheral compartment was a desired consequence of therapy (1583). Relationships between the dose and plateau levels of drugs eliminated by parallel first-order and capacity-limited kinetics were derived by Tsuchiya and Levy (1584). The authors concluded that repetitive administration at constant time intervals of fixed doses of drugs that are eliminated by apparent first-order kinetics usually results in the eventual attainment of a drug level plateau in the body. If a drug is eliminated solely by capacity-limited kinetics in the therapeutic dose range, it accumulates in the body without limit when the dose exceeds a certain amount (1584). Derivation of theoretical relationships useful for the characterization of multiple-dosing pharmacokinetics of hypoprothrombinemic anticoagulant drugs and the computation of optimum dosing regimens for individual patients was presented (1585).

Various parameters of the two-compartment open model were classified into three groups, depending upon how these parameters are influenced by a change induced in the elimination constant. At a given dose of drug, certain parameters are independent of the elimination constant, others change exactly in proportion to the elimination constant, while a third group is nonlinear or hybrid parameters (1586). A relationship between drug distribution and elimination in multicompartment systems was presented, which suggested that under certain conditions a decrease in the elimination rate constant results in a significant decrease in the apparent volume of distribution. The implication of a change in the apparent volume of distribution with respect to dose–response relationships, estimation of bioavailability, absorption rate, *etc.*, was considered (1587). An unusual

example of nonlinear, dose-dependent pharmacokinetics was observed in the case of riboflavin absorption and excretion in the rat. The elimination of the vitamin was shown to involve at least two nonlinear processes occurring simultaneously. One process involved biliary excretion which increased disproportionately with increasing body levels of riboflavin; the other process appeared to be a binding of the vitamin to tissues which function kinetically as deep compartments. Over the dose range studied, the nonlinear tissue-binding phenomenon was predominant over the nonlinear biliary excretion in riboflavin-deficient rats. The converse was true in the normal, nondeficient animal (1588).

The biliary excretion of intravenously administered methyl orange and its metabolites by rats was used to illustrate a one-compartment model in which a drug underwent two successive metabolic reactions. Data were analyzed graphically and with a computer program to estimate successive metabolic rates and the rate of biliary excretion (1589). Graphical analysis of the curves of biliary concentration as a function of time and the rate constants obtained after intravenous injection of fenpentadiol in rats indicated that the system may be represented by a two-compartment open model. Comparison of the pharmacokinetic parameters of biliary excretion with those of the enterohepatic cycle showed that the total elimination period is shortened if excretion occurs without the cycle. Half of the injected dose was observed to undergo total elimination within 1 hr., and 47% was excreted by the biliary route within 2.5 hr. (1590).

A pharmacokinetic model for the distribution and elimination of tubocurarine in man was presented, which represented the body as a three-compartment linear system with the site of drug action located in the central compartment. The decline in neuromuscular blocking effect with increasing dose elicited by tubocurarine was in accordance with the pharmacokinetic characteristics of a multicompartment system (1591, 1592). The distribution kinetics of inulin and urea were studied in the rat to test the validity of a proposed compartmental model. An open two-compartment model provided valid parameters for inulin data, while a three-compartment model fit the urea data (1593). The time course of rifampin (rifampicin) concentration in the serum, bile, and urine was determined in patients after oral administration of the drug. The results were interpreted on the basis of a four-compartment model consisting of intestine, blood, bile, and urine compartments (1594).

The pharmacokinetics of methylene blue, representative of highly ionized drugs, was investigated in the rat, dog, and man by DiSanto and Wagner (1595–1597). The authors concluded that methylene blue is well absorbed in man but poorly absorbed in the dog after oral administration. Plasma concentration–time data obtained from intravenous injection of methylene blue to a dog seemed to fit a linear two-compartment open model; the results of drug concentrations in the lung, liver, kidney, and heart tissues of rats after intravenous injection, with respect to dose, were shown to fit the nonlinear heterogeneous one-compartment open model (1595–1597). The blood level–time relationships for sulfamethazine, sulfisomidine, and sulfathiazole were determined in rabbits after intravenous injection. The results were fitted to a two-compartment open model, and the model parameters were obtained. Differences between drugs, animals, and treatments were studied in terms of urinary and metabolic rate constants, intercompartment diffusion constants, and clearance values (1598). In a similar study comparing pharmacokinetic parameters of sulfanilic acid and 1-naphthylamine-4-sulfonic acid, it was concluded that the latter compound is actively secreted into the renal tubule while the former is not (1599).

Computer simulations were used to determine suitable experimental conditions for distinguishing between a recently developed pharmacokinetic model for salicylate elimination (involving saturable salicyl phenolic glucuronide formation) and a previously proposed model (based on the assumption that the syntheses of salicyl phenolic and acyl glucuronides are apparent first-order processes). Studies in man according to the computer-simulated experimental design confirmed the new pharmacokinetic model, which provided further evidence that man has a limited capacity to form salicyl phenolic glucuronide (1600, 1601).

Additional references on pharmacokinetics are listed in Table XLI.
